CONTENTS

PART THREE
TREASURY, AGENCY, MUNICIPAL, AND CORPORATE BONDS

PART FOUR
MORTGAGE-BACKED AND ASSET-BACKED SECURITIES

PART SEVEN
CREDIT ANALYSIS

PART EIGHT
PORTFOLIO MANAGEMENT AND STRATEGIES

PREFACE

This book is designed to provide extensive coverage of the wide range of fixed income products, fixed income analytics, and fixed income portfolio management strategies. Each chapter is written by an authority on the subject.

The ninth edition of the *Handbook* is divided into ten parts. Part One provides general information about the investment features of fixed income securities, the risks associated with investing in fixed income securities, and the structure of interest rates. Part Two explains the basics of fixed income analytics—bond pricing, yield measures, spot rates, forward rates, total return, and price volatility measures (duration and convexity). It contains a new chapter, Chapter 6, covering data science.

Parts Three and Four cover the basic characteristics of the instruments traded in the market. Government securities and corporate debt obligations (both bonds and loans) are covered in Part Three. Additions to the ninth edition are coverage of Commercial Paper (Chapter 13), Non-U.S. Sovereign Bonds (Chapter 16), and Private Infrastructure Debt (Chapter 20).

Part Four focuses on securitized products—mortgage-backed securities and asset-backed securities. The coverage of the nonagency residential mortgage-backed securities and commercial mortgage-backed securities reflects market developments since the subprime mortgage crisis in 2007. The two new chapters included in Part Four are Agency Mortgage-Passthrough Securities (Chapter 22) and Nonagency Residential Mortgage-Backed Securities (Chapter 25).

The focus in Part Five is on the yield curve and the term structure of interest rates, both the use of the information contained in those rates and the modeling of the term structure. Part Six builds on the analytical framework explained in Part One. In this part, two methodologies for valuing fixed income securities are discussed: the lattice model and the Monte Carlo model. A by-product of these models is the option-adjusted spread. A chapter on relative value trades (Chapter 35) is a new addition to the *Handbook*, as are chapters on the valuation of agency collateralized mortgage obligations (Chapter 37). Unlike the previous edition, there are now two chapters rather than one on the valuation of convertible bonds; the new chapter is Chapter 39.

The topic of credit risk and its analysis is the subject of Part Seven. Traditional methods of credit analysis for corporate bonds and municipal bonds are explained and illustrated. There is also coverage of the various approaches to credit risk modeling.

Part Eight, which has 18 chapters, covers bond portfolio management strategies. There are nine new chapters that are included in this part of the book. I will briefly describe these new chapters. Chapter 44 focuses on several problems, issues, challenges and tools, developments, and tendencies that help to mitigate the problems bond portfolio managers face when they trade. Because bond indexes are important sources of information for managers and investors with respect to performance measurement and new products such as smart beta portfolios, Chapter 45 focuses on bond indexes. Unlike equity indexes, bond indexes have a high level of complexity. Although factor investing has been around for a good number of years in equity portfolio management, it is relatively new in bond portfolio management. Chapters 47, 48, and 58 cover factor investing in bond portfolio management. Chapter 48 also covers applications of machine learning to bond portfolio management. The ESG issues a corporate bond manager faces are covered in Chapter 55. There is a chapter on cash flow matching strategies, Chapter 51. The chapter on international bond portfolio management, Chapter 57, has been completely revised.

Part Nine covers derivative instruments: interest-rate derivatives (futures/forward contracts, options, interest-rate swaps, and caps and floors) and credit derivatives (primarily credit default swaps). The basic feature of each instrument is described as well as how it is valued and used to control the risk of a fixed income portfolio.

Performance evaluation and return attribution analysis are covered in the last three chapters of the *Handbook* in Part Ten. Coverage includes how these models are built and used, as well as the underlying principles in building these models.

SUMMARY OF REVISIONS

The ninth edition is a substantial revision over the eighth edition. Although both editions have roughly the same number of chapters (72 in this ninth edition versus 71 in the eighth edition), there have been substantial changes. The following 18 chapters are new:

6 Data Science and the Corporate Credit Markets
13 Commercial Paper
16 Non-U.S. Sovereign Bonds
20 Private Infrastructure Debt
22 Agency Mortgage Passthrough Securities
25 Nonagency Residential Mortgage-Backed Securities: Legacy, RMBS 2.0, and Non-QM
35 Relative Value Trading
37 Valuation of Mortgage-Backed Securities
38 Convertible Securities
44 Trading in the Bond Market
45 Bond Indexes Bond Portfolio Management
47 Factor Investing in Fixed Income Securities
48 Active Factor Fixed Income Investing

51 Cash-Flow Matching
52 Building Corporate Bond Portfolios
55 Corporate Bonds and ESG
57 International Bond Portfolio Management
58 Factor Investing in Sovereign Bond Markets

Moreover, the following four chapters have been substantially revised:

8 Agency Debt Securities
11 Leveraged Loans
18 Fixed Income Exchange Traded Funds
38 Convertible Securities

Editor

ACKNOWLEDGMENTS

The first edition of *The Handbook of Fixed Income Securities* was published in 1983. Over the 38 years and eight editions of the book, I have benefited from the guidance of many participants in the various sectors of the bond market. I would like to extend my deep personal appreciation to the contributing authors in all editions of the book. Francesco Fabozzi and Steven Mann provided assistance in reviewing and commenting on a majority of the chapters, as well as coauthoring several chapters.

There are two individuals whom I would like to single out who contributed to the first six editions and are now retired from the industry: Jane Tripp Howe and Richard Wilson. Jane was widely recognized as one of the top corporate credit analysts. She contributed not only to the *Handbook* but also to several other books that I edited. She was my "go-to" person when I needed a chapter on any aspect of corporate credit analysis. In the eighth and ninth editions, Martin Fridson, Adam Cohen, and I revised the chapter by Jane on corporate bond credit analysis and we thank her for granting us permission to use the core of her chapter that appeared in the sixth edition.

Richard Wilson contributed several chapters to earlier editions of the *Handbook*. When I began my study of the fixed income market in the late 1970s, he served as my mentor. At that time, there were so many nuances about the institutional aspects of the market that were not in print. His historical perspective and his insights helped me form my view of the market. In addition, from his many contacts in the industry, he identified for me potential contributors to the first edition.

This chapter will explore some of the most important features of bonds, preferred stock, and structured products and provide the reader with a taxonomy of terms and concepts that will be useful in the reading of the specialized chapters to follow.

BONDS

Bonds are instruments of debt; the issuer of a bond borrows money from the bond investor. One important characteristic of a bond is the nature of its issuer. Although non-U.S. governments and firms raise capital in U.S. financial markets, the three largest issuers of debt are domestic corporations, municipal governments, and the federal government and its agencies. Each class of issuer, however, features additional and significant differences.

Domestic corporations, for example, include regulated utilities as well as less regulated manufacturers. Furthermore, each firm may sell different kinds of bonds: Some debt may be publicly placed, whereas other bonds may be sold directly to one or only a few buyers (referred to as a *private placement*); some debt is collateralized or "secured" by specific assets of the company, whereas other debt may be unsecured. Municipal debt is also varied: "general obligation" bonds (GOs) are backed by the full faith, credit, and taxing power of the governmental unit issuing them; "revenue bonds," on the other hand, have a safety, or creditworthiness, that depends on the vitality and success of the particular entity (such as toll roads, hospitals, or water systems) within the municipal government issuing the bond.

The U.S. Treasury has the most voracious appetite for debt, but the bond market often receives calls from its agencies. Federal government agencies include federally related institutions and government-sponsored enterprises (GSEs). Exhibit 1-1 summarizes the breakdown of U.S. fixed income market by issuer categories.

EXHIBIT 1-1

Outstanding Value of U.S. Fixed Income Sectors (as of December 31, 2019)

U.S. Fixed-Income Sector	USD Billion
Treasury	$16,673.3
Mortgage Related	10,333.6
Corporate Debt	9,597.8
Municipals	3,854.5
Federal Agency	1,825.9
Asset-Backed	1,799.3
Money Markets	1,045.2
Total	**$32,996.8**

Based on data from the Securities Industry and Financial Markets Association (SIFMA)

It is important for the investor to realize that, by law or practice or both, these different borrowers have developed different ways of raising debt capital over the years. As a result, the distinctions among the various types of issuers correspond closely to differences among bonds in yield, denomination, safety of principal, maturity, tax status, and such important provisions as the call privilege, put features, and sinking fund. As we discuss the key features of fixed income securities, we will point out how the characteristics of the bonds vary with the obligor or issuing authority. A more extensive discussion is provided in later chapters in this book that explain the various instruments.

Maturity of a Bond

The legal document that sets forth all of the parameters of the agreement between the bondholders and the issuer is the *indenture*. A key feature of any bond that is covered by the indenture is its *term-to-maturity,* that is, the number of years during which the borrower has promised to meet the conditions of the debt (which are contained in the bond's indenture). A bond's term-to-maturity is the date on which the debt will cease, and the borrower will redeem the issue by paying the face value, or principal. One indication of the importance of the maturity is that the code word or name for every bond contains its maturity (and coupon interest payment, described later). Thus, the title of the Anheuser Busch Company bond due, or maturing, in 2029 is given as "Anheuser Busch 4¾ s of 2029." In practice, the words *maturity, term,* and *term-to-maturity* are used interchangeably to refer to the number of years remaining in the life of a bond. Technically, however, *maturity* denotes the date the bond will be redeemed, and either *term* or *term-to-maturity* denotes the remaining number of years until that date.

A bond's maturity is crucial for several reasons. First, maturity indicates the expected life of the instrument, or the number of periods during which the holder of the bond can expect to receive the coupon interest and the number of years before the principal will be paid. Second, the yield on a bond depends substantially on its maturity. More specifically, at any given point in time, the yield offered on a long-term bond may be greater than, less than, or equal to the yield offered on a short-term bond. As will be explained in Chapter 32, the effect of maturity on the yield depends on the *shape of the yield curve*. Third, the volatility of a bond's price is closely associated with maturity: changes in the market level of rates will wrest much larger changes in price from bonds of long maturity than from otherwise similar debt of shorter life. Finally, as explained in Chapter 5, there are other risks associated with the maturity of a bond.

When considering a bond's maturity, the investor should be aware of any provisions that modify, or permit the issuer to modify, the maturity of a bond. Although corporate bonds (referred to as "corporates") are typically *term bonds* (issues that have a single maturity), they often contain arrangements by which the issuing firm either can or must retire the debt early, in full or in part. Some corporate bonds give the issuer a *call privilege,* which permits the issuing firm to redeem the bond before the scheduled maturity under certain conditions (these conditions are discussed below). Municipal bonds may have the same provision. The U.S. government no longer issues bonds that have a call privilege. The last callable bond was called in November 2009. Many industrials and some utilities have *sinking-fund provisions,* which mandate that the firm retire a substantial portion of the debt, according to a prearranged schedule, during its life and before the stated maturity. Municipal bonds may be *serial bonds* or, in essence, bundles of bonds with differing maturities. (Some corporates are of this type, too.)

Usually, the maturity of a corporate bond is between 1 and 30 years. This is not to say that there are not outliers. In fact, financially sound firms have begun to issue longer-term debt in order to lock in long-term attractive financing. For example, in the late 1990s, there were approximately 90 corporate bonds issued with maturities of 100 years.

Although classifying bonds as "short term," "intermediate term," and "long term" is not universally accepted, the following classification is typically used. Bonds with a maturity of 1 to 5 years are generally considered short term; bonds with a maturity between 5 and 12 years are viewed as intermediate term (and are often called *notes*). Long-term bonds are those with a maturity greater than 12 years.

Coupon and Principal

The indenture sets for the interest rate the issuer must pay bondholders, the frequency of the payments, the currency in which it must be paid, and the bond's par value.

The interest rate that the issuer must pay bondholders during the term of the bond is called the *coupon rate*. The coupon rate is always cited, along with maturity, in any quotation of a bond's price. Thus, one might hear about the "IBM 6.5 due in 2028" or the "Campbell's Soup 8.875 due in 2021" in discussions of current bond trading. The coupon rate is the interest rate that when multiplied by the *principal, par value,* or *face value* of the bond, provides the amount of the coupon payment to be made to the bondholders. The indenture will specify the currency in which the payment is to be made and its frequency.

Typically, but not universally, for bonds issued in the United States, the coupon payment is made in semiannual installments. An important exception is mortgage-backed and asset-backed securities that usually deliver monthly cash flows. In contrast, for bonds issued in some European bond markets and all bonds issued in the *Eurobond market,* the coupon payment is made annually.

The coupon rate has another major impact on an investor's experience with a bond. The coupon's size influences the volatility of the bond's price: the larger the coupon, the less the price will change in response to a change in market interest rates. Thus, the coupon and the maturity have opposite effects on the price volatility of a bond. This will be illustrated in Chapter 5.

One reason that debt financing is popular with corporations is that the interest payments are tax-deductible expenses. As a result, the true after-tax cost of debt to a profitable firm is usually much less than the stated coupon interest rate. The level of the coupon on any bond is typically close to the level of yields for issues of its class at the time the bond is first sold to the public. Some bonds are issued initially at a price substantially below par value (called *original-issue discount bonds,* or *OIDs*), and their coupon rate is deliberately set below the current market rate. However, firms usually try to set the coupon at a level that will make the market price close to par value. This goal can be accomplished by placing the coupon rate near the prevailing market rate.

The par value, also referred to as the *face value* or *principal*, of a bond is the amount to be repaid to the investor either at maturity or at those times when the bond is called or retired according to a repayment schedule or sinking-fund provisions that we describe later. But the principal plays another role, too: it is the basis on which the coupon or periodic interest rests. The coupon is the product of the principal and the coupon rate.

Bonds may be *bearer bonds* or *registered bonds.* With bearer bonds, investors clip coupons and send them to the obligor for payment. In the case of registered issues, bond owners receive the payment automatically at the appropriate time. All new bond issues must be registered.

Types of Coupon Structures

The coupon structure of a bond can be a fixed rate or a floating or variable rate. Below we describe the different types of coupon structures.

Zero-Coupon Bonds: Zero-coupon bonds have been issued by corporations and municipalities since the early 1980s. For example, Barclay's Bank PLC has a zero-coupon bond outstanding due in August 2036 that was issued on August 15, 2006. Although the U.S. Treasury does not issue zero-coupon debt with a maturity greater than one year, such securities are created by government securities dealers. Merrill Lynch was the first to do this with its creation of Treasury Investment Growth Receipts (TIGRs) in August 1982. The most popular zero-coupon Treasury securities today are those created by government dealer firms under the Treasury's Separate Trading of Registered Interest and Principal Securities (STRIPS) Program. Just how these securities—commonly referred to as *Treasury strips*—are created will be explained in Chapter 7. The investor in a zero-coupon security typically receives interest by buying the security at a price below its principal, or maturity value, and holding it to the maturity date. The reason for the issuance of zero-coupon securities is explained in Chapter 7. However, some zeros are issued at par and accrue interest during the bond's life, with the accrued interest and principal payable at maturity.

Inflation-Linked Bonds: Sovereign governments and corporations issue securities with the principal tied to the rate of inflation. These debt instruments, referred to as *inflation-linked bonds,* or simply "linkers," have been issued since 1945. The earlier issuers of linkers were the governments of Argentina, Brazil, and Israel. The modern linker is attributed to the U.K. government's index-linked gilt issued in 1981 followed by Australia, Canada, and Sweden. The United States introduced an inflation-linked security in January 1997, calling those securities *Treasury Inflation Protected Securities*, or TIPS. These securities, which carry the full faith and credit of the U.S. government, comprised approximately 10% of the outstanding U.S. Treasury market as of mid-2020. Shortly after the introduction of TIPS in 1997, U.S. government-related entities such as the Federal Farm Credit, the Federal Home Loan Bank, Fannie Mae, and the Tennessee Valley Authority began issuing linkers.

Different designs can be employed for linkers. The reference rate that is a proxy for the inflation rate is changes in the consumer price index (CPI). In the United Kingdom, for example, the index used is the Retail Prices Index (All Items), or RPI. In France, there are two linkers with two different indexes: the French CPI (excluding tobacco) and the Eurozone's Harmonised Index of

Consumer Prices (HICP) (excluding tobacco). In the United States, the Consumer Price Index–Urban, Non-Seasonally Adjusted (denoted by CPI-U), is calculated by the U.S. Bureau of Labor Statistics.[1]

Step-Up Notes: There are securities that have a coupon rate that increases over time. These securities are called *step-up notes* because the coupon rate "steps up" over time. For example, a six-year step-up note might have a coupon rate that is 5% for the first two years, 5.8% for the next two years, and 6% for the last two years. Consider a *stairway note* issued by Barclays Bank PLC in July 2009. The initial coupon was 2.8% until January 2010 and thereafter the coupon rate reset every six months to the maximum of the previous coupon rate or six-month LIBOR.

Floating-Rate Securities: In contrast to a coupon rate that is fixed for the bond's entire life, the term *floating-rate security* or *floater* encompasses several different types of securities with one common feature: the coupon rate will vary over the instrument's life. The coupon rate is reset at designated dates based on the value of some reference rate adjusted for a spread. For example, consider a floating-rate note issued in May 2017 by Apple that matures in May 2022. This floater delivers cash flows quarterly and had a coupon formula equal to three-month LIBOR plus 35 basis points.

Typically, floaters have coupon rates that reset more than once a year (e.g., semiannually, quarterly, or monthly). Conversely, the term *adjustable-rate* or *variable-rate security* refers to those issues whose coupon rates reset not more frequently than annually.

Features of Floaters: There are several features about floaters that deserve mention. First, a floater may have a restriction on the maximum (minimum) coupon rate that will be paid at any reset date called a *cap* (*floor*). Second, while the reference rate for most floaters is a benchmark interest rate or an interest rate index, a wide variety of reference rates appear in the coupon formulas. A floater's coupon could be indexed to movements in foreign exchange-rates, the price of a commodity (e.g., crude oil), movements in an equity index (e.g., the S&P 500), or movements in a bond index. Third, while a floater's coupon rate normally moves in the same direction as the reference rate, there are floaters whose coupon rate moves in the opposite direction from the reference rate. These securities are

1. The CPI-U is the most widely followed and perhaps the most understood inflation index among alternative choices, such as the Gross Domestic Product (GDP) deflator and the Personal Consumption Expenditure (PCE) deflator. Monthly changes in the CPI-U represent the average changes in prices facing urban consumers with regard to a fixed basket of goods and services. This group of urban consumers represents about 87% of the total U.S. population. The Treasury reserves the right to substitute an alternative price index under the following circumstances: (1) the CPI-U is discontinued, (2) the CPI-U is altered materially to the detriment of the investor and/or the security, or (3) the CPI-U is altered by legislation or executive order in a manner harmful to the investor and/or the security.

called *inverse floaters* or *reverse floaters*. Consider a hypothetical inverse floater that makes coupon payments according to the following formula:

$$18\% - 2.5 \times (\text{three-month LIBOR})$$

This inverse floater had a floor of 3% and a cap of 15.5%. Finally, *range notes* are floaters whose coupon rate is equal to the reference rate (adjusted for a spread) as long as the reference rate is within a certain range on the reset date. If the reference rate is outside the range, the coupon rate is zero for that period.

Reference Rates: Note that the Financial Conduct Authority (FCA) which oversees LIBOR submission process, announced in 2017 that FCA will no longer "persuade" London banks to make submission after the end of 2021. (In November 2020, regulators announced an extension of LIBOR publication until June 2023, in order to avoid any disruption from the originally planned ending of publication in 2021. The end date for LIBOR-linked new contracts remains the end of 2021, as originally planned.)To replace the LIBOR rates, a global process started in the search for an alternative reference rate. In the United States, Alternative Reference Rate Committee (ARRC) selected the Broad Treasury Funding Rate in 2017, and later renamed it as Secured Overnight Financing Rate (SOFR). The ARRC was created by the Federal Reserve (Fed), and the participants are over-the-counter derivative market players, supervisors, and central banks.

SOFR is a volume-weighted median rate based on actual transaction data from overnight tri-party repo and cleared overnight bilateral repo markets (excluding Fed transactions). In the past, banks/dealers were not obliged to submit repo trade to the Fed. Since April 2018, it has been mandatory to submit repo deal details via DTCC (Depository Trust & Clearing Corporation) to the Fed. While LIBOR is unsecured term rate with various maturities, SOFR itself is a secured overnight rate. SOFR rate has been published by the New York Fed since April 2, 2018.

As of May 2020, it is estimated that the total SOFR-based debt issuance has reached $630 billion. The biggest issuers of SOFR-linked floating-rate debt that are the Federal Home Loan Bank (FHLB), Freddie Mac, Fannie Mae, as well as banks, insurance companies, and the World Bank. For example, IBRD Floater 08/06/24 that was issued in 2019 pays quarterly coupon based on overnight (O/N) SOFR + 30 basis point formula.

A SOFR-based futures product also was introduced by the Chicago Mercantile Exchange (CME) in May 2018. Both one-month and three-month contracts exist, and the settlement rate is the compounded daily SOFR during the reference contract quarter. Currently SOFR contracts are available for up to 10 years (i.e., 39 quarterly months (March, June, September, December), and an active futures market would be critical for the interest rate swap market. In addition to SOFR in the United States, there is a global search for alternative rates: SONIA in the U.K., EONIA and ESTER in the Eurozone, or TONAR in Japan.

Coupon Structure on High-Yield Bonds: Structures in the *high-yield (junk bond) sector* of the corporate bond market have introduced variations in the way coupon payments are made. For example, in a leveraged buyout or recapitalization financed with high-yield bonds, the heavy interest payment burdens the corporation must bear places severe cash-flow constraints on the firm. To reduce this burden, firms involved in leveraged buyouts (LBOs) and recapitalizations have issued deferred-coupon structures that permit the issuer to defer making cash interest payments for a period of three to seven years. There are three types of deferred-coupon structures: (1) deferred interest bonds, (2) step-up bonds, and (3) payment-in-kind bonds. These structures are described in Chapter 10.

Another high-yield bond structure allows the issuer to reset the coupon rate so that the bond will trade at a predetermined price. The coupon rate may reset annually or reset only once over the life of the bond. Generally, the coupon rate will be the average of rates suggested by two investment banking firms. The new rate will then reflect the level of interest rates at the reset date and the credit spread the market wants on the issue at the reset date. This structure is called an *extendible reset bond.* Notice the difference between this bond structure and the floating-rate issue described earlier. With a floating-rate issue, the coupon rate resets based on a fixed spread to some benchmark, where the spread is specified in the indenture and the amount of the spread reflects market conditions at the time the issue is first offered. In contrast, the coupon rate on an extendible reset bond is reset based on market conditions suggested by several investment banking firms at the time of the reset date. Moreover, the new coupon rate reflects the new level of interest rates and the new spread that investors seek.

Bond Quote Convention

By convention, the prices of most bonds are quoted as percentages of par or face value. To convert the price quote into a dollar figure, one simply divides the price by 100 (converting it to decimal) and then multiplies by the par value. The following table illustrates this.

Price as a Percentage

Par Value ($)	Price Quote	Percent of Par Value	Price in Dollars
$1,000	$91\frac{3}{4}$	91.75	$917.50
5,000	$102\frac{1}{2}$	102.5	5,125.00
10,000	$87\frac{1}{4}$	87.25	8,725.00
25,000	$100\frac{3}{4}$	100.875	25,218.75
100,000	$71\frac{9}{32}$	71.28125	71,281.25
500,000	$97\frac{5}{16}$	97.15625	485,781.25
1,000,000	$88\frac{111}{256}$	88.43359375	884,335.94

Embedded Options

The indenture may have provisions that grant either the bondholders or the issuer the right to alter the maturity of the bond by taking certain action. Such rights are referred to as *embedded options* and the various types of embedded options are described below.

Call and refunding provisions: If a bond's indenture contains a *call feature* or *call provision,* the issuer retains the right to retire the debt, fully or partially, before the scheduled maturity date. The chief benefit of such a feature is that it permits the borrower, should market rates fall, to replace the bond issue with a lower-interest-cost issue. The call feature has added value for corporations and municipalities. It may in the future help them to escape the restrictions that frequently characterize their bonds (about the disposition of assets or collateral). The call feature provides an additional benefit to corporations, which might want to use unexpectedly high levels of cash to retire outstanding bonds or might wish to restructure their balance sheets.

The call provision is detrimental to investors, who run the risk of losing a high-coupon bond when rates begin to decline. When the borrower calls the issue, the investor must find other outlets, which presumably would have lower yields than the bond just withdrawn through the call privilege. Another problem for the investor is that the prospect of a call limits the appreciation in a bond's price that could be expected when interest rates decline.

Because the call feature benefits the issuer and places the investor at a disadvantage, callable bonds carry higher yields than bonds that cannot be retired before maturity. This difference in yields is likely to grow when investors believe that market rates are about to fall, and that the borrower may be tempted to replace a high-coupon debt with a new low-coupon bond. (Such a transaction is called *refunding.*) However, the higher yield alone is often not sufficient compensation to the investor for granting the call privilege to the issuer. Thus, the price at which the bond may be called, termed the *call price,* is normally higher than the principal or face value of the issue. The difference between call price and principal is the *call premium,* whose value may be as much as one year's interest in the first few years of a bond's life and may decline systematically thereafter.

An important limitation on the borrower's right to call is the *period of call protection,* or *deferment period,* which is a specified number of years in the early life of the bond during which the issuer may not call the debt. Such protection is another concession to the investor, and it comes in two forms. Some bonds are *noncallable* (often abbreviated NC) for any reason during the deferment period; other bonds are *nonrefundable* (NF) for that time. The distinction lies in the fact that nonrefundable debt may be called if the funds used to retire the bond issue are obtained from internally generated funds, such as the cash flow from operations or the sale of property or equipment, or from nondebt funding such as the sale of common stock. Thus, although the terminology is unfortunately confusing, a nonrefundable issue may be refunded under the circumstances just described and, as a result, offers less call protection than a noncallable bond, which cannot be called for any reason except to satisfy sinking-fund requirements, explained later. Beginning in early 1986, a number of corporations issued long-term debt with extended call protection, not refunding protection. A number are noncallable for the issue's life, such as Dow Chemical Company's $8^5/_8$s due in 2006. The issuer is expressly prohibited from redeeming the issue prior to maturity. These *noncallable-for-life issues* are referred to as *bullet bonds*. If a bond does not have any protection against an early call, then it is said to be *currently callable.*

Since the mid-1990s, an increasing number of public debt issues include a so-called *make-whole call provision*. Make-whole call provisions have appeared routinely in privately placed issues since the late 1980s. In contrast to the standard call feature that contains a call price fixed by a schedule, a make-whole call price varies inversely with the level of interest rates. A make-whole call price (i.e., redemption amount) is typically the sum of the present values of the remaining coupon payments and principal discounted at a yield on a Treasury security that matches the bond's remaining maturity plus a spread. For example, on January 22, 2008, an industrial firm issued $300 million in bonds with a make-whole call provision that mature on January 15, 2038. These bonds are redeemable at any time in whole or in part at the issuer's option. The redemption price is the greater of (1) 100% of the principal amount plus accrued interest or (2) the make-whole redemption amount plus accrued interest. In this case, the make-whole redemption amount is equal to the sum of the present values of the remaining coupon and principal payments discounted at the Adjusted Treasury Rate plus 15 basis points.[2] The Adjusted Treasury Rate is the bond-equivalent yield on a U.S. Treasury security having a maturity comparable to the remaining maturity of the bonds to be redeemed. Each holder of the bonds will be notified at least 30 days, but not more than 60 days, prior to the redemption date. This issue is callable at any time, as are most issues with make-whole call provisions. Note that the make-whole call price increases as interest rates decrease, so if the issuer exercises the make-whole call provision when interest rates have decreased, the bondholder receives a higher call price. Make-whole call provisions thus provide investors with some protection against reinvestment rate risk.

When will the issuer find it economically beneficial to refund an issue? It is important for investors to understand the process by which a firm decides whether to retire an old bond and issue a new one. A simple and brief example will illustrate that process and introduce the reader to the kinds of calculations a bondholder will make when trying to predict whether a bond will be refunded.

In municipal securities, refunding often refers to something different, although the concept is the same. Municipal bonds can be *prerefunded* prior to maturity (usually on a call date). Here, instead of issuing new bonds to retire the debt, the municipality will issue bonds and use the proceeds to purchase enough risk-free securities to fund all the cash flows on the existing bond issue. It places

2. A 30/360 day-count convention is employed in this present-value calculation.

these in an irrevocable trust. Thus, the municipality still has two issues outstanding, but the old bonds receive a new label—they are "prerefunded." If Treasury securities are used to prerefund the debt, the cash flows on the bond are guaranteed by Treasury obligations in the trust. As a result, they become AAA rated and trade at higher prices than previously. Municipalities often find this an effective means of lowering their cost of debt.

Sinking-fund provision: The *sinking-fund provision,* which is typical for publicly and privately issued industrial bonds and not uncommon among certain classes of utility debt, requires the obligor to retire a certain amount of the outstanding debt each year. Generally, the retirement occurs in one of two ways. The firm may purchase the amount of bonds to be retired in the open market if their price is below par, or the company may make payments to the trustee who is empowered to monitor the indenture and who will call a certain number of bonds chosen by lottery. In the latter case, the investor would receive the prearranged call price, which is usually par value. The schedule of retirements varies considerably from issue to issue. Some issuers, particularly in the private-placement market, retire most, if not all, of their debt before maturity. In the public market, some companies may retire as little as 20% to 30% of the outstanding par value before maturity. Further, the indenture of many issues includes a deferment period that permits the issuer to wait five years or more before beginning the process of sinking-fund retirements.

There are three advantages of a sinking-fund provision from the investor's perspective. The sinking-fund requirement ensures an orderly retirement of the debt so that the final payment, at maturity, will not be too large. Second, the provision enhances the liquidity of some debt, especially for smaller issues with thin secondary markets. Third, the prices of bonds with this requirement are presumably more stable because the issuer may become an active participant on the buy side when prices fall. For these reasons, the yields on bonds with sinking-fund provisions tend to be less than those on bonds without them.

The sinking fund, however, can work to the disadvantage of an investor. Suppose that an investor is holding one of the early bonds to be called for a sinking fund. All the time and effort put into analyzing the bond has now been wasted, and the investor will have to choose new instruments for purchase. Also, an investor holding a bond with a high coupon at the time rates begin to fall is still forced to relinquish the issue. For this reason, in times of high interest rates, one might find investors demanding higher yields from bonds with sinking funds than from other debt.

The sinking-fund provision also may harm the investor's position through the *optional acceleration feature,* a part of many corporate bond indentures. With this option, the corporation is free to retire more than the amount of debt the sinking fund requires (and often a multiple thereof) and to do it at the call price set for sinking-fund payments. Of course, the firm will exercise this option only if the price of the bond exceeds the sinking-fund price (usually near par), and this happens when rates are relatively low. If, as is typically the case, the sinking-fund provision becomes operative before the lapse of the call-deferment period, the firm can retire much of its debt with the optional acceleration feature and can do so at a price far below that of the call price it would have to pay in the event of refunding. The impact of such activity on the investor's position is obvious: The firm can redeem at or near par many of the bonds that appear to be protected from call and that have a market value above the face value of the debt.

Put provisions: A *putable bond* grants the investor the right to sell the issue back to the issuer at par value on designated dates. The advantage to the investor is that if interest rates rise after the issue date, thereby reducing the value of the bond, the investor can force the issuer to redeem the bond at par. Some issues with put provisions may restrict the amount that the bondholder may put back to the issuer on any one put date. Put options have been included in corporate bonds to deter unfriendly takeovers. Such put provisions are referred to as "poison puts."

Put options can be classified as *hard puts* and *soft puts.* A hard put is one in which the security must be redeemed by the issuer only for cash. In the case of a soft put, the issuer has the option to redeem the security for cash, common stock, another debt instrument, or a combination of the three. Soft puts are found in convertible debt, which we describe next.

Convertible or exchangeable debt: A *convertible bond* is one that can be exchanged for specified amounts of common stock in the issuing firm: The conversion cannot be reversed, and the terms of the conversion are set by the company in the bond's indenture. The most important terms are *conversion ratio* and *conversion price.* The conversion ratio indicates the number of shares of common stock to which the holder of the convertible has a claim. The conversion price at issuance is also referred to as the *stated conversion price.*

The conversion privilege may be permitted for all or only some portion of the bond's life. The conversion ratio may decline over time. It is always adjusted proportionately for stock splits and stock dividends. Convertible bonds are typically callable by the issuer. This permits the issuer to force conversion of the issue. (Effectively, the issuer calls the bond, and the investor is forced to convert the bond or allow it to be called.) There are some convertible issues that have call protection. This protection can be in one of two forms: Either the issuer is not allowed to redeem the issue before a specified date, or the issuer is not permitted to call the issue until the stock price has increased by a predetermined percentage price above the conversion price at issuance.

An *exchangeable bond* is an issue that can be exchanged for the common stock of a corporation other than the issuer of the bond. There are a handful of issues that are exchangeable into more than one security. One significant innovation in the convertible bond market was the "Liquid Yield Option Note" (LYON) developed by Merrill Lynch Capital Markets in 1985. A LYON is a zero-coupon, convertible, callable, and putable bond. Techniques for analyzing convertible and exchangeable bonds are described in Chapters 38 and 39.

Warrants: A *warrant* is an option a corporation grants to bondholders that permits the owner to buy from the firm a certain number of shares of common stock at a specified price. It is not uncommon for publicly held corporations to issue warrants with new bonds.

A valuable aspect of a warrant is its rather long life: Most warrants are in effect for at least two years from issuance, and some are perpetual.[3] Another key feature of the warrant is the *exercise price,* the price at which the warrant holder can buy stock from the corporation. This price is normally set at about 15% above the market price of common stock at the time the bond, and thus the warrant, is issued. Frequently, the exercise price will rise through time, according to the schedule in the bond's indenture. Another important characteristic of the warrant is its detachability. *Detachable warrants* are often actively traded on the American Stock Exchange. Other warrants can be exercised only by the bondholder, and these are called *nondetachable warrants.* The chief benefit to the investor is the financial leverage the warrant provides.

Bond Yields

Bond market participants use several measures to describe the potential return from investing in a bond: current yield, yield to maturity, yield-to-call for a callable bond, and yield-to-put for a putable bond. A *yield-to-worst* is often quoted for bonds. This is the lowest yield of the following: yield to maturity, yields to all possible call dates, and yields to all put dates. The calculation and limitations of these yield measures are explained and illustrated in Chapter 4.

Since the Global Financial Crisis of 2008–2009, government yields have continued their already prevailing declining secular trend and yields of several sovereign issuers went into the negative territory, including several governments within the Eurozone, Switzerland, Sweden, as well as Japan (see Exhibit 1-2). This decline in government yields is explained by various factors, including accommodative monetary policy, quantitative easing, as well as low inflation expectations. As of June 4, 2020, 27% of the market value of the Bloomberg Barclays Global Aggregate Treasury Index offer negative yield. The index overall has a duration (a measure described in Chapter 5) of 8.6 years, a yield of 0.55%, and a total market value of $31 trillion, and it is comprised of government bonds of 41 developed and emerging countries.

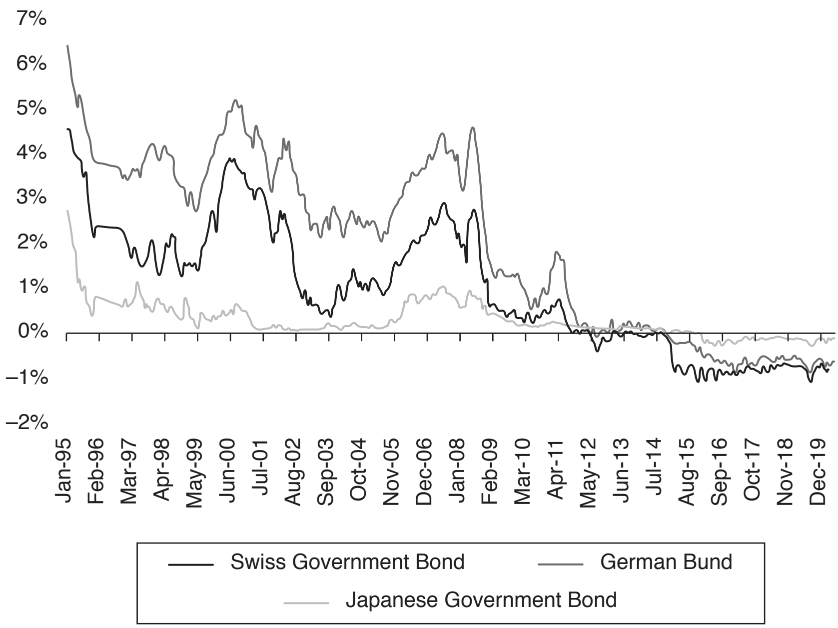
Government bonds "with negative yield" are issued either with positive coupon or no coupon, however, their current purchase price is so high, that the cash-flow stream comprised by their coupons (if any) and the face value at maturity would result in a negative yield to maturity. For example, the current 10-year German Bund matures on 02/15/2030 and has a coupon rate equal to zero, so its current market price of 103.141/103.165 translates to a yield to maturity of –0.319%/–0.321%. In other words, if an investor buys this bond at the currently available price, and holds till maturity, she or he would lock in a negative total

3. This long life contrasts sharply with the short life during which many exchange-traded call options on common stock, similar to warrants, are exercisable.

return. Negative yields alone, however, do not necessarily mean negative total return: a positive return can be generated by selling the bond before maturity at an even higher price, i.e., even more negative yield. This may be achieved either by rebalancing to a target duration while the yield-curve, albeit partly of fully in negative territory, has a positive slope (benefiting from the roll-down effect), or by active trading.

EXHIBIT 1-2

Two-Year Government Bond Yields (January 1995–December 2019)



MEDIUM-TERM NOTES

Medium-term notes are highly flexible debt instruments that can be easily structured in response to changing market conditions and investor tastes. "Medium term'' is a misnomer because these securities have ranged in maturity from nine months to 30 years and longer. Since the latter part of the 1980s, medium-term notes have become an increasingly important financing vehicle for corporations and federal agencies. Typically, medium-term notes are noncallable, unsecured, senior debt securities with fixed-coupon rates that carry an investment-grade credit rating. They generally differ from other bond offerings in their primary distribution process. *Structured medium-term notes,* or simply *structured notes,* are debt instruments linked to a derivative position and are discussed in Chapter12.

For example, structured notes are usually created with an underlying swap transaction. This "hedging swap" allows the issuer to create securities with interesting risk/return features demanded by bond investors.

PREFERRED STOCK

Preferred stock is a class of stock, not a debt instrument, but it shares characteristics of both common stock and debt. Like the holder of common stock, the preferred stockholder is entitled to dividends. Unlike those on common stock, however, preferred stock dividends are a specified percentage of par or face value.[4] The percentage is called the *dividend rate;* it need not be fixed but may float over the life of the issue.

Failure to make preferred stock dividend payments cannot force the issuer into bankruptcy. Should the issuer not make the preferred stock dividend payment, usually paid quarterly, one of two things can happen, depending on the terms of the issue. First, the dividend payment can accrue until it is fully paid. Preferred stock with this feature is called *cumulative preferred stock.* Second, if a dividend payment is missed and the security holder must forgo the payment, the preferred stock is said to be *noncumulative preferred stock.* Failure to make dividend payments may result in imposition of certain restrictions on management. For example, if dividend payments are in arrears, preferred stockholders might be granted voting rights.

Unlike debt, payments made to preferred stockholders are treated as a distribution of earnings. This means that they are not tax deductible to the corporation under the current tax code. (Interest payments, on the other hand, are tax deductible.) Although the after-tax cost of funds is higher if a corporation issues preferred stock rather than borrowing, there is a factor that reduces the cost differential: A provision in the tax code exempts 70% of qualified dividends from federal income taxation if the recipient is a qualified corporation. For example, if Corporation A owns the preferred stock of Corporation B, for each \$100 of dividends received by A, only \$30 will be taxed at A's marginal tax rate. The purpose of this provision is to mitigate the effect of double taxation of corporate earnings. There are two implications of this tax treatment of preferred stock dividends. First, the major buyers of preferred stock are corporations seeking tax-advantaged investments. Second, the cost of preferred stock issuance is lower than it would be in the absence of the tax provision because the tax benefits are passed through to the issuer by the willingness of buyers to accept a lower dividend rate.

Preferred stock has some important similarities with debt, particularly in the case of cumulative preferred stock: (1) the payments to preferred stockholders

---

4. Almost all preferred stock limits the security holder to the specified amount. Historically, there have been issues entitling the preferred stockholder to participate in earnings distribution beyond the specified amount (based on some formula). Preferred stock with this feature is referred to as *participating preferred stock*.

promised by the issuer are fixed, and (2) preferred stockholders have priority over common stockholders with respect to dividend payments and distribution of assets in the case of bankruptcy. (The position of noncumulative preferred stock is considerably weaker than cumulative preferred stock.) It is because of this second feature that preferred stock is called a *senior security.* It is senior to common stock. On a balance sheet, preferred stock is classified as equity.

Preferred stock may be issued without a maturity date. This is called *perpetual preferred stock.* Almost all preferred stock has a sinking-fund provision, and some preferred stock is convertible into common stock. A trademark product of Morgan Stanley is the Preferred Equity Redemption Cumulative Stock (PERCS). This is a preferred stock with a mandatory conversion at maturity.

RESIDENTIAL MORTGAGE-BACKED SECURITIES

A *residential mortgage-backed security* (RMBS) is an instrument whose cash flow depends on the cash flows of an underlying pool of mortgages. In the U.S. market, RMBS are classified into two groups: agency RMBS and nonagency RMBS. An *agency RMBS,* the subject of Chapter 22, is one issued by the Government National Mortgage Association ("Ginnie Mae''), the Federal Home Loan Mortgage Corporation ("Freddie Mac''), or the Federal National Mortgage Association ("Fannie Mae''). Ginnie Mae is a federal government agency within the Department of Housing and Urban Development. The RMBS issued by this entity is guaranteed by the full faith and credit of the U.S. government. Freddie Mac and Fannie Mae are GSEs. In September 2008, these two entities were placed into conservatorship run by the Federal Housing Finance Agency. The agency RMBS market is the second largest sector of the U.S. bond market as of year-end 2019. In bond indexes such as the Bloomberg Barclays U.S. Aggregate Bond Index, this sector is referred to as simply "mortgage-backed securities" or the "MBS" sector despite the fact that there are also private-label RMBS.

Private-label RMBS, also referred to as *nonagency RMBS* and the subject of Chapter 25, are issued by thrifts, commercial banks, or private conduits that are not backed by any government entity. These securities are structured so as to provide credit enhancement that support the credit ratings that they receive. Up to the Great Financial Crisis of 2008–2009, the private-label RMBS market was divided into two sectors: prime RMBS and subprime RMBS. The classification depended on the credit quality of the pool of borrowers and the type of lien on the properties that were mortgaged.

The primary attribute used to categorize the borrower's credit quality has long been the borrower's Fair Isaacs or FICO credit score or any one of other related measures that are not discussed here (e.g., an income ratio indicating the borrower's ability to pay and the loan-to-value ratio measuring the borrower's equity in the property). Prime borrowers are generally those with FICO scores of 660 or higher. Subprime borrowers are those with impaired credit ratings, typically with FICO scores below 660. However, because of the difficulties faced in the RMBS subprime market that started in the summer of 2007, and the poor performance of the collateral underlying both prime and subprime RMBS, investors no longer draw a sharp distinction between these two sectors of the private-label RMBS market.

RMBS can take three forms: (1) mortgage pass-through securities, (2) collateralized mortgage obligations (CMOs), and (3) stripped mortgage-backed securities. Agency RMBS come in all three forms. Typically, private-label RMBS come only in the second form and, as a result, this sector of the market is referred to as the private-label CMO market.

Agency RMBS expose an investor to *prepayment risk*. This is the risk that the borrowers in a mortgage pool will prepay their loans when interest rates decline. Prepayment risk is effectively the same as call risk faced by an investor in a callable corporate or municipal bond. Private-label RMBS expose investors to both prepayment risk and credit risk, although the major concern by investors in this space is credit risk.

COMMERCIAL MORTGAGE-BACKED SECURITIES

Commercial mortgage-backed securities (CMBSs) are backed by a pool of commercial mortgage loans on income-producing property—multifamily properties (i.e., apartment buildings), office buildings, industrial properties (including warehouses), shopping centers, hotels, and health care facilities (i.e., senior housing care facilities). The basic building block of the CMBS transaction is a commercial loan that was originated either to finance a commercial purchase or to refinance a prior mortgage obligation. There are two major types of CMBS deal structures that have been of interest to bond investors, multi-property single borrowers, and multi-property conduits. The fastest-growing segment of the CMBS is conduit-originated transactions. *Conduits* are commercial-lending entities that are established for the sole purpose of generating collateral to securitize.

Unlike residential mortgage loans, where the lender relies on the ability of the borrower to repay and has recourse to the borrower if the payment terms are not satisfied, commercial mortgage loans are nonrecourse loans. This means that the lender can only look to the income-producing property backing the loan for interest and principal repayment. If there is a default, the lender looks to the proceeds from the sale of the property for repayment and has no recourse to the borrower for any unpaid balance. Basically, this means that the lender must view each property as a stand-alone business and evaluate each property using measures that have been found useful in assessing credit risk.

ASSET-BACKED SECURITIES

Asset-backed securities are securities collateralized by assets that are not mortgage loans. In structuring an asset-backed security, issuers have drawn from the structures used in the mortgage-backed securities market. Asset-backed securities have been structured as pass-throughs and as structures with multiple bond classes called *pay-throughs,* which are similar to CMOs. Credit enhancement is provided by letters of credit, over-collateralization, or senior/subordination.

Three common types of asset-backed securities are those backed by credit card receivables, home equity loans, and automobile loans. Chapters 28 and 29 cover these securities. There are also asset-backed securities supported by a pool of manufactured homes, Small Business Administration (SBA) loans, student loans, boat loans, equipment leases, recreational vehicle loans, senior bank loans, and possibly, the future royalties of your favorite entertainer.

COVERED BONDS

In the wake of the financial crisis of 2008–2009, a bond structure very familiar to European investors—covered bonds—was touted as an alternative funding source for residential mortgage loans. Collateral in the typical European covered bond includes residential/commercial mortgages and public sector debt.

A *covered bond* is a debt instrument secured by a specific pool of collateralizing assets. Covered bonds, the subject of Chapter 26, differ from the typical mortgage-backed security issued in the United States on a number of dimensions. First, the cover pool remains on the issuer's balance sheet rather than being sold to a special-purpose entity. Second, the mortgages in the cover pool serve only as collateral for investors, whereas the covered bond's principal and interest are serviced by the issuer's cash flows. Third, mortgage-backed securities are claims to static pools, whereas the cover pool is dynamic, and nonperforming mortgages must be replaced with performing ones. Fourth, unlike MBS, covered bonds are structured to prevent prepayments before maturity. Finally, investors in covered bonds retain an unsecured claim on the issuer for any shortfall due to them (i.e., unpaid principal and interest).

BEYOND TRADITIONAL LIQUID FIXED INCOME INSTRUMENT

Before the Great Financial Crisis of 2008–2009, traditional liquid fixed income market was the place for investors to get interest rate and credit exposure. Regulatory changes, pressures on banks to rebuild their capital and keep their balance sheet lean, as well as the secular decline in interest rates gave a boost to the rise of private credit since then. Private credit is usually mentioned within the context of *alternative credit*. The concept of alternative credit is very broad and covers a wide range of strategies—including liquid investments like below-investment-grade corporate and securitized bonds, as well as less liquid or illiquid strategies like direct lending, nonperforming loans, and distressed credit.

Private direct lending grew as a result of banks lending less than before the crisis, while borrowers who could not access the public market are still in need of funding. Private debt borrowers can be grouped into residential (e.g., nonqualified mortgage borrowers), commercial real estate (e.g., commercial real estate whole loans), corporate (e.g., middle market direct lending, mezzanine lending), and other categories (e.g., trade finance). By investing in private credit, investors can take advantage of higher expected return since these opportunities reside in less efficient markets, as well as demanding an additional illiquidity premium.

Compared to traditional bond investments when a portfolio manager is buying and selling publicly traded securities, the fund manager of private credit strategies has more direct control over the lending decisions, and, if necessary, is actively involved in the workout process. Investors can get exposure to alternative credit either in a hedge fund structure or in a drawdown structure as private direct lending fund limited partners.

KEY POINTS

- Bonds differ on a number of dimensions, which include type of issuer, maturity, coupon, principal amount, method of redemption, and embedded options.
- Embedded options in a debt instrument are call and refunding provisions, prepayment provisions, optional accelerated provision, put provision, and conversion provision.
- Medium-term notes are highly flexible debt instruments that can be easily structured in response to changing market conditions and investor tastes.
- Structured notes are debt instruments that are linked to a derivative position and allow an issuer to create a customized debt instrument for an investor.
- Preferred stock is a security that shares characteristics of debt and equity.
- Residential RMBS are classified into agency and private-label (also called nonagency) securities.
- There are three types of RMBS: (1) pass-throughs, (2) collateralized mortgage obligations (CMOs), and (3) stripped mortgage-backed securities. Private-label RMBS typically have the CMO structure.
- Asset-backed securities are collateralized by financial assets other than residential mortgages.
- A covered bond is a debt instrument secured by a specific pool of collateral called a collateral pool and remains on the balance sheet of the issuer.
- Alternative credit covers a wide range of strategies such as including liquid investments like below-investment-grade corporate and securitized bonds, as well as less liquid or illiquid strategies like direct lending, nonperforming loans, and distressed credit.

The return obtained from a fixed income security from the day it is purchased to the day it is sold can be divided into two parts: (1) the change in market value of the security when it is eventually sold and (2) the cash flows received from the security over the time period that it is held, plus any additional income from reinvestment of the cash flow. Several environmental factors affect one or both of these two parts. We can define the risk associated with any security as a measure of the impact of these factors on the return characteristics of the security.

The different types of risk that an investor in individual fixed income securities is exposed to are as follows:

- Interest-rate risk
- Reinvestment risk
- Call/prepayment risk
- Credit risk
- Inflation, or purchasing-power, risk
- Liquidity risk
- Exchange-rate, or currency, risk

- Volatility risk
- Political or legal risk
- Event risk
- Sector risk

There are also risks associated with bond portfolio strategies. These include statistical measures of portfolio risk and tracking error risk.

Each risk is briefly described in this chapter. A more detailed description of these risks is provided in the chapters that follow.

To manage a bond portfolio, it is important that a manager be able to quantify these risks. In later chapters, multifactor risk models for building and controlling a portfolio's risk profile relative to a bond index or benchmark will be described. These models depend crucially on the ability to measure the primary risk factors. Although not all of the risks described in this chapter are quantifiable, the primary risk factors associated with any bond index and portfolio can be quantified. The key in active bond portfolio management in which the investor's benchmark is a bond index is to quantify the major risk factors so that a portfolio manager who seeks to take a view on some or all of the primary risk factors can do so by constructing a portfolio with a targeted risk profile relative to the benchmark. In the case of passive bond portfolio management, the portfolio manager seeks to match the risk profile of the benchmark.

INTEREST-RATE RISK

Interest-rate risk is the risk associated with an adverse change in interest rates. This risk includes two types of risk: level risk and yield-curve risk. In multifactor risk models described in later chapters, interest-rate risk is referred to as *yield-curve risk* or *term structure risk.*

Level Risk

The price of a typical fixed income security moves in the opposite direction of the change in interest rates: as interest rates rise (fall), the price of a fixed income security will fall (rise).[1] This property is illustrated in Chapter 4. For an investor who plans to hold a fixed income security to maturity, the change in its price before maturity is not of concern, although a decline in the security's market value reflects on the opportunity cost of not investing at a higher yield; however, for an investor who may have to sell the fixed income security before the maturity date, an increase in interest rates will mean the realization of a capital loss. This risk is referred to as *interest-rate risk,* which is one of the primary risks faced by an investor in the fixed income market.

1. There are certain fixed income instruments whose price changes in the same direction as interest rates. Examples are put options and interest-only mortgage-backed securities.

It is customary to represent the market by the yield levels on Treasury securities. Most other yields are compared to the Treasury levels and are quoted as spreads off appropriate Treasury yields. To the extent that the yields of all fixed income securities are interrelated, their prices respond to changes in Treasury rates. As discussed in Chapter 5, the actual magnitude of the price response for any security depends on various characteristics of the security, such as coupon, maturity, and the options embedded in the security (e.g., call and put provisions).

To control interest-rate risk, it is necessary to quantify it. The most commonly used measure of interest-rate risk is *duration.* Duration is the approximate percentage change in the price of a bond or bond portfolio due to a 100-basis point change in yields. This measure and how it is computed is explained in Chapter 5.

Yield-Curve Risk

The yield curve is the graphic depiction of the relationship between the yield on bonds of the same credit quality but different maturities. The yield curve, and a related relationship called the *term structure of interest rates,* will be discussed in more detail in later chapters. A bond portfolio typically contains holdings with different maturities and each bond is subject to interest-rate risk. So, for example, consider two bond portfolios both consisting of three bonds: a 5-year bond, a 10-year bond, and a 20-year bond. The exposure of that portfolio depends on how interest rates change for each of the maturities. Suppose the first bond portfolio has 45% in both the 5-year and 20-year bonds and 10% in the 10-year bond. Suppose that the second bond portfolio has 5% in both the 5-year and 20-year bonds and 90% in the 10-year bond. It is not difficult to understand that the way in which interest rates change on the yield curve can have a substantially different impact on the change in these two bond portfolios.

Yield-curve risk is the exposure of a portfolio to changes in the shape (i.e., movement) of the yield curve. There are various measures that have been suggested for quantifying a portfolio's exposure to changes in the yield curve. The most common measure used is *key rate duration*.

Yield-curve risk is an important risk in bond portfolio management, and with the exception of mortgage-backed securities in which case refinancing risk could impact cohorts of MBS with various coupons and seasoning to a different degree, it is primarily a risk that must be dealt with at the portfolio level.

REINVESTMENT RISK

As explained in Chapter 4, the cash flows received from a security are usually (or are assumed to be) reinvested. The additional income from such reinvestment, sometimes called *interest-on-interest,* depends on the prevailing interest-rate levels at the time of reinvestment, as well as on the reinvestment strategy.

The variability in the returns from reinvestment from a given strategy due to changes in market rates is called *reinvestment risk.* The risk here is that the interest rate at which interim cash flows can be reinvested will fall. Reinvestment risk is greater for longer holding periods. It is also greater for securities with large, early cash flows such as high-coupon bonds. This risk is analyzed in more detail in Chapter 4.

It should be noted that interest-rate risk and reinvestment risk oppose each other. For example, interest-rate risk is the risk that interest rates will rise, thereby reducing the price of a fixed income security. In contrast, reinvestment risk is the risk that interest rates will fall.

CALL/PREPAYMENT RISK

As explained in Chapter 1, bonds may contain a provision that allows the issuer to retire, or "call," all or part of the issue before the maturity date. By including this provision, the issuer retains the right to refinance the bond in the future if market interest rates decline below the coupon rate.

From the investor's perspective, there are three disadvantages of the call provision and hence faces *call risk*. First, the cash-flow pattern of a callable bond is not known with certainty. Second, because the issuer may call the bonds when interest rates have dropped, the investor is exposed to reinvestment risk. That is, the investor will have to reinvest the proceeds received when the bond is called at lower interest rates. Finally, the capital appreciation potential of a bond will be reduced because the price of a callable bond may not rise much above the price at which the issuer may call the bond. (We describe this property of a callable bond, referred to as *negative convexity*, in Chapter 4.)

Agency, corporate, and municipal bonds may have embedded in them the option on the part of the borrower to call, or terminate, the issue before the stated maturity date. All mortgage-backed securities have this option. Even though the investor is usually compensated for taking the risk of call by means of a lower price or a higher yield, it is not easy to determine if this compensation is sufficient. In any case, the returns from a bond with call risk can be dramatically different from those obtained from a noncallable bond. The magnitude of this risk depends on the various parameters of the call, as well as on market conditions.

In the case of mortgage-backed securities, the cash flow depends on prepayments of principal made by the homeowners in the pool of mortgages that is the collateral for the security. Call risk in this case is called *prepayment risk.* It includes *contraction risk*—the risk that homeowners will prepay all or part of their mortgage when mortgage interest rates decline. The risk that prepayments will slow down when mortgage interest rates rise and force an investor who expected that the pool of mortgages would prepay at a faster rate is called *extension risk.*

CORPORATE CREDIT RISK

The *credit risk* of a bond includes:

1. The risk that the issuer will default on its obligation

2. The risk that the bond's value will decline and/or the bond's price performance will be worse than that of other bonds against which the investor is compared because either (a) the market requires a higher spread due to a perceived increase in the risk that the issuer will default or (b) companies that assign ratings to bonds will lower a bond's rating

The first risk is referred to as *default risk*. The second risk is labeled based on the reason for the adverse or inferior performance. The risk attributable to an increase in the spread or, more specifically, the credit spread demanded by the market, is referred to as *credit-spread risk*; the risk attributable to a lowering of the credit rating (i.e., a downgrading) is referred to as *downgrade risk*.

Credit-risk-bearing bonds are traded at higher yield levels than presumably credit-risk-free government bonds with similar maturity. This credit spread offers investors with (1) protection against credit default, and (2) extra yield compensation against taking credit risk. In case no credit event happens, such as default or downgrade, the investor would ideally harvest all the credit spread as excess return over government bonds. At the other extreme, in a theoretical "risk-neutral world," investors would not require extra compensation for risk taking, so all the spread would simply compensate realized credit losses.

In practice, the reality is somewhere in between these two extremes: credit events happen, reducing the excess return relative to the initial credit spreads, but over the long term, credit spreads still turn into some excess return for a well-diversified long-term credit investor. Rising credit spread levels, nevertheless, reflect increased expectation of coming credit losses, as well as more elevated risk aversion. In a risk-neutral world, a one-year credit risk bearing bond, say, 2% probability of default with zero recovery rate, would be fairly "compensated" with a 2.1% spread (or about 1.0% with a 50% recovery rate). However, should default happen, the 100% loss on a single bond would be devastating, so diversification is critical for a corporate bond portfolio. Note, however, that the average spread level of the Bloomberg Barclays U.S. Aggregate Corporate Bond index has been 1.34% from January 1988 to May 2020, whereas the default rate of investment-grade bonds have stayed below 0.5% every year (0.1% per year on average) between 1981 and 2019 based on S&P Global Rating reports.[2] This suggests that credit spreads offer extra compensation to investors beyond covering credit losses over the long term.

A *credit rating* is a formal opinion given by a specialized company of the default risk faced by investing in a particular issue of debt securities. The specialized companies that provide credit ratings are referred to as *rating agencies*. The three nationally recognized rating agencies in the United States are Moody's Investors Service, Standard & Poor's Corporation, and Fitch Ratings. The symbols used by these rating agencies and a summary description of each rating are given in Chapter 10.

2. S&P Global Ratings, "Default, Transition, and Recovery: 2019 Annual Global Corporate Default and Rating Transition Study." April 2020.

Once a credit rating is assigned to a debt obligation, a rating agency monitors the credit quality of the issuer and can reassign a different credit rating to its bonds. An "upgrade" occurs when there is an improvement in the credit quality of an issue; a "downgrade" occurs when there is a deterioration in the credit quality of an issue. As noted earlier, downgrade risk is the risk that an issue will be downgraded.

Typically, before an issue's rating is changed, the rating agency will announce in advance that it is reviewing the issue with the potential for upgrade or downgrade. The issue in such cases is said to be on "rating watch" or "credit watch." In the announcement, the rating agency will state the direction of the potential change in rating—upgrade or downgrade. Typically, a decision will be made within three months.

In addition, rating agencies will issue rating outlooks. A *rating outlook* is a projection of whether an issue in the long term (from six months to two years) is likely to be upgraded, be downgraded, or maintain its current rating. Rating agencies designate a rating outlook as either positive (i.e., likely to be upgraded), negative (i.e., likely to be downgraded), or stable (i.e., likely to be no change in the rating).

Gauging Default Risk and Downgrade Risk

The information available to investors from rating agencies about credit risk are (1) ratings, (2) rating watches or credit watches, and (3) rating outlooks. A study by Moody's found that for corporate bonds, its ratings combined with its rating watches and rating outlook status provide a better gauge for default risk than using the ratings alone.[3] Moreover, periodic studies by the rating agencies provide information to investors about credit risk.

Below we describe how the information provided by rating agencies can be used to gauge two forms of credit risk: default risk and downgrade risk.

For long-term debt obligations, a credit rating is a forward-looking assessment of (1) the probability of default and (2) the relative magnitude of the loss should a default occur. For short-term debt obligations (i.e., obligations with initial maturities of one year or less), a credit rating is a forward-looking assessment of the probability of default. Consequently, credit ratings are the rating agencies' assessments of the default risk associated with a bond issue.

Periodic studies by rating agencies provide information about two aspects of default risk—default rates and default loss rates. First, rating agencies study and make available to investors the percentage of bonds of a given rating at the beginning of a period that have defaulted at the end of the period. This percentage is referred to as the *default rate*. A *default loss rate* is a measure of the magnitude of the potential of the loss should a default occur.

Rating transition tables published periodically by rating agencies also provide information. A rating transition table shows the percentage of issues of each rating at the beginning of a period that were downgraded or upgraded by the end

3. David T. Hamilton and Richard Cantor, "Rating Transitions and Defaults Conditional on Watchlist, Outlook and Rating History," Moody's Investors Service, February 2004.

of the time period. Consequently, by looking at the percentage of downgrades for a given rating, an estimate can be obtained of the probability of a downgrade, and this can serve as a measure of downgrade risk.

Credit Risk Models

Beyond credit ratings, portfolio managers are employing other methodologies for estimating the probability distribution of losses for a bond portfolio in order to compute loss measures such as value at risk (VaR) and conditional VaR (CVaR). For banks, there have been changes in the supervisory framework, as put forward in the Basel II Capital Accord, that require new tools and concepts for measuring credit risk and the development of an internal rating system (IRB), as well as the collection of detailed data on credit exposures and recovery rates. These new tools and concepts will aid banks in evaluating and managing their credit risk profile.

Models for credit risks have long existed in the actuarial and corporate finance literatures. The traditional models concentrate on default rates, credit ratings, and credit risk premiums and focus on diversification, making the assumption that default risks are idiosyncratic and hence can be diversified away in large portfolios. For single isolated credits, the models calculate risk premiums as markups onto the risk-free rate. Since the mid-1990s, however, there have been major advances in modeling credit risk for estimating the probability distribution of losses for a bond portfolio. The models are divided into three categories: structural models, reduced-form models, and incomplete-information models. Each of these models is described in Chapter 42.

SOVEREIGN CREDIT RISK[4]

While we often speak about government bonds in terms of "risk-free" assets, in reality, sovereign issuers are not free of credit risk either. *Sovereign credit risk* has periodically become a concern, and while over the past decades, government defaults were mainly associated with developing and emerging countries, government balance sheets of developed markets can come under pressure as well. Governments in the United States and across Europe have accumulated significant debt by stimulating the economy after the Global Financial Crisis, and would potentially add to the sovereign debt as result of the additional stimulus packages that have been introduced during the COVID-19 pandemic.

Sovereign debt covers the outstanding debt obligations of the federal government, central administration, local governments, and all entities that borrow with an explicit guarantee from the government. Sovereign credit risk is the possibility

4. This discussion is based on Adam Kobor, "Sovereign Credit Risk Assessment: From Traditional Indicators to The Contingent Claim Approach," in Jerome L. Kreuser (ed.), *Risk Management for Sovereign Institutions: The Marketing & Management Collection*, Henry Stewart Talks Ltd, London 2012 (online at https://hstalks.com/expert/2134/dr-adam-kobor/).

that the government may default on its debt, thus it fails to service its interest and principal payment obligations in a timely manner. As discussed in the previous section in the context of corporate credit risk, sovereign credit risk can also impact investors by not only losing all or more typically part of the principal, but in many other forms as well. Credit risk may manifest in debt restructuring by credit downgrade, or significant spread widening as the market is anticipating a default.

While the concept of a credit default in principle is the same for sovereigns and corporate issuers, sovereign borrowers and corporations also differ in many respects. In the case of sovereigns, a default occurs either because the borrower is not able to repay its debt, or particularly in the case of local currency debt, because it is unwilling to service its obligation. Sovereigns, unlike corporations, do not go bankrupt, and a sovereign default may be a result of choice, by taking political and social as well as economic and financial consequences into account. With that in mind, why are investors willing to lend money to sovereigns? Unlike in the case of corporate debt, there are very limited legal means to reinforce the contract, especially in the case of domestic debt. Still, there are several incentives for a government to honor its debt. First, a default hugely deteriorates a country's market access and reputation and makes future borrowings particularly difficult and expensive. Second, a default can very negatively impact trade relations with other countries, and broad international relations and alliances can be also damaged by a default.

INFLATION, OR PURCHASING-POWER, RISK

Inflation risk, or *purchasing-power risk,* arises because of the variation in the value of cash flows from a security due to inflation, as measured in terms of purchasing power. For example, if an investor purchases a five-year bond in which he or she can realize a coupon rate of 7%, but the rate of inflation is 8%, then the purchasing power of the cash flow has declined. For all but inflation-linked securities (sometime referred to as "linkers"), an investor is exposed to inflation risk because the interest rate the issuer promises to make is fixed for the life of the security. To the extent that interest rates reflect the expected inflation rate, floating-rate bonds have a lower level of inflation risk than fixed-rate bonds.

LIQUIDITY RISK

Liquidity risk is the risk that the investor will have to sell a bond below its true value where the true value is indicated by a recent transaction. The primary measure of liquidity is the size of the spread between the bid price and the ask price quoted by a dealer. The wider the bid/ask spread, the greater is the liquidity risk.

A liquid market generally can be defined by "small bid/ask spreads which do not materially increase for large transactions."[5] How to define the bid/ask

5. Robert I. Gerber, "A User's Guide to Buy-Side Bond Trading," Chapter 16 in Frank J. Fabozzi (ed.), *Managing Fixed Income Portfolios* (New Hope, PA: Frank J. Fabozzi, 1997), p. 278.

spread in a multiple-dealer market is subject to interpretation. For example, consider the bid/ask spread for four dealers. Each quote is for 92 plus the number of 32nds shown:

	Dealer			
	1	2	3	4
Bid price	1	1	2	2
Ask price	4	3	4	5

The bid/ask spread for each dealer (in 32nds) is

	Dealer			
	1	2	3	4
Bid/ask spread	3	2	2	3

The bid/ask spread as computed above is measured relative to a dealer. The best bid/ask spread is two 32nds for Dealers 2 and 3.

From the perspective of the *market overall,* the bid/ask spread can be computed by looking at the best bid price (high price at which one of the dealers is willing to buy the security) and the lowest ask price (lowest offer price at which one of the dealers is willing to sell the security). This liquidity measure is called the *market bid/ask spread.* For the four dealers, the highest bid price is 92 plus two 32nds and the lowest ask price is 92 plus three 32nds. Thus, the market bid/ask spread is one 32nd.

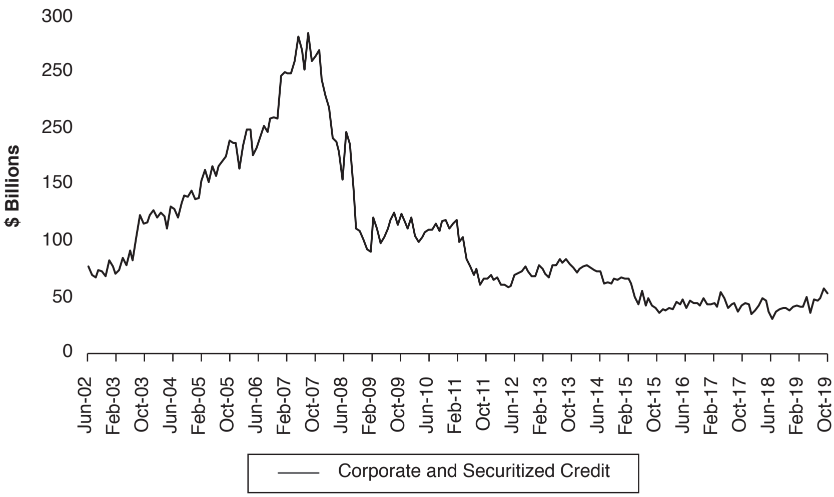
For investors who plan to hold a bond until maturity and need not mark a position to market, liquidity risk is not a major concern. An institutional investor who plans to hold an issue to maturity but is periodically marked to market is concerned with liquidity risk. By marking a position to market, it is meant that the security is revalued in the portfolio based on its current market price. For example, mutual funds are required to mark to market at the end of each day the holdings that are in their portfolio in order to compute the net asset value (NAV). While other institutional investors may not mark to market as frequently as mutual funds, they are marked to market when reports are periodically sent to clients or the board of directors or trustees.

Where are the prices obtained to mark a position to market? Typically, a portfolio manager will solicit indicative bids from several dealers and then use some process to determine the bid price used to mark the position. The less liquid the issue, the greater the variation there will be in the bid prices obtained from dealers. With an issue that has little liquidity, the price may have to be determined by a pricing service rather than by dealers. Moreover, lack of dealer indicative bids and concern with models used by pricing services may lead the manager to occasionally override a bid (subject to internal approval beyond the control of the manager).

Investors have faced challenging general fixed income market liquidity conditions several times over the recent years. Market liquidity is the capacity to sell or buy securities over reasonably short period of time without an adverse impact on the security prices. Traditionally, brokers/dealers have provided liquidity to the fixed income market, but regulatory changes following the Global Financial Crisis have reduced this liquidity-providing capacity.[6] Elevated bank capital requirements by the Dodd–Frank Act, and prohibitions on proprietary trading by the Volcker Rule have led to shrinking dealer inventories, and thus to declining bond market liquidity, following the crisis (see Exhibit 2-1). This shrinkage in dealer inventory did not only lead to a choppier bond market liquidity, but a declining repo market liquidity at the same time, especially challenging to investors during times close to quarter or year ends, as well as market stress periods like the outbreak of COVID-19.

EXHIBIT 2-1

Primary Dealer Position: Corporate and Securitized Credit



Source of data: Federal Reserve Bank of New York.

Another relatively recent market development has been the introduction of fixed income exchange-traded funds (ETFs). While bonds are typically traded in an over-the-counter market, fixed income ETFs made it easy for retail as well as

6. Arnab Das, Jennifer Johnson-Calari, and Adam Kobor, "Managing Liquidity Risk," Central Bank Whitepaper, INVESCO, October 20, 2017.

institutional investors to increase or reduce their portfolio's fixed income exposures by one click at an exchange traded market. Under a healthy market conditions, investors can buy and sell these fixed income index-replicating (and other, more exotic) products in a very short time, while the Authorized Participant may create or redeem shares in the underlying bond market if and as needed. During dried-up liquidity conditions, while investors could still trade these ETFs with a single click, the ETF prices and NAV could significantly deviate from each other, suggesting that investors cannot fully escape the adverse impact of the lack of liquidity in the underlying market.

EXCHANGE-RATE RISK (CURRENCY RISK)

A non-dollar-denominated bond (i.e., a bond whose payments occur in a foreign currency) has unknown U.S. dollar cash flows. The dollar cash flows are dependent on the foreign-exchange-rate at the time the payments are received. For example, suppose that an investor purchases a bond whose payments are in Japanese yen. If the yen depreciates relative to the U.S. dollar, then fewer dollars will be received. The risk of this occurring is referred to as *exchange-rate risk,* or *currency risk.* Of course, should the yen appreciate relative to the U.S. dollar, the investor will benefit by receiving more dollars.

In addition to the change in the exchange-rate, an investor is exposed to the interest-rate, or market, risk in the local market. For example, if a U.S. investor purchases German government bonds denominated in euros, the proceeds received from the sale of that bond prior to maturity will depend on the level of interest rates in the German bond market, in addition to the exchange-rate.

VOLATILITY RISK

As will be explained in later chapters, the price of a bond with an embedded option depends on the level of interest rates and factors that influence the value of the embedded option. One of the factors is the expected volatility of interest rates. Specifically, the value of an option rises when expected interest-rate volatility increases. In the case of a callable bond or mortgage-backed security, because the investor has granted an option to the borrower, the price of the security falls because the investor has given away a more valuable option. The risk that a change in volatility will adversely affect the price of a security is called *volatility risk.*

Multifactor risk models often refer to volatility risk as *vega*. This is because in option theory, there are measures of the exposure of an option to changes in the factors that affect an option's value. One of the factors is volatility, and vega is the term used to measure the sensitivity of an option's price to a change in volatility. Hence, the sensitivity of bonds with embedded options and a bond portfolio containing bonds with embedded options to changes in volatility is given the same name.

POLITICAL OR LEGAL RISK

Sometimes the government can declare withholding or other additional taxes on a bond or declare a tax-exempt bond taxable. In addition, a regulatory authority can conclude that a given security is unsuitable for investment entities that it regulates. These actions can adversely affect the value of the security. Similarly, it is also possible that a legal or regulatory action affects the value of a security positively. The possibility of any political or legal actions adversely affecting the value of a security is known as *political* or *legal risk*.

To illustrate political or legal risk, consider investors who purchase tax-exempt municipal securities. They are exposed to two types of political risk that can be more appropriately called *tax risk*. The first type of tax risk is that the federal income tax rate will be reduced. The higher the marginal tax rate, the greater is the value of the tax-exempt nature of a municipal security. As the marginal tax rates decline, the price of a tax-exempt municipal security will decline. For example, proposals for a flat tax with a low tax rate significantly reduced the potential tax advantage of owning municipal bonds. As a result, tax-exempt municipal bonds began trading at lower prices. The second type of tax risk is that a municipal bond issued as tax exempt eventually will be declared taxable by the Internal Revenue Service (IRS). This may occur because many municipal (revenue) bonds have elaborate security structures that could be subject to future adverse congressional actions and IRS interpretations. As a result of the loss of the tax exemption, the municipal bond will decline in value in order to provide a yield comparable to similar taxable bonds.

EVENT RISK

Occasionally, the ability of an issuer to make interest and principal payments is seriously and unexpectedly changed by (1) a natural disaster or industrial accident or (2) a takeover or corporate restructuring. These risks are referred to as *event risk*. The cancellation of plans to build a nuclear power plant illustrates the first type of event in relation to the utility industry.

An example of the second type of event risk is the takeover in 1988 of RJR Nabisco for $25 billion via a financing technique known as a *leveraged buyout* (LBO). In such a transaction, the new company incurred a substantial amount of debt to finance the acquisition of the firm. Because the corporation was required to service a substantially larger amount of debt, its quality rating was reduced to non-investment-grade quality. As a result, the change in yield spread to a benchmark Treasury, demanded by investors because of the LBO announcement, increased from about 100 to 350 basis points.

There are also spillover effects of event risk on other firms. For example, if there is a nuclear accident, this will affect all utilities producing nuclear power.

SECTOR RISK

Bonds in different sectors of the market respond differently to environmental changes because of a combination of some or all of the preceding risks, as well as others. Examples include discount versus premium coupon bonds, industrial versus utility bonds, and corporate versus mortgage-backed bonds. The possibility of adverse differential movement of specific sectors of the market is called *sector risk.*

OTHER RISKS

The various risks of investing in the fixed income markets reviewed in this chapter do not represent the entire range of risks. In the marketplace, it is customary to combine almost all risks other than market risk (interest-rate risk) and refer to it as *basis risk.*

STATISTICAL MEASURES OF PORTFOLIO RISK

In the development of portfolio theory as formulated by Harry Markowitz (also known as mean-variance analysis), a portfolio's risk is measured by the *standard deviation* of historical portfolio returns.[7] This statistical measure provides a range around the average return of a portfolio within which the actual return over a period is likely to fall with some specific probability. In evaluating actual and potential performance relative to a benchmark that is a bond index, the mean return and standard deviation of returns of the bond index and the portfolio are compared.

In addition to the standard deviation of returns, investors may be interested in various measures quantifying the downside risk they are facing. *Value at risk* (VaR) would quantify the lowest return over a specified time horizon they should expect at a certain (e.g., 95% or 99%) confidence level. *Drawdown at risk* (DaR) would indicate the lowest cumulative return from a portfolio peak to trough either based on historical and Monte Carlo simulation analysis.

Extensions of portfolio risk to take into account other statistical measures of a return distribution are being used in practice.[8] Two statistical measures most commonly used are skewness and kurtosis. A return distribution is said to be symmetric based on the probability distribution around the mean or expected value. If the return distribution is the same above and below the mean value, then the distribution is said to be symmetric. If a return distribution does not exhibit this property, it is said to be *asymmetric. Skewness* is a measure of the symmetry of a return distribution. Actually, it is more meaningful to say that skewness is a

7. Harry M. Markowitz, "Portfolio Selection," *Journal of Finance* 7(1), 1952, pp. 77–91.

8. Svetlozar T. Rachev, Christian Menn, and Frank J. Fabozzi, *Fat-Tailed and Skewed Asset Return Distributions: Implications for Risk Management, Portfolio Selection, and Option Pricing* (New York: John Wiley & Sons, 2005).

measure of the lack of symmetry of the return distribution. The normal distribution is a symmetric distribution. Consequently, when the return distribution is assumed to be normally distributed, skewness is not a concern. Return on fixed income securities or portfolios in fact exhibit some negative skewness: callability, refinanceability. Moreover, credit defaults contribute to a longer downside tail compared to the upside.

Kurtosis is a statistical measure of whether a return distribution is peaked or flat relative to a normal distribution. That is, a return distribution with high kurtosis tends to have a distinct peak near the mean value, decline rather rapidly, and have fat (or heavy) tails. This property for a return distribution occurs when in addition to many modest-sized deviations from the mean value there are also infrequent extreme deviations from the mean value. Return distributions that exhibit low kurtosis tend to have a flat top near the mean value rather than a sharp peak. Credit spreads exhibit much larger jumps during stressful periods than under normal conditions, thus the total return of credit risk dominated portfolios usually exhibits heavy tails.

TRACKING ERROR RISK

A bond portfolio's standard deviation and a designated benchmark's standard deviation are absolute numbers. A portfolio manager can compare the mean values and standard deviations to try to get a feel for the risk profile of the portfolio relative to the benchmark. If skewness and kurtosis are also considered, this would provide an expanded profile of the relative risks of the bond portfolio and the bond index.

A portfolio manager or client can also assess what the variation in the portfolio's return is relative to a benchmark (such as a bond index) by looking at the deviations of the periodic (weekly or monthly) portfolio return from that of the benchmark. The difference between the two is called the *active return*. That is,

Active return = Portfolio's actual return – Benchmark's actual return

From the active returns, a portfolio's risk relative to the benchmark can be calculated by the standard deviation of the active returns. This standard deviation is referred to as *tracking error risk* or *tracking error volatility,* or simply *tracking error*.

The larger a portfolio's tracking error, the more its risk profile deviates from that of the benchmark. In fact, when bond portfolio strategies are discussed in later chapters, we will see that there are active and passive strategies. The latter strategies involve little tracking error. For example, a portfolio constructed to match the performance of a bond index will have a tracking error close to zero. Active strategies will have higher tracking error, how much higher depends on the degree of risk the portfolio manager or client is willing to accept.

There are two types of tracking error. Tracking error calculated from a portfolio's historical active returns is called *backward-looking tracking error*. It is also called *historical tracking error* and *ex-post tracking error*. The limitation of backward-looking tracking error is that it fails to take into account the effect of current decisions by the portfolio manager on the future active returns and therefore may have little predictive value and can be misleading regarding the portfolio risks going forward. The other type of tracking error is *forward-looking tracking error*—also called *predicted tracking error* and *ex-ante tracking error*. This form of tracking error seeks to accurately reflect the portfolio's risk going forward. In practice, forward-looking tracking error is estimated using a multifactor risk model as described in Chapters 49 and 50.

KEY POINTS

- The risks associated with investing in individual fixed income securities are interest-rate risk, reinvestment risk, call/prepayment risk, credit risk, inflation (or purchasing-power) risk, liquidity risk, exchange-rate (or currency) risk, volatility risk, political or legal risk, event risk, and sector risk.
- Interest-rate risk is the risk associated with an adverse change in interest rates and includes level risk and yield-curve risk. The most popular measure of level risk is duration; key rate duration is the most popular measure of yield-curve risk.
- Credit risk includes default risk, credit-spread risk, and downgrade risk. Credit risk models seek to estimate the probability distribution of losses for a bond portfolio.
- Portfolio risk measures include statistical measures of return and tracking error risk.
- Statistical measures of portfolio and benchmark risk include the standard deviation, skewness, and kurtosis.
- Tracking error risk is the standard deviation of the active return of a portfolio (i.e., the difference between the portfolio's return and the benchmark's return). Backward-looking tracking error is used to assess a portfolio's performance relative to a benchmark. Forward-looking tracking error is used to predict future performance relative to a benchmark.

CHAPTER
THREE

THE STRUCTURE OF INTEREST RATES

Frank J. Fabozzi, Ph.D., CFA, CPA
Professor of Finance
EDHEC Business School

There is no single interest rate for any economy; rather, there is an interdependent structure of interest rates. The interest rate that a borrower has to pay depends on a myriad of factors. In this chapter we describe these factors. We begin with a discussion of the *base interest rate:* the interest rate on U.S. government securities. Next, we explain the factors that affect the yield spread or risk premium for non-Treasury securities. Finally, we focus on one particular factor that affects the interest rate demanded in an economy for a particular security: maturity. The relationship between yield and maturity (or term) is called the *term structure of interest rates*, and this relationship is critical in the valuation of securities.

THE BASE INTEREST RATE

The securities issued by the U.S. Department of the Treasury are backed by the full faith and credit of the U.S. government. Despite the credit concerns arising from the U.S. budget deficit and the downgrading of the U.S. government credit rating from triple A to AA+ by the credit rating agency of Standard & Poor's in August 2011 (Moody's and Fitch still maintained a triple A rating but Fitch had a negative outlook as of July 2020), market participants throughout the world view U.S. government obligations as having minimal credit risk. Therefore, interest rates on Treasury securities are the benchmark interest rates throughout the U.S. economy. The large sizes of Treasury issues have contributed to making the Treasury market the most active and hence the most liquid market in the world.

The minimum interest rate or *base interest rate* that investors will demand for investing in a non-Treasury security is the yield offered on a comparable maturity for an on-the-run Treasury security. The base interest rate is also referred to as the *benchmark interest rate.*

RISK PREMIUM

Market participants describe interest rates on non-Treasury securities as trading at a spread to a particular on-the-run Treasury security. For example, if the yield on a 10-year non-Treasury security is 5% and the yield on a 10-year Treasury security is 4%, the spread is 100 basis points. This spread reflects the additional risks the investor faces by acquiring a security that is not issued by the U.S. government and therefore can be called a *risk premium*. Thus we can express the interest rate offered on a non-Treasury security as

Base interest rate + spread

or equivalently,

Base interest rate + risk premium

The factors that affect the spread include (1) the type of issuer, (2) the issuer's perceived creditworthiness, (3) the term or maturity of the instrument, (4) provisions that grant either the issuer or the investor the option to do something, (5) the taxability of the interest received by investors, and (6) the expected liquidity of the issue.

Types of Issuers

A key feature of a debt obligation is the nature of the issuer. In addition to the U.S. government, there are agencies of the U.S. government, municipal governments, corporations (domestic and foreign), and foreign governments that issue bonds.

The bond market is classified by the type of issuer. These are referred to as *market sectors*. The spread between the interest rate offered in two sectors of the bond market with the same maturity is referred to as an *intermarket-sector spread*.

Excluding the Treasury market sector, other market sectors have a wide range of issuers, each with different abilities to satisfy bond obligations. For example, within the corporate market sector, issuers are classified as utilities, transportations, industrials, and banks and finance companies. The spread between two issues within a market sector is called an *intramarket-sector spread*.

Perceived Creditworthiness of Issuer

Default risk or *credit risk* refers to the risk that the issuer of a bond may be unable to make timely payment of principal or interest payments. Most market participants rely primarily on commercial rating companies (Fitch Ratings, Moody's Investors Service, and Standard & Poor's) to assess the default risk of an issuer. The spread between Treasury securities and non-Treasury securities that are identical in all respects except for quality is referred to as a *credit spread* or *quality spread*.

Term-to-Maturity

As explained in Chapter 4, the price of a bond will fluctuate over its life as yields in the market change. As demonstrated in Chapter 5, the volatility of a bond's price is dependent on its maturity. With all other factors constant, the longer the maturity of a bond, the greater is the price volatility resulting from a change in market yields.

The spread between any two maturity sectors of the market is called a *yield-curve spread* or *maturity spread.* The relationship between the yields on comparable securities with different maturities, as mentioned earlier, is called the *term structure of interest rates*.

The term-to-maturity topic is very important, and we have devoted more time to this topic later in this chapter.

Inclusion of Options

It is not uncommon for a bond issue to include a provision that gives the bondholder or the issuer an option to take some action against the other party. An option that is included in a bond issue is referred to as an *embedded option.* We discussed the various types of embedded options in Chapter 1. The most common type of option in a bond issue is the call provision, which grants the issuer the right to retire the debt, fully or partially, before the scheduled maturity date. The inclusion of a call feature benefits issuers by allowing them to replace an old bond issue with a lower-interest-cost issue when interest rates in the market decline. In effect, a call provision allows the issuer to alter the maturity of a bond. The exercise of a call provision is disadvantageous to the bondholder because the bondholder must reinvest the proceeds received at a lower interest rate.

The presence of an embedded option affects both the spread of an issue relative to a Treasury security and the spread relative to otherwise comparable issues that do not have an embedded option. In general, market participants will require a larger spread to a comparable Treasury security for an issue with an embedded option that is favorable to the issuer (such as a call option) than for an issue without such an option. In contrast, market participants will require a smaller spread to a comparable Treasury security for an issue with an embedded option that is favorable to the investor (such as a put option or a conversion option). In fact, the interest rate on a bond with an option that is favorable to an investor may be less than that on a comparable Treasury security.

Taxability of Interest

Unless exempted under the federal income tax code, interest income is taxable at the federal level. In addition to federal income taxes, there may be state and local taxes on interest income.

The federal tax code specifically exempts the interest income from qualified municipal bond issues. Because of this tax exemption, the yield on municipal bonds is less than on Treasuries with the same maturity. The difference in yield between tax-exempt securities and Treasury securities is typically measured not in basis points but in percentage terms. More specifically, it is measured as the percentage of the yield on a tax-exempt security relative to a comparable Treasury security.

The yield on a taxable bond issue after federal income taxes are paid is equal to

$$\text{After-tax yield} = \text{pretax yield} \times (1 - \text{marginal tax rate})$$

For example, suppose that a taxable bond issue offers a yield of 4% and is acquired by an investor facing a marginal tax rate of 35%. The after-tax yield would be

$$\text{After-tax yield} = 0.04 \times (1 - 0.35) = 0.026 = 2.60\%$$

Alternatively, we can determine the yield that must be offered on a taxable bond issue to give the same after-tax yield as a tax-exempt issue. This yield is called the *equivalent taxable yield* and is determined as follows:

$$\text{Equivalent taxable yield} = \frac{\text{tax-exempt yield}}{(1 - \text{marginal tax rate})}$$

For example, consider an investor facing a 35% marginal tax rate who purchases a tax-exempt issue with a yield of 2.6%. The equivalent taxable yield is then

$$\text{Equivalent taxable yield} = \frac{0.026}{(1 - 0.35)} = 0.04 = 4\%$$

Notice that the lower the marginal tax rate, the lower is the equivalent taxable yield. For example, in our previous example, if the marginal tax rate is 25% rather than 35%, the equivalent taxable yield would be 3.47% rather than 4%, as shown below.

$$\text{Equivalent taxable yield} = \frac{0.026}{(1 - 0.25)} = 0.0347 = 3.47\%$$

State and local governments may tax interest income on bond issues that are exempt from federal income taxes. Some municipalities exempt interest income from all municipal issues from taxation; others do not. Some states exempt interest income from bonds issued by municipalities within the state but tax the interest income from bonds issued by municipalities outside the state. The implication is that two municipal securities of the same quality rating and the same maturity may trade at some spread because of the relative demand for bonds of municipalities in different states. For example, in a high-income-tax state such as New York, the demand for bonds of municipalities will drive down their yield relative to municipalities in a low-income-tax state, holding all credit issues aside.

Municipalities are not permitted to tax the interest income from securities issued by the U.S. Treasury. Thus part of the spread between Treasury securities and taxable non-Treasury securities of the same maturity reflects the value of the exemption from state and local taxes.

Expected Liquidity of an Issue

Bonds trade with different degrees of liquidity. The greater the expected liquidity at which an issue will trade, the lower is the yield that investors require. As noted earlier, Treasury securities are the most liquid securities in the world. The lower yield offered on Treasury securities relative to non-Treasury securities reflects the difference in liquidity as well as perceived credit risk. Even within the Treasury market, on-the-run issues have greater liquidity than off-the-run issues.

THE TERM STRUCTURE OF INTEREST RATES

In future chapters we will see the key role that the term structure of interest rates plays in the valuation of bonds. For this reason, we devote a good deal of space to this important topic.

The Yield Curve

The graphic depiction of the relationship between the yield on bonds of the same credit quality but different maturities is known as the *yield curve*. In the past, most market participants have constructed yield curves from the observations of prices and yields in the Treasury market. Two reasons account for this tendency. First, Treasury securities are viewed as free of default risk, and differences in creditworthiness do not affect yield estimates. Second, as the most active bond market, the Treasury market offers the fewest problems of illiquidity or infrequent trading. Exhibit 3-1 shows the shape of three hypothetical Treasury yield curves that have been observed in the United States, as well as other countries.

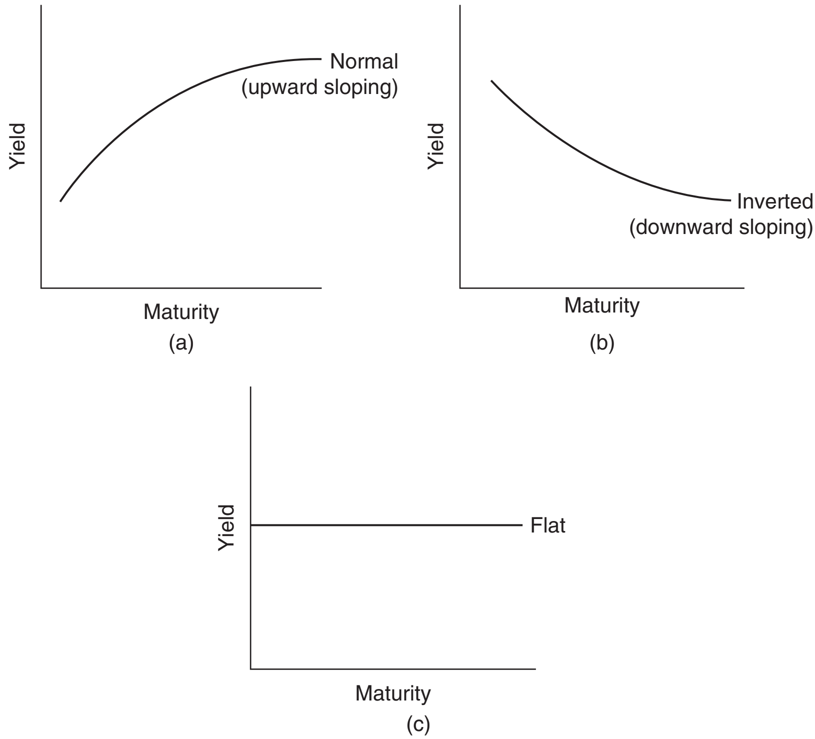
From a practical viewpoint, as we explained earlier in this chapter, the key function of the Treasury yield curve is to serve as a benchmark for pricing bonds and setting yields in other sectors of the debt market. However, market participants are coming to realize that the traditionally constructed Treasury yield curve is an unsatisfactory measure of the relation between required yield and maturity. The key reason is that securities with the same maturity actually may carry different yields. As we will explain, this phenomenon reflects the impact of differences in the bonds' coupon rates. Hence it is necessary to develop more accurate and reliable estimates of the Treasury yield curve. We will show the problems posed by traditional approaches to the Treasury yield curve, and we will explain the proper approach to building a yield curve. The approach consists of identifying yields that apply to zero-coupon bonds and, therefore, eliminates the problem of nonuniqueness in the yield-maturity relationship.

Using the Yield Curve to Price a Bond

The price of a bond is the present value of its cash flows. However, in the pricing of a bond as explained in Chapter 4, it is assumed that one interest rate should be used to discount all the bond's cash flows. The appropriate interest rate is the

EXHIBIT 3-1

Three Hypothetical Yield Curves



yield on a Treasury security with the same maturity as the bond plus an appropriate risk premium or spread.

However, there is a problem with using the Treasury yield curve to determine the appropriate yield at which to discount the cash flow of a bond. To illustrate this problem, consider two hypothetical five-year Treasury securities, A and B. The difference between these two Treasury securities is the coupon rate, which is 12% for A and 3% for B. The cash flow for these two securities per $100 of par value for the 10 six-month periods to maturity would be as follows:

Period	Cash Flow for A	Cash Flow for B
1–9	$ 6.00	$ 1.50
10	106.00	101.50

Because of the different cash flow patterns, it is not appropriate to use the same interest rate to discount all cash flows. Instead, each cash flow should be discounted at a unique interest rate that is appropriate for the time period in which the cash flow will be received. But what should be the interest rate for each period?

The correct way to think about Treasury securities A and B is not as a debt instrument but as packages of cash flows. More specifically, they are packages of zero-coupon instruments. Thus the interest earned is the difference between the maturity value and the price paid. For example, security A can be viewed as 10 zero-coupon instruments: One with a maturity value of $6 maturing six months from now, a second with a maturity value of $6 maturing one year from now, a third with a maturity value of $6 maturing 1.5 years from now, and so on. The final zero-coupon instrument matures 10 six-month periods from now and has a maturity value of $106. Likewise, security B can be viewed as 10 zero-coupon instruments: One with a maturity value of $1.50 maturing six months from now, one with a maturity value of $1.50 maturing one year from now, one with a maturity value of $1.50 maturing 1.5 years from now, and so on. The final zero-coupon instrument matures 10 six-month periods from now and has a maturity value of $101.50. Obviously, in the case of each coupon security its value or price is equal to the total value of its component zero-coupon instruments.

In general, any bond can be viewed as a package of zero-coupon instruments. That is, each zero-coupon instrument in the package has a maturity equal to its coupon payment date or, in the case of the principal, the maturity date. The value of the bond should equal the value of all the component zero-coupon instruments. If this does not hold, a market participant may generate riskless profits by stripping the security and creating stripped securities.

To determine the value of each zero-coupon instrument, it is necessary to know the yield on a zero-coupon Treasury with that same maturity. This yield is called the *spot rate,* and the graphic depiction of the relationship between the spot rate and its maturity is called the *spot-rate curve.* Because there are no zero-coupon Treasury debt issues with a maturity greater than one year issued by the U.S. Department of the Treasury, it is not possible to construct such a curve solely from observations of Treasury yields. Rather, it is necessary to derive this curve from theoretical considerations as applied to the yields of actual Treasury securities. Such a curve is called a *theoretical spot-rate curve.*

Constructing the Theoretical Spot-Rate Curve

The theoretical spot-rate curve is constructed from the yield curve based on the observed yields of Treasury bills and Treasury coupon securities. The process of creating a theoretical spot-rate curve in this way is called *bootstrapping.*[1]

1. In practice, the securities used to construct the theoretical spot-rate curve are the most recently auctioned Treasury securities of a given maturity. Such issues are referred to as the *on-the-run Treasury issues*. As explained in Chapter 7, there are actual zero-coupon Treasury securities with a maturity greater than one year that are outstanding in the market. These securities are not issued by the U.S. Treasury but are created by market participants from actual coupon Treasury securities. It would seem logical that the observed yield on zero-coupon Treasury securities can be used to construct an actual spot-rate curve. However, there are problems with this approach. First, the liquidity of these securities is not as great as that of the coupon Treasury market. Second, there are maturity sectors of the zero-coupon Treasury market that attract specific investors who may be willing to trade yield in exchange for an attractive feature associated with that particular maturity sector, thereby distorting the term-structure relationship.

EXHIBIT 3-2

Maturity and Yield-to-Maturity for 20 Hypothetical Treasury Securities

Maturity	Coupon Rate	Yield-to-Maturity	Price
0.50 years	0.0000	0.0800	$ 96.15
1.00	0.0000	0.0830	92.19
1.50	0.0850	0.0890	99.45
2.00	0.0900	0.0920	99.64
2.50	0.1100	0.0940	103.49
3.00	0.0950	0.0970	99.49
3.50	0.1000	0.1000	100.00
4.00	0.1000	0.1040	98.72
4.50	0.1150	0.1060	103.16
5.00	0.0875	0.1080	92.24
5.50	0.1050	0.1090	98.38
6.00	0.1100	0.1120	99.14
6.50	0.0850	0.1140	86.94
7.00	0.0825	0.1160	84.24
7.50	0.1100	0.1180	96.09
8.00	0.0650	0.1190	72.62
8.50	0.0875	0.1200	82.97
9.00	0.1300	0.1220	104.30
9.50	0.1150	0.1240	95.06
10.00	0.1250	0.1250	100.00

To explain this process, we use the data for the hypothetical price, annualized yield (yield-to-maturity), and maturity of the 20 Treasury securities shown in Exhibit 3-2.

Throughout the analysis and illustrations to come, it is important to remember that the basic principle of bootstrapping is that the value of a Treasury coupon security should be equal to the value of the package of zero-coupon Treasury securities that duplicates the coupon bond's cash flow.

Consider the six-month Treasury bill in Exhibit 3-2. As explained in Chapter 7, a Treasury bill is a zero-coupon instrument. Therefore, its annualized yield of 8% is equal to the spot rate. Similarly, for the one-year Treasury bill, the cited yield of 8.3% is the one-year spot rate. Given these two spot rates, we can compute the spot rate for a theoretical 1.5-year zero-coupon Treasury. The price of a theoretical 1.5-year Treasury should equal the present value of three cash flows from an actual 1.5-year coupon Treasury, where the yield used for discounting is the spot rate corresponding to the cash flow. Using $100 as par, the cash flow for the 1.5-year coupon Treasury is as follows:

$$\begin{array}{lll} 0.5 \text{ years} & 0.085 \times \$100 \times 0.5 & = \$4.25 \\ 1.0 \text{ years} & 0.085 \times \$100 \times 0.5 & = \$4.25 \\ 1.5 \text{ years} & 0.085 \times \$100 \times 0.5 + 100 & = \$104.25 \end{array}$$

The present value of the cash flow is then

$$\frac{4.25}{(1+z_1)^1} + \frac{4.25}{(1+z_2)^2} + \frac{104.25}{(1+z_3)^3}$$

where

z_1 = one-half the annualized six-month theoretical spot rate
z_2 = one-half the one-year theoretical spot rate
z_3 = one-half the 1.5-year theoretical spot rate

Because the six-month spot rate and one-year spot rate are 8.0% and 8.3%, respectively, we know that

$$z_1 = 0.04 \qquad \text{and} \qquad z_2 = 0.0415.$$

We can compute the present value of the 1.5-year coupon Treasury security as

$$\frac{4.25}{(1.0400)^1} + \frac{4.25}{(1.0415)^2} + \frac{104.25}{(1+z_3)^3}$$

Because the price of the 1.5-year coupon Treasury security (from Exhibit 3-2) is $99.45, the following relationship must hold:

$$99.45 = \frac{4.25}{(1.0400)^1} + \frac{4.25}{(1.0415)^2} + \frac{104.25}{(1+z_3)^3}$$

We can solve for the theoretical 1.5-year spot rate as follows:

$$99.45 = 4.08654 + 3.91805 + \frac{104.25}{(1+z_3)^3}$$

$$91.44541 = \frac{104.25}{(1+z_3)^3}$$

$$(1+z_3)^3 = 1.140024$$

$$z_3 = 0.04465$$

Doubling this yield, we obtain the bond-equivalent yield of 0.0893, or 8.93%, which is the theoretical 1.5-year spot rate. This rate is the rate that the market would apply to a 1.5-year zero-coupon Treasury security, if such a security existed.

Given the theoretical 1.5-year spot rate, we can obtain the theoretical two-year spot rate. The cash flow for the two-year coupon Treasury in Exhibit 3-2 is

$$\begin{array}{lll} 0.5 \text{ years} & 0.090 \times \$100 \times 0.5 & = \$4.50 \\ 1.0 \text{ years} & 0.090 \times \$100 \times 0.5 & = \$4.50 \\ 1.5 \text{ years} & 0.090 \times \$100 \times 0.5 & = \$4.50 \\ 2.0 \text{ years} & 0.090 \times \$100 \times 0.5 + 100 & = \$104.50 \end{array}$$

The present value of the cash flow is then

$$\frac{4.50}{(1+z_1)^1} + \frac{4.50}{(1+z_2)^2} + \frac{4.50}{(1+z_3)^3} + \frac{104.50}{(1+z_4)^4}$$

where

z_4 = one-half the two-year theoretical spot rate

Because the six-month spot rate, the one-year spot rate, and the 1.5-year spot rate are 8.0%, 8.3%, and 8.93%, respectively, then

$$z_1 = 0.04 \qquad z_2 = 0.0415 \qquad \text{and} \qquad z_3 = 0.04465$$

Therefore, the present value of the two-year coupon Treasury security is

$$\frac{4.50}{(1.0400)^1} + \frac{4.50}{(1.0415)^2} + \frac{4.50}{(1.04465)^3} + \frac{104.50}{(1+z_4)^4}$$

Because the price of the two-year coupon Treasury security is \$99.64, the following relationship must hold:

$$99.64 = \frac{4.50}{(1.0400)^1} + \frac{4.50}{(1.0415)^2} + \frac{4.50}{(1.04465)^3} + \frac{104.50}{(1+z_4)^4}$$

We can solve for the theoretical two-year spot rate as follows:

$$99.64 = 4.32692 + 4.14853 + 3.94730 + \frac{104.50}{(1+z_4)^4}$$

$$87.21725 = \frac{104.50}{(1+z_4)^4}$$

$$(1+z_4)^4 = 1.198158$$

$$z_4 = 0.046235$$

Doubling this yield, we obtain the theoretical two-year spot rate bond-equivalent yield of 9.247%.

One can follow this approach sequentially to derive the theoretical 2.5-year spot rate from the calculated values of z_1, z_2, z_3, and z_4 (the six-month, one-year, 1.5-year, and two-year rates) and the price and coupon of the bond with a maturity of 2.5 years. Further, one could derive theoretical spot rates for the remaining

EXHIBIT 3-3

Theoretical Spot Rates

Maturity	Yield-to-Maturity	Theoretical Spot Rate
0.50 years	0.0800	0.08000
1.00	0.0830	0.08300

10.00	0.1250	0.13623

15 half-yearly rates. The spot rates thus obtained are shown in Exhibit 3-3. They represent the term structure of interest rates for maturities up to 10 years at the particular time to which the bond price quotations refer.

Why Treasuries Must Be Priced Based on Spot Rates

Financial theory tells us that the theoretical price of a Treasury security should be equal to the present value of the cash flows, where each cash flow is discounted at the appropriate theoretical spot rate. What we did not do, however, is demonstrate the economic force that ensures that the actual market price of a Treasury security does not depart significantly from its theoretical price.

To demonstrate this, we will use the 20 hypothetical Treasury securities introduced in Exhibit 3-2. The longest-maturity bond given in that exhibit is the 10-year, 12.5% coupon bond selling at par with a yield-to-maturity of 12.5%. Suppose that a government dealer buys the issue at par and strips it, expecting to sell the zero-coupon Treasury securities at the yields-to-maturity indicated in Exhibit 3-3 for the corresponding maturity.

EXHIBIT 3-4

10.00	106.25	31.6046	0.1250	31.6046
Total		100.0000		$104.1880

Exhibit 3-4 shows the price that would be received for each zero-coupon Treasury security created. The price for each is the present value of the cash flow from the stripped Treasury discounted at the yield-to-maturity corresponding to the maturity of the security (from Exhibit 3-2). The total proceeds received from selling the zero-coupon Treasury securities created would be $104.1880 per $100 of par value of the original Treasury issue. This would result in an arbitrage profit of $4.1880 per $100 of the 10-year, 12.5% coupon Treasury security purchased.

To understand why the government dealer has the opportunity to realize this profit, look at the third column of Exhibit 3-4, which shows how much the government dealer paid for each cash flow by buying the entire package of cash flows (i.e., by buying the bond). For example, consider the $6.25 coupon payment in four years. By buying the 10-year Treasury bond priced to yield 12.5%, the dealer effectively pays a price based on 12.5% (6.25% semiannually) for that coupon payment or, equivalently, $3.8481. Under the assumptions of this illustration, however, investors were willing to accept a lower yield-to-maturity, 10.4% (5.2% semiannually), to purchase a zero-coupon Treasury security with four years to maturity. Thus investors were willing to pay \$4.1663. On this one coupon payment, the government dealer realizes a profit equal to the difference between \$4.1663 and \$3.8481 (or \$0.3182). From all the cash flows, the total profit is \$4.1880. In this instance, coupon stripping shows that the sum of the parts is greater than the whole.

Suppose that instead of the observed yield-to-maturity from Exhibit 3-2, the yields investors want are the same as the theoretical spot rates shown in Exhibit 3-3. If we use these spot rates to discount the cash flows, the total proceeds from the sale of the zero-coupon Treasury securities would be equal to \$100, making coupon stripping uneconomic.

In our illustration of coupon stripping, the price of the Treasury security is less than its theoretical price. Suppose instead that the price of the Treasury security is greater than its theoretical price. In such cases, investors can purchase a package of zero-coupon Treasury securities such that the cash flow of the package of securities replicates the cash flow of the mispriced coupon Treasury security. By doing so, the investor will realize a yield higher than the yield on the coupon Treasury security. For example, suppose that the market price of the 10-year Treasury security we used in our illustration (Exhibit 3-4) is \$106. By buying the 20 zero-coupon bonds shown in Exhibit 3-4 with a maturity value identical to the cash flow shown in the second column, the investor is effectively purchasing a 10-year Treasury coupon security at a cost of \$104.1880 instead of \$106.

The process of coupon stripping and reconstituting prevents the actual spot-rate curve observed on zero-coupon Treasuries from departing significantly from the theoretical spot-rate curve. As more stripping and reconstituting occurs, forces of demand and supply will cause rates to return to their theoretical spot-rate levels. This is what has happened in the Treasury market.

Forward Rates

Consider an investor who has a one-year investment horizon and is faced with the following two alternatives:

Alternative 1: Buy a one-year Treasury bill.

Alternative 2: Buy a six-month Treasury bill, and when it matures in six months, buy another six-month Treasury bill.

The investor will be indifferent between the two alternatives if they produce the same return over the one-year investment horizon. The investor knows the spot rate on the six-month Treasury bill and the one-year Treasury bill. However, the investor does not know what yield will be available on a six-month Treasury bill that will be purchased six months from now. The yield on a six-month Treasury bill six months from now is called a *forward rate.* Given the spot rates for the six-month Treasury bill and the one-year bill, we wish to determine the forward rate on a six-month Treasury bill that will make the investor indifferent between the two alternatives. That rate can be readily determined.

At this point, however, we need to digress briefly and recall several present-value and investment relationships. First, if you invested in a one-year Treasury bill, you would receive \$100 at the end of one year. The price of the one-year Treasury bill would be

$$\frac{100}{(1+z_2)^2}$$

where z_2 is one-half the bond-equivalent yield of the theoretical one-year spot rate.

Second, suppose that you purchased a six-month Treasury bill for \$$X$. At the end of six months, the value of this investment would be

$$X(1+z_1)$$

where z_1 is one-half the bond-equivalent yield of the theoretical six-month spot rate.

Let f represent one-half the forward rate (expressed as a bond-equivalent basis) on a six-month Treasury bill available six months from now. If the investor were to renew the investment by purchasing that bill at that time, then the future dollars available at the end of one year from the \$$X$ investment would be

$$X(1+z_1)(1+f)$$

Third, it is easy to use this formula to find out how many \$$X$ the investor must invest in order to get \$100 one year from now. This can be found as follows:

$$X(1+z_1)(1+f)=100$$

which gives us

$$X=\frac{100}{(1+z_1)(1+f)}$$

We are now prepared to return to the investor's choices and analyze what that situation says about forward rates. The investor will be indifferent between the two alternatives if the same dollar investment is made and \$100 is received from both alternatives at the end of one year. That is, the investor will be indifferent if

$$\frac{100}{(1+z_2)^2}=\frac{100}{(1+z_1)(1+f)}$$

Solving for f, we get

$$f=\frac{(1+z_2)^2}{(1+z_1)^1}-1$$

Doubling f gives the bond-equivalent yield for the six-month forward rate six months from now.

We can illustrate the use of this formula with the theoretical spot rates shown in Exhibit 3-3. From that exhibit, we know that

$$\text{Six-month bill spot rate} = 0.080 \quad \text{so} \quad z_1 = 0.0400$$
$$\text{One-year bill spot rate} = 0.083 \quad \text{so} \quad z_2 = 0.0415$$

Substituting into the formula, we have

$$\begin{aligned} f &= \frac{(1.0415)^2}{1.0400} - 1 \\ &= 0.043 \end{aligned}$$

Therefore, the forward rate on a six-month Treasury security, quoted on a bond-equivalent basis, is 8.6% (0.043 × 2). Let's confirm our results. The price of a one-year Treasury bill with a $100 maturity value is

$$\frac{100}{(1.0415)^2} = 92.19$$

If $92.19 is invested for six months at the six-month spot rate of 8%, the amount at the end of six months would be

$$92.19(1.0400) = 95.8776$$

If $95.8776 is reinvested for another six months in a six-month Treasury offering 4.3% for six months (8.6% annually), the amount at the end of one year would be

$$95.8776(1.043) = 100$$

Both alternatives will have the same $100 payoff if the six-month Treasury bill yield six months from now is 4.3% (8.6% on a bond-equivalent basis). This means that if an investor is guaranteed a 4.3% yield (8.6% bond-equivalent basis) on a six-month Treasury bill six months from now, the investor will be indifferent between the two alternatives.

We used the theoretical spot rates to compute the forward rate. The resulting forward rate is also called the *implied forward rate.*

We can take this sort of analysis much further. It is not necessary to limit ourselves to implied forward rates six months from now. The yield curve can be used to calculate the implied forward rate for any time in the future for any investment horizon. For example, the following can be calculated:

- The two-year implied forward rate five years from now
- The six-year implied forward rate two years from now
- The seven-year implied forward rate three years from now

Relationship Between Spot Rates and Short-Term Forward Rates

Suppose that an investor purchases a five-year zero-coupon Treasury security for \$58.42 with a maturity value of \$100. The investor could instead buy a six-month Treasury bill and reinvest the proceeds every six months for five years. The number of dollars that will be realized depends on the six-month forward rates. Suppose that the investor actually can reinvest the proceeds maturing every six months at the implied six-month forward rates. Let's see how many dollars would accumulate at the end of five years. The implied six-month forward rates were calculated for the yield curve given in Exhibit 3-3. Letting f_t denote the six-month forward rate beginning t six-month periods from now, the semiannual implied forward rates using the spot rates shown in that exhibit are as follows:

$$f_1 = 0.043000 \quad f_2 = 0.050980 \quad f_3 = 0.051005 \quad f_4 = 0.051770$$
$$f_5 = 0.056945 \quad f_6 = 0.060965 \quad f_7 = 0.069310 \quad f_8 = 0.064625$$
$$f_9 = 0.062830$$

If the investor invests the \$58.48 at the six-month spot rate of 4% (8% on a bondequivalent basis) and reinvests at the forward rates shown above, the number of dollars accumulated at the end of five years would be

$$\begin{aligned}&\$58.48(1.04)(1.043)(1.05098)(1.051005)(1.05177)(1.056945)\\&\times(1.060965)(1.069310)(1.064625)(1.06283) = \$100\end{aligned}$$

Therefore, we see that if the implied forward rates are realized, the \$58.48 investment will produce the same number of dollars as an investment in a five-year zero-coupon Treasury security at the five-year spot rate. From this illustration, we can see that the five-year spot rate is related to the current six-month spot rate and the implied six-month forward rates.

In general, the relationship between a t-period spot rate, the current six-month spot rate, and the implied six-month forward rates is as follows:

$$z_t = [(1+z_1)(1+f_1)(1+f_2)(1+f_3)\cdots(1+f_{t-1})]^{1/t} - 1$$

Why should an investor care about forward rates? There are actually very good reasons for doing so. Knowledge of the forward rates implied in the current long-term rate is relevant in formulating an investment policy. In addition, forward rates are key inputs into the valuation of bonds with embedded options.

For example, suppose that an investor wants to invest for one year (two six-month periods); the current six-month or short rate (z_1) is 7%, and the one-year (two-period) rate (z_2) is 6%. Using the formulas we have developed, the investor finds that by buying a two-period security, the investor is effectively making a forward contract to lend money six months from now at the rate of 5% for six months. If the investor believes that the second-period rate will turn out to be higher than 5%, it will be to the investor's advantage to lend initially on a one-period contract and then at the end of the first period to reinvest interest and principal in the one-period contract available for the second period.

Determinants of the Shape of the Term Structure

If we plot the term structure—the yield-to-maturity, or the spot rate, at successive maturities against maturity—what will it look like? Exhibit 3-1 shows three shapes that have appeared with some frequency over time. Panel *a* shows an upward-sloping yield curve; that is, yield rises steadily as maturity increases. This shape is commonly referred to as a *normal* or *upward-sloping yield curve.* Panel *b* shows a *downward-sloping* or *inverted yield curve,* where yields decline as maturity increases. Finally, panel *c* shows a *flat yield curve.*

Two major theories have evolved to account for these shapes: the *expectations theory* and the *market-segmentation theory*.

There are three forms of the expectations theory: the *pure expectations theory,* the *liquidity theory*, and the *preferred-habitat theory*. All share a hypothesis about the behavior of short-term forward rates and also assume that the forward rates in current long-term bonds are closely related to the market's expectations about future short-term rates. These three theories differ, however, on whether other factors also affect forward rates and how. The pure expectations theory postulates that no systematic factors other than expected future short-term rates affect forward rates; the liquidity theory and the preferred-habitat theory assert that there are other factors. Accordingly, the last two forms of the expectations theory are sometimes referred to as *biased expectations theories*.

The Pure Expectations Theory

According to the pure expectations theory, the forward rates exclusively represent expected future rates. Thus the entire term structure at a given time reflects the market's current expectations of future short-term rates. Under this view, a rising term structure, as shown in panel *a* of Exhibit 3-1, must indicate that the market expects short-term rates to rise throughout the relevant future. Similarly, a flat term structure reflects an expectation that future short-term rates will be mostly constant, and a falling term structure must reflect an expectation that future short-term rates will decline steadily.

We can illustrate this theory by considering how an expectation of a rising short-term future rate would affect the behavior of various market participants resulting in a rising yield curve. Assume an initially flat term structure, and suppose that economic news leads market participants to expect interest rates to rise.

- Market participants interested in a long-term investment would not want to buy long-term bonds because they would expect the yield structure to rise sooner or later, resulting in a price decline for the bonds and a capital loss on the long-term bonds purchased. Instead, they would want to invest in short-term debt obligations until the rise in yield had occurred, permitting them to reinvest their funds at the higher yield.

- Speculators expecting rising rates would anticipate a decline in the price of long-term bonds and therefore would want to sell any long-term bonds they own and possibly to "short sell" some they do not now own. (Should interest rates rise as expected, the price of longer-term bonds will fall. Because the speculator sold these bonds short and can then purchase them at a lower price to cover the short sale, a profit will be earned.) The proceeds received from the selling of long-term debt issues or the shorting of longer-term bonds will be invested in short-term debt obligations.
- Borrowers wishing to acquire long-term funds would be pulled toward borrowing now, in the long end of the market, by the expectation that borrowing at a later time would be more expensive.

All these responses would tend either to lower the net demand for or to increase the supply of long-maturity bonds, and two responses would increase demand for short-term debt obligations. This would require a rise in long-term yields in relation to short-term yields; that is, these actions by investors, speculators, and borrowers would tilt the term structure upward until it is consistent with expectations of higher future interest rates. By analogous reasoning, an unexpected event leading to the expectation of lower future rates will result in a downward-sloping yield curve.

Unfortunately, the pure expectations theory suffers from one serious shortcoming. It does not account for the risks inherent in investing in bonds and like instruments. If forward rates were perfect predictors of future interest rates, then the future prices of bonds would be known with certainty. The return over any investment period would be certain and independent of the maturity of the instrument initially acquired and of the time at which the investor needed to liquidate the instrument. However, with uncertainty about future interest rates and hence about future prices of bonds, these instruments become risky investments in the sense that the return over some investment horizon is unknown.

There are two risks that cause uncertainty about the return over some investment horizon. The first is the uncertainty about the price of the bond at the end of the investment horizon. For example, an investor who plans to invest for five years might consider the following three investment alternatives: (1) invest in a 5-year bond and hold it for five years, (2) invest in a 12-year bond and sell it at the end of five years, and (3) invest in a 30-year bond and sell it at the end of five years. The return that will be realized for the second and third alternatives is not known because the price of each long-term bond at the end of five years is not known. In the case of the 12-year bond, the price will depend on the yield on 7-year debt securities five years from now, and the price of the 30-year bond will depend on the yield on 25-year bonds five years from now. Because forward rates implied in the current term structure for a future 7-year bond and a future 25-year bond are not perfect predictors of the actual future rates, there is uncertainty about the price for both bonds five years from now. Thus there is *price risk:* The risk that the price of the bond will be lower than currently expected at the end of the investment horizon. As explained in Chapter 5, an important feature of price risk is that it increases as the maturity of the bond increases.

The second risk involves the uncertainty about the rate at which the proceeds from a bond that matures during the investment horizon can be reinvested and is known as *reinvestment risk*. For example, an investor who plans to invest for five years might consider the following three alternative investments: (1) invest in a five-year bond and hold it for five years, (2) invest in a six-month instrument and, when it matures, reinvest the proceeds in six-month instruments over the entire five-year investment horizon, and (3) invest in a two-year bond and, when it matures, reinvest the proceeds in a three-year bond. The risk in the second and third alternatives is that the return over the five-year investment horizon is unknown because rates at which the proceeds can be reinvested are unknown.

Several interpretations of the pure expectations theory have been put forth by economists. These interpretations are not exact equivalents, nor are they consistent with each other, in large part because they offer different treatments of price risk and reinvestment risk.[2]

The broadest interpretation of the pure expectations theory suggests that investors expect the return for any investment horizon to be the same, regardless of the maturity strategy selected.[3] For example, consider an investor who has a five-year investment horizon. According to this theory, it makes no difference if a 5-year, 12-year, or 30-year bond is purchased and held for five years because the investor expects the return from all three bonds to be the same over five years. A major criticism of this very broad interpretation of the theory is that because of price risk associated with investing in bonds with a maturity greater than the investment horizon, the expected returns from these three very different bond investments should differ in significant ways.[4]

A second interpretation, referred to as the *local-expectations* form of the pure expectations theory, suggests that the return will be the same over a short-term investment horizon starting today. For example, if an investor has a six-month investment horizon, buying a 5-year, 10-year, or 20-year bond will produce the same six-month return. It has been demonstrated that the local expectations formulation, which is narrow in scope, is the only interpretation of the pure expectations theory that can be sustained in equilibrium.[5]

The third interpretation of the pure expectations theory suggests that the return an investor will realize by rolling over short-term bonds to some investment horizon will be the same as holding a zero-coupon bond with a maturity that is the same as that investment horizon. (A zero-coupon bond has no reinvestment risk, so future interest rates over the investment horizon do not affect the return.)

2. These formulations are summarized by John Cox, Jonathan Ingersoll, Jr., and Stephen Ross, "A Re-Examination of Traditional Hypotheses about the Term Structure of Interest Rates," *Journal of Finance* (September 1981), pp. 769–799.

3. F Lutz, "The Structure of Interest Rates," *Quarterly Journal of Economics* (1940–41), pp. 36–63.

4. Cox, Ingersoll, and Ross, *op. cit*., pp. 774–775.

5. Cox, Ingersoll, and Ross, *op. cit*., p. 788.

This variant is called the *return-to-maturity expectations* interpretation. For example, let's once again assume that an investor has a five-year investment horizon. If the investor buys a five-year zero-coupon bond and holds it to maturity, the return is the difference between the maturity value and the price of the bond, all divided by the price of the bond. According to the return-to-maturity expectations, the same return will be realized by buying a six-month instrument and rolling it over for five years. At this time, the validity of this interpretation is subject to considerable doubt.

The Liquidity Theory

We have explained that the drawback of the pure expectations theory is that it does not account for the risks associated with investing in bonds. Nonetheless, we have just shown that there is indeed risk in holding a long-term bond for one period, and that risk increases with the bond's maturity because maturity and price volatility are directly related.

Given this uncertainty, and the reasonable consideration that investors typically do not like uncertainty, some economists and financial analysts have suggested a different theory. This theory states that investors will hold longer-term maturities if they are offered a long-term rate higher than the average of expected future rates by a risk premium that is positively related to the term to maturity.[6] Put differently, the forward rates should reflect both interest-rate expectations and a liquidity premium (which is really a risk premium), and the premium should be higher for longer maturities.

According to this theory, which is called the *liquidity theory of the term structure,* the implied forward rates will not be an unbiased estimate of the market's expectations of future interest rates because they include a liquidity premium. Thus an upward-sloping yield curve may reflect expectations that future interest rates either will rise or will be flat (or even fall) but with a liquidity premium increasing fast enough with maturity so as to produce an upward-sloping yield curve.

The Preferred-Habitat Theory

Another theory, known as the *preferred-habitat theory,* also adopts the view that the term structure reflects the expectation of the future path of interest rates as well as a risk premium. However, the preferred-habitat theory rejects the assertion that the risk premium must rise uniformly with maturity.[7] Proponents of the preferred-habitat theory say that the latter conclusion could be accepted if all investors intend to liquidate their investment at the shortest possible date and all borrowers are anxious to borrow long. This assumption can be rejected because institutions have holding periods dictated by the nature of their liabilities.

6. John R. Hicks, *Value and Capital*, 2d ed. (London: Oxford University Press, 1946), pp. 141–145.

7. Franco Modigliani and Richard Sutch, "Innovations in Interest Rate Policy," *American Economic Review* (May 1966), pp. 178–197.

The preferred-habitat theory asserts that, to the extent that the demand and supply of funds in a given maturity range do not match, some lenders and borrowers will be induced to shift to maturities showing the opposite imbalances. However, they will need to be compensated by an appropriate risk premium that reflects the extent of aversion to either price or reinvestment risk.

Thus this theory proposes that the shape of the yield curve is determined by both expectations of future interest rates and a risk premium, positive or negative, to induce market participants to shift out of their preferred habitat. Clearly, according to this theory, yield curves sloping up, down, flat, or humped are all possible.

Market-Segmentation Theory

The *market-segmentation theory* recognizes that investors have preferred habitats dictated by the nature of their liabilities. This theory also proposes that the major reason for the shape of the yield curve lies in asset/liability management constraints (either regulatory or self-imposed) and creditors (borrowers) restricting their lending (financing) to specific maturity sectors.[8] However, the market-segmentation theory differs from the preferred-habitat theory in that it assumes that neither investors nor borrowers are willing to shift from one maturity sector to another to take advantage of opportunities arising from differences between expectations and forward rates. Thus, for the segmentation theory, the shape of the yield curve is determined by supply of and demand for securities within each maturity sector.

KEY POINTS

- In all economies, there is not just one interest rate but a structure of interest rates. The yield spread is the difference between the yields on any two bonds.
- The base interest rate is the yield on a Treasury security.
- The yield spread between a non-Treasury security and a comparable on-the-run Treasury security is called a risk premium. The factors that affect the risk premium include (1) the type of issuer (e.g., agency, corporate, municipality), (2) the issuer's perceived creditworthiness as measured by the rating system of commercial rating companies, (3) the term or maturity of the instrument, (4) the embedded options in a bond issue (e.g., call, put, or conversion provisions), (5) the taxability of interest income at the federal and municipal levels, and (6) the expected liquidity of the issue.
- The relationship between yield and maturity is referred to as the term structure of interest rates. The graphic depiction of the relationship between the yield on bonds of the same credit quality but different maturities is known as the yield curve.

---

8. This theory was suggested in J. M. Culbertson, "The Term Structure of Interest Rates," *Quarterly Journal of Economics* (November 1957), pp. 489–504.

- Because the yield on Treasury securities is the base rate from which a nongovernment bond's yield often is benchmarked, the most commonly constructed yield curve is the Treasury yield curve.
- There is a problem with using the Treasury yield curve to determine the one yield at which to discount all the cash payments of any bond. Each cash flow should be discounted at a unique interest rate that is applicable to the time period in which the cash flow is to be received. Because any bond can be viewed as a package of zero-coupon instruments, its value should equal the value of all the component zero-coupon instruments. The zero-coupon rate is also known as the spot rate.
- The theoretical spot-rate curve for Treasury securities can be estimated from the Treasury yield curve using a bootstrapping method.
- Under certain assumptions, the market's expectation of future interest rates can be extrapolated from the theoretical Treasury spot-rate curve. The resulting forward rate is called the implied forward rate.
- Several theories have been proposed about the determinants of the term structure: the pure expectations theory, the biased expectations theories (the liquidity theory and the preferred-habitat theory), and the market-segmentation theory.
- All the expectation theories hypothesize that the one-period forward rates represent the market's expectations of future rates. The pure expectations theory asserts that these rates constitute the only factor. The biased expectations theories assert that there are other factors that determine the term structure.

CHAPTER
FOUR

BOND PRICING, YIELD MEASURES, AND TOTAL RETURN

Frank J. Fabozzi, Ph.D., CFA, CPA
Professor of Finance
EDHEC Business School

In this chapter the pricing of fixed income securities and the various measures of computing return (or yield) from holding a fixed income security will be explained and illustrated. The chapter is organized as follows: In the first section, we apply the present-value analysis to explain how a bond's price is determined. Then we turn to yield measures, first focusing on conventional yield measures for a fixed-rate bond (yield-to-maturity and yield-to-call in the case of a callable bond) and a floating-rate bond. After highlighting the deficiencies of the conventional yield measures, a better measure of potential return—total return—is then presented.

BOND PRICING

The price of any financial instrument is equal to the present value of the expected cash flow. The interest rate or discount rate used to compute the present value depends on the yield offered on comparable securities in the market. In this chapter we shall explain how to compute the price of an option-free bond (i.e, a bond that is not callable, putable, or convertible). The pricing of callable and putable bonds is explained in Chapter 36. Chapters 38 and 39 describe models for the pricing of convertible bonds. The valuation of agency mortgage-backed securities is the subject of Chapter 37.

Determining the Cash Flow

The first step in determining the price of a bond is to determine its cash flow. The cash flow of an option-free bond consists of (1) periodic coupon interest payments to the maturity date and (2) the par (or maturity) value at maturity. Although the periodic coupon payments can be made over any time interval (weekly, monthly, quarterly, semiannually, or annually), most bonds issued in the United States pay coupon interest semiannually. In our illustrations, we shall assume that the coupon interest is paid semiannually. Also, to simplify the analysis, we shall assume that the next coupon payment for the bond will be made exactly six months from now. Later in this section we explain how to price a bond when the next coupon payment is less than six months from now.

In practice, determining the cash flow of a bond is not simple, even if we ignore the possibility of default. The only case in which the cash flow is known with certainty is for fixed-rate, option-free bonds. For callable bonds, the cash flow depends on whether the issuer elects to call the issue. In the case of a putable bond, it depends on whether the bondholder elects to put the issue. In either case, the date that the option will be exercised is not known. Thus the cash flow is uncertain. For mortgage-backed and asset-backed securities, the cash flow depends on prepayments. The amount and timing of future prepayments are not known, and therefore, the cash flow is uncertain. When the coupon rate is floating rather than fixed, the cash flow depends on the future value of the reference rate. The techniques discussed in Part 6 have been developed to cope with the uncertainty of cash flows. In this chapter, the basic elements of bond pricing where the cash flow is assumed to be known are presented.

The cash flow for an option-free bond consists of an annuity (i.e., the fixed coupon interest paid every six months) and the par or maturity value. For example, a 20-year bond with a 9% (4.5% per six months) coupon rate and a par or maturity value of $1,000 has the following cash flows:

$$\begin{aligned}\text{Semiannual coupon interest} &= \$1{,}000 \times 0.045\\ &= \$45\\ \text{Maturity value} &= \$1{,}000\end{aligned}$$

Therefore, there are 40 semiannual cash flows of $45, and a $1,000 cash flow 40 six-month periods from now.

Notice the treatment of the par value. It is *not* treated as if it will be received 20 years from now. Instead, it is treated on a consistent basis with the coupon payments, which are semiannual.

Determining the Required Yield

The interest rate that an investor wants from investing in a bond is called the *required yield.* The required yield is determined by investigating the yields offered on comparable bonds in the market. By comparable, we mean option-free bonds of the same credit quality and the same maturity.[1]

The required yield typically is specified as an annual interest rate. When the cash flows are semiannual, the convention is to use one-half the annual interest rate as the periodic interest rate with which to discount the cash flows. A periodic interest

1. In Chapter 5, we introduce a measure of interest-rate risk known as *duration*. Instead of talking in terms of a bond with the same maturity as being comparable, we can recast the analysis in terms of the same duration.

rate that is one-half the annual yield will produce an effective annual yield that is greater than the annual interest rate.

Although one yield is used to calculate the present value of all cash flows, there are theoretical arguments for using a different yield to discount the cash flow for each period. Essentially, the theoretical argument is that each cash flow can be viewed as a zero-coupon bond, and therefore, the cash flow of a bond can be viewed as a package of zero-coupon bonds. As explained in Chapter 3, the appropriate yield for each cash flow then would be based on the theoretical rate on a zero-coupon bond with a maturity equal to the time that the cash flow will be received. For purposes of this chapter, however, we shall use only one yield to discount all cash flows.

Determining the Price

Given the cash flows of a bond and the required yield, we have all the necessary data to price the bond. The price of a bond is equal to the present value of the cash flows, and it can be determined by adding (1) the present value of the semiannual coupon payments and (2) the present value of the par or maturity value.

Because the semiannual coupon payments are equivalent to an ordinary annuity, the present value of the coupon payments and maturity value can be calculated from the following formula:[2]

$$c\left[\frac{1-\left\{\frac{1}{(1+i)^n}\right\}}{i}\right]+\frac{M}{(1+i)^n}$$

where

c = semiannual coupon payment ($)
n = number of periods (number of years times 2)
i = periodic interest rate (required yield divided by 2) (in decimal)
M = maturity value

Illustration 1. Compute the price of a 9% coupon bond with 20 years to maturity and a par value of $1,000 if the required yield is 12%.

The cash flows for this bond are as follows: (1) 40 semiannual coupon payments of $45 and (2) $1,000 40 six-month periods from now. The semiannual or periodic interest rate is 6%.

2. The first term in the formula is the same as the formula for the present value of an ordinary annuity for n periods.

The present value of the 40 semiannual coupon payments of \$45 discounted at 6% is \$677.08, as shown below:

$$c = \$45$$
$$n = 40$$
$$i = 0.06$$

$$\$45\left[\frac{1-\left\{\frac{1}{(1.06)^{40}}\right\}}{0.06}\right]$$

$$= \$45\left[\frac{1-\left\{\frac{1}{10.28572}\right\}}{0.06}\right]$$

$$= \$45\left[\frac{1-0.097222}{0.06}\right]$$

$$= \$45(15.04630)$$

$$= \$677.08$$

The present value of the par or maturity value *40 six-month periods* from now discounted at 6% is \$97.22, as shown below:

$$M = \$1{,}000$$
$$n = 0.40$$
$$i = 0.06$$

$$\$1{,}000\left[\frac{1}{(1.06)^{40}}\right]$$

$$= \$1{,}000\left[\frac{1}{10.28572}\right]$$

$$= \$1{,}000(0.097222)$$

$$= \$97.22$$

The price of the bond is then equal to the sum of the two present values:

Present value of coupon payments	\$677.08
Present value of par (maturity) value	97.22
Price	\$774.30

Illustration 2. Compute the price of the bond in Illustration 1 assuming that the required yield is 7%.

The cash flows are unchanged, but the periodic interest rate is now 3.5% (7%/2).

The present value of the 40 semiannual coupon payments of \$45 discounted at 3.5% is \$960.98, as shown below:

$$c = \$45$$
$$n = 40$$
$$i = 0.035$$
$$\$45\left[\frac{1-\left\{\frac{1}{(1.035)^{40}}\right\}}{0.035}\right]$$
$$= \$45\left[\frac{1-\left\{\frac{1}{3.95926}\right\}}{0.035}\right]$$
$$= \$45\left[\frac{1-0.252572}{0.035}\right]$$
$$= \$45(21.35509)$$
$$= \$960.98$$

The present value of the par or maturity value of \$1,000 *40 six-month periods from now* discounted at 3.5% is \$252.57, as shown below:

$$M = \$1,000$$
$$n = 40$$
$$= 0.035$$
$$\$1,000\left[\frac{1}{(1.035)^{40}}\right]$$
$$= \$1,000\left[\frac{1}{3.95926}\right]$$
$$= \$1,000(0.252572)$$
$$= \$252.57$$

The price of the bond is then equal to the sum of the two present values:

Present value of coupon payments	\$960.98
Present value of par (maturity) value	252.57
Price	\$1,213.55

EXHIBIT 4-1

Price/Yield Relationship for a 20-Year, 9% Coupon Bond

Required Yield	Price of Bond
5%	$1,502.05
6	1,346.72
7	1,213.55
8	1,098.96
9	1,000.00
10	914.21
11	839.54
12	774.30
13	717.09
14	666.71

Relationship Between Required Yield and Price at a Given Time

The price of an option-free bond changes in the direction opposite to the change in the required yield. The reason is that the price of the bond is the present value of the cash flows. As the required yield increases, the present value of the cash flows decreases; hence the price decreases. The opposite is true when the required yield decreases: The present value of the cash flows increases, and therefore, the price of the bond increases.

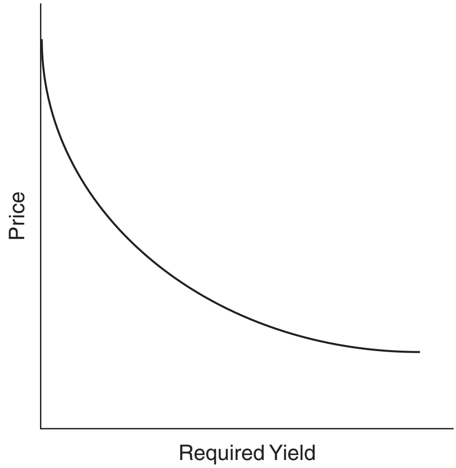
We can see this by comparing the price of the 20-year, 9% coupon bond that we priced in Illustrations 1 and 2. When the required yield is 12%, the price of the bond is $774.30. If, instead, the required yield is 7%, the price of the bond is $1,213.55. Exhibit 4-1 shows the price of the 20-year, 9% coupon bond for required yields from 5% to 14%.

If we graphed the price/yield relationship for any option-free bond, we would find that it has the "bowed" shape shown in Exhibit 4-2. This shape is referred to as *convex*.[3] The convexity of the price/yield relationship has important implications for the investment properties of a bond. We've devoted Chapter 5 to examining this relationship more closely.

3. In the exhibit, the curve representing the price/yield relationship intersects the price axis when the required yield is zero and is the maximum price for the bond assuming positive yields. That price is simply the undiscounted value of the cash flows.

EXHIBIT 4-2

Price/Yield Relationship



The Relationship Among Coupon Rate, Required Yield, and Price

For a bond issue at a given point in time, the coupon rate and the term-to-maturity are fixed. Consequently, as yields in the marketplace change, the only variable that an investor can change to compensate for the new yield required in the market is the price of the bond. As we saw in the preceding section, as the required yield increases (decreases), the price of the bond decreases (increases).

Generally, when a bond is issued, the coupon rate is set at approximately the prevailing yield in the market.[4] The price of the bond then will be approximately equal to its par value. For example, in Exhibit 4-1, we see that when the required yield is equal to the coupon rate, the price of the bond is its par value. Consequently, we have the following properties:

When the coupon rate equals the required yield, the price equals the par value.

When the price equals the par value, the coupon rate equals the required yield.

When yields in the marketplace rise above the coupon rate *at a given point in time,* the price of the bond has to adjust so that the investor can realize some additional interest. This adjustment is accomplished by having the bond's price fall below the par value. The difference between the par value and the price is a capital gain and represents a form of interest to the investor to compensate for the coupon rate being lower than the required yield. When a bond sells below its par value, it is said to be selling at a *discount.* We can see this in Exhibit 4-1. When the required

4. The exception is an original-issue discount bond such as a zero-coupon bond.

yield is greater than the coupon rate of 9%, the price of the bond is always less than the par value. Consequently, we have the following properties:

When the coupon rate is less than the required yield, the price is less than the par value.

When the price is less than the par value, the coupon rate is less than the required yield.

Finally, when the required yield in the market is below the coupon rate, the price of the bond must be above its par value. This occurs because investors who could purchase the bond at par would be getting a coupon rate in excess of what the market requires. As a result, investors would bid up the price of the bond because its yield is attractive. It will be bid up to a price that offers the required yield in the market. A bond whose price is above its par value is said to be selling at a *premium*. Exhibit 4-1 shows that for a required yield less than the coupon rate of 9%, the price of the bond is greater than its par value. Consequently, we have the following properties:

When the coupon rate is greater than the required yield, the price is greater than the par value.

When the price is greater than the par value, the coupon rate is greater than the required yield.

Time Path of a Bond

If the required yield is unchanged between the time the bond is purchased and the maturity date, what will happen to the price of the bond? For a bond selling at par value, the coupon rate is equal to the required yield. As the bond moves closer to maturity, the bond will continue to sell at par value. Thus, for a bond selling at par, its price will remain at par as the bond moves toward the maturity date.

The price of a bond will *not* remain constant for a bond selling at a premium or a discount. For all discount bonds, the following is true: As the bond moves toward maturity, its price will increase if *the required yield* does not change. This can be seen in Exhibit 4-3, which shows the price of the 20-year, 9% coupon bond as it moves toward maturity, assuming that the required yield remains at 12%. For a bond selling at a premium, the price of the bond declines as it moves toward maturity. This can also be seen in Exhibit 4-3, which shows the time path of the 20-year, 9% coupon bond selling to yield 7%.

Reasons for the Change in the Price of a Bond

The price of a bond will change because of one or more of the following reasons:

- *A change in the level of interest rates in the economy.* For example, if interest rates in the economy increase (fall) because of Fed policy, the price of a bond will decrease (increase).

EXHIBIT 4-3

Time Paths of 20-Year, 9% Coupon Discount and Premium Bonds

Years Remaining to Maturity	Price of Discount Bond*	Price of Premium Bond†
20	$774.30	$1,213.55
18	780.68	1,202.90
16	788.74	1,190.89
14	798.91	1,176.67
12	811.75	1,160.59
10	827.95	1,142.13
8	848.42	1,120.95
6	874.24	1,096.63
4	906.85	1,068.74
2	948.02	1,036.73
1	972.50	1,019.00
0	1,000.00	1,000.00

*Selling to yield 12%.
†Selling to yield 7%.

- *A change in the price of the bond selling at a price other than par as it moves toward maturity without any change in the required yield.* As we demonstrated, over time a discount bond's price increases if yields do not change; a premium bond's price declines over time if yields do not change.
- *For non-Treasury bonds, a change in the required yield due to changes in the spread to Treasuries.* If the Treasury rate does not change but the spread to Treasuries changes (narrows or widens), non-Treasury bond prices will change.
- *A change in the perceived credit quality of the issuer.* Assuming that interest rates in the economy and yield spreads between non-Treasuries and Treasuries do not change, the price of a non-Treasury bond will increase (decrease) if its perceived credit quality has improved (deteriorated).
- *For bonds with embedded options (callable bonds, putable bonds, and convertible bonds), the price of the bond will change as the factors that affect the value of the embedded options change.*

Pricing a Zero-Coupon Bond

So far we have determined the price of coupon-bearing bonds. Some bonds do not make any periodic coupon payments. Instead, the investor realizes interest by the difference between the maturity value and the purchase price.

The pricing of a zero-coupon bond is no different from the pricing of a coupon bond: Its price is the present value of the expected cash flows. In the case of a zero-coupon bond, the only cash flow is the maturity value. Therefore, the price of a zero-coupon bond is simply the present value of the maturity value. The number of periods used to discount the maturity value is double the number of years to maturity. This treatment is consistent with the manner in which the maturity value of a coupon bond is handled.

Illustration 3. The price of a zero-coupon bond that matures in 10 years and has a maturity value of \$1,000 if the required yield is 8.6% is equal to the present value of \$1,000 20 periods from now discounted at 4.3%. That is,

$$\$1{,}000\left[\frac{1}{(1.043)^{20}}\right] = \$430.83$$

Determining the Price When the Settlement Date Falls Between Coupon Periods

In our illustrations we assumed that the next coupon payment is six months away. This means that settlement occurs on the day after a coupon date. Typically, an investor will purchase a bond between coupon dates so that the next coupon payment is less than six months away. To compute the price, we have to answer the following three questions:

- How many days are there until the next coupon payment?
- How should we determine the present value of cash flows received over fractional periods?
- How much must the buyer compensate the seller for the coupon interest earned by the seller for the fraction of the period that the bond was held?

The first question is the day-count question. The second is the compounding question. The last question asks how accrued interest is determined. Below we address these questions.

Day Count

Market conventions for each type of bond dictate the answer to the first question: The number of days until the next coupon payment.

For Treasury coupon securities, a nonleap year is assumed to have 365 days. The number of days between settlement and the next coupon payment is therefore the actual number of days between the two dates. The day count convention for a coupon-bearing Treasury security is said to be "actual/actual," which means the actual number of days in a month and the actual number of days in the coupon period. For example, consider a Treasury bond whose last coupon payment was on March 1; the next coupon would be six months later on September 1. Suppose that this bond is purchased with a settlement date of July 17. The actual number of days between July 17 (the settlement date) and September 1 (the date of the next coupon payment) is 46 days (the actual number of days in the coupon period is 184), as shown below:

July 17 to July 31	14 days
August	31 days
September 1	1 day
	46 days

In contrast to the actual/actual day count convention for coupon-bearing Treasury securities, for corporate and municipal bonds and agency securities, the day count convention is "30/360." That is, each month is assumed to have 30 days and each year 360 days. For example, suppose that the security in our previous example is not a coupon-bearing Treasury security but instead either a coupon-bearing corporate bond, municipal bond, or agency security. The number of days between July 17 and September 1 is shown below:

Remainder of July	13 days
August	30 days
September 1	1 day
	44 days

Compounding

Once the number of days between the settlement date and the next coupon date is determined, the present value formula must be modified because the cash flows will not be received six months (one full period) from now. The Street convention is to compute the price is as follows:

1. Determine the number of days in the coupon period.
2. Compute the following ratio:

$$w = \frac{\text{number of days between settlement and next coupon payment}}{\text{number of days in the coupon period}}$$

For a corporate bond, a municipal bond, and an agency security, the number of days in the coupon period will be 180 because a year is assumed to have 360 days. For a coupon-bearing Treasury security, the number of days is the actual number of days. The number of days in the coupon period is called the *basis*.

3. For a bond with n coupon payments remaining to maturity, the price is

$$p = \frac{c}{(1+i)^w} + \frac{c}{(1+i)^{1+w}} + \frac{c}{(1+i)^{2+w}} + \cdots + \frac{c}{(1+i)^{n-1+w}} + \frac{M}{(1+i)^{n-1+w}}$$

where

p = price ($)
c = semiannual coupon payment ($)
M = maturity value
n = number of coupon payments remaining
i = periodic interest rate (required yield divided by 2) (in decimal)

The period (exponent) in the formula for determining the present value can be expressed generally as $t - 1 + w$. For example, for the first cash flow, the period is $1 - 1 + w$, or simply w. For the second cash flow, it is $2 - 1 + w$, or simply $1 + w$. If the bond has 20 coupon payments remaining, the last period is $20 - 1 + w$, or simply $19 + w$.

Illustration 4. Suppose that a corporate bond with a coupon rate of 10% maturing March 1, 2027 is purchased with a settlement date of July 17, 2021. What would the price of this bond be if it is priced to yield 6.5%?

The next coupon payment will be made on September 1, 2021. Because the bond is a corporate bond, based on a 30/360 day-count convention, there are 44 days between the settlement date and the next coupon date. The number of days in the coupon period is 180. Therefore,

$$w = \frac{44}{180} = 0.24444$$

The number of coupon payments remaining, n, is 12. The semiannual interest rate is 3.25% (6.5%/2).

The calculation based on the formula for the price is given in Exhibit 4-4. The price of this corporate bond would be $120.0281 per $100 par value. The price calculated in this way is called the *full price* or *dirty price* because it reflects the portion of the coupon interest that the buyer will receive but that the seller has earned.

Accrued Interest and the Clean Price

The buyer must compensate the seller for the portion of the next coupon interest payment the seller has earned but will not receive from the issuer because the issuer will send the next coupon payment to the buyer. This amount is called *accrued interest* and depends on the number of days from the last coupon payment to the settlement date.[5] The accrued interest is computed as follows:

$$\text{AI} = c\left(\frac{\text{number of days from last coupon payment to settlement date}}{\text{number of days in coupon period}}\right)$$

5. Accrued interest is not computed for all bonds. No accrued interest is computed for bonds in default or income bonds. A bond that trades without accrued interest is said to be traded “flat.”

EXHIBIT 4-4

Price Calculation When a Bond Is Purchased Between Coupon Payments

Period	Cash Flow per \$100 of Par	Present Value of \$1 at 3.25%	Present Value of Cash Flow
0.24444	\$ 5.000	\$0.992212	\$4.961060
1.24444	5.000	0.960980	4.804902
2.24444	5.000	0.930731	4.653658
3.24444	5.000	0.901435	4.507175
4.24444	5.000	0.873060	4.365303
5.24444	5.000	0.845579	4.227896
6.24444	5.000	0.818963	4.094815
7.24444	5.000	0.793184	3.965922
8.24444	5.000	0.768217	3.841087
9.24444	5.000	0.744036	3.720181
10.24444	5.000	0.720616	3.603081
11.24444	105.000	0.697933	73.283000
		Total	\$120.028100

where

AI = accrued interest (\$)
c = semiannual coupon payment (\$)

Illustration 5. Let's continue with the hypothetical corporate bond in Illustration 4. Because the number of days between settlement (July 17, 2021) and the next coupon payment (September 1, 2021) is 44 days and the number of days in the coupon period is 180, the number of days from the last coupon payment date (March 1, 2021) to the settlement date is 136 (180 − 44). The accrued interest per \$100 of par value is

$$\text{AI} = \$5\left(\frac{136}{180}\right) = \$3.777778$$

The full or dirty price includes the accrued interest that the seller is entitled to receive. For example, in the calculation of the full price in Exhibit 4-4, the next coupon payment of \$5 is included as part of the cash flow. The *clean price* or *flat price* is the full price of the bond minus the accrued interest.

The price that the buyer pays the seller is the full price. It is important to note that in calculation of the full price, the next coupon payment is a discounted value, but in calculation of accrued interest, it is an undiscounted value. Because of this market practice, if a bond is selling at par and the settlement date is not a coupon date, the yield will be slightly less than the coupon rate. Only when the settlement date and coupon date coincide is the yield equal to the coupon rate for a bond selling at par.

In the U.S. bond market, the convention is to quote a bond's clean or flat price. The buyer, however, pays the seller the full price. In some non-U.S. bond markets, the full price is quoted.

CONVENTIONAL YIELD MEASURES

In the preceding section we explained how to compute the price of a bond given the required yield. In this section we'll show how various yield measures for a bond are calculated given its price. First let's look at the sources of potential return from holding a bond.

An investor who purchases a bond can expect to receive a *dollar* return from one or more of the following sources:

- The coupon interest payments made by the issuer
- Any capital gain (or capital loss—negative dollar return) when the bond matures, is called, or is sold
- Income from reinvestment of the coupon interest payments

This last source of dollar return is referred to as *interest-on-interest.*

Three yield measures are commonly cited by market participants to measure the potential return from investing in a bond—current yield, yield-to-maturity, and yield-to-call. These yield measures are expressed as a *percent* return rather than as a dollar return. However, any yield measure should consider each of the three potential sources of return just cited. Below we discuss these three yield measures and assess whether they consider the three sources of potential return.

Current Yield

The current yield relates the *annual* coupon interest to the market price. The formula for the current yield is

$$\text{Current yield} = \frac{\text{annual dollar coupon interest}}{\text{price}}$$

Illustration 6. The current yield for an 18-year, 6% coupon bond selling for \$700.89 per \$1,000 par value is 8.56%, as shown below:

$$\begin{aligned}\text{Annual dollar coupon interest} &= \$1{,}000 \times 0.06\\ &= \$60\end{aligned}$$

$$\text{Current yield} = \frac{\$60}{\$700.89} = 0.0856, \text{ or } 8.56\%$$

The current yield considers only the coupon interest and no other source of return that will affect an investor's return. For example, in Illustration 6, no consideration is given to the capital gain that the investor will realize when the bond matures. No recognition is given to a capital loss that the investor will realize when a bond selling at a premium matures. In addition, interest-on-interest from reinvesting coupon payments is ignored.

Yield-to-Maturity

The yield or internal rate of return on any investment is the interest rate that will make the present value of the cash flows equal to the price (or initial investment).[6] The yield-to-maturity is computed in the same way as the yield; the cash flows are those which the investor would realize by holding the bond to maturity. For a semiannual-pay bond, doubling the interest rate or discount rate gives the yield-to-maturity.

The calculation of a yield involves a trial-and-error procedure. Practitioners usually use calculators or software to obtain a bond's yield-to-maturity. There are several calculators available online. The following illustration shows how to compute the yield-to-maturity for a bond.

Illustration 7. In Illustration 6 we computed the current yield for an 18-year, 6% coupon bond selling for $700.89. The maturity value for this bond is $1,000. The yield-to-maturity for this bond is 9.5%, as shown in Exhibit 4-5. Cash flows for the bond are

- 36 coupon payments of $30 every six months
- $1,000 36 six-month periods from now

Different interest rates must be tried until one is found that makes the present value of the cash flows equal to the price of $700.89. Because the coupon rate on the bond is 6% and the bond is selling at a discount, the yield must be greater than 6%. Exhibit 4-5 shows the present value of the cash flows of the bond for semiannual interest rates from 3.25% to 4.75% (corresponding to annual interest rates from 6.5% to 9.50%). As can be seen, when a 4.75% interest rate is used, the present value of the cash flows is $700.89. Therefore, the yield-to-maturity is 9.50% (4.75% $\times$ 2).

The yield-to-maturity considers the coupon income and any capital gain or loss that the investor will realize by *holding the bond to maturity.* The yield-to-maturity also considers the timing of the cash flows. It does consider interest-on-interest; *however, it assumes that the coupon payments can be reinvested at an interest rate equal to the yield-to-maturity.* Thus, if the yield-to-maturity for a bond is 9.5%, to earn that yield, the coupon payments must be reinvested at an interest rate equal to 9.5%. The following example clearly demonstrates this.

6. For asset-backed and mortgage-backed securities, the equivalent measure is called the cash flow yield.

EXHIBIT 4-5

Computation of Yield-to-Maturity for an 18-Year, 6% Coupon Bond Selling at $700.89

Objective: Find, by trial and error, the semiannual interest rate that will make the present value of the following cash flows equal to $700.89:

36 coupon payments of $30 every six months
$1,000 36 six-month periods from now

Annual Interest Rate	Semi-annual Rate	Present Value of 36 Payments of $30*	Present Value of $1,000 10 Periods from Now†	Present Value of Cash Flows
6.50%	3.25%	$631.20	$316.20	$947.40
7.00	3.50	608.71	289.83	898.54
7.50	3.75	587.42	265.72	853.14
8.00	4.00	567.25	243.67	810.92
8.50	4.25	548.12	223.49	771.61
9.00	4.50	529.98	205.03	735.01
9.50	4.75	512.76	188.13	700.89

$$*30\left[\frac{1-\left\{\dfrac{1}{(1+\text{semiannual interest rate})^{36}}\right\}}{\text{semiannual interest rate}}\right]$$

$$^{\dagger}\$1{,}000\left[\frac{1}{(1+\text{semiannual interest rate})^{36}}\right]$$

Suppose that an investor has $700.89 and places the funds in a certificate of deposit (CD) that pays 4.75% every six months for 18 years, or 9.5% per year. At the end of 18 years, the $700.89 investment will grow to $3,726. Instead, suppose that the investor buys a 6%, 18-year bond selling for $700.89. This is the same as the price of our bond in Illustration 7. The yield-to-maturity for this bond is 9.5%. The investor would expect that at the end of 18 years, the total dollars from the investment will be $3,726.

Let's look at what he will receive. There will be 36 semiannual interest payments of $30, which will total $1,080. When the bond matures, the investor will receive $1,000. Thus the total dollars that he will receive is $2,080 if the investor holds the bond to maturity, but this is $1,646 less than the $3,726 necessary to produce a yield of 9.5% (4.75% semiannually). How is this deficiency supposed to be made up? If the investor reinvests the coupon payments at a semiannual interest rate of 4.75% (or a 9.5% annual rate), it is a simple exercise to demonstrate that the interest earned on the coupon payments will be $1,646.

Consequently, of the \$3,025 total dollar return (\$3,726 – \$700.89) necessary to produce a yield of 9.5%, about 54% (\$1,646 divided by \$3,025) must be generated by reinvesting the coupon payments.

Clearly, the investor will realize the yield-to-maturity stated at the time of purchase only if (1) the coupon payments can be reinvested at the yield-to-maturity and (2) if the bond is held to maturity. With respect to the first assumption, the risk that an investor faces is that future reinvestment rates will be less than the yield-to-maturity at the time the bond is purchased. This risk is referred to as *reinvestment risk.* If the bond is not held to maturity, the price at which the bond may have to be sold is less than its purchase price, resulting in a return that is less than the yield-to-maturity. The risk that a bond will have to be sold at a loss because interest rates rise is referred to as *interest-rate risk.*

Reinvestment Risk

There are two characteristics of a bond that determine the degree of reinvestment risk. First, for a given yield-to-maturity and a given coupon rate, the longer the maturity, the more the bond's total dollar return is dependent on the interest-on-interest to realize the yield-to-maturity at the time of purchase. That is, the greater the reinvestment risk. The implication is that the yield-to-maturity measure for long-term coupon bonds tells little about the potential yield that an investor may realize if the bond is held to maturity. In high-interest-rate environments, the interest-on-interest component for long-term bonds may be as high as 80% of the bond's potential total dollar return.

The second characteristic that determines the degree of reinvestment risk is the coupon rate. For a given maturity and a given yield-to-maturity, the higher the coupon rate, the more dependent the bond's total dollar return will be on the reinvestment of the coupon payments in order to produce the yield-to-maturity at the time of purchase. This means that holding maturity and yield-to-maturity constant, premium bonds will be more dependent on interest-on-interest than bonds selling at par. For zero-coupon bonds, none of the bond's total dollar return is dependent on interest-on-interest; a zero-coupon bond carries no reinvestment risk if held to maturity.

Interest-Rate Risk

As we explained in the preceding section, a bond's price moves in the direction opposite to the change in interest rates. As interest rates rise (fall), the price of a bond will fall (rise). For an individual investor who plans to hold a bond to maturity, the change in the bond's price before maturity is of no concern; however, for an individual investor who may have to sell the bond prior to the maturity date, an increase in interest rates after the bond is purchased will mean the realization of a capital loss. Not all bonds have the same degree of interest-rate risk. In Chapter 5, the characteristics of a bond that determine its interest-rate risk are discussed.

Given the assumptions underlying yield-to-maturity, we can now demonstrate that yield-to-maturity has limited value in assessing the potential return of bonds.

Suppose that an investor who has a five-year investment horizon is considering the following four option-free bonds:

Bond	Coupon Rate	Maturity	Yield-to-Maturity
W	5%	3 years	9.0%
X	6	20	8.6
Y	11	15	9.2
Z	8	5	8.0

Assuming that all four bonds are of the same credit quality, which one is the most attractive to this investor? An investor who selects bond Y because it offers the highest yield-to-maturity is failing to recognize that the bond must be sold after five years, and the selling price of the bond will depend on the yield required in the market for 10-year, 11% coupon bonds at that time. Hence there could be a capital gain or capital loss that will make the return higher or lower than the yield-to-maturity promised now. Moreover, the higher coupon rate on bond Y relative to the other three bonds means that more of this bond's return will be dependent on the reinvestment of coupon interest payments.

Bond W offers the second highest yield-to-maturity. On the surface, it seems to be particularly attractive because it eliminates the problem faced by purchasing bond Y of realizing a possible capital loss when the bond must be sold before the maturity date. In addition, the reinvestment risk seems to be less than for the other three bonds because the coupon rate is the lowest. However, the investor would not be eliminating the reinvestment risk because after three years the investor must reinvest the proceeds received at maturity for two more years. The return that the investor will realize will depend on interest rates three years from now when the investor must roll over the proceeds received from the maturing bond.

Which is the best bond? The yield-to-maturity doesn't seem to help us identify the best bond. The answer depends on the expectations of the investor. Specifically, it depends on the interest rate at which the coupon interest payments can be reinvested until the end of the investor's investment horizon. Also, for bonds with a maturity longer than the investment horizon, it depends on the investor's expectations about interest rates at the end of the investment horizon. Consequently, any of these bonds can be the best investment vehicle based on some reinvestment rate and some future interest rate at the end of the investment horizon. In the next section we present an alternative return measure for assessing the potential performance of a bond.

Yield-to-Maturity for a Zero-Coupon Bond

When there is only one cash flow, it is much easier to compute the yield on an investment. A zero-coupon bond is characterized by a single cash flow resulting from an investment. Consequently, the following formula can be applied to compute the yield-to-maturity for a zero-coupon bond:

$$y = (\text{future value per dollar invested})^{1/n} - 1$$

where

$$y = \text{one-half the yield-to-maturity}$$

$$\text{Future value per dollar invested} = \frac{\text{maturity value}}{\text{price}}$$

Once again, doubling y gives the yield-to-maturity. *Remember that the number of periods used in the formula is double the number of years.*

Illustration 8. The yield-to-maturity for a zero-coupon bond selling for \$274.78 with a maturity value of \$1,000, maturing in 15 years, is 8.8%, as computed below:

$$n = 15 \times 2 = 30$$

$$\text{Future value per dollar invested} = \frac{\$1{,}000.00}{\$274.78} = 3.639275$$

$$\begin{aligned} y &= (3.639275)^{1/30} - 1 \\ &= (3.639275)^{0.033333} - 1 \\ &= 1.044 - 1 \\ &= 0.044, \text{ or } 4.4\% \end{aligned}$$

Doubling 4.4% gives the yield-to-maturity of 8.8%.

Relationship Among Coupon Rate, Current Yield, and Yield-to-Maturity

The following relationship should be recognized between the coupon rate, current yield, and yield-to-maturity:

Bond Selling at	Relationship
Par	Coupon rate = current yield = yield-to-maturity
Discount	Coupon rate < current yield < yield-to-maturity
Premium	Coupon rate > current yield > yield-to-maturity

Problem with the Annualizing Procedure

Multiplying a semiannual interest rate by 2 will give an underestimate of the effective annual yield. The proper way to annualize the semiannual yield is by applying the following formula:

$$\text{Effective annual yield} = (1 + \text{periodic interest rate})^k - 1$$

where

$$k = \text{number of payments per year}$$

For a semiannual-pay bond, the formula can be modified as follows:

$$\text{Effective annual yield} = (1 + \text{semiannual interest rate})^2 - 1$$

or

$$\text{Effective annual yield} = (1+y)^2 - 1$$

For example, in Illustration 7, the semiannual interest rate is 4.75%, and the effective annual yield is 9.73%, as shown below:

$$\begin{aligned}\text{Effective annual yield} &= (1.0475)^2 - 1\\ &= 1.0973 - 1\\ &= 0.0973, \text{ or } 9.73\%\end{aligned}$$

Although the proper way for annualizing a semiannual interest rate is given in the preceding formula, the convention adopted in the bond market is to double the semiannual interest rate. The yield-to-maturity computed in this manner—doubling the semiannual yield—is called a *bond-equivalent yield.* In fact, this convention is carried over to yield calculations for other types of fixed income securities.

Yield-to-Call

For a callable bond, investors also compute another yield (or internal rate of return) measure, the *yield-to-call*. The cash flows for computing the yield-to-call are those which would result if the issue were called on some assumed call date. Two commonly used call dates are the *first call date* and the *first par call date*. The yield-to-call is the interest rate that will make the present value of the cash flows if the bond is held to the assumed call date equal to the price of the bond (i.e., the full price).

Illustration 9. In Illustrations 6 and 7, we computed the current yield and yield-to-maturity for an 18-year, 6% coupon bond selling for \$700.89. Suppose that this bond is first callable in five years at \$1,030. The cash flows for this bond if it is called in five years are

- 10 coupon payments of \$30 every six months
- \$1,030 in 10 six-month periods from now

The interest rate we seek is one that will make the present value of the cash flows equal to \$700.89. From Exhibit 4-6, it can be seen that when the interest rate is 7.6%, the present value of the cash flows is \$700.11, which is close enough to \$700.89 for our purposes. Therefore, the yield-to-call on a bond-equivalent basis is 15.2% (double the periodic interest rate of 7.6%).

According to the conventional approach, conservative investors will compute the yield-to-call and yield-to-maturity for a callable bond selling at a premium, selecting the lower of the two as a measure of potential return. It is the smaller of the two yield measures that investors would use to evaluate the yield for a bond. Some investors calculate not just the yield to the first call date and yield to first par call date but the yield to all possible call dates. Because most bonds can be called

EXHIBIT 4-6

Computation of Yield-to-Call for an 18-Year, 6% Coupon Bond Callable in 5 Years at $1,030, Selling at $700.89

Objective: Find, by trial and error, the semiannual interest rate that will make the present value of the following cash flows equal to $700.89:

10 coupon payments of $30 every six months
$1,030 10 six-month periods from now

Annual Interest Rate	Semi-annual Rate	Present Value of 10 Payments of $30*	Present Value of $1,030 10 Periods from Now†	Present Value of Cash Flows
11.20%	5.60%	$225.05	$597.31	$822.36
11.70	5.85	222.38	585.35	805.73
12.20	6.10	219.76	569.75	789.51
12.70	6.35	217.19	556.50	773.69
13.20	6.60	214.66	543.58	758.24
13.70	6.85	212.18	531.00	743.18
14.20	7.10	209.74	518.73	728.47
14.70	7.35	207.34	506.78	714.12
15.20	7.60	204.99	495.12	700.11

$$^*\$30\left[\frac{1-\left\{\dfrac{1}{(1+\text{semiannual interest rate})^{10}}\right\}}{\text{semiannual interest rate}}\right]$$

$$^{\dagger}\$1,030\left[\frac{1}{(1+\text{semiannual interest rate})^{10}}\right]$$

at any time after the first call date, the approach has been to compute the yield to every coupon anniversary date following the first call date. Then all calculated yields-to-call and the yield-to-maturity are compared. The lowest of these yields is called the *yield-to-worst*. The conventional approach would have us believe that this yield is the appropriate one a conservative investor should use.

Let's take a closer look at the yield-to-call as a measure of the potential return of a callable bond. The yield-to-call does consider all three sources of potential return from owning a bond. However, as in the case of the yield-to-maturity, it assumes that all cash flows can be reinvested at the computed yield—in this case, the yield-to-call—until the assumed call date. As we noted earlier in this chapter, this assumption may be inappropriate. Moreover, the yield-to-call assumes that (1) the investor will hold the bond to the assumed call date and (2) the issuer will call the bond on that date.

The assumptions underlying the yield-to-call are often unrealistic. They do not take into account how an investor will reinvest the proceeds if the issue is called. For example, consider two bonds, M and N. Suppose that the yield-to-maturity for bond M, a five-year option-free bond, is 6.0%, whereas for bond N the yield-to-call, assuming that the bond will be called in three years, is 6.5%. Which bond is better for an investor with a five-year investment horizon? It's not possible to tell from the yields cited. If the investor intends to hold the bond for five years and the issuer calls the bond after three years, the total dollars that will be available at the end of five years will depend on the interest rate that can be earned from reinvesting funds from the call date to the end of the investment horizon.

More will be said about the analysis of callable bonds in Chapter 36.

Yield (Internal Rate of Return) for a Portfolio

The yield for a portfolio of bonds is not simply the average or weighted average of the yield-to-maturity of the individual bond issues. It is computed by determining the cash flows for the portfolio and then finding the interest rate that will make the present value of the cash flows equal to the market value of the portfolio.[7] As with any yield measure, it suffers from the same assumptions.

Illustration 10. Consider the following three-bond portfolio:[8]

Bond	Coupon Rate	Maturity	Par Value	Price Value	Yield-to-Maturity
A	7.0%	5 years	$ 10,000,000	$ 9,209,000	9.0%
B	10.5	7	20,000,000	20,000,000	10.5
C	6.0	3	30,000,000	28,050,000	8.5

The portfolio's total market value is $57,259,000. The cash flow for each bond in the portfolio and for the whole portfolio is as follows:

Period Cash Flow Received	Bond A	Bond B	Bond C	Portfolio
1	$ 350,000	$ 1,050,000	$ 900,000	$ 2,300,000
2	350,000	1,050,000	900,000	2,300,000
3	350,000	1,050,000	900,000	2,300,000
4	350,000	1,050,000	900,000	2,300,000
5	350,000	1,050,000	900,000	2,300,000
6	350,000	1,050,000	30,900,000	32,300,000
7	350,000	1,050,000	—	1,400,000
8	350,000	1,050,000	—	1,400,000

(Continued)

7. Chapter 5 discusses the concept of duration. A good approximation to the yield for a portfolio can be obtained by using duration to weight the yield-to-maturity of the individual bonds in the portfolio.
8. To simplify the illustration, it is assumed that the coupon payment date is the same for each bond.

(Continued)

Period Cash Flow Received	Bond A	Bond B	Bond C	Portfolio
9	350,000	1,050,000	—	1,400,000
10	10,350,000	1,050,000	—	11,400,000
11	—	1,050,000	—	1,050,000
12	—	1,050,000	—	1,050,000
13	—	1,050,000	—	1,050,000
14	—	21,050,000	—	21,050,000

To determine the yield (internal rate of return) for this three-bond portfolio, the interest rate that makes the present value of the cash flows shown in the last column of the table above equal to $57,259,000 (the total market value of the portfolio) must be found. If an interest rate of 4.77% is used, the present value of the cash flows will equal $57,259,000. Doubling 4.77% gives 9.54%, which is the yield on the portfolio on a bond-equivalent basis.

Yield Measure for Floating-Rate Securities

The coupon rate for a floating-rate security changes periodically based on some reference rate (such as LIBOR).[9] Because the value for the reference rate in the future is not known, it is not possible to determine the cash flows. This means that a yield-to-maturity cannot be calculated.

A conventional measure used to estimate the potential return for a floating-rate security is the security's *discount margin.* This measure estimates the average spread or margin over the reference rate that the investor can expect to earn over the life of the security. The procedure for calculating the discount margin is as follows:

1. Determine the cash flows assuming that the reference rate does not change over the life of the security.
2. Select a margin (spread).
3. Discount the cash flows found in step 1 by the current value of the reference rate plus the margin selected in step 2.
4. Compare the present value of the cash flows as calculated in step 3 to the price. If the present value is equal to the security's price, the discount margin is the margin assumed in step 2. If the present value is not equal to the security's price, go back to step 2 and try a different margin.

For a security selling at par, the discount margin is simply the spread over the reference rate.

Illustration 11. To illustrate the calculation, suppose that a six-year floating-rate security selling for 99.3098 pays a rate based on some reference rate plus 80 basis points. The coupon rate is reset every six months. Assume that the

9. Other spread measures are explained in Chapter 14.

current value for the reference rate is 10%. Exhibit 4-7 shows the calculation of the discount margin for this security. The second column shows the current discounted value for the reference rate (10%). The third column sets forth the cash flows for the security. The cash flow for the first 11 periods is equal to one-half the current value for the reference rate (5%) plus the semiannual spread of 40 basis points multiplied by 100. In the twelfth six-month period, the cash flow is 5.4 plus the maturity value of 100. The top row of the last five columns shows the assumed margin. The rows below the assumed margin show the present value of each cash flow. The last row gives the total present value of the cash flows. For the five assumed yield spreads, the present value is equal to the price of the floating-rate security (99.3098) when the assumed margin is 96 basis points. Therefore, the discount margin on a semiannual basis is 48 basis points and 96 basis points on an annual basis. (Notice that the discount margin is 80 basis points, the same as the spread over the reference rate, when the security is selling at par.)

EXHIBIT 4-7

Calculation of the Discount Margin for a Floating-Rate Security

Floating-rate security: Maturity = 6 years
Coupon rate = reference rate + 80 basis points
Reset every six months

			Present Value of Cash Flow: Assumed Annual Yield Spread (in bp)				
Period	**Reference Rate**	**Cash Flow***	**80**	**84**	**88**	**96**	**100**
1	10%	5.4	5.1233	5.1224	5.1214	5.1195	5.1185
2	10	5.4	4.8609	4.8590	4.8572	4.8535	4.8516
3	10	5.4	4.6118	4.6092	4.6066	4.6013	4.5987
4	10	5.4	4.3755	4.3722	4.3689	4.3623	4.3590
5	10	5.4	4.1514	4.1474	4.1435	4.1356	4.1317
6	10	5.4	3.9387	3.9342	3.9297	3.9208	3.9163
7	10	5.4	3.7369	3.7319	3.7270	3.7171	3.7122
8	10	5.4	3.5454	3.5401	3.5347	3.5240	3.5186
9	10	5.4	3.3638	3.3580	3.3523	3.3409	3.3352
10	10	5.4	3.1914	3.1854	3.1794	3.1673	3.1613
11	10	5.4	3.0279	3.0216	3.0153	3.0028	2.9965
12	10	105.4	56.0729	55.9454	55.8182	55.5647	55.4385
Present value			100.0000	99.8269	99.6541	99.3098	99.138

*For periods 1–11: cash flow = 100 (reference rate + assumed margin) (0.5); for period 12: cash flow = 100 (reference rate + assumed margin) (0.5) + 100.

There are two drawbacks of the discount margin as a measure of the potential return from investing in a floating-rate security. First, this measure assumes that the reference rate will not change over the life of the security. Second, if the floating-rate security has a cap or floor, this is not taken into consideration. Techniques described in Chapter 36 can allow interest rate volatility to be considered and can handle caps or floors.

TOTAL RETURN ANALYSIS

If conventional yield measures such as the yield-to-maturity and yield-to-call offer little insight into the potential return of a bond, what measure of return can be used? The proper measure is one that considers all three sources of potential dollar return over the investment horizon. This requires that an investor first project the total future dollars over an investment horizon. The return is then the interest rate that will make the bond's price (full price) grow to the projected total future dollars at the end of the investment horizon. The yield computed in this way is known as the *total return,* also referred to as the *horizon return.* In this section we explain this measure and demonstrate how it can be applied in assessing the potential return from investing in a bond.

Calculating the Total Return

The total return requires that the investor specify

- An investment horizon
- A reinvestment rate
- A selling price for the bond at the end of the investment horizon (which depends on the assumed yield at which the bond will sell at the end of the investment horizon)

More formally, the steps for computing a total return over some investment horizon are as follows.

Step 1: Compute the total coupon payments plus the interest-on-interest based on an assumed reinvestment rate. The reinvestment rate is one-half the annual interest rate that the investor believes can be earned on the reinvestment of coupon interest payments.

The total coupon payments plus interest-on-interest can be calculated using the formula for the future value of an annuity as shown:

$$\text{Coupon plus interest-on-interest} = \text{semiannual coupon}\left[\frac{\left\{(1+r)^h - 1\right)\}}{r}\right]$$

where

h = length of the investment horizon (in semiannual periods)
r = assumed semiannual reinvestment rate

Step 2: Determine the projected sale price at the end of the investment horizon. The projected sale price will depend on the projected yield on comparable bonds at the end of the investment horizon.

Step 3: Add the values computed in steps 1 and 2. The sum is the *total future dollars* that will be received from the investment given the assumed reinvestment rate and projected required yield at the end of the investment horizon.

Step 4: To obtain the semiannual total return, use the following formula:

$$\left(\frac{\text{total future dollars}}{\text{purchase price of bond}}\right)^{1/h} - 1$$

Step 5: Because coupon interest is assumed to be paid semiannually, double the interest rate found in step 4. The resulting interest rate is the total return expressed on a bond-equivalent basis. Alternatively, the total return can be expressed on an effective annual interest rate basis by using the following formula:

$$(1 + \text{semiannual total return})^2 - 1$$

Illustration 12. Suppose that an investor with a three-year investment horizon is considering purchasing a 20-year, 8% coupon bond for \$828.40. The yield-to-maturity for this bond is 10%. The investor expects to reinvest the coupon interest payments at an annual interest rate of 6% and that at the end of the investment horizon the 17-year bond will be selling to offer a yield-to-maturity of 7%. The total return for this bond is computed in Exhibit 4-8.

Objections to the total return analysis cited by some portfolio managers are that it requires them to make assumptions about reinvestment rates and future yields and forces a portfolio manager to think in terms of an investment horizon. Unfortunately, some portfolio managers find comfort in meaningless measures such as the yield-to-maturity because it is not necessary to incorporate any expectations. As explained below, the total return framework enables the portfolio manager to analyze the performance of a bond based on different interest-rate scenarios for reinvestment rates and future market yields. By investigating multiple scenarios, the portfolio manager can see how sensitive the bond's performance is in each scenario. There is no need to assume that the reinvestment rate will be constant for the entire investment horizon.

For portfolio managers who want to use the market's expectations of short-term reinvestment rates and the yield on the bond at the end of the investment

EXHIBIT 4-8

Illustration of Total Return Calculation

Assumptions:

Bond = 8% 20-year bond selling for \$828.40 (yield-to-maturity is 10%)

Annual reinvestment rate = 6%

Investment horizon = 3 years

Yield for 17-year bonds at end of investment horizon = 7%

Step 1: Compute the total coupon payments plus the interest-on-interest assuming an annual reinvestment rate of 6%, or 3% every six months. The coupon payments are \$40 every six months for three years or six periods (the investment horizon). The total coupon interest plus interest-on-interest is

$$\text{Coupon plus interest-on-interest} = \$40\left(\frac{(1.03)^6 - 1}{0.03}\right) = \$258.74$$

Step 2: The projected sale price at the end of 3 years, assuming that the required yield-to-maturity for 17-year bonds is 7%, is found by determining the present value of 34 coupon payments of \$40 plus the present value of the maturity value of \$1,000, discounted at 3.5%. The price can be shown to be \$1,098.51.

Step 3: Adding the amount in steps 1 and 2 gives total future dollars of \$1,357.25.

Step 4: Compute the following:

$$= \left(\frac{\$1,357.25}{828.40}\right)^{1/6} - 1$$

$$= (1.63840)^{0.16667} - 1$$

$$1.0858 - 1$$

$$= 0.0858, \text{ or } 8.58\%$$

Step 5: Doubling 8.58% gives a total return of 17.16% on a bond-equivalent basis. On an effective annual interest-rate basis, the total return is

$$(1.0858)^2 - 1$$

$$= 1.1790 - 1$$

$$= 0.1790$$

$$= 17.90\%$$

horizon, implied forward rates can be calculated from the yield-curve. Implied forward rates are explained in Chapters 3 and 31, and are calculated based on arbitrage arguments. A total return computed using implied forward rates is called an *arbitrage-free total return.*

Scenario Analysis

Because the total return depends on the reinvestment rate and the yield at the end of the investment horizon, portfolio managers assess performance over a wide range of scenarios for these two variables. This approach is referred to as *scenario analysis.*

Illustration 13. Suppose that a portfolio manager is considering the purchase of bond A, a 20-year, 9% option-free bond selling at $109.896 per $100 of par value. The yield-to-maturity for this bond is 8%. Assume also that the portfolio manager's investment horizon is three years and that the portfolio manager believes that the reinvestment rate can vary from 3% to 6.5% and that the yield at the end of the investment horizon can vary from 5% to 12%.

The top panel of Exhibit 4-9 shows the total future dollars at the end of three years under various scenarios. The bottom panel shows the total return (based on the effective annualizing of the six-month total return). The portfolio manager knows that the maximum and minimum total return for the scenarios analyzed will be 16.72% and –1.05%, respectively, and the scenarios under which each will be realized. If the portfolio manager faces three-year liabilities guaranteeing, say, 6%, the major consideration is scenarios that will produce a three-year total return of less than 6%. These scenarios can be determined from Exhibit 4-9.

Illustration 14. Suppose that the same portfolio manager owns bond B, a 14-year option-free bond with a coupon rate of 7.25% and a current price of $94.553 per $100 par value. The yield-to-maturity is 7.9%. Exhibit 4-10 reports the total future dollars and total return over a three-year investment horizon under the same scenarios as Exhibit 4-9. A portfolio manager considering swapping from bond B to bond A would compare the relative performance of the two bonds as reported in Exhibits 4-9 and 4-10. Exhibit 4-11 shows the difference between the performance of the two bonds in basis points. This comparative analysis assumes that the two bonds are of the same investment quality and ignores the financial accounting and tax consequences associated with the disposal of bond B to acquire bond A.

Evaluating Potential Bond Swaps

Portfolio managers commonly swap an existing bond in a portfolio for another bond. Bond swaps can be categorized as pure yield pickup swaps, substitution swaps, intermarket-spread swaps, or rate-anticipation swaps. Total return analysis can be used to assess the potential return from a swap.

- *Pure yield pickup swap.* Switching from one bond to another that has a higher yield is called a *pure yield pickup swap.* The swap may be undertaken to achieve either higher current coupon income or higher yield-to-maturity or both. No expectation is made about changes in interest rates, yield spreads, or credit quality.

EXHIBIT 4-9

- *Rate-anticipation swap.* A portfolio manager who has expectations about the future direction of interest rates will use bond swaps to position the portfolio to take advantage of the anticipated interest-rate move. These are known as *rate-anticipation swaps.* If rates are expected to fall, for example, bonds with a greater price volatility will be swapped for existing bonds in the portfolio with lower price volatility (to take advantage of the larger change in price that will result if interest rates do in fact decline). The opposite will be done if rates are expected to rise.

EXHIBIT 4-10

- *Intermarket-spread swap.* These swaps are undertaken when the portfolio manager believes that the current yield spread between two bonds in the market is out of line with its historical yield spread and that the yield spread will realign by the end of the investment horizon. Yield spreads between bonds exist for the following reasons: (1) there is a difference in the credit quality of bonds (e.g., between Treasury bonds and double-A-rated public utility bonds of the same maturity),

EXHIBIT 4-11

Scenario Analysis Showing the Relative Performance of Bonds A and B

Reinvestment Rate	Total Return for Bond A minus Total Return for Bond B (in Basis Points)							
	5.00%	6.00%	7.00%	8.00%	9.00%	10.00%	11.00%	12.00%
3.0%	207	136	77	28	–12	–43	–67	–85

5.5	208	137	78	29	–10	–41	–65	–82
6.0	208	137	78	30	–10	–41	–64	–82
6.5	208	137	78	30	–9	–40	–64	–81

or (2) there are differences in the features of corporate bonds that make them more or less attractive to investors (for example, callable and noncallable bonds, and putable and nonputable bonds).

- *Substitution swap.* In a substitution swap, a portfolio manager swaps one bond for another bond that is thought to be identical in terms of coupon, maturity, price sensitivity to interest-rate changes, and credit quality, but that offers a higher yield. This swap depends on a capital market imperfection. Such situations sometimes exist in the bond market because of temporary market imbalances. The risk that the portfolio manager faces is that the bond purchased may not be identical to the bond for which it is exchanged. For example, if credit quality is not the same, the bond purchased may be offering a higher yield because of higher credit risk rather than because of a market imbalance.

Comparing Municipal and Corporate Bonds

The conventional methodology for comparing the relative performance of a tax-exempt municipal bond and a taxable corporate bond is to compute the *taxable equivalent yield.* The taxable equivalent yield is the yield that must be earned on a taxable bond in order to produce the same yield as a tax-exempt municipal bond. The formula is

$$\text{Taxable equivalent yield} = \frac{\text{tax-exempt yield}}{1 - \text{marginal tax rate}}$$

For example, suppose that an investor in the 35% marginal tax bracket is considering a 10-year municipal bond with a yield-to-maturity of 4.5%. The taxable equivalent yield is

$$\frac{4.5\%}{1-0.35}=6.92\%$$

If the yield-to-maturity offered on a comparable-quality corporate bond with 10 years to maturity is more than 6.92%, those who use this approach would recommend that the corporate bond be purchased. If, instead, a yield-to-maturity of less than 6.92% on a comparable corporate bond is offered, the investor should invest in the municipal bond.

What's wrong with this approach? The tax-exempt yield of the municipal bond and the taxable equivalent yield suffer from the same limitations we discussed with respect to yield-to-maturity. Consider the difference in reinvestment opportunities for a corporate and a municipal bond. For the former, coupon payments will be taxed; therefore, the amount to be reinvested is not the entire coupon payment but an amount net of taxes. In contrast, because the coupon payments are free from taxes for a municipal bond, the entire coupon can be reinvested.

The total return framework can accommodate this situation by allowing us to explicitly incorporate the reinvestment opportunities. There is another advantage to the total return framework as compared with the conventional taxable equivalent yield approach. Changes in tax rates (because investors expect either their tax rate to change or the tax structure to change) can be incorporated into the total return framework.

KEY POINTS

- The price of a bond is equal to the present value of the expected cash flow.
- For bonds with embedded options, the cash flow is difficult to estimate.
- The required yield used to discount the cash flow is determined by the yield offered on comparable securities.
- The two most popular yield measures cited in the bond market are the yield-to-maturity and yield-to-call. Both yield measures consider the coupon interest and any capital gain (or loss) at the maturity date or call date in the case of the yield-to-call.
- The coupon interest and capital gain (or loss), however, are only two of the three components of the potential dollar return from owning a bond until it matures or is called. The other component is the reinvestment of coupon income, commonly referred to as the interest-on-interest component. This component can be as large as 80% of a bond's total dollar return.

- The yield-to-maturity assumes that the coupon payments can be reinvested at the calculated yield-to-maturity.
- The yield-to-call assumes that the coupon payments can be reinvested at the calculated yield-to-call.
- A better measure of the potential return from holding a bond over a predetermined investment horizon is the total return measure. This measure considers all three sources of potential dollar return and can be used to analyze bond swaps and bond performance.

The value of a bond changes in the opposite direction of the change in interest rates. A long bond position's value will decline if interest rates rise, resulting in a loss. For a short bond position, a loss will be realized if interest rates fall. However, an investor wants to know more than simply when a position will realize a loss. To control interest-rate risk, an investor must be able to quantify what will result.

The key to measuring interest-rate risk is the accuracy of the estimate of the value of the position after an adverse rate change. A valuation model is used to determine the value of a position after an adverse rate move. Consequently, if a reliable valuation model is not used, there is no way to properly measure interest-rate risk exposure.

There are two approaches to measuring interest-rate risk—*the full-valuation approach* and the *duration/convexity approach.* We begin with a discussion of the full-valuation approach. The balance of the chapter is devoted to the duration/convexity approach. As a background to the duration/convexity approach, we discuss the price volatility characteristics of option-free bonds and bonds with embedded options. We then look at how duration can be used to estimate interest-rate risk and distinguish between various duration measures (effective, modified, and Macaulay). Next, we show how a measure referred to as "convexity" can be used to improve the duration estimate of the price volatility of a bond to rate changes. In the next-to-the-last section we show the relationship between duration and another measure of price volatility used by investors, the price value of a basis point (or dollar value of an 01). In the last section we discuss the importance of incorporating yield volatility in estimates of exposure to interest-rate risk.

THE FULL-VALUATION APPROACH

The most obvious way to measure the interest-rate risk exposure of a bond position or a portfolio is to revalue it when interest rates change. The analysis is performed for a given scenario with respect to interest-rate changes. For example, an investor may want to measure the interest-rate exposure to a 50 basis point, 100 basis point, and 200 basis point instantaneous change in interest rates. This approach requires the revaluation of a bond or bond portfolio for a given interest-rate change scenario and is called the *full-valuation approach.* It is sometimes referred to as "scenario analysis" because it involves assessing the exposure to interest-rate change scenarios.

To illustrate this approach, suppose that an investor has a \$10 million par value position in a 5% coupon 20-year bond. The bond is option-free. The current price is 106.5484 for a yield (i.e., yield to maturity) of 4.5%. The market value of the position is \$10,654,840 (106.5484% × \$10 million). Since the investor owns the bond, she is concerned with a rise in yield, since this will decrease the market value of the position. To assess the exposure to a rise in market yields, the investor decides to look at how the value of the bond will change if yields change instantaneously for the following three scenarios: (1) 50 basis point increase, (2) 100 basis point increase, and (3) 200 basis point increase. This means that the investor wants to assess what will happen to the bond position if the yield on the bond increases from 4.5% to (1) 5%, (2) 5.5%, and (3) 6.5%. Because this is an option-free bond, valuation is straightforward. We will assume that one yield is used to discount each of the cash flows. That is, we will assume a flat yield-curve. The price of this bond per \$100 par value and the market value of the \$10 million par position is shown in Exhibit 5-1. Also shown is the change in the market value and the percentage change.

In the case of a portfolio, each bond is valued for a given scenario, and then the total value of the portfolio is computed for the scenario. For example, suppose that a manager has a portfolio with the following two option-free bonds: (1) 4% coupon 5-year bond and (2) 5% coupon 20-year bond. For the shorter-term bond, \$5 million of par value is owned, and the price is 109.4713 for a yield of 2%. For the longer-term bond, \$10 million of par value is owned, and the price is 106.5484 for a yield of 4.5%. Suppose that the manager wants to assess the interest-rate risk of this portfolio for a 50, 100, and 200 basis point increase in interest rates assuming that both the 5-year yield and the 20-year yield change by the same number

EXHIBIT 5-1

Illustration of Full-Valuation Approach to Assess the Interest-Rate Risk of a Bond Position for Three Scenarios

Current bond position: 5% coupon 20-year bond (option-free)
Price: 106.5484
Yield to maturity: 4.5%
Par value owned: $10 million
Market value of position: $10,654,840.00

Scenario	Yield Change (bp)	New Yield	New Price	New Market Value ($)	Percentage Change in Market Value (%)
1	50	5.0%	100.0000	10,000,000	–6.15%
2	100	5.5%	93.9805	9,398,050	–11.80%
3	200	6.5%	83.3437	8,334,370	–21.78%

of basis points. Exhibit 5-2 shows the exposure. Panel *a* of the exhibit shows the market value of the 5-year bond for the three scenarios. Panel *b* does the same for the 20-year bond. Panel *c* shows the total market value of the portfolio and the percentage change in the market value for the three scenarios.

In Exhibit 5-2, it is assumed that both the 5-year and the 20-year yields changed by the same number of basis points. The full-valuation approach also can handle scenarios where the yield-curve does not change in a parallel fashion. Exhibit 5-3 illustrates this for our portfolio that includes the 5-year and the 20-year bonds. The scenario analyzed is a yield-curve shift scenario combined with scenarios for shifts in the level of yields. In the illustration in Exhibit 5-3, the following yield changes for the 5-year and 20-year yields are assumed:

Scenario	Change in 5-Year Rate (bp)	Change in 20-Year Rate (bp)
1	50	10
2	100	50
3	200	100

The last panel in Exhibit 5-3 shows how the market value of the portfolio changes for each scenario.

The full-valuation approach seems straightforward. If one has a good valuation model, assessing how the value of a portfolio or individual bond will change for different scenarios for parallel and nonparallel yield-curve shifts measures the interest-rate risk of a portfolio.

EXHIBIT 5-2

Illustration of Full-Valuation Approach to Assess the Interest-Rate Risk of a Bond Portfolio for Three Scenarios Assuming a Parallel Shift in the Yield-Curve

Two-bond portfolio (both bonds are option-free bonds)

Panel a

Bond 1:	4% coupon 5-year bond	Par value:	$5,000,000
Initial price:	109.4713	Market value:	$5,473,565
Yield:	2%		

Scenario	Yield Change (bp)	New Yield	New Price	New Market Value ($)
1	50	2.5%	107.0091	5,350,455
2	100	3.0%	104.6111	5,230,555
3	200	4.0%	100.0000	5,000,000

Panel b

Bond 2:	5% coupon 20-year bond	Par value:	$10,000,000
Initial price:	106.5484	Market value:	$10,654,838
Yield:	4.5%		

Scenario	Yield Change (bp)	New Yield	New Price	New Market Value ($)
1	50	5.0%	100.0000	10,000,000
2	100	5.5%	93.9805	9,398,050
3	200	6.5%	83.3437	8,334,370

Panel c

Portfolio Market value: $16,128,403

		Market Value of			
Scenario	Yield Change (bp)	Bond 1 ($)	Bond 2 ($)	Portfolio ($)	Percentage Change in Market Value (%)
1	50	5,350,455	10,000,000	15,350,455	–4.82%
2	100	5,230,555	9,398,050	14,628,605	–9.30%
3	200	5,000,000	8,334,370	13,334,370	–17.32%

A common question that often arises when using the full-valuation approach is what scenarios should be evaluated to assess interest-rate risk exposure. For some regulated entities, there are specified scenarios established by regulators. For example, it is common for regulators of depository institutions to require

2	5,230,555	10,000,000	15,230,555	–5.57%
3	5,000,000	9,398,050	14,398,050	–10.73%

entities to determine the impact on the value of their bond portfolio for a 100, 200, and 300 basis point instantaneous change in interest rates (up and down). (Regulators tend to refer to this as "simulating" interest-rate scenarios rather than scenario analysis.) Risk managers and highly leveraged investors such as hedge funds tend to look at extreme scenarios to assess exposure to interest-rate changes. This practice is called *stress testing.*

Of course, in assessing how changes in the yield-curve can affect the exposure of a portfolio, there are an infinite number of scenarios that can be evaluated. The state-of-the-art technology involves using a complex statistical procedure to determine a likely set of yield-curve shift scenarios from historical data.

We can use the full-valuation approach to assess the exposure of a bond or portfolio to interest-rate change to evaluate any scenario, assuming—and this must be repeated continuously—*that the investor has a good valuation model to estimate what the price of the bonds will be in each interest-rate scenario.* While the full-valuation approach is the recommended approach for assessing the position of a single bond or a portfolio of a few bonds, for a portfolio with a large number of bonds and with even a minority of those bonds being complex (i.e., having embedded options), the full-valuation process is time-consuming. Investors want one measure they can use to get an idea of how a portfolio or even a single bond will change if rates change in a parallel fashion rather than having to revalue a portfolio to obtain that answer. Such a measure is duration. We will discuss this measure as well as a supplementary measure (convexity). To build a foundation to understand the limitations of these measures, we describe next the basic price volatility characteristics of bonds. The fact that there are limitations of using one or two measures to describe the interest-rate exposure of a position or portfolio should not be surprising. What is important to understand is that these measures provide a starting point for assessing interest-rate risk.

PRICE VOLATILITY CHARACTERISTICS OF BONDS

The characteristics of a bond that affect its price volatility are (1) maturity, (2) coupon rate, and (3) presence of embedded options. We also will see how the level of yields affects price volatility.

Price Volatility Characteristics of Option-Free Bonds

We begin by focusing on option-free bonds (i.e., bonds that do not have embedded options). A fundamental characteristic of an option-free bond is that the price of the bond changes in the opposite direction from a change in the bond's required yield. Exhibit 5-4 illustrates this property for four hypothetical bonds assuming a par value of $100.

When the price/yield relationship for any option-free bond is graphed, it exhibits the shape shown in Exhibit 5-5. Notice that as the required yield increases, the price of an option-free bond declines. However, this relationship is not linear (i.e., not a straight-line relationship). The shape of the price/yield relationship

EXHIBIT 5-4

6.00	91.4698	76.8852	95.7349	88.4426

for any option-free bond is called *convex*. This price/yield relationship is for an instantaneous change in the required yield.

The price sensitivity of a bond to changes in the required yield can be measured in terms of the dollar price change or the percentage price change. Exhibit 5-6 uses the four hypothetical bonds in Exhibit 5-4 to show the percentage change in each bond's price for various changes in yield, assuming that the initial yield for all

5.00	–4.38	–12.55	–4.30	–12.03
6.00	–8.53	–23.11	–8.38	–22.20

four bonds is 4%. An examination of Exhibit 5-6 reveals the following properties concerning the price volatility of an option-free bond:

Property 1: Although the price moves in the opposite direction from the change in required yield, the percentage price change is not the same for all bonds.

Property 2: For small changes in the required yield, the percentage price change for a given bond is roughly the same, whether the required yield increases or decreases.

Property 3: For large changes in required yield, the percentage price change is not the same for an increase in required yield as it is for a decrease in required yield.

Property 4: For a given large change in basis points in the required yield, the percentage price increase is greater than the percentage price decrease.

While the properties are expressed in terms of percentage price change, they also hold for dollar price changes.

The implication of Property 4 is that if an investor is long a bond, the price appreciation that will be realized if the required yield decreases is greater than the capital loss that will be realized if the required yield increases by the same number of basis points. For an investor who is short a bond, the reverse is true: The potential capital loss is greater than the potential capital gain if the yield changes by a given number of basis points.

Bond Features That Affect Interest-Rate Risk

The degree of sensitivity of a bond's price to changes in market interest rates (i.e., a bond's interest-rate risk) depends on various features of the issue, such as maturity, coupon rate, and embedded options.

The Impact of Maturity

All other factors constant, *the longer the bond's maturity, the greater is the bond's price sensitivity to changes in interest rates.* For example, for a 4% 20-year bond selling to yield 4%, a rise in the yield required by investors to 4.5% will cause the bond's price to decline from 100 to 93.4516, a 6.55% price decline. For a 4% 5-year bond selling to yield 4%, the price is 100. A rise in the yield required by investors from 4% to 4.5% would decrease the price to 97.7834. The decline in the bond's price is only 2.22%.

The Impact of Coupon Rate

A property of a bond is that all other factors constant, *the lower the coupon rate, the greater is the bond's price sensitivity to changes in interest rates.* For example, consider a 5% 20-year bond selling to yield 4%. The price of this bond would be 113.6777. If the yield required by investors increases by 50 basis points to 4.5%, the price of this bond would fall by 6.27% to 106.5484. This decline is less than the 6.55% decline for the 4% 20-year bond selling to yield 4%.

An implication is that zero-coupon bonds have greater price sensitivity to interest-rate changes than same-maturity bonds bearing a coupon rate and trading at the same yield.

The Impact of Embedded Options

In Chapter 1 the various embedded options that may be included in a bond issue were discussed. The value of a bond with embedded options will change depending on how the value of the embedded options changes when interest rates change. For example, as interest rates decline, the price of a callable bond may not increase as much as an otherwise option-free bond (i.e., a bond with no embedded options).

To understand why, we decompose the price of a callable bond into two parts, as shown below:

$$\begin{aligned}&\text{Price of callable bond}\\&\quad= \text{price of option-free bond} - \text{price of embedded call option}\end{aligned}$$

The reason for subtracting the price of the embedded call option from the price of the option-free bond is that the call option is a benefit to the issuer and a disadvantage to the bondholder. This reduces the price of a callable bond relative to an option-free bond.

Now, when interest rates decline, the price of an option-free bond increases. However, the price of the embedded call option increases when interest rates decline because the call option becomes more valuable to the issuer. Thus, when interest rates decline, both components increase, *but* the change in the price of the callable bond depends on the relative price change of the two components. Typically, a decline in interest rates will result in an increase in the price of the callable bond but not by as much as the price change of an otherwise comparable option-free bond.

Similarly, when interest rates rise, the price of a callable bond will not fall by as much as an otherwise option-free bond. The reason is that the price of the embedded call option declines. When interest rates rise, the price of the option-free bond declines but is partially offset by the decrease in the price of the embedded call option.

Price Volatility Characteristics of Bonds with Embedded Options

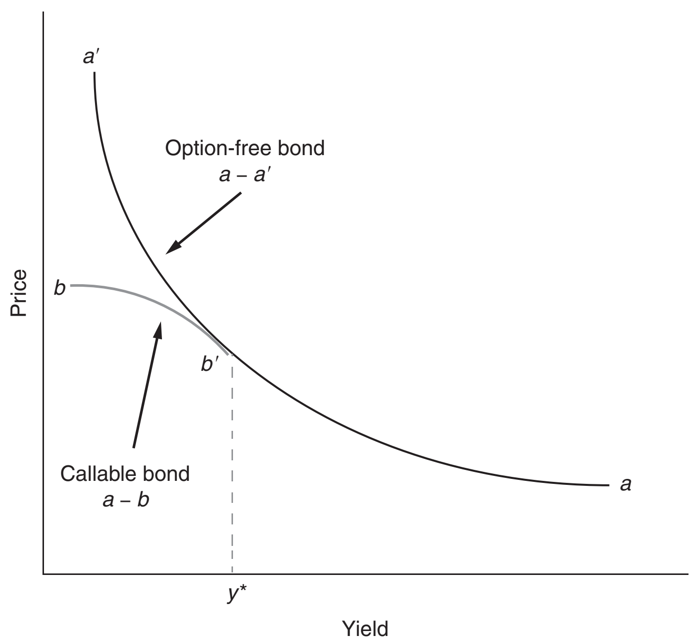
In this section we examine the price/yield relationship for bonds with both types of options (calls and puts) and implications for price volatility.

Bonds with Call and Prepay Options

In the discussion below we will refer to a bond that may be called or is prepayable as a callable bond. Exhibit 5-7 shows the price/yield relationship for an option-free bond and a callable bond. The convex curve given by *a–a′* is the price/yield relationship for an option-free bond. The unusually shaped curve denoted by *a–b* in the exhibit is the price/yield relationship for the callable bond.

EXHIBIT 5-7

Price/Yield Relationship for a Callable Bond and an Option-Free Bond



The reason for the price/yield relationship for a callable bond is as follows. When the prevailing market yield for comparable bonds is higher than the coupon rate on the callable bond, it is unlikely that the issuer will call the issue. For example, if the coupon rate on a bond is 3% and the prevailing market yield on comparable bonds is 6%, it is highly unlikely that the issuer will call a 3% coupon bond so that it can issue a 6% coupon bond. Since the bond is unlikely to be called, the callable bond will have a similar price/yield relationship as an otherwise comparable option-free bond. Consequently, the callable bond is going to be valued as if it is an option-free bond. However, since there is still some value to the call option, the bond won't trade exactly like an option-free bond.

As yields in the market decline, the concern is that the issuer will call the bond. The issuer won't necessarily exercise the call option as soon as the market yield drops below the coupon rate. Yet the value of the embedded call option increases as yields approach the coupon rate from higher yield levels. For example, if the coupon rate on a bond is 3% and the market yield declines to 3.50%, the issuer most likely will not call the issue. However, market yields are at a level at which the investor is concerned that the issue eventually may be called if market yields decline further. Cast in terms of the value of the embedded call option, that option becomes more valuable to the issuer, and therefore, it reduces the price relative to an otherwise comparable option-free bond.[1] In Exhibit 5-7, the value of the embedded call option at a given yield can be measured by the difference between the price of an option-free bond (the price shown on the curve a–a') and the price on the curve a–b. Notice that at low yield levels (below y^* on the horizontal axis), the value of the embedded call option is high.

Let's look at the difference in the price volatility properties relative to an option-free bond given the price/yield relationship for a callable bond shown in Exhibit 5-7. Exhibit 5-8 blows up the portion of the price/yield relationship for the callable bond where the two curves in Exhibit 5-7 depart (segment b–b' in Exhibit 5-7). We know from our discussion of the price/yield relationship that for a large change in yield of a given number of basis points, the price of an option-free bond increases by more than it decreases (Property 4 discussed previously). Is that what happens for a callable bond in the region of the price/yield relationship shown in Exhibit 5-8? No, it is not. In fact, as can be seen in the exhibit, the opposite is true! That is, for a given large change in yield, the price appreciation is less than the price decline.

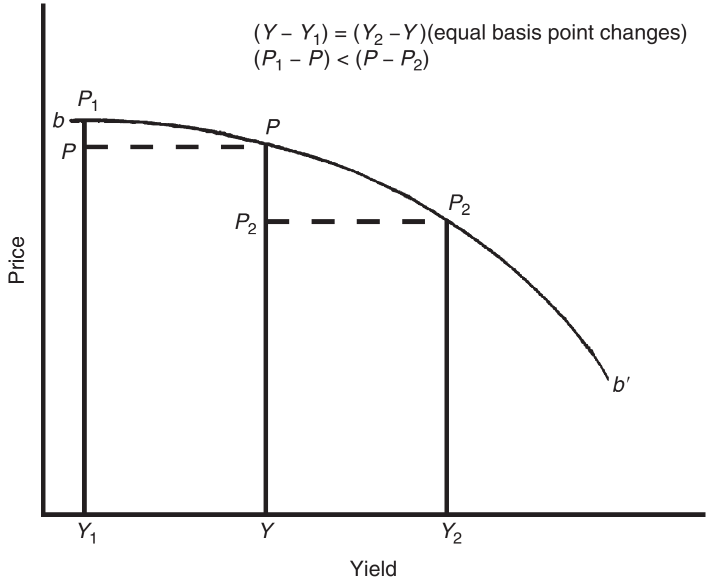
The price volatility characteristic of a callable bond is important to understand. The characteristic of a callable bond that its price appreciation is less than its price decline when rates change by a large number of basis points is called *negative convexity*.[2] But notice from Exhibit 5-7 that callable bonds do not exhibit this characteristic at every yield level. When yields are high (relative to

1. For readers who are already familiar with option theory, this characteristic can be restated as follows: When the coupon rate for the issue is below the market yield, the embedded call option is said to be "out-of-the-money." When the coupon rate for the issue is above the market yield, the embedded call option is said to be "in-the-money."

2. Mathematicians refer to this shape as being "concave."

EXHIBIT 5-8

Negative Convexity Region of the Price/Yield Relationship for a Callable Bond



the issue's coupon rate), the bond exhibits the same price/yield relationship as an option-free bond and therefore at high-yield levels also has the characteristic that the gain is greater than the loss. Because market participants have referred to the shape of the price/yield relationship shown in Exhibit 5-8 as negative convexity, market participants call the relationship for an option-free bond *positive convexity.* Consequently, a callable bond exhibits negative convexity at low yield levels and positive convexity at high-yield levels.

As can be seen from the exhibits, when a bond exhibits negative convexity, as rates decline, the bond compresses in price. That is, at a certain yield level there is very little price appreciation when rates decline. When a bond enters this region, the bond is said to exhibit "price compression."

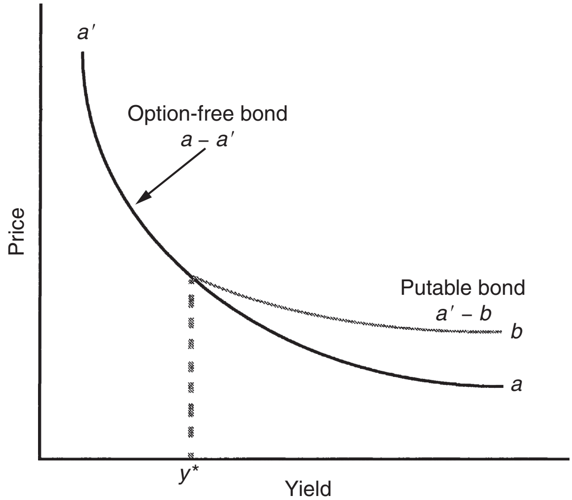
Bonds with Embedded Put Options

Putable bonds may be redeemed by the bondholder on the dates and at the put price specified in the indenture. Typically, the put price is par value. The advantage to the investor is that if yields rise such that the bond's value falls below the put price, the investor will exercise the put option. If the put price is par value, this means that if market yields rise above the coupon rate, the bond's value will fall below par, and the investor will then exercise the put option.

The value of a putable bond is equal to the value of an option-free bond plus the value of the put option. Thus the difference between the value of a putable bond and the value of an otherwise comparable option-free bond is the value of the embedded

EXHIBIT 5-9

Price/Yield Relationship for a Putable Bond and an Option-Free Bond



put option. This can be seen in Exhibit 5-9 which shows the price/yield relationship for a putable bond (the curve *a′–b*) and an option-free bond (the curve *a′–a*).

At low yield levels (low relative to the issue's coupon rate), the price of the putable bond is basically the same as the price of the option-free bond because the value of the put option is small. As rates rise, the price of the putable bond declines, but the price decline is less than that for an option-free bond. The divergence in the price of the putable bond and an otherwise comparable option-free bond at a given yield level is the value of the put option. When yields rise to a level where the bond's price would fall below the put price, the price at these levels is the put price.

Interest-Rate Risk for Floating-Rate Securities

The change in the price of a fixed-rate coupon bond when market interest rates change is due to the fact that the bond's coupon rate differs from the prevailing market interest rate. For a floating-rate security, the coupon rate is reset periodically based on the prevailing value for the reference rate plus the quoted margin. The quoted margin is set for the life of the security. The price of a floating-rate security will fluctuate depending on three factors.

First, the longer the time to the next coupon reset date, the greater is the potential price fluctuation.[3] For example, consider a floating-rate security whose coupon resets every six months and the coupon formula is the six-month Treasury rate plus

3. The coupon rate is set at the beginning of the period but is not paid until the end of the period.

20 basis points. Suppose that on the coupon reset date the six-month Treasury rate is 0.35%. If on the day after the coupon is reset the six-month Treasury rate rises to 0.75%, this means that this security is offering a six-month coupon rate that is less than the prevailing six-month rate for the remaining six months. The price of the security must decline to reflect this. Suppose instead that the coupon resets every month at the one-month Treasury rate and that this rate rises immediately after the coupon rate is reset. In this case, while the investor would be realizing a submarket one-month coupon rate, it is for only a month. The price decline will be less than for the security that resets every six months.

The second reason why a floating-rate security's price will fluctuate is that the required margin that investors demand in the market changes. For example, consider once again the security whose coupon formula is the six-month Treasury rate plus 20 basis points. If market conditions change such that investors want a margin of 30 basis points rather than 20 basis points, this security would be offering a coupon rate that is 10 basis points below the market rate. As a result, the security's price will decline.

Finally, a floating-rate security typically will have a cap. Once the coupon rate as specified by the coupon formula rises above the cap rate, the coupon will be set at the cap rate, and the security then will offer a below-market coupon rate, and its price will decline. In fact, once the cap is reached, the security's price will react much the same way to changes in market interest rates as that of a fixed-rate coupon security. This risk for a floating-rate security is called *cap risk.*

The Impact of the Yield Level

Because of credit risk, different bonds trade at different yields, even if they have the same coupon rate, maturity, and embedded options. How, then, holding other factors constant, does the level of interest rates affect a bond's price sensitivity to changes in interest rates? As it turns out, the higher the level of interest rates that a bond trades, the lower is the price sensitivity.

To see this, we can compare a 5% 20-year bond initially selling at a yield of 5% and a 5% 20-year bond initially selling at a yield of 9%. The former is initially at a price of 100, and the latter, 63.20. Now, if the yield on both bonds increases by 100 basis points, the first bond trades down by 11.56 points (11.56%) to a price of 88.44. After the assumed increase in yield, the second bond will trade at a price of 57.10, for a price decline of only 6.09 points (or 9.64%). Thus we see that the bond that trades at a lower yield is more volatile in both percentage price change and absolute price change as long as the other bond characteristics are the same. An implication is that for a given change in interest rates, price sensitivity is lower when the level of interest rates in the market is high, and price sensitivity is higher when the level of interest rates is low.

DURATION

With this background about the price volatility characteristics of a bond, we can now turn to an alternate approach to full valuation: the duration/convexity approach. *Duration is a measure of the approximate sensitivity of a bond's value to rate changes.* More specifically, *it is the approximate percentage change in value for a 100 basis point change in rates.* We'll see in this section that duration is the first approximation of the percentage price change. To improve the estimate provided by duration a measure called *convexity* can be used. Hence, using duration combined with convexity to estimate the percentage price change of a bond to changes in interest rates is called the *duration/convexity approach.*

Calculating Duration

The duration of a bond is estimated as follows:

$$\frac{\text{Price if yields decline} - \text{price if yields rise}}{2(\text{initial price})(\text{change in yield in decimal})}$$

If we let

$$\Delta y = \text{change in yield in decimal}$$
$$V_0 = \text{initial price}$$
$$V_- = \text{price if yields decline by } \Delta y$$
$$V_+ = \text{price if yields increase by } \Delta y$$

then duration can be expressed as

$$\text{Duration} = \frac{V_- - V_+}{2(V_0)(\Delta y)} \tag{5-1}$$

For example, consider a 5% coupon 20-year option-free bond selling at 113.6777 to yield 4% (see Exhibit 5-4). Let's change (i.e., shock) the yield down and up by 20 basis points and determine what the new prices will be for the numerator. If the yield is decreased by 20 basis points from 4.0% to 3.8%, the price would increase to 116.7049. If the yield increases by 20 basis points, the price would decrease to 110.7527. Thus

$$\Delta y = 0.002$$
$$V_0 = 113.6777$$
$$V_- = 116.7049$$
$$V_+ = 110.5727$$

Then

$$\text{Duration} = \frac{116.7049 - 110.7527}{2 \times (113.6777) \times (0.002)} = 13.09$$

Duration is interpreted as the approximate percentage change in price for a 100 basis point change in rates. Consequently, a duration of 13.09 means that the approximate change in price for this bond is 13.09% for a 100 basis point change in rates.

A common question asked about this interpretation of duration is the consistency between the yield change that is used to compute duration using Eq. (5-1) and the interpretation of duration. For example, recall that in computing the duration of the 5% coupon 20-year bond, we used a 20 basis point yield change to obtain the two prices to use in the numerator of Eq. (5-1). Yet we interpret the duration computed as the approximate percentage price change for a 100 basis point change in yield. The reason is that regardless of the yield change used to estimate duration in Eq. (5-1), the interpretation is the same. If we used a 25 basis point change in yield to compute the prices used in the numerator of Eq. (5-1), the resulting duration is interpreted as the approximate percentage price change for a 100 basis point change in yield. Later we will use different changes in yield to illustrate the sensitivity of the computed duration.

Approximating the Percentage Price Change Using Duration

The following formula is used to approximate the percentage price change for a given change in yield and a given duration:

$$\text{Approximate percentage price change} = -\text{duration} \times \Delta y \times 100 \tag{5-2}$$

The reason for the negative sign on the right-hand side of Eq. (5-2) is due to the inverse relationship between price change and yield change.

For example, consider the 5% 20-year bond trading at 113.6777 whose duration we just showed is 13.09. The approximate percentage price change for a 10 basis point increase in yield (i.e., $\Delta y = +0.001$) is

$$\text{Approximate percentage price change} = -13.09 \times (+0.001) \times 100 = -1.309\%$$

How good is this approximation? The actual percentage price change is –1.30% (as shown in Exhibit 5-6 when yield increases to 4.10%). Duration, in this case, did an excellent job in estimating the percentage price change. We would come to the same conclusion if we used duration to estimate the percentage price change if the yield declined by 10 basis points (i.e., $\Delta y = -0.001$). In this case, the approximate percentage price change would be +1.309% (i.e., the direction of the estimated price change is the reverse but the magnitude of the change is the same). Exhibit 5-6 shows that the actual percentage price change is +1.32%.

In terms of estimating the new price, let's see how duration performed. The initial price is 113.6777. For a 10 basis point increase in yield, duration estimates that the price will decline by 1.309%. Thus the price will decline to 112.1897 (found by multiplying 113.6777 by 1 minus 0.01309). The actual price from Exhibit 5-4 if the yield increases by 10 basis points is 112.2027. Thus the price estimated using duration is close to the actual price. For a 10 basis point decrease in yield, the actual price from Exhibit 5-4 is 115.1783, and the estimated price using duration is 115.1658 (a price increase of 1.309%). Consequently, the new price estimated by duration is close to the actual price for a 10 basis point change in yield.

Let's look at how well duration does in estimating the percentage price change if the yield increases by 200 basis points instead of 10 basis points. In this case, Δy is equal to +0.02. Substituting into Eq. (5-2) we have

$$\text{Approximate percentage price change} = -13.09 \times (+0.02) \times 100 = -26.18\%$$

How good is this estimate? From Exhibit 5-6 we see that the actual percentage price change when the yield increases by 200 basis points to 6% is –22.20%. Thus the estimate is not as accurate as when we used duration to approximate the percentage price change for a change in yield of only 10 basis points. If we use duration to approximate the percentage price change when the yield decreases by 200 basis points, the approximate percentage price change in this scenario is +26.18%. The actual percentage price change as shown in Exhibit 5-6 is +31.29%.

Again, let's look at the use of duration in terms of estimating the new price. Since the initial price is 113.6777 and a 200 basis point increase in yield will decrease the price by 26.18%, the estimated new price using duration is 83.9169 (found by multiplying 113.6777 by 1 minus 0.2618). From Exhibit 5-4 the actual price if the yield is 6% is 88.4426. Consequently, the estimate is not as accurate as the estimate for a 10 basis point change in yield. The estimated new price using duration for a 200 basis point decrease in yield is 143.4386 compared with the actual price (from Exhibit 5-4) of 149.2520. Once again, the estimation of the price using duration is not as accurate as for a 10 basis point change. *Notice that whether the yield is increased or decreased by 200 basis points, duration underestimates what the new price will be.* We will see why shortly.

Let's summarize what we found in our application of duration to approximate the percentage price change:

		New Price		***Percent Price Change***		
Yield Change (bp)	**Initial Price**	**Based on Duration**	**Actual**	**Based on Duration**	**Actual**	**Comment**
+10	113.6777	112.1897	112.2027	–1.309	–1.30	Estimated price close to new price
–10	113.6777	115.1658	115.1783	+1.309	+1.32	Estimated price close to new price
+200	113.6777	83.9169	88.4426	–26.180	–22.20	Underestimates new price
–200	113.6777	143.4386	149.2520	+26.180	+31.29	Underestimates new price

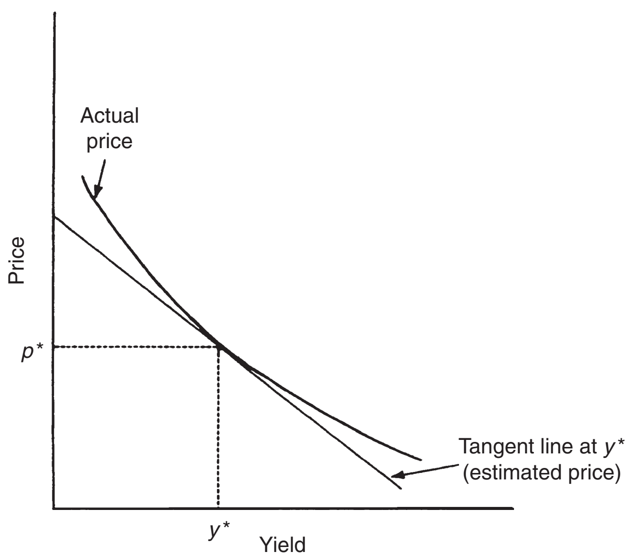
Look again at Eq. (5-2). Notice that whether the change in yield is an increase or a decrease, the approximate percentage price change will be the same except that the sign is reversed. This violates Properties 3 and 4 with respect to the price volatility of option-free bonds when yields change. Recall that Property 3 states that the percentage price change will not be the same for a large increase and decrease in yield by the same number of basis points. This is one reason why we see that the estimate is inaccurate for a 200 basis point yield change. Why did the duration estimate of the price change do a good job for a small change in yield of 10 basis points? Recall from Property 2 that the percentage price change will be approximately the same whether there is an increase or decrease in yield by a small number of basis points. We also can explain these results in terms of the graph of the price/yield relationship. We will do this next.

Graphic Depiction of Using Duration to Estimate Price Changes

The shape of the price/yield relationship for an option-free bond is convex. Exhibit 5-10 shows this relationship. In the exhibit, a tangent line is drawn to the price/yield relationship at yield y^*. [For those unfamiliar with the concept of a tangent line, it is a straight line that just touches a curve at one point within a relevant (local) range.] In Exhibit 5-10, the tangent line touches the curve at the point where the yield is equal to y^* and the price is equal to p^*. The tangent line

EXHIBIT 5-10

Price/Yield Relationship for an Option-Free Bond with a Tangent Line



can be used to estimate the new price if the yield changes. If we draw a vertical line from any yield (on the horizontal axis), as in Exhibit 5-10, the distance between the horizontal axis and the tangent line represents the price approximated by using duration starting with the initial yield y^*.

Now how is the tangent line, used to approximate what the new price will be if yields change, related to duration? Duration tells us the approximate percentage price change. Given the initial price and the approximate percentage price change provided by duration [i.e., as given by Eq. (5-2)], the approximate new price can be estimated. Mathematically, it can be demonstrated that the estimated price that is provided by duration is on the tangent line.

This helps us to understand why duration did an effective job of estimating the percentage price change or, equivalently, the new price when the yield changes by a small number of basis points. Look at Exhibit 5-11. Notice that for a small change in yield, the tangent line does not depart much from the price/yield relationship. Hence, when the yield changes up or down by 10 basis points, the tangent line does a good job of estimating the new price, as we found in our earlier numerical illustration.

Exhibit 5-11 also shows what happens to the estimate using the tangent line when the yield changes by a large number of basis points. Notice that the error in the estimate gets larger the further one moves from the initial yield. The estimate is less accurate the more convex the bond. This is illustrated in Exhibit 5-12.

EXHIBIT 5-11

Estimating the New Price Using a Tangent Line

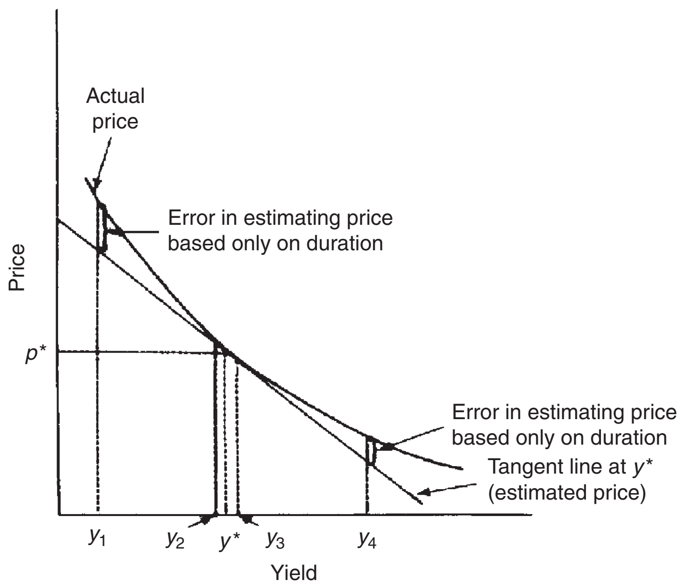


EXHIBIT 5-12

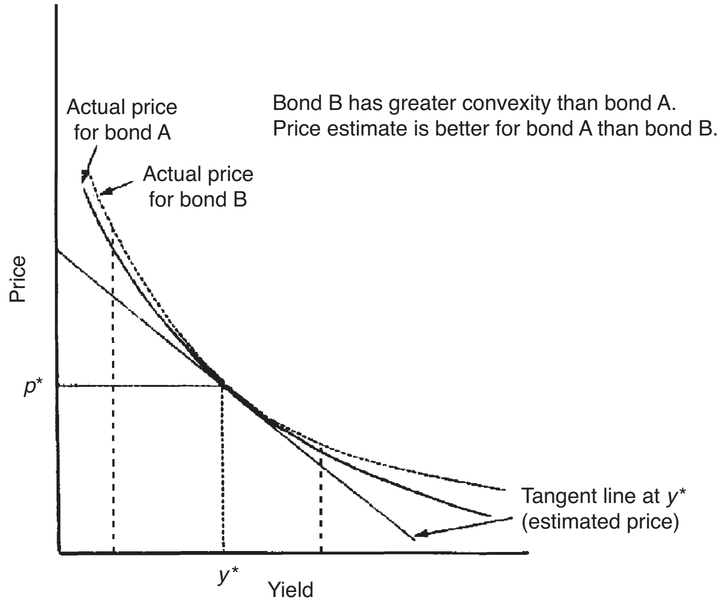
Estimating the New Price for a Large Yield Change for Bonds with Different Convexities



Also note that regardless of the magnitude of the yield change, the tangent line always underestimates what the new price will be for an option-free bond because the tangent line is below the price/yield relationship. This explains why we found in our illustration that when using duration we underestimated what the actual price will be.

Rate Shocks and Duration Estimate

In calculating duration using Eq. (5-1), it is necessary to shock interest rates (yields) up and down by the same number of basis points to obtain the values for V_- and V_+. In our illustration, 20 basis points was arbitrarily selected. But how large should the shock be? That is, how many basis points should be used to shock the rate?

In Exhibit 5-13, the duration estimate for our four hypothetical bonds using Eq. (5-1) for rate shocks of 1 basis point to 200 basis points is reported. The duration estimates for the two 5-year bonds are not affected by the size of the shock. The two 5-year bonds are less convex than the two 20-year bonds. But even for the two 20-year bonds, for the size of the shocks reported in Exhibit 5-13, the duration estimates are not materially affected by the greater convexity.

Thus it would seem that the size of the shock is unimportant. However, the results reported in Exhibit 5-13 are for option-free bonds. When we deal with more

EXHIBIT 5-13

Duration Estimates for Different Rate Shocks

Bond	1 bp	10 bps	20 bps	50 bps	100 bps	150 bps	200 bps
4% 5-year	4.49	4.49	4.49	4.49	4.49	4.50	4.50
4% 20-year	13.68	13.68	13.68	13.70	13.75	13.85	13.99
5% 5-year	4.41	4.41	4.41	4.41	4.41	4.42	4.42
5% 20-year	13.09	13.09	13.09	13.10	13.16	13.25	13.37

Initial yield: 4%

complicated securities, small rate shocks that do not reflect the types of rate changes that may occur in the market do not permit the determination of how prices can change because expected cash flows may change when dealing with bonds with embedded options. In comparison, if large rate shocks are used, we encounter the asymmetry caused by convexity. Moreover, large rate shocks may cause dramatic changes in the expected cash flows for bonds with embedded options that may be far different from how the expected cash flows will change for smaller rate shocks.

There is another potential problem with using small rate shocks for complicated securities. The prices that are inserted into the duration formula as given by Eq. (5-1) are derived from a valuation model. In Chapters 36 and 37 we will discuss various valuation models and their underlying assumptions. The duration measure depends crucially on a valuation model. If the rate shock is small and the valuation model used to obtain the prices for Eq. (5-1) is poor, dividing poor price estimates by a small shock in rates in the denominator will have a significant effect on the duration estimate.

What is done in practice by dealers and vendors of analytical systems? Each system developer uses rate shocks he or she believes to be realistic based on historical rate changes.

MODIFIED DURATION VERSUS EFFECTIVE DURATION

One form of duration that is cited by practitioners is *modified duration.* Modified duration is the approximate percentage change in a bond's price for a 100 basis point change in yield *assuming that the bond's expected cash flows do not change when the yield changes.* What this means is that in calculating the values of V_- and V_+ in Eq. (5-1), the same cash flows used to calculate V_0 are used. Therefore, the change in the bond's price when the yield is changed is due solely to discounting cash flows at the new yield level.

The assumption that the cash flows will not change when the yield is changed makes sense for option-free bonds such as noncallable Treasury securities. This is so because the payments made by the U.S. Department of the Treasury to holders of its obligations do not change when interest rates change. However, the same

EXHIBIT 5-14

Modified Duration versus Effective Duration

Duration

Interpretation: Generic description of the sensitivity of a bond's price (as a percentage of initial price) to a change in yield

Modified duration

Duration measure in which it is assumed that yield changes do not change the expected cash flows

Effective duration

Duration measure in which recognition is given to the fact that yield changes may change the expected cash flows

cannot be said for bonds with embedded options (i.e., callable and putable bonds and mortgage-backed securities). For these securities, a change in yield may alter the expected cash flows significantly.

Earlier we showed the price/yield relationship for callable and prepayable bonds. Failure to recognize how changes in yield can alter the expected cash flows will produce two values used in the numerator of Eq. (5-1) that are not good estimates of how the price actually will change. The duration is then not a good number to use to estimate how the price will change.

In later chapters where valuation models for bonds with embedded options will be discussed, it will be explained how these models take into account how changes in yield will affect the expected cash flows. Thus, when V_- and V_+ are the values produced from these valuation models, the resulting duration takes into account both the discounting at different interest rates and how the expected cash flows may change. When duration is calculated in this manner, it is called *effective duration* or *option-adjusted duration.* Exhibit 5-14 summarizes the distinction between modified duration and effective duration.

The difference between modified duration and effective duration for bonds with embedded options can be quite dramatic. For example, a callable bond could have a modified duration of 5 but an effective duration of only 3. For certain collateralized mortgage obligations, the modified duration could be 7 and the effective duration 20! Thus, using modified duration as a measure of the price sensitivity of a security with embedded options to changes in yield would be misleading. The more appropriate measure for any bond with an embedded option is effective duration.

Macaulay Duration and Modified Duration

It is worth comparing the relationship between modified duration and Macaulay duration. Modified duration also can be written as[4]

$$\frac{1}{(1+\text{yield}/k)}\left(\frac{1\times \text{PVCF}_1 + 2\times \text{PVCF}_2 + \cdots + n\times \text{PVCF}_n}{k\times \text{price}}\right) \qquad (5\text{-}3)$$

4. More specifically, this is the formula for the modified duration of a bond on a coupon anniversary date.

where

k = number of periods, or payments, per year (e.g., $k = 2$ for semiannual-pay bonds and $k = 12$ for monthly-pay bonds)
n = number of periods until maturity (i.e., number of years to maturity times k)
yield = yield to maturity of the bond
PVCF_t = present value of the cash flow in period t discounted at the yield to maturity

The expression in the parentheses on the right of the modified duration formula given by Eq. (5-3) is a measure formulated in 1938 by Frederick Macaulay.[5] This measure is popularly called the *Macaulay duration.* Thus modified duration is commonly expressed as

$$\text{Modified duration} = \frac{\text{Macaulay duration}}{(1 + \text{yield}/k)}$$

The general formulation for duration as given by Eq. (5-1) provides a shortcut procedure for determining a bond's modified duration. Because it is easier to calculate the modified duration using the shortcut procedure, most vendors of analytical software will use Eq. (5-1) rather than Eq. (5-3) to reduce computation time.

However, it must be understood clearly that modified duration is a flawed measure of a bond's price sensitivity to interest-rate changes for a bond with an embedded option, and therefore, so is Macaulay duration. The use of the formula for duration given by Eq. (5-3) *misleads* the user because it masks the fact that changes in the expected cash flows must be recognized for bonds with embedded options. Although Eq. (5-3) will give the same estimate of percent price change for an option-free bond as Eq. (5-1), Eq. (5-1) is still better because it acknowledges that cash flows and thus value can change owing to yield changes.

Interpretations of Duration

At the outset of this section we defined duration as the approximate percentage change in price for a 100 basis point change in rates. If you understand this definition, you need never use the equation for the approximate percentage price change given by Eq. (5-2), and you can easily calculate the change in a bond's value.

For example, suppose that we want to know the approximate percentage change in price for a 50 basis point change in yield for our hypothetical 5% coupon 20-year bond selling for 113.6777. Since the duration is 13.09, a 100 basis point change in yield would change the price by about 13.09%. For a 50 basis point

5. Frederick Macaulay, *Some Theoretical Problems Suggested by the Movement of Interest Rates, Bond Yields, and Stock Prices in the U.S. Since 1856* (New York: National Bureau of Economics Research, 1938).

change in yield, the price will change by approximately 6.545% (= 13.09%/2). Thus, if the yield changes by 50 basis points, the price will change by 6.545% from 113.6777 to 106.2375.

Now let's look at some other definitions or interpretations of duration that have been used.

Duration Is the "First Derivative"

Sometimes a market participant will refer to duration as the "first derivative of the price/yield function" or simply the "first derivative." *Derivative* here has nothing to do with "derivative instruments" (i.e., futures, swaps, options, etc.). A derivative as used in this context is obtained by differentiating a mathematical function. There are first derivatives, second derivatives, and so on. When market participants say that duration is the first derivative, here is what they mean. If it were possible to write a mathematical equation for a bond in closed form, the first derivative would be the result of differentiating that equation the first time. While it is a correct interpretation of duration, it is an interpretation that in no way helps us understand what the interest-rate risk is of a bond. That is, it is an operationally meaningless interpretation.

Why is it an operationally meaningless interpretation? Go back to the \$10 million bond position with a duration of 6. Suppose that a client is concerned with the exposure of the bond to changes in interest rates. Now, tell that client the duration is 6 and that it is the first derivative of the price function for that bond. What have you told the client? Not much. In contrast, tell that client that the duration is 6 and that duration is the approximate price sensitivity of a bond to a 100 basis point change in rates, and you've told the client a great deal with respect to the bond's interest-rate risk.

Duration Is Some Measure of Time

When the concept of duration was introduced by Macaulay in 1938, he used it as a gauge of the time that the bond was outstanding. More specifically, Macaulay defined *duration* as the weighted average of the time to each coupon and principal payment of a bond. Subsequently, *duration* has too often been thought of in temporal terms, that is, years. This is most unfortunate for two reasons.

First, in terms of dimensions, there is nothing wrong with expressing duration in terms of years because that is the proper dimension of this value. But the proper interpretation is that duration is the price volatility of a zero-coupon bond with that number of years to maturity. Thus, when a manager says that a bond has a duration of four years, it is not useful to think of this measure in terms of time, but rather that the bond has the price sensitivity to rate changes of a four-year zero-coupon bond.

Second, thinking of duration in terms of years makes it difficult for managers and their clients to understand the duration of some complex securities. Here are a few examples. For a mortgage-backed security that is an interest-only security, the duration is negative. What does a negative number of, say, –4 mean? In terms of our interpretation as a percentage price change, it means that when rates change by 100 basis points, the price of the bond changes by about 4%, but the change is in the same direction as the change in rates.

As a second example, consider the duration of an option that expires in one year. Suppose that it is reported that its duration is 60. What does that mean? To someone who interprets duration in terms of time, does that mean 60 years, 60 days, or 60 seconds? It doesn't mean any of these. It simply means that the option tends to have the price sensitivity to rate changes of a 60-year zero-coupon bond.

Forget First Derivatives and Temporal Definitions

The bottom line is that one should not care if it is technically correct to think of duration in terms of years (volatility of a zero-coupon bond) or in terms of first derivatives. There are even some who interpret duration in terms of the "half life" of a security. Subject to the limitations that we will describe later, duration is used as a measure of the sensitivity of a security's price to changes in yield. We will fine-tune this definition as we move along.

Users of this interest-rate risk measure are interested in what it tells them about the price sensitivity of a bond (or a portfolio) to changes in rates. Duration provides the investor with a feel for the dollar price exposure or the percentage price exposure to potential rate changes.

Spread Duration

For non-Treasury securities, the yield is equal to the Treasury yield plus a spread to the Treasury yield-curve. Non-Treasury securities are called *spread products.* The risk that the price of a bond changes due to changes in spreads is called *spread risk.* A measure of how a spread product's price changes if the spread sought by the market changes is called *spread duration.* Spread duration indicates the approximate percentage change in price for a 100 basis point change in the spread, holding the Treasury yield constant. For example, suppose that the spread duration of a corporate bond is 1. This means that for a 100 basis point change in the spread, the value of the corporate bond will change by approximately 1%.

Portfolio Duration

A portfolio's duration can be obtained by calculating the weighted average of the duration of the bonds in the portfolio. The weight is the proportion of the portfolio that a security comprises. Mathematically, a portfolio's duration can be calculated as follows:

$$w_1 D_1 + w_2 D_2 + w_3 D_3 + \cdots + w_K D_K$$

where

w_i = market value of bond i/market value of the portfolio
D_i = duration of bond i
K = number of bonds in the portfolio

To illustrate this calculation, consider the following three-bond portfolio in which all three bonds are option free:

Bond	Price ($)	Yield (%)	Par Amount Owned	Market Value	Duration
9% 5-year	122.4565	4	$5 million	$6,122,823	4.147
5% 20-year	113.6777	4	2 million	2,273,555	13.087
5.5% 30-year	126.0707	4	2 million	2,521,413	16.290

In this illustration it is assumed that the next coupon payment for each bond is exactly six months from now (i.e., there is no accrued interest). The market value for the portfolio is $10,917,791. Since each bond is option free, the modified duration can be used. The market price per $100 par value of each bond, its yield, and its duration are given below:

In this illustration, K is equal to 3 and:

$$w_1 = \$6{,}122{,}823/\$10{,}917{,}791 = 0.561 \quad D_1 = 4.147$$
$$w_2 = \$2{,}273{,}555/\$10{,}917{,}791 = 0.208 \quad D_2 = 13.087$$
$$w_3 = \$2{,}521{,}413/\$10{,}917{,}791 = 0.231 \quad D_3 = 16.290$$

The portfolio's duration is:

$$0.561\ (4.147) + 0.208\ (13.087) + 0.231\ (16.290) = 8.81$$

A portfolio duration of 8.81 means that for a 100 basis point change in the yield of all three bonds, the market value of the portfolio will change by approximately 8.81%. But keep in mind that the yield on all three bonds must change by 100 basis points for the duration measure to be useful. This is a *critical assumption,* and its importance cannot be overemphasized.[6]

An alternative procedure for calculating the duration of a portfolio is to calculate the dollar price change for a given number of basis points for each security in the portfolio and then add up all the price changes. Dividing the total of the price changes by the initial market value of the portfolio produces a percentage price change that can be adjusted to obtain the portfolio's duration.

For example, consider the three-bond portfolio shown above. Suppose that we calculate the dollar price change for each bond in the portfolio based on its respective duration for a 50 basis point change in yield. We would then have

6. This is equivalent to saying that the correlation between the yield change for every maturity is equal to 1.

Bond	Market Value	Duration	Change in Value for 50 bp Yield Change
9% 5-year	$6,122,823	4.147	$126,957
5% 20-year	2,273,555	13.087	148,770
5.5% 30-year	2,521,413	16.290	205,369
		Total	$481,096

Thus a 50 basis point change in all rates changes the market value of the three-bond portfolio by $481,096. Since the market value of the portfolio is $10,917,791, a 50 basis point change produced a change in value of 4.41% ($481,096 divided by $10,917,791). Since duration is the approximate percentage change for a 100 basis point change in rates, this means that the portfolio duration is 8.82 (found by doubling 4.41). This is the same value for the portfolio's duration as found earlier.

The spread duration for a portfolio or a bond index is computed as a market-weighted average of the spread duration for each sector.

Contribution to Portfolio Duration

Some portfolio managers look at exposure of a portfolio or a benchmark index to an issue or to a sector simply in terms of the market value percentage of that issue or sector in the portfolio. A better measure of exposure to an individual issue or sector is its *contribution to portfolio duration* or *contribution to benchmark index duration*. This is found by multiplying the percentage of the market value of the portfolio represented by the individual issue or sector by the duration of the individual issue or sector. That is,

$$\text{Contribution to portfolio duration} = \text{weight of issue or sector in portfolio} \times \text{duration of issue or sector}$$

$$\text{Contribution to benchmark index duration} = \text{weight of issue or sector in benchmark index} \times \text{duration of issue or sector}$$

A portfolio manager who wants to determine the contribution of a sector to portfolio duration relative to the contribution of the same sector in a broad-based market index can compute the difference between the two contributions. The difference in the percentage distribution by sector is not as meaningful as is the difference in the contribution to duration.

CONVEXITY

The duration measure indicates that regardless of whether interest rates increase or decrease, the approximate percentage price change is the same. However, as we noted earlier, this is not consistent with Property 3 of a bond's price volatility. Specifically, while for small changes in yield the percentage price change will be the same for an increase or decrease in yield, for large changes in yield this is not true. This suggests that duration is only a good approximation of the percentage price change for small changes in yield.

We demonstrated this property earlier using a 5% 20-year bond selling to yield 4% with a duration of 13.09. For a 10 basis point change in yield, the estimate was accurate for both an increase or a decrease in yield. However, for a 200 basis point change in yield, the approximate percentage price change was off considerably.

The reason for this result is that duration is in fact a first (linear) approximation for a small change in yield.[7] The approximation can be improved by using a second approximation. This approximation is referred to as "convexity." *The use of this term in the industry is unfortunate because the term convexity is also used to describe the shape or curvature of the price/yield relationship.* The *convexity measure* of a security can be used to approximate the change in price that is not explained by duration.

Convexity Measure

The convexity measure of a bond is approximated using the following formula:

$$\text{Convexity measure} = \frac{V_+ + V_- - 2V_0}{2V_0(\Delta y)^2} \tag{5-4}$$

where the notation is the same as used earlier for duration as given by Eq. (5-1).

For our hypothetical 5% 20-year bond selling to yield 4%, we know that for a 20 basis point change in yield ($\Delta y = 0.002$),

$$V_0 = 113.6777, \quad V_- = 116.7049, \quad \text{and} \quad V_+ = 110.7527$$

Substituting these values into the convexity measure given by Eq. (5-4) gives

$$\text{Convexity measure} = \frac{110.7527 + 116.7049 - 2(113.6777)}{2(113.6777)(0.002)^2} = 112.38$$

We'll see how to use this convexity measure shortly. Before doing so, there are three points that should be noted. First, there is no simple interpretation of the convexity measure. Second, in contrast to duration, it is more common for market participants to refer to the value computed in Eq. (5-4) as the "convexity of a bond" rather than the "convexity measure of a bond." Finally, the convexity measure reported by dealers and vendors will differ for an option-free bond. The reason is that the value obtained from Eq. (5-4) is often scaled for the reason explained after we demonstrate how to use the convexity measure.

7. The reason it is a linear approximation can be seen in Exhibit 5-11, where the tangent line is used to estimate the new price. That is, a straight line is being used to approximate a nonlinear (i.e., convex) relationship.

Convexity Adjustment to Percentage Price Change

Given the convexity measure, the approximate percentage price change adjustment due to the bond's convexity (i.e., the percentage price change not explained by duration) is

$$\text{Convexity adjustment} = \text{convexity measure} \times (\Delta y)^2 \times 100 \qquad (5\text{-}5)$$

For example, for the 5% coupon bond maturing in 20 years, the convexity adjustment to the percentage price change based on duration if the yield increases from 4% to 6% is

$$112.38 \times (0.02)^2 \times 100 = 4.50\%$$

If the yield decreases from 4% to 2%, the convexity adjustment to the approximate percentage price change based on duration also would be 4.50%.

The approximate percentage price change based on duration and the convexity adjustment is found by adding the two estimates. Thus, for example, if yields change from 4% to 6%, the estimated percentage price change would be

$$\begin{aligned} \text{Estimated change using duration} &= -26.18\% \\ \text{Convexity adjustment} &= \underline{+4.50\%} \\ \text{Total estimated percentage price change} &= -21.68\% \end{aligned}$$

The actual percentage price change is –22.20%.

For a decrease of 200 basis points, from 4% to 2%, the approximate percentage price change would be as follows:

$$\begin{aligned} \text{Estimated change using duration} &= +26.18\% \\ \text{Convexity adjustment} &= \underline{+4.50\%} \\ \text{Total estimated percentage price change} &= +30.68\% \end{aligned}$$

The actual percentage price change is +31.29%. Thus duration combined with the convexity adjustment does a better job of estimating the sensitivity of a bond's price change to large changes in yield.

Notice that when the convexity measure is positive, we have the situation described earlier that the gain is greater than the loss for a given large change in rates. That is, the bond exhibits positive convexity. We can see this in the preceding example. However, if the convexity measure is negative, we have the situation where the loss will be greater than the gain. For example, suppose that a callable bond has an effective duration of 4 and a convexity measure of –30. This means that the approximate percentage price change for a 200 basis point change is 8%. The convexity adjustment for a 200 basis point change in rates is then

$$-30 \times (0.02)^2 \times 100 = -1.2$$

The convexity adjustment is –1.2%, and therefore, the bond exhibits the negative convexity property illustrated in Exhibit 5-7. The approximate percentage price change after adjusting for convexity is

$$\begin{aligned} \text{Estimated change using duration} &= -8.0\% \\ \text{Convexity adjustment} &= \underline{-1.2\%} \\ \text{Total estimated percentage price change} &= -9.2\% \end{aligned}$$

For a decrease of 200 basis points, the approximate percentage price change would be as follows:

$$\begin{aligned} \text{Estimated change using duration} &= +8.0\% \\ \text{Convexity adjustment} &= \underline{-1.2\%} \\ \text{Total estimated percentage price change} &= 6.8\% \end{aligned}$$

Notice that the loss is greater than the gain—a property called *negative convexity* that we discussed earlier and illustrated in Exhibit 5-7.

Scaling the Convexity Measure

The convexity measure as given by Eq. (5-4) means nothing in isolation. It is the substitution of the computed convexity measure into Eq. (5-5) that provides the estimated adjustment for convexity. Therefore, it is possible to scale the convexity measure in any way and obtain the same convexity adjustment.

For example, in some books the convexity measure is defined as follows:

$$\text{Convexity measure} = \frac{V_+ + V_- - 2V_0}{V_0(\Delta y)^2} \tag{5-6}$$

Equation (5-6) differs from Eq. (5-4) because it does not include 2 in the denominator. Thus the convexity measure computed using Eq. (5-6) will be double the convexity measure using Eq. (5-4). Thus, for our earlier illustration, since the convexity measure using Eq. (5-4) is 112.38, the convexity measure using Eq. (5-6) would be 224.76.

Which is correct, 112.38 or 224.76? The answer is both. The reason is that the corresponding equation for computing the convexity adjustment would not be given by Eq. (5-5) if the convexity measure is obtained from Eq. (5-6). Instead, the corresponding convexity adjustment formula would be

$$\text{Convexity adjustment} = (\text{convexity measure}/2) \times (\Delta y)^2 \times 100 \tag{5-7}$$

Equation (5-7) differs from Eq. (5-5) in that the convexity measure is divided by 2. Thus the convexity adjustment will be the same whether one uses Eq. (5-4) to get the convexity measure and Eq. (5-5) to get the convexity adjustment or one uses Eq. (5-6) to compute the convexity measure and Eq. (5-7) to determine the convexity adjustment.

Some dealers and vendors scale the convexity measure in a different way. One also can compute the convexity measure as follows:

$$\text{Convexity measure} = \frac{V_+ + V_- - 2V_0}{2V_0(\Delta y)^2(100)} \tag{5-8}$$

Equation (5-8) differs from Eq. (5-4) by the inclusion of 100 in the denominator. In our illustration, the convexity measure would be 1.1238 rather than 112.38 using Eq. (5-4). The convexity adjustment formula corresponding to the convexity measure given by Eq. (5-8) is then

$$\text{Convexity adjustment} = \text{convexity measure} \times (\Delta y)^2 \times 10{,}000 \tag{5-9}$$

Similarly, one can express the convexity measure as shown in Eq. (5-10):

$$\text{Convexity measure} = \frac{V_+ + V_- - 2V_0}{V_0(\Delta y)^2(100)} \tag{5-10}$$

For the bond we have been using in our illustrations, the convexity measure is 2.2476. The corresponding convexity adjustment is

$$\text{Convexity adjustment} = (\text{convexity measure}/2) \times (\Delta y)^2 \times 10{,}000 \tag{5-11}$$

Consequently, the convexity measures (or just simply "convexity" as it is referred to by some market participants) that could be reported for this option-free bond are 112.38, 224.76, 1.1238, and 2.2476. All these values are correct, but they mean nothing in isolation. To use them to obtain the convexity adjustment to the price change estimated by duration requires knowing how they are computed so that the correct convexity adjustment formula is used. *It is the convexity adjustment that is important—not the convexity measure in isolation.*

It is also important to understand this when comparing the convexity measures reported by dealers and vendors. For example, if one dealer shows a portfolio manager bond A with a duration of 4 and a convexity measure of 50, and a second dealer shows the manager bond B with a duration of 4 and a convexity measure of 80, which bond has the greater percentage price change response to changes in interest rates? Since the duration of the two bonds is identical, the bond with the larger convexity measure will change more when rates decline. However, not knowing how the two dealers computed the convexity measure means that the manager does not know which bond will have the greater convexity adjustment. If the first dealer used Eq. (5-4) and the second dealer used Eq. (5-6), then the convexity measures must be adjusted in terms of either equation. For example, using Eq. (5-4), the convexity measure of 80 computed using Eq. (5-6) is equal to a convexity measure of 40 based on Eq. (5-4).

Modified Convexity and Effective Convexity

The prices used in Eq. (5-4) to calculate convexity can be obtained by assuming that when the yield changes the expected cash flows either do not change or they do change. In the former case, the resulting convexity is called *modified convexity.* (Actually, in the industry, convexity is not qualified by the adjective *modified.*) In contrast, *effective convexity* assumes that the cash flows do change when yields change. This is the same distinction made for duration.

As with duration, there is little difference between modified convexity and effective convexity for option-free bonds. However, for bonds with embedded options, there can be quite a difference between the calculated modified convexity and the effective convexity measures. In fact, for all option-free bonds, either convexity measure will have a positive value. For bonds with embedded options, the calculated effective convexity can be negative when the calculated modified convexity measure is positive.

Illustrations of Effective Duration and Convexity

As noted earlier, modified duration and effective duration are two ways to measure the price sensitivity of a fixed income security. Modified duration ignores any effect on cash flows that might take place as a result of changes in interest rates. Effective duration does not ignore the potential for such changes in cash flows. For example, bonds with embedded options will have very different cash flow properties as interest rates (or yields) change. Modified duration ignores these effects completely. In order to apply effective duration, an available interest-rate model and corresponding valuation model are needed. The example in this section shows how to compute the effective duration of securities with cash flows that are dependent on interest rates.

There is no difference between modified and effective duration for option-free or straight bonds. In fact, it can be shown that they are mathematically identical when the change in rates (or yields) becomes very small. As shown in the example, even for bonds with embedded options, the differences between the two measures are minimal over certain ranges of yields. For example, when the embedded option is far out-of-the-money, the cash flows of the bond are not affected by small changes in yields, resulting in almost no difference in cash flows between the two measures.

Convexity (sometimes referred to as "standard convexity") suffers the same limitations as modified duration and therefore is not generally useful for securities with embedded options. However, similar to the duration measures, in ranges of rates (or yields) where the cash flows are not materially affected by small changes in yields, the two convexity measures are almost identical.

The following example illustrates how to calculate and interpret effective duration and effective convexity for option-free bonds and bonds with embedded options.

Suppose that we need to measure the interest-rate sensitivity of the following three securities:

1. A five-year 2.50% coupon option-free semiannual coupon bond with a current price of 97.69% of par
2. A five-year 2.25% coupon bond, callable at par in years 2 through 5 on the semiannual coupon dates, with a current price of 96.54% of par
3. A five-year 2.75% coupon bond, putable at par in years 2 through 5 on the semiannual coupon dates, with a current price of 100.4410453 of par

The cash flows of these securities are very different as interest rates change. Consequently, the sensitivities to changes in interest rates are also very different.

Using an interest-rate model that is based on the existing term structure,[8] the term structure of interest rates is shifted up and down by 10 basis points (bps), and the resulting price changes are recorded. Using the notation for duration and convexity earlier in this chapter, V_- corresponds to the price after a downward shift in interest rates, V_+ corresponds to the price after an upward shift in interest rates, V_0 is the current price, and Δy is the assumed shift in the term structure.[9] Exhibit 5-15 shows these prices for each bond using Eq. (5-1) for duration and Eq. (5-6) for the convexity measure.

It is very important to realize the importance of the valuation model in this exercise. The model must account for the change in cash flows of the securities as interest rates change. The callable and putable bonds have very different cash flow characteristics that depend on the level of interest rates. The valuation model used must account for this property. (Note that when calculating the measures, users are cautioned not to round values. Since the denominators of both the duration and convexity terms are very small, any rounding will have a significant impact on results.)

Option-Free Bond

The effective duration for the straight bond is found by recording the price changes from shifting the term structure up (V_+) and down (V_-) by 10 bps and then substituting these values into Eq. (5-1). The prices are shown in Exhibit 5-15. Consequently, the computation is

$$\text{Effective duration} = \frac{99.3018797 - 98.3796865}{2(98.8395557)(0.001)} = 4.67$$

Similarly, the calculation for effective convexity is found by substituting the corresponding prices into Eq. (5-6):

8. The Black-Derman-Toy no arbitrage binomial model was used to perform this analysis. See Fischer Black, Emanuel Derman, and William Toy, "A One-Factor Model of Interest Rates and Its Application to Treasury Bond Options," *Financial Analysts Journal* (January–February 1990), pp. 24–32.

9. Note that shifting the term structure in a parallel manner will result in a change in yields equal to the shift for option-free bonds.

EXHIBIT 5-15

Original Prices and Resulting Prices from a Downward and Upward 10 Basis Point Interest-Rate Shift and the Corresponding Effective Duration and Effective Convexity for Three Bonds Based on the Black-Derman-Toy Model

Price Changes Following 10-bp Shift

Variable	Original Price, V_0	Upward Shift of 10 bp, V_+	Downward Shift of 10 bp, V_-
Option-free bond price	98.8395557	98.3796865	99.3018797
Callable bond price	97.6550524	97.2132182	98.0922517
Putable bond price	100.4410453	100.1343384	100.7706854

Effective Duration and Effective Convexity Measures Calculated from Using the Price Changes Resulting from the 10-bp Shifts in the Term Structure

	Effective Duration	Effective Convexity
Option-free bond	4.67	24.84
Callable bond	4.50	–47.46
Putable bond	3.17	228.32

$$\text{Effective convexity} = \frac{99.3018797 + 98.3796865 - 2(98.8395557)}{98.8395557(0.001)^2}$$

$$= 24.84$$

For the option-free bond, the modified duration is 4.67 and the convexity is 24.84. These are very close to the effective measures shown in Exhibit 5-15. This demonstrates that, for option-free bonds, the two measures are almost the same for small changes in yields.

Exhibit 5-16 shows the effects of the term structure shifts on the effective duration and effective convexity of the option-free bond. The effective duration increases as yields decrease because as yields decrease the slope of the price/yield relationship for option-free bonds becomes steeper and effective duration (and modified duration) is directly proportional to the slope of this relationship. For example, the effective duration at very low yields (–250-bp shift) is 4.74 and decreases to 4.44 at very high rates (+1,000 bps). Exhibit 5-17 illustrates this phenomenon; as yields increase, notice how the slope of the price/yield relationship decreases (becomes more horizontal or flatter).

As the term structure shifts up (i.e., as rates rise), the yield to maturity on an option-free bond increases by approximately the same amount. As the yield increases, the bond's convexity decreases. Exhibit 5-17 illustrates this property. As yields increase, the curvature (or the rate of change of the slope) decreases.

EXHIBIT 5-16

Effective Duration and Effective Convexity for Various Shifts in the Term Structure for Three Bonds

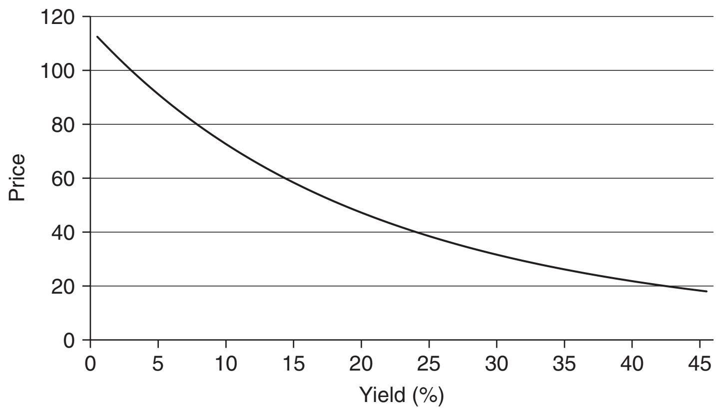
Term Structure Shift (bps)	Option-Free Bond		Callable Bond		Putable Bond	
	Effective Duration	Effective Convexity	Effective Duration	Effective Convexity	Effective Duration	Effective Convexity
–250	4.74	25.59	1.97	4.88	4.72	25.43
0	4.67	24.84	4.50	–47.46	3.17	228.32
250	4.59	24.10	4.61	24.28	1.91	4.62
500	4.51	23.39	4.54	23.57	1.88	4.50
1,000	4.44	22.70	4.47	22.89	1.86	4.39

The results in Exhibit 5-16 for the option-free bond also bear this out. The effective convexity values become smaller as yields increase. For example, the effective convexity at very low yields (–250-bp shift) is 25.59 and decreases to 22.70 at very high rates (+1,000-bp shift).

These are both well-documented properties of option-free bonds. The modified duration and convexity numbers for the option-free bond are almost identical to the effective measures for the option-free bond shown in Exhibit 5-16.

EXHIBIT 5-17

Price/Yield Relationship of the Option-Free Bond



Callable Bond

The effective duration for the callable bond is found by recording the price changes from shifting the term structure up (V_+) and down (V_-) by 10 bps and then substituting these values into Eq. (5-1). The prices are shown in Exhibit 5-15. Note that these prices take into account the changing cash flows resulting from the embedded call option. Consequently, the computation is

$$\text{Effective duration} = \frac{98.0922517 - 97.2132182}{2(97.6550524)(0.001)} = 4.50$$

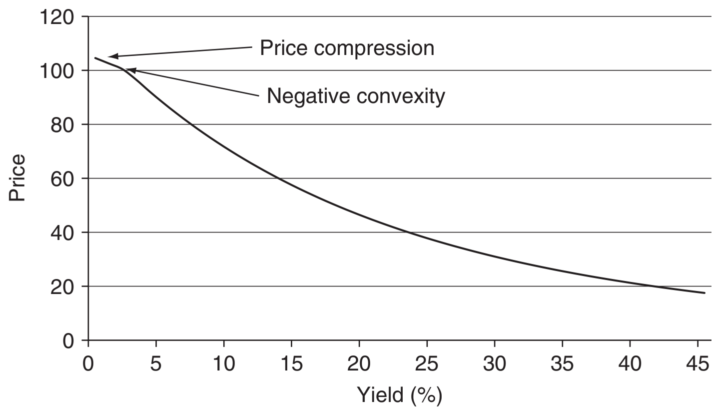
Similarly, the calculation for effective convexity is found by substituting the corresponding prices into Eq. (5-6):

$$\text{Effective convexity} = \frac{98.0922517 + 97.2132182 - 2(97.6550524)}{97.6550524(0.001)^2}$$
$$= -47.46$$

The relationship between the shift in rates and effective duration is shown in Exhibit 5-16 and in Exhibit 5-18. As rates increase, the effective duration of the callable bond becomes larger. For example, the effective duration at very low yields (–250-bp shift) is 1.97 and increases to 4.47 at very high rates (+1,000 bps). This reflects the fact that as rates increase, the likelihood of the bond being called decreases, and as a result, the bond behaves more like an option-free bond; hence its effective duration increases. Conversely, as rates drop, this likelihood increases, and the bond and its effective duration behave more like a bond with a two-year maturity because of the call option becoming effective in two years. As rates decrease significantly, the likelihood of the issuer calling the bond in two years increases. Consequently, at very low and intermediate rates, the difference between the effective duration measure and modified duration is large, and at very high rates, the difference is small.

EXHIBIT 5-18

Price/Yield Relationship of the Callable Bond



Effective convexity measures the curvature of the price/yield relationship of bonds. Low values for effective convexity simply mean that the relationship is becoming linear (an effective convexity of zero represents a linear relationship). As shown in Exhibit 5-16, the effective convexity values of the callable bond at extremely low interest rates (i.e., for the –250-bp shift in the term structure) are very small positive numbers 4.88. This means that the relationship is almost linear but exhibits slight convexity. This is due to the call option being delayed by two years. At these extremely low interest rates, the callable bond exhibits slight positive convexity because the price compression at the call price is not complete for another two years.[10] If this bond were immediately callable, the price/yield relationship would exhibit positive convexity at high yields and negative convexity at low yields. At the current level of interest rates, the effective convexity is negative, as expected. At these rate levels, the embedded call option causes enough price compression to cause the curvature of the price/yield relationship to be negatively convex (i.e., concave). Exhibit 5-18 illustrates these properties. It is at these levels that the embedded option has a significant effect on the cash flows of the callable bond.

Exhibit 5-16 shows that for large positive yield-curve shifts (i.e., for the +250-bp, +500-bp, and +1,000-bp shifts in the term structure), the effective convexity of the callable bond becomes positive and very close to the effective convexity values of the straight bond. For example, the effective convexity at the +250-bp shift is 24.28 for the callable bond and 24.10 for the straight bond. The only reason they are not the same is because the coupon rates of the bonds are not equal. Consequently, at very low and intermediate rates, the difference between effective convexity and standard convexity is large, and at very high rates, the difference is small. The intuition behind these findings is straightforward. At low rates, the cash flows of the callable bond are severely affected by the likelihood of the embedded call option being exercised by the issuer. At high rates, the embedded call option is so far out-of-the-money that it has almost no effect on the cash flows of the callable bond, and so the callable bond behaves like an option-free bond.

Putable Bond

The effective duration for the putable bond is found by recording the price changes from shifting the term structure up (V_+) and down (V_-) by 10 bps and then substituting these values into Eq. (5-1). The prices are shown in Exhibit 5-15. Note that these prices take into account the changing cash flows resulting from the embedded put option. Consequently, the computation is

$$\text{Effective duration} = \frac{100.7706854 - 100.1343384}{2(100.4410453)(0.001)} = 3.17$$

10. As noted earlier in this chapter, price compression for a callable bond refers to the property that a callable bond's price appreciation potential is severely limited as yields decline. As shown in Exhibit 5-18, as yields fall below a certain level (i.e., where the yield corresponds to the call price), the price appreciation of the callable bond is being compressed.

Similarly, the calculation for effective convexity is found by substituting the corresponding prices into Eq. (5-6):

$$\text{Effective convexity} = \frac{100.7706854 + 100.1343384 - 2(100.4410453)}{100.4410453(0.001)^2}$$
$$= 228.32$$

Because the putable bond behaves so differently from the other two bonds, the effective duration and effective convexity values are very different. As rates increase, the bond behaves more like a two-year bond because the owner will, in all likelihood, exercise his right to put the bond back at the put price as soon as possible. As a result, the effective duration of the putable bond is expected to decrease as rates increase. This is due to the embedded put option severely affecting the cash flows of the putable bond. Conversely, as rates fall, the putable bond behaves more like a five-year straight bond because the embedded put option is so far out-of-the-money and has little effect on the cash flows of the putable bond. Effective duration should reflect these properties. Exhibit 5-16 shows that this is indeed the case. For example, the effective duration at very low yields (–250-bp shift) is 4.72 and decreases to 1.86 at very high rates (+1,000 bps). Consequently, at very high and intermediate rates, the difference between the effective duration and modified duration measures is large, and at low rates, the difference is small.

Exhibit 5-16 shows that the effective convexity of the putable bond is positive for all rate shifts, as would be expected, but it becomes smaller as rates increase (i.e., for the +250-bp, +500-bp, and +1,000-bp shifts in the term structure). As rates increase, the putable bond price/yield relationship will become linear because of the bond's price truncation at the put price.[11] This is the reason for the small effective convexity values for the putable bond for the three positive shifts in the term structure (4.62, 4.50, and 4.39, respectively). It is at these levels that the embedded put option has a significant effect on the cash flows of the putable bond. Consequently, at very high and intermediate rates, the difference between the effective convexity and standard convexity is very large. Exhibit 5-19 illustrates these properties.

At very low rates (i.e., for the 250-bp downward shift in the term structure), the putable bond behaves like a five-year straight bond because the put option is so far out-of-the-money. Therefore, as the term structure is shifted downward, the putable bond's effective convexity values approach those of a comparable five-year option-free bond. Comparing the effective convexity measures for the putable bond and the option-free bond illustrates this characteristic. For example, the effective convexity at the –250-bp shift is 25.43 for the putable bond and 25.59 for the option-free bond. The two convexity measures are almost identical. In fact, they would be identical if their coupon rates were equal.

---

11. *Price truncation* for a putable bond refers to the property that the putable bond's price depreciation potential is severely limited as yields increase. As shown in Exhibit 5-19, as yields rise above a certain level (i.e., where the yield corresponds to the put price), the price depreciation of the putable bond is truncated.

EXHIBIT 5-19

Price/Yield Relationship of the Putable Bond

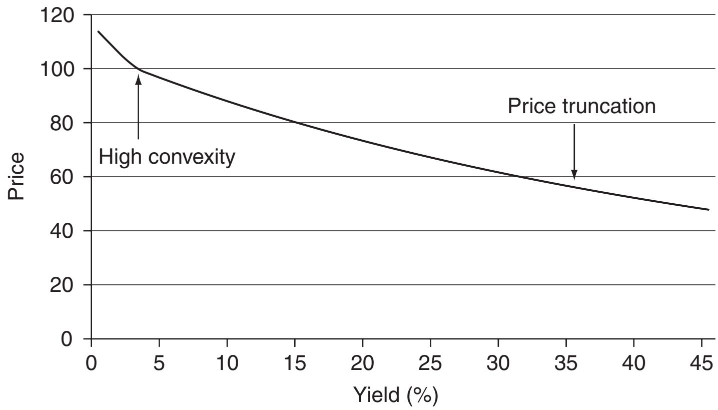


Exhibit 5-19 illustrates these properties. Also notice how the transition from low yields to high yields forces the price/yield relationship to have a very high convexity at intermediate levels of yields. For example, the current effective convexity of the putable bond is 228.32 compared with 24.84 for the straight bond and 47.46 for the callable bond. This is so because as yields increase, the embedded put option moves from out-of-the-money to in, and the behavior of the bond goes from that of a five-year bond to a two-year bond as a result. This corresponding price truncation causes the price/yield relationship to have to transition very quickly from the five-year (high effective duration) to the two-year (low effective duration), resulting in very high effective convexity.

Putting It All Together

Notice in Exhibit 5-16 how effective duration changes much more across yields for the callable and putable bonds than it does for the option-free bond. This is to be expected because the embedded options have such a significant influence over cash flows as yields change over a wide spectrum. Interestingly, at high (low) yields, the callable (putable) bond's effective duration is very close to the option-free bond. This is where the embedded call (put) option is so far out-of-the-money that the two securities behave similarly. The same intuition holds for the effective convexity measures.

As explained and illustrated earlier, the common use of effective duration and effective convexity is to estimate the percentage price changes in fixed income securities for assumed changes in yield. In fact, it is not uncommon for effective duration and effective convexity to be presented in terms of estimated percentage price change for a given change in yield (typically 100 bp). Exhibits 5-20 and 5-21 show this alternative presentation for a ±100-bp change in yield using Eqs. (5-2) and (5-7).

PRICE VALUE OF A BASIS POINT

Some managers use another measure of the price volatility of a bond to quantify interest-rate risk—*the price value of a basis point* (PVBP). This measure, also called the *dollar value of an 01* (DV01), is the absolute value of the change in the price of a bond for a 1 basis point change in yield. That is,

$$\text{PVBP} = \left|\, \text{initial price} - \text{price if yield is changed by 1 basis point} \,\right|$$

Does it make a difference if the yield is increased or decreased by 1 basis point? It does not because of Property 2—the change will be about the same for a small change in basis points.

To illustrate the computation, we use the values in Exhibit 5-4. If the initial yield is 4%, we can compute the PVBP by using the prices for either the yield at 3.99% or 4.01%. The PVBP for both for each bond is shown below:

Coupon	**4.0%**	**4.0%**	**5.0%**	**5.0%**
Maturity	**5**	**20**	**5**	**20**
Initial price	$100.0000	$100.0000	$104.4913	$113.6777
Price at 3.99%	100.0449	100.1369	104.5374	113.8266
PVBP at 3.99%	$0.0449	$0.1369	$0.0461	$0.1489
Price at 4.01%	99.9551	99.8633	104.4452	113.5291
PVBP at 4.01%	$0.0449	$0.1367	$0.0461	$0.1486

The PVBP is related to duration. In fact, PVBP is simply a special case of dollar duration. We know that the duration of a bond is the approximate percentage price change for a 100 basis point change in interest rates. We also know how to compute the approximate percentage price change for any number of basis points given a bond's duration using Eq. (5-2). Given the initial price and the approximate percentage price change for 1 basis point, we can compute the change in price for a 1 basis point change in rates.

For example, consider the 5% 20-year bond. The duration for this bond is 13.09. Using Eq. (5-2), the approximate percentage price change for a 1 basis point increase in interest rates (i.e., $\Delta y = 0.0001$) ignoring the negative sign in Eq. (5-2) is

$$13.09 \times (0.0001) \times 100 = 0.1309\%$$

Given the initial price of 113.6777, the dollar price change estimated using duration is

$$0.1309\% \times 113.6777 = \$0.1488$$

This is the same price change as shown above for a PVBP for this bond. Below is (1) the PVBP based on a 1 basis point increase for each bond and (2) the estimated price change using duration for a 1 basis point increase for each bond:

Coupon	4.0%	4.0%	5.0%	5.0%
Maturity	5	20	5	20
PVBP for 1 bp increase	\$0.0449	\$0.1367	\$0.0461	\$0.1486
Duration of bond	4.4913	13.6777	4.4107	13.0871
Duration estimate	\$0.0449	\$0.1368	\$0.0461	\$0.01488

THE IMPORTANCE OF YIELD VOLATILITY

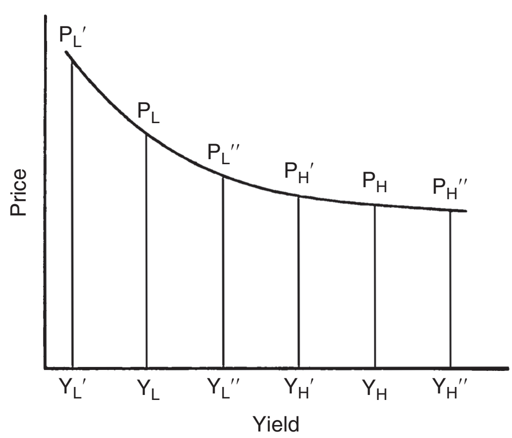
What we have not considered thus far is the volatility of interest rates. All other factors equal, the higher the coupon rate, the lower is the price volatility of a bond to changes in interest rates. In addition, the higher the level of yields, the lower is the price volatility of a bond to changes in interest rates. This is illustrated in Exhibit 5-22, which shows the price/yield relationship for an option-free bond. When the yield level is high (Y_H in the exhibit), a change in interest rates does not produce a large change in the initial price (P_H in the exhibit). However, when the yield level is low (Y_L in the exhibit), a change in interest rates of the same number of basis points as shown when the yield is high does produce a large change in the initial price (P_L in the exhibit).

This also can be cast in terms of duration properties: the higher the coupon, the lower is the duration, and the higher the yield level, the lower is the duration. Given these two properties, a 10-year non-investment-grade bond has a lower

EXHIBIT 5-22

The Effect of Yield Level on Price Volatility

$(Y_H' - Y_H) = (Y_H - Y_H'') = (Y_L' - Y_L) = (Y_L - Y_L'')$
$(P_H - P_H') < (P_L - P_L')$ and
$(P_H - P_H'') < (P_L - P_L'')$



duration than a current coupon 10-year Treasury note because the former has a higher coupon rate and trades at a higher yield level. Does this mean that a 10-year non-investment-grade bond has less interest-rate risk than a current coupon 10-year Treasury note? Consider also that a 10-year Swiss government bond has a lower coupon rate than a current coupon 10-year U.S. Treasury note and trades at a lower yield level. Therefore, a 10-year Swiss government bond will have a higher duration than a current coupon 10-year Treasury note. Does this mean that a 10-year Swiss government bond has greater interest-rate risk than a current coupon 10-year U.S. Treasury note? The missing link is the relative volatility of rates, which we shall call *yield volatility* or *interest-rate volatility.*

The greater the expected yield volatility, the greater is the interest-rate risk for a given duration and current value of a position. In the case of non-investment-grade bonds, while their durations are less than current coupon Treasuries of the same maturity, the yield volatility of non-investment-grade bonds is greater than that of current coupon Treasuries. For the 10-year Swiss government bond, while the duration is greater than for a current coupon 10-year U.S. Treasury note, the yield volatility of 10-year Swiss bonds is considerably less than that of 10-year U.S. Treasury notes.

A framework that ties together the price sensitivity of a bond position to rate changes and yield volatility is the value-at-risk (VaR) framework. *Risk* in this framework is defined as the maximum estimated loss in market value of a given position that is expected to happen with a specified probability.

KEY POINTS

- The full-valuation approach to interest-rate risk management involves repricing bonds under different interest rate scenarios to quantify price sensitivity to interest-rate changes.
- Important bond price volatility properties for option-free bonds are (1) prices move inversely to yields, but percentage price changes are not the same for all bonds; (2) for small changes in yield, the percentage price change is roughly the same, whether yields increase or decrease; (3) for large changes in yield, the percentage price change is not the same for yield increases compared with yield decreases, and; (4) for a given large change in yield, the percentage price increase is greater than the percentage price decrease.
- Bond features affect interest-rate risk. For option-free bonds, a longer maturity leads to more interest-rate risk, a higher coupon rate leads to less interest-rate risk, and interest-rate risk is greater at lower yields. Additionally, embedded options affect interest-rate risk.
- An alternative to the full-valuation approach is the duration/convexity approach. Duration is the approximate percentage price change in a bond's value for a 100 basis point change in rates.

- Duration assumes the term structure is flat and all interest-rate changes result from parallel shifts.
- Convexity adjustments improve duration estimates, particularly for large interest-rate changes.
- Bonds with embedded options, such as the issuer's right to call the bond or an investor's right to put the bond, have cash flows that change as interest rates change. Effective duration accounts for changes in the bond's cash flow. For this purpose, a term structure model is required.
- Callable bonds exhibit negative convexity and price compression at low interest rates. Putable bonds exhibit price truncation at high yields and high convexity at low yields.

DATA SCIENCE AND THE CORPORATE CREDIT MARKETS

Robert S. Kricheff
Senior Vice President
Portfolio Manager & Global Strategist
Shenkman Capital Management Inc.

The field of data science encompasses skills and techniques from statistical and scientific analysis and combines them with computer science. Data science is being applied to finance in innovative ways, not just for finding trading anomalies in stocks and modeling of structured credit. In corporate credit markets it is being applied to credit selection, portfolio construction, scenario analysis, and multi-asset credit portfolio management as well as performance and risk analysis. While data science has been part of the investment world for decades utilizing statistical techniques that have been in place a long time, the analytical capabilities are being transformed by creatively applying modern computer science tools such as artificial intelligence (AI).

Virtually all analysts, portfolio managers, and traders need to be data scientists to some extent. They do not need to be running algorithms themselves, but they have to understand what the basic techniques behind the statistical side of data science are and what the more advanced algorithms can and cannot do. These tools improve with the input and collaboration from the investment team in the design of these systems. It also puts the investment team in a better position to question and exploit the output.

Data science has helped make the growth of passive investing possible. However, within credit markets, the greater value of data science is how it can improve the decision-making process within actively managed portfolios. It can be especially valuable to refine investment styles and create customized fixed-income solutions to meet investors' specific needs

Active management is about making decisions and making them better and faster. The amount of raw data that is available in digital form has boomed over time, and this will likely continue. The real differentiator in investment performance will not come from who has that data, but who can sort through it, prioritize it, and empower it. Data science can help drive this process and avoid the analysis paralysis that can come from massive dumps of data.

Data science can improve the speed at which you can transmit a research idea into an executed transaction. Applying data science to corporate credit portfolios has some great hurdles when compared to markets such as equities and rates. However, many of the same characteristics that cause these hurdles also create opportunities. The trading illiquidity and the vast diversity of data fields needed to analyze corporate bonds and loans are some of the defining features of these markets, but they increase the level of difficulty in using data science. The fact that many bonds and loans in the credit markets do not trade every day, week, or even month makes pricing data very poor. The diversity of the data that is needed for good analysis arises from the multitude of factors that can influence the performance of an investment in corporate debt. Corporate bonds and loans are influenced by the same macro and micro business trends that impact movement in equity valuations, but also require the integration of interest rate factors, bond math and structural analysis—that can vary for each bond and loan. These structural issues can include items such as coupons, maturity, seniority, imbedded options, and covenants. Additionally, the ability of companies to call bonds and loans and the natural turnover due to maturity schedules is constantly causing the constituents in the credit markets to change. All of these complexities can create great opportunities for those that can harness the data. In a market that lacks homogeneity, like credit, there is a high probability of asset values being mispriced.

One could argue that using data science for investment analysis goes back to the 1952 portfolio allocation model by Harry M. Markowitz, popularly referred to as "modern portfolio theory," where he distinguished between inefficient and efficient portfolios. However, Markowitz. wrote that the concepts probably go back at least to Shakespeare.[1] Whichever timeline you prefer, the application of statistical and economic techniques to making investment decisions is not new. What is new is the power and design of storing data and computing. This has allowed data science to be applied to an enormous amount of creative investment problems. Scenario analyses that could only be theoretical a few years ago now can be run in unending iterations. Analysis and decision techniques based on tools such as probability, regression, correlation, and decision trees can now be used by computers with selected algorithms to run and rerun scenarios to come up with the best potential solutions and unearth relationships that have not even been thought of by investors. This does not just improve the ability to pick good investments but also improves analysis of how all the factors in a portfolio interact and respond to shifts in market sentiment and changes in the macroeconomic outlook.

One of the challenges with all this potential is that all the data and all the possible analysis that could be undertaken can be distracting. That is why a defined process and structured approach to undertaking data science projects improves the output along with helping to maintain a clear view of goals and priorities to keep the process on track. The plan needs to be designed in the right

1. Harry M. Markowitz, "The Early History of Portfolio Theory: 1600–1960," *Financial Analysts Journal* 55 (4), 1999, pp. 5–16.

way for each firm, with regular collaboration from all stakeholders. To achieve better decisions with data science takes commitment to structure and process as well as a commitment to invest in the systems, people, and time necessary to produce useful reporting. It also requires an understanding that even when a great analytical system is built, the work is not over. It will take more commitment to keep the systems evolving so that the competitive edge does not get dulled and the system keeps up with the constant changes that occur in the corporate fixed income markets.

The chapter starts with trying to define and categorize types of data science. It then goes through some of the key techniques used in data science and how they can aid decision-making, increase efficiency, and enhance performance and risk analysis. It then addresses some of the unique challenges in using data analysis in corporate credit markets and ends with a summary of some items to consider when undertaking data science projects.

DEFINING DATA SCIENCE

Data science is always described as being a multidisciplinary field, but after that you can find a broad array of explanations of what it incorporates. Broadly, it involves analyzing data by applying statistics, economics, scientific methods, and related mathematical techniques with advanced computer science, often involving algorithms in AI. The field has grown along with the ability to gather and store digital data.

One way of thinking of the techniques in data science is to separate them into descriptive analysis and predictive analysis. Some tools can be used for both—as an example, certain aspects of regression and probability analysis are descriptive and other aspects can be used as predictive.

Descriptive techniques may focus more on analyzing what has happened and the drivers behind it. Much of this field can be aligned with a focus on central tendencies. In other words, establishing an average for a group of data (i.e., mean, mode, or median) and then using various techniques to analyze the data in relationship to this central tendency (e.g., standard deviation, coefficient of variation). These types of techniques could be used to highlight a bond or a loan that is an outlier or an anomaly in how a portfolio performed versus its historical trend. The growth in big data and the ability to rapidly manipulate data has dramatically increased the potential for this field. However, descriptive analysis can lead to the development of predictive techniques, as data distribution can be used to derive the probability of an outcome. There is also research done on whether changes in things like the skew of a distribution can be predictive of market movements.[2]

2. See, for example, Roman Kozhan, Anthony Neuberger, and Paul Schneider, "The Skew Risk Premium in the Equity Index Market," *Review of Financial Studies* 26(9), 2013, pp. 2174–2203, and James Picerno, "Considering Skewness Of Returns as a Risk Metric," Seekingalpha.com, March 22, 2018.

Predictive techniques use data to create models that can make a prediction about something. Regression models are a basic technique that is frequently used to make a prediction. In its simplest form, it shows how one data point (the dependent variable) will likely react in relation to the change in another data point (the independent variable) based on the relationship of how the two had acted in the past. So, if you can make a statement about the independent variable, it can make a prediction of where the dependent variable will move. Predictive techniques can take that simple concept to much more complex and intricate levels, and historical probabilities can get factored into the equation as well. Predictive techniques can be improved by running various iterations of probability and regression and examining patterns of past performance. The ability to run these types of scenarios is greatly enhanced by the use of AI.

AI is a field that is increasingly exciting to investors. However, it worries people, too. It was entertaining when AI programs beat people in chess and go, but as the possibility of it taking jobs away became real there has been pushback from some quarters. Like other technological developments, AI is not going to stop advancing and being used just because of some Luddite-like outcries against it. Many of the tools are likely to eventually become commonplace as AI becomes more accessible and will likely be part of almost everyone's daily life in the future.

AI should be understood and embraced as a tool to help make decisions. However, it should be recognized that it is not infallible and it can sometimes create a conclusion when the relationship between the data is actually random. Many of these techniques and methods have evolved from work in the physical sciences, and finance and economics are not physical sciences. Financial markets, and the economic and corporate actions behind them, are still driven by individual choices. Even great models cannot always predict what a chief executive officer will choose to post on social media, what event will go viral and change shopping habits, or who will win an election.

Typically, AI systems use different types of algorithms that often mimic the way humans learn. This allows computers to take massive amounts of information and process it to generate output that helps explain patterns in the data. Ideally, the more recent the data is that the system has to analyze, the smarter and timelier its output becomes. This is making good-quality digital data increasingly valuable.

There are different types of algorithms used in AI; these may include neural networks, clustering, and random forests, among others. AI techniques are broadly divided in to supervised learning and unsupervised learning. There are also techniques involving semi-supervised learning and reinforcement learning.

The data used in supervised learning are labeled. This labeling is a differentiator between supervised and unsupervised learning. So that if there is a bond and a loan in the data set, they will each be labeled when using supervised learning algorithms. These algorithms may also have more clearly defined output goals than in unsupervised methods. Supervised learning algorithms can include decision tress, regression techniques, and some Bayesian-related algorithms.

Unsupervised learning techniques do not have data labels and often have less guidance about inputs and output goals. These types of algorithms include clustering and density estimates (e.g., distribution information). These methods can take reams of data that the algorithm starts to identify and put it in patterns, and as it does this it begins to sort and make note of relationships. This is how AI programs do things like recognize that convenience store shoppers tend to buy beer and diapers at the same time.

Semi-supervised learning includes techniques where the data has some explanatory labels, but not every data field is labeled. This can minimize the time and expense of labeling data. Reinforcement learning is where the algorithm gets feedback if it is accomplishing certain tasks correctly to know if it needs to change direction or can keep going along the same pattern; theoretically, the outcomes will improve from that feedback.

Natural language processing (NLP), another area of AI, is designed to scan and search for key words or patterns of words. NLP increasingly is being used in voice recognition—reportedly, national security intelligence agencies use this technology in their communications intelligence gathering to sort through all the intercepted messages and prioritize them. In the investment world, similar technology can be used to find key words in economic reports or corporate filings and sort them, send alerts, or analyze the patterns or changes in the language. This can be useful to see if language about the earnings outlook has changed in a company's financial statement, or it could be used to sweep through thousands of quarterly reports to see if there is an increasing trend in the use of a phrase like "cost savings" versus prior reports.

This is by no means an exhaustive review of how data science is being used. However, it hopefully gives a rough idea of the major categories of data science tools and demystifies a bit how these techniques, which are based on basic statistical tools, are allowing investment teams to think of creative ways to analyze and improve their performance.

SELECTED DATA SCIENCE TOOLS, TECHNIQUES, AND USES FOR INVESTING

The base of data science involves various statistical techniques that have been applied to investment analysis for decades. However, computer science has allowed these techniques to move from evolutionary changes to revolutionary changes.

One of the unique challenges in applying statistical and economic tools to the credit markets is how many variables there are that can impact performance at each individual investment and across the entire portfolio. Choosing the right items to focus on and the best techniques to use can make a huge difference in plowing through all the available data. One of the advantages of computer science is it can take a technique like regression or probability analysis and run iterative calculations, using different variables to find the most meaningful factors on which to focus for different market environments or for different investment styles.

Using these techniques are not foolproof when applied to investing. Economics is not physics; there are very few laws of investment and portfolio construction that cannot change or produce frequent anomalies because of how much they are impacted by human actions. Additionally, with so much data being analyzed, the danger of randomness has to be considered. Techniques such as data mining have come under criticism that they torture the data until a relationship is created. You can find any number of scholarly and sensational articles wary of the misuse of algorithms in everything from driverless cars to mortgage approvals.[3] You always have to be aware that even though computers are being used, all of the typical biases that get discussed in behavioral economics can creep into the analysis. This can happen by what data is selected to input and what is being asked for on the output as well as how the data is presented. There are often statistical tests that can be run on the output of any analysis to check the validity of the conclusion, but in all cases, it is always good to apply common sense, especially when data analysis shows a shocking relationship.

What follows is a sampling of some of the most common decision-making tools used in data science. Investment professionals continue to develop creative ways to marry these techniques with computer science to address new problems and look for more opportunities.

Regression and Correlation

Regression is usually at the top of a list of data science techniques. Its output can produce both valuable descriptive statistics and be used predictively. Like many data science techniques, regression is a relational tool, it compares the relationship between various data sets. It can be used to aid decision-making in credit selection, portfolio construction, and about the macroeconomic drivers.

Regression is used to take the data about movements in the value of one or more "independent" variables and tries to fit this data into a relationship with the movements in value of a "dependent" variable. Linear regression forces this data into a formula that describes a line. The line tells you what the predicted value of the dependent variable is for each value of the independent variable. If the relationship is not strong, there are techniques that can be used to help smooth out the data and create a stronger relationship, such as using logs and exponents to fit the data into a stronger "fit."

The data from this analysis can generate interesting descriptive data. One of the most widely used outputs explains how strong the relationship between the independent and dependent variable is. Advanced computing techniques can help run series upon series of this data to see which set of independent variables has the most impact on the dependent variable you are trying to solve for. For

3. Ben Shneiderman, "The Dangers of Faulty, Biased, or Malicious Algorithms Requires Independent Oversight," *Proceedings of the National Academy of Sciences of the United States of America* 113(48), November 29, 2016, pp. 13538–13540.

example, if you are trying to solve for what the likely volatility of returns on a portfolio will be (dependent variable), you might want to see which has a stronger relationship with the changes in volatility: aggregate credit score changes, interest rates, or GDP (all independent variables). A data science program could run thousands of combinations of variables to try and solve for the strongest relationship.

Regression is often used as a predictive tool. Once a linear formula for a relationship is found, you could make an assumption on how the independent variable might move and the formula could predict an outcome for the dependent variable. Data analysis techniques can be combined and a program could run the probability of changes in the independent variable based on past patterns and choose the data points that had the highest probability, thus strengthening the predictive power of the regression model.

Regression output also produces residuals that show how far data points are from the regression line and this can be used for relative value analysis or as a predictive tool for what the gain or loss could be if an investment were to move to trade in line with the "fair value" predicted by the line.

Correlation

Correlation information is an output from regression analysis. Correlation is used to try to explain how strong a relationship there is between two or more variables. For example, you might want to examine the relationship between rising interest rates and consumer spending. In theory, the relationship could be strong, weak, nonexistent, or negative (meaning one goes up when the other goes down). Correlations can help to tell how well regression might work as a predictive tool. In situations where negative correlations exist between two investible assets, investors could create hedged positions being long one asset and short the other. The strength of the negative correlation could give some guidance of what ratio to use between the long and the short. Correlations are also often used in portfolio analysis; as an example, in credit markets you often want to look at the relationship between certain macroeconomic factors and how correlated your portfolio's performance is to them (e.g., sensitivity to interest rate movements or credit rating changes).

One of the valuable uses of tracking correlations is to have a system that can alert you when relationships between two assets breaks down or changes dramatically. If two assets regularly have a strong relationship but periodically this relationship gets disrupted, it may create investment opportunities, especially if the relationship is expected to revert. For example, there may be an extended period of time when the relationship in spread between BB-rated bonds and BBB-rated bonds is highly correlated. However, when investors' view of risk begins to change, this correlation can breakdown quickly and BB-rated bonds may sell off more than BBB-rated bonds. If an investor expects this breakdown in correlation to be short-lived, they may find this an opportunity to buy BB-rated bonds. This analysis could be enhanced by running probabilities of this reversion based on past periods of decoupling. However, you should be cautious on jumping in blindly when you see a correlation change; sometimes these changes are warranted and they are permanent. This is especially true when investing in corporates as technological disruption has increased the potential for more permanent disconnects.

Once you run one regression and look at the output, it is easy to see that you will want to run several others to refine your analysis and move down an iterative path. With advanced computing, it is much easier to proceed down this road. However, the information does have to be analyzed properly and tested. If you have sat through one statistics class, you have probably heard that "correlation is not causation" and any conclusion from regression has to be examined from both a logical and mathematical approach. Regression is so widely used that too often the output is not examined and simple tests are not run to check for items that could weaken the conclusions, including issues such as goodness of fit, as well as heteroskedasticity, autocorrelation, or multicollinearity in the variables.

Probability

Probability is used all the time in decision-making, though often it is done informally and intuitively. It is also the basis of many data science techniques. Conditional probability and specifically Bayesian probability could be viewed as the basis of much of AI. However, improper use of probability can result in poor decision-making whether in anchor and confirmation bias or base rate fallacy.[4]

Bayes' theorem helps you adjust the probability of an event as you get new data. With all the factors that impact a credit portfolio, it can be critical to understanding how new information can impact the probability of an outcome. For example, understanding how a change in interest rates, credit quality, or exchange rates may influence the probability of your portfolio outperforming a benchmark or how a decrease in interest rates could increase the probability of bonds being refinanced in a short-duration portfolio are all valuable pieces of information.

With the advent of digital data and increased computing power, the data available from which probabilities of events can be analyzed has exploded and enhanced the value of Bayes' theorem and this can improve the decision process exponentially. It also increases the value of decision trees, as you can build out a series of conditional probability relationships. As always, you do need to be aware that noise in the data (e.g., bad data, gaps in data sets, or biased selection of data) can distort probabilities.

Bayes' theorem lets you take an event that you have the probability for and then see how that probability changes due to another event occurring. To illustrate how conditional probability can help with decision-making, we will run through a quick scenario. In credit markets, much of the return comes from interest income. Therefore, the drag on performance from sitting in cash can be meaningful. Understanding the likelihood of more cash coming into a fixed income fund

4. Eric Angner, *A Course in Behavioral Economics* (New York: Palgrave MacMillan, 2012).

and managing the cash balance can impact performance. Assume you know the probability of a large amount of cash coming into the fund in the month after the European Central Bank meets, and assume you know the probability of the bank cutting interest rates at any given meeting. What you want to know is how does the probability of a large amount of cash coming into the fund change if the bank cuts rates at its meeting.

The theorem needs three key pieces of data: (1) the probability of an event A occurring, designated by $P(\mathrm{A})$, (2) the probability of a second event B occurring, designated by $P(\mathrm{B})$, and (3) the probability of event B occurring given that A has occurred; this is designated by $P(\mathrm{B}|\mathrm{A})$—the vertical line is read as "given that." You are solving for what the probability is of event A occurring if event B has occurred.

In the Bayes' theorem below, P = probability and $P(\mathrm{A}|\mathrm{B})$ reads "the probability of A given that B has occurred":

$$P(\mathrm{A}|\mathrm{B}) = [P(\mathrm{B}|\mathrm{A}) \times P(\mathrm{A})]/P(\mathrm{B})$$

If event B occurs (e.g., the European Central Bank cuts rates), it is clear that you have the ability to see how that changes the probability for event A. You have been able to apply new information and analyze how this new information impacted the probability of an event occurring. This also may help illustrate how AI takes new data and "learns" from it.

Imagine a program that has an enormous decision tree. Maybe it starts with an analysis of how often a key word appears in a central bank press release, like "unemployment," and calculates based on past data what the probability of a rate cut is if that word appears a certain number of times. The change in this probability then impacts the probability of new flows into credit mutual funds, which effects the probability of bond prices rising, which increases the probability of your portfolio underperforming the benchmark. This would likely alert you to consider realigning your portfolio. This type of modeling is all based on probability and is possible through the use of data science. You can come up with a broad array of ways to apply this capability if you had the data and endless computing power.

There are also adjustments to the Bayes' theorem that can make it more flexible. In some cases, you want to factor in a binary event, such as an interest rate cut occurring or not occurring. In this case, you would need the probability of B occurring given that A had occurred $P(\mathrm{B}|\mathrm{A}+)$ and the probability of B occurring given that A did not occur $P(\mathrm{B}|\mathrm{A}-)$. This binary model is often the case in investment analysis. The formula for this is

$$P(\mathrm{A}|\mathrm{B}) = \frac{[P(\mathrm{B}|\mathrm{A}) \times P(\mathrm{A})]}{[P(\mathrm{B}|\mathrm{A}-) \times (P\mathrm{A}-)] + [P(\mathrm{B}|\mathrm{A}+) \times (P(\mathrm{A}+)]}$$

A common intuitive problem that arises in probability is base rate fallacy, which can occur in many ways. Often it occurs when one takes the latest data and ignores prior probability data that is available, such as assuming $P(\mathrm{B}|\mathrm{A})$ is applicable to the probability of $P(A|B)$ without factoring in the information that you have on the separate probabilities of A and B. Bayes' theorem prevents this base rate fallacy.[5]

Momentum and Technical Measures

Moving averages have been used for many years to try to predict momentum and trends in prices of assets. Studying these trends as well as supply and demand is often lumped into an area referred to as technical analysis. In more liquid markets, computers have been used to follow some of these trading patterns and find various anomalies to exploit through high-frequency trading. The illiquidity of the credit markets does not allow for such strategies, but studying these technical factors still can give insight into investment opportunities.

Moving averages are a tool to follow trends in data over time and to smooth out short-term spikes in the data. It does this by not just using one individual data point for each entry (e.g,. the yield of an index on a given day), but by also using the average of a group of trailing data for each entry (e.g., the yield for date X/XX/XXXX would use the average of the previous 50 trading days). An example of how this might be used would be to compare the moving average of the prices of a stock for the last 200 days and compare it to the moving average of the last 50 days to see if more recent trends are diverging from longer-term trends. In stocks, it is common to also look at the trading volume along with the price movements. In the credit markets, price movements are not always the best data point to track; at times, relative value measures such as option-adjusted spreads and yields can be more valuable to use.

There are also various moving average calculations designed to give more weight to certain data points than others within a moving average, such as a weighted moving average and an exponential weighted moving average. Most commonly, these adjusted moving averages give more weight to the most recent prices, but weighted moving averages could theoretically be designed to give more weight to price movements on days when there is a higher trading volume or when markets trade down to try to emphasize selected events.

The tracking of inflows and outflows of capital into various asset classes can theoretically be a valuable tool, as these technical flows can influence asset prices. Unfortunately, usually by the time the data is available the flows have already moved and the impact on prices has already occurred. Increasingly, work has been done on trying to track intra- and interday activity in exchange-traded funds (ETFs) to get a sense of flows, but there is considerable noise in this data, especially in the corporate credit markets. Because liquidity of individual securities can be challenged in credit market, ETFs in these markets are often used by tactical investors to get short-term exposure to the asset class and may not

5. Richards J. Heuer Jr., *Psychology of Intelligence Analysis* (Washington, DC: CSI Publications, 2007).

be more broadly indicative of the larger and longer-term flows in and out of the corporate debt asset classes. An arena where more work can be done is to use unsupervised AI to see if there are predictable patterns of capital shifts from one asset class to another based on changes in the relationships in asset class performance, yields, volatility, or some other performance measure.

Regime Recreation and Mean Reversion

Regime recreation is where analysts try to find previous time periods that resemble current events (or expected events) and study what happened in that prior "regime." This is a form of scenario analysis, but it is based on a very specific set of circumstances. This technique has a high-level of subjectivity (and can make up endless chatter on business news channels). You could set a series of parameters that you believe are going to align with the anticipated events and use a program to see which prior period fits this profile the best, or you could just choose the period you think best resembles the expected one. Ideally, you would get information on which factors performed the best and the worst in this prior period and might even be able to run a scenario analysis on how your portfolio would perform in such an environment. However, one has to consider that the makeup of markets changes over time and the knowledge that investors have from these prior regimes may change how they react in the current one.

Mean reversion techniques are not that dissimilar to regime re-creation. In this technique, it is assumed that when a price shock happens, the price will eventually return toward its mean. Proponents of this technique often can point to periods when a year of bad results is followed by a year of very strong results. This technique can also be applied to trend reversion. In other words, if the price of an asset is trending upward at a certain trajectory and then falls off that trajectory, the assumption is that over time it would revert back to that trend, not dissimilar to when correlations breakdown and it has some of the same shortcomings.

Optimization

The concepts of portfolio optimization grew out of modern portfolio theory. The initial idea was to find the investment mix for a portfolio that can maximize the return per unit of risk along an efficient frontier. The original models used volatility of returns as a measure of risk, and this is still common, as portfolio optimization is often run to solve for the best Sharpe ratio.

With increased computing power, optimization techniques can be significantly more varied than just maximizing the Sharpe ratio. You can run optimization programs to try to maximize other measurements such as the information ratio and the Sortino ratio, or to balance maximum drawdown relative to returns. With the increasing popularity of multi-asset credit, portfolio optimization can be used to experiment with the optimal mix of assets to meet the customized needs of an investor.

Factor and Factor Investing

Factor investing has been very popular in the equity markets for some time. It isolates a specific, defining characteristics of an asset and analyzes how assets with that characteristic perform over time relative to others. Ideally, this "factor" can be clearly defined and its performance can be quantified. How the factors are defined and what mix of factors are used is part of what can make each factor strategy unique.

Within equities, some of the common investment factors include: size (e.g., large-cap, mid-cap), growth versus value stocks, and volatility. A stock may have multiple factors (e.g., both large-cap and growth). To do factor investing properly, you need significant data to run testing of how the factor performed over time. You also need to be able to define the factor clearly so that the data sets have minimal noise.

A boom in available computing power may have led to an overexpansion of research on factors. Some of these factors that have been "discovered" through cross-sectional research are quite likely not as meaningful or as investible as others. One research paper stated that from 1980 to 2003 about 84 factors were discovered in equity investing; however, spurred by well-publicized cross-sectional research in equities and the expansion of computing power, the number of factors discovered doubled over the next nine years, and if working papers were included the figure would have been even greater. This was referred to by one researcher as a "zoo of factors." Many of these factors have likely not proven to be helpful to professional investors, and some of the analysis on these factors have been deemed statistically "significant by chance."[6]

So just because you can define a factor does not therefore make it meaningful. There should be enough historical data to support the factor. In credit markets, if the factor is based on bond math, (e.g., price movements based on duration and convexity), you can rationalize having less data to back it up, but if the attraction of the factor is due to data mining, be wary of randomness in the data. The factor performance should make sense in various environments. Also, the factor should not be so carefully selected as to make it overly biased, unrealistic, or un-investible. The factor should also make common sense.

Credit markets can lend themselves to a vast array of factors. As examples, you can define factors by industry groups, by corporate performance, by credit quality, or by issuer size. Furthermore, factors can utilize structural issues such as callability, covenant strength, or coupon. Factors can be very helpful in trying to express a theme within a portfolio and in achieving a certain investment style. Factors are particularly valuable to analyze and manage within a portfolio when trying to create a customized solution for a client that desires certain goals and characteristics. Data science techniques are critical in developing, defining, and back-testing factors that can be used in credit markets

6. Campbell R. Harvey, Yan Liu and Heqing Zhu, ". . . and the Cross-Section of Expected Returns," *Review of Financial Studies*, 29(1), 2016, pp. 5–68.

Passive Investing

In passive investing, the manager is usually trying to mimic the performance of an index. Usually the index is based on market value, so that a database and computing system has to constantly generate orders to match the portfolio relative to the changing market value. Additionally, many passive products are in the form of an ETF, so that the fund has intraday liquidity needs that also have to be managed while maintaining weightings in line with the index. The ETFs also have to factor in the regular inclusion and exclusion of issues in the index it is mimicking. For corporate credit markets, all of this has to be done in asset classes that are much less liquid than the equity or the government bond market and that usually have a vast array of constituents. This requires programs that can take data and generate buy and sell orders rapidly to optimize the portfolio to be aligned with the index.

Data management systems have been built by broker-dealer firms to be able to create and unwind these portfolio optimization trades for passive ETFs. It has also allowed broker-dealers to be able to expand their capability to do large portfolio trades for actively managed accounts, matching a multitude of buy and sell lists together to get a large trade in many issues at the same time.

ETFs within the credit markets have tended to have much higher volatility than the market overall and higher than actively managed funds. However, because of their forced buying and selling, they do appear to have added to the liquidity in the corporate debt markets.

DATA SCIENCE AND INVESTMENT EFFICIENCY

Data science is widely used to make middle office and back-office operations more efficient. Similarly, it can enhance client services and marketing. On the investment side, it can be used to make information flow and execution more efficient. Below, we outline some examples of how it can enhance the investment process by speeding up access to information that can speed the time from idea generation to execution.

Query Systems

Assuming that you have valuable investment data and it is in a usable format, the other necessary step to exploit the data is to easily access it. Not only do you want the analytical algorithms to be able to use the data, but you want the investment team on the frontline to be able to access it too. To do this, the ability to run queries is key.

A good database and well-designed query technology can allow an analyst or a portfolio manager to put in criteria for a data search and a list of options meeting that criteria can be generated. For example, a manager may be looking to reduce exposure to credits in commodity-based industries. If they had a good database and query system, there could be a set of fields where they could enter the criteria they were looking for. The query for possible buys could include:

1. A yield-to-worst of greater than 5% but less than 7%
2. A credit rating between B– to B+
3. A fixed-rate bond structure
4. Duration of less than three years
5. A credit analyst recommendation of "overweight" or higher
6. No commodity sectors

Ideally, the database would produce a sortable list of bonds with various information about each one. A similar process could be set up for the sell-side of the equation, but perhaps item (5) would now read, "a credit analyst recommendation of 'hold' or lower" and item (6) "only include commodity sectors."

There are so many potential factors within corporate credit, it is important that query systems are built so that they can include all of the parameters that might be considered in a search. It also highlights how critical designing data fields and entering the right data is when building data science systems These types of systems are in fairly wide use and are hugely valuable, but they become really empowered when linked with other data science tools, such as the ability to run scenario analysis on how these buys and sells would impact the portfolio.

There can also be automated queries. For example, identifying anomalies and outliers rapidly can be of great value for investors. This could be done each day through entering a query (e.g., a list of bonds that have traded off the most in the last week), but it is more valuable if an automated system could run pre-set sorts—it could be programmed to send an alert if the movement was outside a band of preset parameters.

Research Links

Quality credit research is critical in driving performance within fixed-income markets. Highly functioning database management systems should be able to link research information so that it can reach portfolio management and trading teams efficiently. Likewise, it should give research analysts updates on market prices.

Databases should be linked to research and query systems that are able to search for research recommendations and commentary as easily as it can search for bond prices. Most research teams now have credit-scoring systems and recommendation rankings. In the example in the preceding section, the list of bonds produced by the query should include recent research credit scores, recommendations, and a link to any recent research notes.

The research process can be more automated as well. To make research more efficient, many of the inputs for credit scores can be automated and data can be extracted from various third-party databases. Financial reports can be scanned using natural language processing for key changes in words and terminology and alerts can be sent, the same way news alerts are. With enough data, programs can run relational reports of credit scores and relative value and look for patterns between price movements and credit scores over time. As an example, it could also breakdown relationships between parts of a credit score and yields to see which aspects of a credit score appear to influence market levels the most.

One of the critical features in successfully integrating research into a firmwide database is consistency in how the data is calculated and how it is entered. Credit scores and recommendations, along with other key data, need to be processed and placed in the same format for all credits in the system and for all bonds and loans. With so many critical datapoints in corporate debt markets, this requires a significant investment and may limit how much historical data can be utilized.

Trading Execution

With liquidity and execution costs much more of a concern in credit markets than in many other capital markets, data science can bring considerable value if it can lower transaction costs and quickly analyze if investment ideas are actionable. Some of the systems used by ETFs and broker-dealers were mentioned earlier, but asset managers can gain an advantage by investing and using systems that can analyze which bonds and loans may actually trade based on various characteristics. For example, studies can be run to show what data points are likely to correlate with the ability to trade bonds; these might include data such as how many market makers there are and who the market makers are, the size of the issue, and the regularity of two-sided price quotes.

There has already been significant progress in "scraping" lists of markets offered by broker-dealers to see all of the markets in one place; there has also been improved information on trades that have actually taken place. Electronic trading platforms could improve this information flow and the ability to transact. There have been numerous trading platforms for credit markets introduced, but they are still challenged to win the bulk of the volume in trading. Loans present another array of trading issue as the agent banks tend to still control most of the activity.

It still appears that credit markets are in the fairly early days of the ability to transact. It is likely that more developments in predictive analysis will evolve regarding which bond or loan is actually the most tradable on any given day, at any given hour, and at the best value.

RISK AND PERFORMANCE

The section is focused on the use of data science for performance analysis and risk management. These are not just-backward looking or administrative tools, but can also help guide decisions on portfolio positioning. The more rapidly you can receive performance and risk analysis, the more valuable it is.

Attribution Analysis

One of the most common tools to breakdown performance is attribution analysis. Like many analytical investment tools, the most commonly used attribution model was originally developed for the equity market and is often referred to as Brinson attribution, or BHB attribution.[7] This is a tool to compare a portfolio's return relative to a benchmark, but it can just as easily be used to compare two portfolios of similar or different style. The goal is to see what has driven the differences in performance during a given time period.

The basics of this methodology start by separating the returns by industry and then getting the data for the average weighting (W) of each industry (i) and the return (R) for each industry for the portfolio (p) and the benchmark (b) as well the overall return for the benchmark.

The terms for the equations are the following:

W_{bi} = Weighting of the industry within the benchmark
W_{pi} =Weighting of the industry within the portfolio
$R_b i$ = Return of the industry in the benchmark
R_b = Return of the benchmark
R_{pi} = Return of the industry in the portfolio

The methodology includes separating out three effects:

1. Allocation effect, which measures how the portfolio weighted an industry versus the benchmark. If the industry was overweighted in the portfolio and, within the benchmark, that industry outperformed relative to the broad returns of the benchmark, then this allocation would be viewed as having a positive effect on the portfolio's return. Note that in this allocation effect it uses the return of the benchmark, not the return of the portfolio, this is an area of some debate.

   A simple formula for this is:

   $$\textbf{Allocation effect} = (W_{pi} - W_{bi}) \times (R_b i - R_b)$$

   The right side of the formula takes the "industry return for the benchmark" ($R_b i$) and nets out the overall return for the benchmark as this assumes that the alternative for investing in the industry would be just buying the whole benchmark, so in a sense this is the opportunity cost of investing in the industry.

2. Selection effect measures how well the portfolio chose the investments within a specific industry and quantifies the impact of choosing

7. See Gary P. Brinson, L. Randolph Hood, and Gilbert L. Beebower, "Determinants of Portfolio Performance," *Financial Analysts Journal*, 42(4), 1986, pp. 39–44, and Mark Kritzman, L. Randolph Hood, and Gary P. Brinson, "Determinants of Portfolio Performance: 20 Years Later," *Financial Analysts Journal*, 62(1), 2006, pp. 10–13.

securities that provide different returns than the benchmark. In this equation the weighing for the benchmark is used and the industry excess return for the portfolio (R_{pi}) is used.

A simple formula for this is

$$\textbf{Selection effect} = W_{bi} \times (R_{pi} - R_{bi})$$

3. Interaction effect measures the combined impact, or the portfolio's allocation and selection. This effect is more controversial, and some analysts prefer to leave it out or combine it with selection. Others argue that you should adjust the selection effect and change the right side of the formula to W_{pi} instead of W_{bi} and use a two-factor model. It could be argued that as the interaction effect penalizes a portfolio if it makes good selections but underweights the sector, it is a measure of how well the portfolio understands in which sectors it has an edge and in which sectors it does not, or how well it can maximize its investment selection style.

   A simple formula for this is

$$\textbf{Interaction effect} = (W_{pi} - W_{bi}) \times (R_{pi} - R_{bi})$$

All of these effects are added together to get total attribution for a sector, sometimes referred to as an "active manager" effect.

One aspect of industry attribution is that it assumes that investors make an industry allocation decision first (and that they make that decision relative to the benchmark), and then this is followed by making security selections within that industry. This may not be the case. An investor could determine industry weightings as a random factor based on how many good ideas their analysts have in that sector.

This analysis can also be utilized to isolate many other factors other than just industry selection, and this can enhance its use as a risk management tool. This is particularly valuable in corporate credit markets. An attribution analysis can be run for any number of factors such as credit rating, credit scores, duration, or issuer size, and it can show where the relative risks have been as well as where the relative rewards have come from.

Data science has the potential to improve the value of attribution analysis. Assume an algorithm was designed to scour historical attribution analysis in various periods, not just by industry allocation decisions but across numerous characteristics. The algorithm's goal could be to examine periods where the portfolio outperformed above a certain threshold and to see which categories tended to have the biggest effect on performance. For example, a study could find that when the portfolio outperformed its benchmark by 10% or more, 80% of the time the largest allocation effect occurred in BB-rated long-duration bonds and the biggest selection effect occurred in utilities. This would obviously warrant more work to see how these investments contributed in other performance cycles, but it might lead the portfolio management team to rethink its base case weighting to these investment factors.

Data Science and Risk

While attribution measurements often focus on how to get the best reward, using data to manage risk is equally valuable. The return profile of non-convertible corporate debt is asymmetrically skewed toward the downside as the upside is limited due to maturities and call structures. Therefore, minimizing drawdowns and permanent impairments can be a major differentiator in performance and heightens the importance of risk management when investing in these debt markets.

There are many aspects where data science can be used to monitor thresholds within a portfolio. These risk controls could be items like issuer limits, duration limits, or interest income targets. However, given the strength of computing power and good historical data sets, a risk management system could do more than just monitor these levels. Analyses could be run to help rationalize what the best thresholds are and to run estimates of the increased risk and reward to the portfolio if those limits were raised or lowered. It could also use historical data to analyze what are the probabilities of hitting the existing risk thresholds.

Scenario analysis is another important risk management tool that can give a portfolio manager a better sense of how a portfolio is positioned for certain events. It is somewhat similar to regime recreation, but in this you can change multiple variables. One common risk test is to induce interest rate shocks to the portfolio to see how it performs. This should be done in multiple ways; three common interest rate tests are often referred to as shift, twist, and butterfly.[8] Similarly, there are various scenarios that can be run using value-at-risk type models. These types of models tend to look at historical losses over some period of time and shock the portfolio's prices accordingly. Drawdowns could be analyzed by any number of factors:

Drawdowns by rating category
Drawdowns by issuer
Drawdowns by industry
Drawdowns by seniority and structure
Drawdowns by a credit score
Drawdowns by duration
Drawdowns by issuer size

Risk metrics can be designed to monitor the portfolio for anomalies. For example, if volatility within a sector breaks out of a range, an alert could be sent to review the movements and positioning in that sector. One of the tricky aspects of this for credit is to try to determine what is causing the anomaly. It could be driven by changes in an industry or by a broad move in interest rates; thus the sudden increase in volatility might not be a real change in risk relative to that sector.

8. These movements of the yield curve are denoted as follows: shift = a parallel shift in the yield curve, twist = a steepening or flattening of the yield curve, and butterfly = changes to the curvature of the yield curve.

Risk monitoring, if properly organized, is not just a governor on position limits. With good data and systems, it can be an active tool to improve portfolio construction and understand where the risks exist relative to the potential rewards

Putting It All Together

Many of these tools are designed to produce better decision-making information and to increase the efficiency in finding and executing investment ideas. Whether the idea involves a transaction in a single investment, a repositioning of a portfolio, or a realignment of a multi-asset credit portfolio, good data science can improve the process. Below is a simplified hypothetical flow of how these systems can work.

1. After reviewing data on interest rates and shifting market risk-tolerance, the CIO and strategist teams make a determination to lower duration parameters.
2. A report on the rationale of this decision and how much duration has to change is sent to the portfolio management teams.
3. The report includes a summary of other key data on the portfolio as well (e.g., yield, spread, average credit score, key active industry exposures).
4. Portfolio managers note that they are at the low end of their healthcare and gaming weighting targets but at the high end of auto and retail weighting targets.
5. A query is sent to the system for potential buys in bonds in healthcare and gaming with lower duration targets and sells in auto and retail with higher duration. The query also states what the goal is for the impact of these on the portfolio's overall duration.
6. The system runs different iterations that would involve different amounts of buys and sells to meet the criteria.
7. Using the bonds that meet the query criteria, the system runs a regression based on a number of credit statistics and credit scores relative to the option-adjusted spread and then ranks the selected bonds based on relative value.
8. The system also scrapes trader runs to prioritize names that have the characteristics that give them a high likelihood of being tradable.
9. The sortable list that is sent to the portfolio management team includes potential buys and sells, relative value, credit scores, most recent analyst notes, and expected duration contribution in the portfolio; additionally, the analysts are alerted about the query output and asked if any updates are pending.

10. The report allows the portfolio management team to experiment with buys and sells from the list and immediately see the potential impact on the portfolio for a variety of characteristics.
11. Trades are entered and executed.

WHY DATA SCIENCE IS DIFFERENT IN CREDIT

Many of the quantitative and data-driven techniques that have been developed in finance have their roots in the equity markets. This is important to remember when applying these methods to the credit markets. There are numerous significant differences in how these securities are structured and how these markets act.

Equity is an ownership stake in a corporation, and prices tend to move on the perceived value of that company. Assuming a company does not distribute a huge portion of its earnings to shareholders through dividends, the way to make money when buying an equity is to make other people want to buy it at a higher price. Corporate credit instruments are a contract with a corporation. They pay a stated interest rate, and the principle has to be repaid at a stated date. This means that in the long run, if the company honors its obligations, your return can be calculated based on a yield regardless of whether other investors decide to buy the bonds or not. Of course, in reality, a credit portfolio's performance is not measured during the entire life of a bond, but in shorter increments. However, this difference in how these markets produce returns is important when you utilize data analysis techniques that were developed based on research in the equity markets.

In most corporate credit markets, the bulk of the return is usually from interest income, other than in the convertible bond market. If you are running a shock analysis on an equity portfolio, the time it takes for that shock to occur may not have a huge impact on the absolute return, but for credit if you run the scenario over a short time period or a long period it can make a big difference because of the interest income effect.

Building data sets in credit can be more difficult and costly than in other markets. Most public companies have one share class of equity. However, they may have a multitude of bonds and loans outstanding, and each bond typically has different structures. The differences in seniority, coupon, maturity, call schedules, and covenants can make two bonds issued by the same company each perform very differently in different environments. Not only are there potentially more structural factors to model and consider, but by the nature of having scheduled maturities there is greater turnover in the market constituents than you would see in the equity markets.

Because of the maturity schedules and the interest component fixed income markets have several ways of expressing relative value. While stocks are usually quoted by price, fixed income uses price, various yield measures (e.g., yield to call, yield to maturity, yield to take-out), and also spread, which is measured relative to a "risk-free" fixed-income instrument like U.S. Treasuries or LIBOR.

Imbedded options also cause complexity, in part because they can make return calculations more complex, but also because they vary so much. Loans are almost always callable, and usually with less of a penalty to the issuer than in the bond market. Some bonds have call options and others have non-call structures. Call options have a variety of structures. Additionally, in the high-yield bond market there are often call provisions that can get triggered if an equity offering is completed (i.e., equity clawbacks), and sometimes secured bonds give the issuer the option to call a small percentage of the bonds each year for a period of time at a premium; this is usually a carve-out that is separate from whatever other call protection are in the bonds. There are often change of control puts in investment-grade and below-investment-grade bonds.[9] Then convertible bonds have an imbedded equity option, which gives convertibles a much different potential return profile. While the issuer of the convertible still owes par at maturity, the bond's equity call option can cause it to trade at prices well above where a nonconvertible from the same issuer would trade. Convertibles also often have unique call and put features. All of this not only adds complexity to the credit markets, but also can create significant noise in pricing data, given how many of these structural issues can impact performance.

It has been mentioned several times in this chapter, but it is important to point out again that liquidity is a major difference in corporate credit markets versus equities or rates. Transaction costs have to be considered when managing portfolios in these markets. Many corporate bonds and loans do not trade every day, every week, or sometimes even every month. This also means that pricing data is suspect and that it can be harder to execute any recommendations. Additionally, the liquidity varies among the corporate credit asset classes, and these differences in trading liquidity can send false signals about volatility as a measure of risk. If an asset is seeing less price movement simply because it is not trading, does that really make it less risky? It adds another dimension of difficulty in comparing these asset classes within corporate credit.

In addition to all these hurdles outlined above, corporate credit is different than other fixed income markets because in some ways it is so similar to the equity market. Performance can be impacted by how an individual company performs, what corporate actions they take, and what is happening within an industry. The further you move down the credit spectrum, the less sensitive the corporate debt market is to macro factors and the more sensitive it is to corporate actions and industry trends. So along with all the unique fixed income features that have to be factored into analysis, tools from the equity market must be applied as well.

The turnover of the constituents in corporate credit markets is fairly high. Given the maturity schedule, call options, and corporate actions, there is a fairly active natural flow of entry and exit of constituents in these markets. This can lead to fairly dramatic changes in the characteristic of the markets over time.

9. Some investment-grade bonds are also issued with a pick-up in the stated interest rate if the bonds get downgraded to below investment grade.

A market's exposure to industries and weightings by rating categories can shift meaningfully. In some markets, like high-yield bonds, it can make longer-term time-series analysis very misleading because the characteristics of the market have changed so much over time.

The differences between the asset classes within the credit markets also present challenges and opportunities, particularly for multi-asset credit managers. The difficulty in comparing data on volatility and in using long-term time-series data was outlined above. Additionally, there are difficulties in analyzing relative value between nonconvertible corporate bonds, loans, and convertible bonds. Each of these asset classes tends to have differences in debt ranking, coupon structures, maturity, and embedded options. Each of these markets also tends to be dominated by different industries and corporate ownership structures. This can make cross-asset analysis more difficult, but it also can allow for asset class rotations and thematic investing and can give a multi-asset credit strategy more flexibility to capture better performance in a more varied set of circumstances.

ORGANIZATION AND PLANNING

Designing, building, and integrating data science systems into a credit-focused investment management business requires many things to be successful, not the least of which is a thorough plan and buy-in from many parties within the firm.

The first step is to be clear on your investment identities and style. How your investment strategy and its goals are defined is likely to drive your prioritization and plan. While an investment manager is likely to have one overriding ethos, they may have several strategies or styles. There is no problem with that, but to get the best and most expandable system, those involved in the plan need to have a clear definition of all these styles.

There also has to be open and thoughtful discussion of where the overall business is likely to be in the next three to five years. If certain businesses, styles, or markets are expected to grow and others are not, that may be a factor in how systems are designed and prioritized.

There needs to be a clear definition of the problems you want to address. The firm also needs to determine if the investment in fixing these problems aligns with a reasonable expectation of rewards. Matching the problem with the opportunity can quicken the process of prioritizing projects. This process also has to factor in which projects are the most doable and what the longer-term goal is for the systems. For example, can one project be the building block for another? If the list of potential projects is a long one, it is often helpful to go through an iterative process of prioritization. This should not be an arbitrary decision from one person and should involve all invested parties from system designers to the front-end users.

Assessing the quality of the data you have available is critical. There are numerous questions to be addressed about the data. Is the quality of the data clean, are there gaps in it, are figures correct? Is the data in a form that is easily usable by the systems, and can it be sorted and labeled? Can the data be updated in an efficient manner, and are there sources that are able to supply real-time information for your models so they stay relevant? The decision of what data to use and how it is entered into the system is one area where bias can creep into the process and eventually show up in the analysis; this needs to be guarded against.

For developing internal data, such as credit scores and other thematic identifiers, you must have an exceptionally disciplined approach. The analysts and strategists that are working on creating the data must buy in to the approach. The data fields must be defined and be as consistent as possible across all of the bonds and loans that are entered into the system so that the data is usable. The science improves if the definitions and calculations for each of the data fields is consistent. A matrix for data calculations and entry rules can be extremely helpful in this regard. The more comprehensive the documentation the cleaner the data will be and the more repeatable the process.

A map should be made of who will be touching the systems. This means end-users, managers, risk teams, project managers, programmers, IT teams, among others. They all need to be involved in the project on a regular basis as it evolves. These types of projects do not work well when a person locks themselves in a room and comes out with a plan that they expect everyone to use. It can take longer, but projects work better if there is regular involvement and input along the way, as long as there is a clear decision process when a deadlock occurs. Quite often, it is actually the investment team that avoids involvement in the process; they focus on the markets and the portfolios and take an attitude of "show me when it is done," but then when the final project is presented they may complain that it doesn't help them and it is impractical—thus proving the adage "It is easier to criticize than create."

It may sound trivial, but a schedule of goals and a regular meeting schedule of updates and discussions with the interested parties can solve many problems. An increasingly popular management style for large projects is called Agile and involves relatively short development periods followed by collaborative meetings. This type of development style can help keep the project flexible as roadblocks develop and priorities can shift. It is also important that decisions are documented and circulated to those involved to avoid ambiguity

Deciding on how the project will be measured is a necessary part of the process. There are several aspects of measurement that need to be made clear. Time frames and deadlines are one goal. More importantly, what are the rewards that the project is expected to produce that justify the investment and how can they be measured (e.g., lowering transaction costs, more rapid generation of research updates)? Any project related to improving investment results should consider how the investment goals are measured. For example, are the portfolio returns being measured versus a benchmark or in some other way, or is the priority to have the best absolute total return or best risk-adjusted return?

Modeling and testing are vital, too, because the first technique tried may not be the best. Many data scientists will tell you that in many cases there may be multiple methods that theoretically could be used to address the same problem, and the data science team may want to model and do testing to make sure the project makes sense and they are using the best tools.

An important part of the planning is also an understanding of the expectations for the front end. In what format is the output going to be accessible and usable. It should have some flexibility, because the demands of the end-users almost always change as they actually start using the data.

To be involved in helping to plan data science projects and to use the output you do not need to know how to design and use complex algorithms, nor do you need to be a data scientist or a statistician to exploit these tools as an investor. However, understanding the basics of how they work can help you comprehend what they are capable of. It can be helpful to refresh the benefits of using regression and probability techniques and thinking about the potential for these tools given supercharged computing power. But it is also important to understand their shortcomings. While it is not necessary to become an expert, getting some rudimentary basics of how programs that data scientists commonly use for statistical analysis and AI algorithms (e.g., R and Python) can help improve your understanding of what is involved and what is possible in using data science to make better investment decisions.

All of this is not possible without having a firm-wide commitment to make the investment of money and time. It is also important that management realize it is not a onetime project; implementing data science is an ongoing and evolutionary process. Rushing a system into production that is not properly tested and checked can be damaging to a franchise.

KEY POINTS

- Data science has been utilized in corporate credit markets for some time, but the advances in computer science are creating valuable tools that can drive better investment decisions, increase efficiency, and analyze performance and risk management in ways that can improve portfolio construction.
- Data science tools tend to fall into two categories: descriptive analytics or predictive analytics; both are very valuable to improve decision-making. Both tend to have their roots in regression and probability, and their capabilities can be supercharged with AI algorithms.
- Using data science in corporate credit markets presents unique problems and opportunities. There is significant noise in the data, a lack of homogeneity among the constituents, a vast area of factors impacting performance, and a high level of difficulty to execute investment ideas.
- Defining the process improves the output. In defining goals, it is important to be sure that the cost of the problem you want to fix is balanced against expected rewards.

- Data science should improve investment decision-making. However, it cannot be accepted at face value—testing and applying common sense is key to prevent misusing output, using data that has bias, or relying on statistical conclusions achieved through randomness.
- Despite all the math that is used, investing is not an exact field. Even with advanced data techniques, the best investment models are fallible as human actions cannot always be modeled.

PART THREE

TREASURY, AGENCY, MUNICIPAL, AND CORPORATE BONDS

This page intentionally left blank

CHAPTER
SEVEN

U.S. TREASURY SECURITIES

Michael J. Fleming, Ph.D.
Vice President
Federal Reserve Bank of New York

Frank J. Fabozzi, Ph.D., CFA, CPA
Professor of Finance
EDHEC Business School

U.S. Treasury securities are direct obligations of the U.S. government issued by the Department of the Treasury. They are backed by the full faith and credit of the U.S. government and are therefore considered to be free of credit risk. Issuance to pay off maturing debt and raise needed funds has created a stock of marketable Treasury securities that totaled $16.7 trillion on December 31, 2019.[1] The creditworthiness and supply of the securities has resulted in a highly liquid, round-the-clock secondary market with high levels of trading activity and narrow bid/ask spreads.

Because of their liquidity, Treasury securities are commonly used to price and hedge positions in other fixed income securities and to speculate on the course of interest rates. The securities' creditworthiness and liquidity also makes them a widespread benchmark for risk-free rates. These same attributes make Treasury securities a key reserve asset of central banks and other financial institutions. Moreover, exemption of interest income from state and local taxes helps make the securities a popular investment asset to institutions and individuals.

As of September 30, 2019, foreign and international investors held 40% of the publicly held Treasury debt.[2] Federal Reserve Banks held an additional 13% of the debt. The remaining public debt was held by mutual funds (13%), pension

We thank Francisco Ruela for his research assistance. Michael Fleming's views expressed in this chapter are his and not necessarily those of the Federal Reserve Bank of New York or the Federal Reserve System.

1. The stock of nonmarketable Treasury securities on the same date totaled $6.5 trillion. Of this, $6.3 trillion was nonpublic debt (held in government accounts), $0.2 trillion was held by private investors in the form of U.S. savings bonds, and $0.1 trillion was held in a special series by state and local governments (Monthly Statement of the Public Debt, www.treasurydirect.gov/govt/reports/pd/mspd/mspd.htm).
2. The publicly held debt includes marketable and nonmarketable securities held in nongovernment accounts. Figures are calculated from Table OFS-2 of the *Treasury Bulletin* and the Federal Reserve's H.4.1 statistical release.

funds (7%), depository institutions (5%), state and local governments (4%), insurance companies (1%), and other investors, including individuals (17%).

In this chapter, we discuss U.S. Treasury securities. Our focus is on marketable Treasury securities.

TYPES OF SECURITIES

Treasury securities are issued as either *discount* or *coupon securities*. Discount securities pay a fixed amount at maturity, called *face value* or *par value*, with no intervening interest payments. Discount securities are so called because they are issued at a price below face value with the return to the investor being the difference between the face value and the issue price. Coupon securities are issued with a stated rate of interest, pay interest every six months (for the most part), and are redeemed at par value (or *principal value*) at maturity. Coupon securities are issued at a price close to par value with the return to the investor being primarily the coupon payments received over the security's life.

The Treasury issues securities with original maturities of one year or less as discount securities. These securities are called *Treasury bills*. The Treasury currently issues bills with original maturities of 4 weeks (1 month), 8 weeks (2 months), 13 weeks (3 months), 26 weeks (6 months), and 52 weeks (1 year) as well as cash management bills with various maturities. On December 31, 2019, Treasury bills accounted for $2.4 trillion (14%) of the $16.7 trillion in outstanding marketable Treasury securities, as shown in Exhibit 7-1.

EXHIBIT 7-1

Marketable U.S. Treasury Securities

Issue Type	Security Type	Issues	Amount Outstanding (December 31, 2019)
Treasury bills	discount	cash management, 4-week, 8-week, 13-week, 26-week, 52-week	$2,417 billion
Treasury notes	coupon	2-year, 3-year, 5-year, 7-year, 10-year	$9,929 billion
Treasury bonds	coupon	30-year	$2,379 billion
Treasury inflation-protected securities	coupon	5-year, 10-year, 30-year	$1,507 billion
Floating-rate notes	coupon	2-year	$441 billion

Source: Department of the Treasury, Monthly Statement of the Public Debt (http://www.treasurydirect.gov/govt/reports/pd/mspd/mspd.htm) for amounts outstanding.

Securities with original maturities of more than one year are issued as coupon securities. Coupon securities with original maturities of more than 1 year but not more than 10 years are called *Treasury notes*. The Treasury currently issues notes with maturities of 2 years, 3 years, 5 years, 7 years, and 10 years. On December 31, 2019, Treasury notes accounted for $9.9 trillion (60%) of the outstanding marketable Treasury securities.

Coupon securities with original maturities of more than 10 years are called *Treasury bonds*. The Treasury currently issues bonds with maturities of 20 years and 30 years. On December 31, 2019, Treasury bonds accounted for $2.4 trillion (14%) of the outstanding marketable Treasury securities. In the past, the Treasury issued callable bonds. The last callable bond was issued in 1984 and the last callable bond outstanding was called in 2009.

In January 1997, the Treasury began selling *Treasury Inflation-Protected Securities* (TIPS). The principal of these securities is adjusted for inflation using the consumer price index for urban consumers. Semi-annual interest payments are a fixed percentage of the inflation-adjusted principal, and the inflation-adjusted principal is paid at maturity. On December 31, 2019, TIPS accounted for $1.5 trillion (9%) of the outstanding marketable Treasury securities. TIPS are discussed in detail in Chapter 15.

In January 2014, the Treasury began selling *Floating Rate Notes* (FRNs). FRNs are fixed-principal securities but pay varying amounts of interest depending on the course of short-term rates. FRNs have original maturities of two years and make interest payments quarterly, with the rate based on auction rates on 13-week Treasury bills. On December 31, 2019, FRNs accounted for $441 billion (3%) of the outstanding marketable Treasury securities.

THE PRIMARY MARKET

Marketable Treasury securities are sold in the primary market through sealed-bid, *single-price* (or *uniform price*) *auctions*. Each auction is usually announced one or more days in advance by means of a Treasury Department press release. The announcement provides details of the offering, including the offering amount and the term and type of security being offered, and describes some of the auction rules and procedures.

Treasury auctions are open to all entities. Bids must be made in multiples of $100 (with a $100 minimum) and submitted to the Treasury or through an authorized financial institution. Competitive bids must be made in terms of yield and must typically be submitted by 1:00 p.m. eastern time on auction day. Noncompetitive bids must typically be submitted by noon on auction day.[3]

All noncompetitive bids from the public up to $5 million are accepted. The lowest yield (i.e., highest price) competitive bids are then accepted up to the yield

3. Bidding procedures are described in detail on the Bureau of the Public Debt's website at www.treasurydirect.gov/.

required to cover the amount offered (less the amount of noncompetitive bids). The highest yield accepted is often called the *stop-out yield*. All accepted tenders (competitive and noncompetitive) are awarded at the stop-out yield. There is no maximum acceptable yield, and the Treasury does not add to or reduce the size of the offering according to the strength of the bids.

Historically, the Treasury auctioned securities through *multiple-price* (or *discriminatory*) *auctions*. With multiple-price auctions, the Treasury still accepted the lowest-yielding bids up to the yield required to sell the amount offered (less the amount of noncompetitive bids), but accepted bids were awarded at the particular yields bid, rather than at the stop-out yield. Noncompetitive bids were awarded at the weighted-average yield of the accepted competitive bids rather than at the stop-out yield. In September 1992, the Treasury started conducting single-price auctions for the two- and five-year notes. In November 1998 the Treasury adopted the single-price method for all auctions.

Within minutes of the 1:00 p.m. auction deadline, the Treasury announces the auction results. Announced results include the stop-out yield, the associated price, and the proportion of securities awarded to those investors who bid exactly the stop-out yield. For notes and bonds, the announcement includes the coupon rate of the new security. The coupon rate is set to be that rate (in increments of 1/8 of a percent) that produces the price closest to, but not above, par when evaluated at the yield awarded to successful bidders.

Accepted bidders make payment on issue date through a Federal Reserve account or account at their financial institution, or they provide payment in full with their tender. Marketable Treasury securities are issued in book-entry form and held in the commercial book-entry system operated by the Federal Reserve Banks or in other accounts maintained by the Treasury.

Primary Dealers

While the primary market is open to all investors, the *primary government securities dealers* play a special role. Primary dealers are trading counterparties of the Federal Reserve Bank of New York in its implementation of monetary policy. Among their responsibilities, primary dealers are expected to participate consistently in open market operations conducted by the New York Fed's trading desk, provide the desk with insight into market developments, participate competitively in all Treasury auctions, and make markets for the New York Fed on behalf of its foreign official account holders. The dealers must also meet certain minimum capital requirements. The 24 primary dealers as of December 31, 2019, are listed in Exhibit 7-2.

Historically, Treasury auction rules tended to facilitate bidding by the primary dealers. In August 1991, however, Salomon Brothers Inc. admitted deliberate and repeated violations of auction rules. While the rules preclude any bidder from being awarded more than 35% of any issue, Salomon amassed significantly larger positions by making unauthorized bids on behalf of its customers. For the

five-year note auctioned on February 21, 1991, for example, Salomon bid for 105% of the issue (including two unauthorized customer bids) and was awarded 57% of the issue. Rule changes enacted later that year allowed any government securities broker or dealer to submit bids on behalf of its customers and facilitated competitive bidding by nonprimary dealers.[4]

Auction Schedule

To minimize uncertainty surrounding auctions, and thereby reduce borrowing costs, the Treasury offers securities on a regular, predictable schedule. Four-, 8-, 13-, and 26-week bills are offered weekly, and 52-week bills are offered every four weeks, as shown in Exhibit 7-3. Four- and 8-week bills are typically announced for auction on Tuesday, auctioned two days later, on Thursday, and issued the following Tuesday. Thirteen- and 26-week bills are typically announced for auction on Thursday, auctioned the following Monday, and issued the following Thursday. Fifty-two-week bills are also typically announced for auction on Thursday, auctioned the following Tuesday, and issued the following Thursday. Cash management bills are issued when required by the Treasury's short-term cash-flow needs, and not on a regular schedule.

4. For further information on the auction violations and subsequent rule changes, see the *Joint Report on the Government Securities Market*, published by the Department of the Treasury, the Securities and Exchange Commission, and the Board of Governors of the Federal Reserve System in January 1992.

EXHIBIT 7-3

Auction Schedule for U.S. Treasury Bills

Issue	Auction Frequency	Offering Amount
Cash management bill	ad hoc	$15–50 billion
4-week bill	weekly	$35–60 billion
8-week bill	weekly	$30–40 billion
13-week bill	weekly	$36–48 billion
26-week bill	weekly	$36–42 billion
52-week bill	every 4 weeks	$26–28 billion

Notes: Auction frequency and offering amount are reported for regularly issued Treasury bills as of 2019. Offering amounts exclude amounts issued to refund maturing securities of Federal Reserve Banks.

Source: Department of the Treasury.

Two-, three-, five-, and seven-year notes are offered monthly, as shown in Exhibit 7-4. Two-, five-, and seven-year notes are usually announced for auction in the second half of the month, auctioned a few days later, and issued on the last day of the month. Three-year notes are usually announced for auction in the first half of the month, auctioned a few days later, and issued on the 15th of the month.

EXHIBIT 7-4

Auction Schedule for U.S. Treasury Notes and Bonds

Issue	Auction Frequency	Offering Amount
2-year note	monthly	$40 billion
3-year note	monthly	$38 billion
5-year note	monthly	$41 billion
7-year note	monthly	$32 billion
10-year note	quarterly	$27 billion
30-year bond	quarterly	$19 billion

Notes: Auction frequency and offering amount are reported for Treasury notes and bonds as of 2019. New 10-year notes and 30-year bonds are auctioned quarterly, with additional amounts of the notes auctioned one and two months later. Offering amounts exclude amounts issued to refund maturing securities of Federal Reserve Banks.

Source: Department of the Treasury.

Ten-year notes and 30-year bonds are issued as a part of the Treasury's *quarterly refunding* in February, May, August, and November. The Treasury holds a press conference on the first Wednesday of the refunding month (or on the last Wednesday of the preceding month) at which it announces details of the upcoming auctions. The auctions then take place the following week, with issuance on the 15th of the refunding month.

While the Treasury seeks to maintain a regular issuance cycle, its borrowing needs change over time. For example, the 2007–09 financial crisis and the government's response increased the Treasury's borrowing needs, resulting in increased issuance and a rising stock of outstanding Treasury securities. As a consequence, the Treasury increased the issuance frequency of some securities, such as the three-year note (from quarterly to monthly), and reintroduced issuance of other securities, including the 52-week bill (in 2008) and the seven-year note (in 2009). More recently, Treasury introduced FRNs (in 2014) and eight-week bills (in 2018), and reintroduced 20-year bonds (in 2020).

In addition to maintaining a regular issuance cycle, the Treasury tries to maintain a stable issue size for issues of a given maturity. Public offering amounts in 2019 were $15–60 billion for bills, $27–40 billion for notes, and $19 billion for the 30-year bond. Issue sizes have also changed in recent years in response to the government's increased funding needs. Issue sizes for two-year notes, for example, rose from $26 billion in 2017 to $40 billion in 2019.

Reopenings

While the Treasury regularly offers new securities at auction, it often offers additional amounts of outstanding securities. Such additional offerings are called *reopenings*. Current Treasury practice is to reopen 10-year notes and 30-year bonds one and two months after their initial issuance. Moreover, shorter-term bills are typically fungible with previously issued and outstanding bills, so that every 13-week bill is a reopening of a previously issued 26-week bill, every fourth 26-week bill is a reopening of a 52-week bill, and every 4-week bill is a reopening of a previously issued 8-week bill. The Treasury also reopens securities on an ad hoc basis from time to time.

Buybacks

To maintain the sizes of its new issues and help manage the maturity of its debt in a time of federal budget surpluses, the Treasury launched a debt buyback program in January 2000. Under the program, the Treasury redeemed outstanding unmatured Treasury securities by purchasing them in the secondary market through reverse auctions. Buyback operations were announced one day in advance. Each announcement contained details of the operation, including the operation size, the eligible securities, and some of the operation rules and procedures.

The Treasury conducted 45 buyback operations between March 2000 and April 2002. Operation sizes ranged from $750 million par to $3 billion par, with all but three between $1 and 2 billion. The number of eligible securities in the operations ranged from 6 to 26, but was more typically in the 10 to 13 range. Eligible securities were limited to those with original maturities of 30 years, consistent with the Treasury's goal of using buybacks to prevent an increase in the average maturity of the public debt.

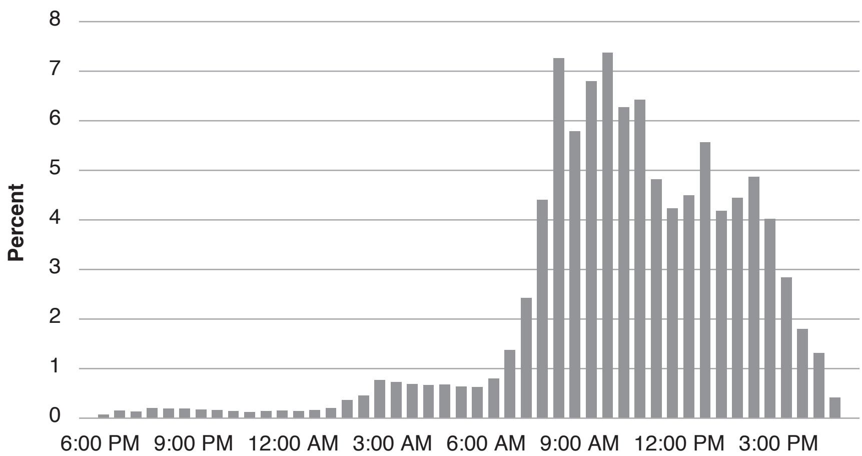
While there have been no buyback operations of meaningful size since 2002, the Treasury has held one or two small-value buyback operations per year since 2014. Such operations are intended to ensure operational readiness of Treasury's buyback infrastructure.

THE SECONDARY MARKET

Secondary trading in Treasury securities occurs in a multiple-dealer over-the-counter market rather than through an organized exchange. Trading takes place around the clock during the week, from the three main trading centers of Tokyo, London, and New York. As shown in Exhibit 7-5, the vast majority of trading takes place during New York trading hours, roughly 7:30 a.m. to 5:00 p.m. eastern time. The primary dealers are the principal market makers, buying and selling securities from customers for their own accounts at their quoted bid and ask prices. In 2019, primary dealers reported daily trading activity in the secondary market that averaged \$594 billion per day.[5]

EXHIBIT 7-5

Trading Volume of U.S. Treasury Securities by Half Hour



Notes: Average half-hourly trading volume as a percent of average daily trading volume for the on-the-run notes and bonds for the January 2010-December 2011 period. Times on the horizontal axis indicate the beginning of intervals (Eastern time).

5. Federal Reserve Bank of New York (www.newyorkfed.org/markets/primarydealers.html). As the data is collected from the primary dealers but no other entities, trades between primary dealers are counted twice, and trades between non-primary dealers are not counted at all.

Interdealer Brokers

In addition to trading with their customers, the dealers trade among themselves through *interdealer brokers*. The brokers offer the dealers and certain other financial firms proprietary trading platforms that post the best bid and offer prices of the participating firms, along with the associated quantities bid or offered (minimums are $5 million for bills and $1 million for notes and bonds). The firms execute trades by notifying the brokers (by phone or electronically), who then post the resulting trade price and size. Interdealer brokers thus facilitate information flows in the market while providing anonymity to the trading firms. In compensation for their services, the brokers charge a small fee.

The interdealer market has undergone significant structural change in recent years. Until 1999, nearly all trading in the IDB market for U.S. Treasury securities occurred over the phone via voice-assisted brokers. Voice-assisted brokers provide firms with proprietary electronic screens that post the best bid and offer prices, along with the associated quantities, but trades are executed over the phone. Brokers then post the resulting trade price and size on their screens.

In 1999, Cantor Fitzgerald introduced its fully automated eSpeed (now Nasdaq Fixed Income) electronic trading platform, whereby trades are executed electronically so that buyers are matched to sellers without human intervention. In 2000, BrokerTec, a rival electronic trading platform, began operations. Over the span of a few years, nearly all trading of the most actively traded Treasury securities migrated to these electronic platforms.[6]

Historically, participation on the electronic platforms was limited to government securities dealers. In the mid-2000s, however, the platforms opened to other professional traders, including hedge funds and high-frequency trading firms (HFTs). A 2015 study found that HFTs now account for more than half of trading activity in this segment of the market.[7]

Federal Reserve

The Federal Reserve is another important participant in the secondary market for Treasury securities by virtue of its open market operations, security holdings, and surveillance activities. The Federal Reserve Bank of New York buys and sells Treasury securities through open market operations as one of the tools used to implement the monetary policy directives of the Federal Open Market Committee

(FOMC). As of September 30, 2019, the Federal Reserve Banks held $2.1 trillion in Treasury securities, or 13% of the publicly held stock. The New York Fed also follows and analyzes the Treasury market and communicates market developments to other government agencies, including the Federal Reserve Board and the Treasury Department.

Trading Activity

While the Treasury market is extremely active and liquid, much of the activity is concentrated in a small number of the roughly 400 issues outstanding. The most recently issued securities of a given maturity, called *on-the-run securities*, are particularly active, accounting for 69% of trading volume.[8] Older issues of a given maturity are called *off-the-run securities*. While nearly all Treasury securities are off-the-run, they account for only 27% of interdealer trading.

The small share of remaining trading occurs in *when-issued securities*. When-issued securities are securities that have been announced for auction but not yet issued. When-issued trading facilitates price discovery for new issues and can serve to reduce uncertainty about bidding levels surrounding auctions. The when-issued market also enables dealers to sell securities to their customers in advance of the auctions, and thereby bid competitively with relatively little risk. While most Treasury market trades settle the following day, trades in the when-issued market settle on the issue date of the new security.

There are also notable differences in trading activity by issue type and maturity, with trading concentrating in the intermediate-term notes. The on-the-run five-year note is the single most traded Treasury security, with average daily volume of $115 billion, followed by the 10- and 2-year issues, with $93 and $52 billion in daily volume, respectively.[9] For on-the-run bills, in contrast, average daily volumes for the 4-, 13-, and 26-week issues are $9 billion, $8 billion, and $6 billion, respectively.

Quoting Conventions for Treasury Bills

The convention in the Treasury market is to quote bills on a discount rate basis. The rate on a discount basis is computed as

$$Y_d = \frac{(F - P)}{F} \times \frac{360}{t}$$

where

8. See Doug Brain, Michiel De Pooter, Dobrislav Dobrev, Michael Fleming, Peter Johansson, Frank Keane, Michael Puglia, Anthony Rodrigues, and Or Shachar, "Breaking Down TRACE Volumes Further," Federal Reserve Bank of New York *Liberty Street Economics*, November 29, 2018.

9. See Doug Brain, Michiel De Pooter, Dobrislav Dobrev, Michael Fleming, Peter Johansson, Frank Keane, Michael Puglia, Anthony Rodrigues, and Or Shachar, "Breaking Down TRACE Volumes Further," Federal Reserve Bank of New York *Liberty Street Economics*, November 29, 2018.

Y_d = the rate on a discount basis
F = the face value
P = the price
t = the number of days to maturity

For example, the 26-week bill auctioned August 1, 2019, sold at a price (P) of \$99.014167 per \$100 face value (F). At issue, the bill had 182 days to maturity (t). The rate on a discount basis is then calculated as

$$Y_d = \frac{\$100 - \$99.014167}{\$100} \times \frac{360}{182} = 1.950\%$$

Conversely, given the rate on a discount basis, the price can be computed as

$$P = F - (F \times Y_d \times \frac{t}{360})$$

For our example,

$$P = \$100 - \left(\$100 \times 1.950\% \times \frac{182}{360}\right) = \$99.014167$$

The discount rate differs from more standard return measures for two reasons: First, the measure compares the dollar return to the face value rather than to the price. Second, the return is annualized based on a 360-day year rather than a 365-day year. Nevertheless, the discount rate can be converted to a bond-equivalent yield (as discussed in Chapter 4), and such yields are often reported alongside the discount rate.

Treasury bill discount rates are typically quoted to two decimal places in the secondary market, so that a quoted discount rate might be 1.18%. For more active issues, the last digit is often split into halves, so that a quoted rate might be 1.175%.

Typical bid–ask spreads for the on-the-run bills are 1.0 basis points, as shown in Exhibit 7-6 A basis point equals one one-hundredth of a percentage point, so that quotes for a one point spread might be 1.18%/1.17%. Spreads vary with market conditions, ranging from 0.5 to about 2.5–3.0 basis points most of the time. A spread of zero (called a "locked market") can also exist in the interdealer market because of the transaction fee paid to the broker who mediates a trade. Bid–ask spreads are typically wider outside of the interdealer market and for less active issues.

Quoting Conventions for Treasury Coupon Securities

In contrast to Treasury bills, Treasury notes and bonds are quoted in the secondary market on a price basis in points where one point equals 1 percent of par.[10] The points are split into units of 32nds, so that a price of 97-14, for example,

10. Notes and bonds are quoted in yield terms in when-issued trading because coupon rates for new notes and bonds are not set until after these securities are auctioned.

EXHIBIT 7-6

Bid–Ask Spreads for U.S. Treasury Bills

Issue	Median Spread	90% Range
4-week bill	1.0 basis points	0.5–3.0 basis points
8-week bill	1.0 basis points	0.5–3.0 basis points
13-week bill	1.0 basis points	0.5–2.5 basis points
26-week bill	1.0 basis points	0.5–2.5 basis points
52-week bill	1.0 basis points	0.5–2.5 basis points

Notes: Statistics for the spread between the best bid and the best offer are reported for the on-the-run bills of each issue. Spreads are reported in discount rate terms in basis points.

Source: Authors' calculations, based on 2019 data from GovPX.

refers to a price of 97 and 14/32 or 97.4375. The 32nds are themselves split by the addition of a plus sign or a number, with a plus sign indicating that half a 32nd (or 1/64) is added to the price and a number indicating how many eighths of 32nds (or 256ths) are added to the price. A price of 97-14+ therefore refers to a price of 97 and 14.5 / 32 or 97.453125, while a price of 97-142 refers to a price of 97 and 14.25 / 32 or 97.4453125. The yield to maturity, discussed in Chapter 4, is typically reported alongside the price.

Typical bid–ask spreads in the interdealer market for the on-the-run coupon securities range from 1 / 256 point for the two-year note to 1/32 point for the 30-year bond, as shown in Exhibit 7-7. A two-year note might thus be quoted as 99-172/99-173 whereas a 30-year bond might be quoted as 95-23/95-24. As with bills, the spreads vary with market conditions, and are usually wider outside of the interdealer market and for less active issues.

EXHIBIT 7-7

Bid–Ask Spreads for U.S. Treasury Notes and Bonds

Issue	Median Spread	90% Range
2-year note	1/256 point	1/256–1/128 point
3-year note	1/128 point	1/128–1/64 point
5-year note	1/128 point	1/128–1/64 point
7-year note	1/64 point	1/64–1/32 point
10-year note	1/64 point	1/64–1/32 point
30-year bond	1/32 point	1/64–1.5/32 point

Notes: Statistics for the spread between the best bid and the best offer in the interdealer broker market are reported for the on-the-run notes and bonds of each issue. Spreads are reported in price terms in points.

Source: Authors' calculations, based on 2019 data from BrokerTec.

ZERO-COUPON TREASURY SECURITIES

Zero-coupon Treasury securities are created from existing Treasury notes and bonds through coupon stripping (the Treasury does not issue them). Coupon stripping is the process of separating the coupon payments of a security from the principal and from one another. After stripping, each piece of the original security can trade by itself, entitling its holder to a particular payment on a particular date. A newly issued 10-year Treasury note, for example, can be split into its 20 semi-annual coupon payments (called *coupon strips*) and its principal payment (called the *principal strip*), resulting in 21 individual securities. As the components of stripped Treasury securities consist of single payments (with no intermediate coupon payments), they are often referred to as zero coupons or zeros, as well as strips.

As they make no intermediate payments, zeros sell at discounts to their face value, and frequently at deep discounts due to their oftentimes long maturities. On December 4, 2019, for example, the closing price for the November 2049 principal strip was just $52.06 (per $100 face value). As zeros have known cash values at specific future dates, they enable investors to closely match their liabilities with Treasury cash flows, and are thus popular with pension funds and insurance companies. Zeros also appeal to speculators because their prices are more sensitive to changes in interest rates than coupon securities with the same maturity date.

The Treasury introduced its *Separate Trading of Registered Interest and Principal Securities* (STRIPS) program in February 1985 to improve the liquidity of the zero-coupon market. The program allows the individual components of eligible Treasury securities to be held separately in the Federal Reserve's book-entry system. Institutions with book-entry accounts can request that a security be stripped into its separate components by sending instructions to a Federal Reserve Bank. Each stripped component receives its own CUSIP (or identification) number and can then be traded and registered separately. The components of stripped Treasury securities remain direct obligations of the U.S. government. The STRIPS program was originally limited to new coupon security issues with maturities of 10 years or longer, but was expanded to include all new coupon issues in September 1997.

Since May 1987, the Treasury has also allowed the components of a stripped Treasury security to be reassembled into their fully constituted form. An institution with a book-entry account assembles the principal component and all remaining interest components of a given security and then sends instructions to a Federal Reserve Bank requesting the reconstitution.

As of December 31, 2019, $331 billion of Treasury notes and bonds were held in stripped form, representing about 3% of the $12.3 trillion in notes and bonds outstanding.[11] There is wide variation across issue types and across issues

11. Figures are from Table V of the Treasury's Monthly Statement of the Public Debt (www.treasurydirect.gov/govt/reports/pd/mspd/mspd.htm).

of a particular type in the rate of stripping. As of December 31, 2019, roughly 14% of bonds were stripped but only 0.1% of notes were stripped. Among individual bond issues, the proportion stripped ranged from 1% to 32%. On a flow basis, securities were stripped at a rate of $27 billion per month in the last quarter of 2019, and reconstituted at a rate of $21 billion per month.

KEY POINTS

- U.S. Treasury securities are debt obligations of the U.S. government issued by the Department of the Treasury.
- Marketable Treasury securities are sold in the primary market through sealed-bid, single-price (or uniform price) auctions.
- Treasury securities are issued as either discount securities (bills) or coupon securities (notes, bonds, TIPS, and FRNs) and are issued as either fixed-principal or inflation-protected securities.
- Secondary trading in Treasury securities occurs in a multiple-dealer over-the-counter market rather than through an organized exchange.
- Treasury securities trade in a highly liquid secondary market, and are used by market participants as a pricing and hedging instrument, risk-free benchmark, reserve asset, and investment asset.
- Zero-coupon Treasury securities are created from existing Treasury notes and bonds through the Treasury's Separate Trading of Registered Interest and Principal Securities (STRIPS) program. Coupon stripping is the process of separating the coupon payments of a security from the principal and from one another.

CHAPTER

EIGHT

AGENCY DEBT SECURITIES

Mark Cabana
Head of U.S. Rates Strategy
BofA Securities

Agency debt securities are direct obligations of federal government agencies or government-sponsored enterprises. Federal agencies are entities of the U.S. government, such as the Tennessee Valley Authority (TVA). Government-sponsored enterprises (GSEs) are designed as publicly chartered but privately owned and operated entities, such as the Federal National Mortgage Association (Fannie Mae), the Federal Home Loan Mortgage Corporation (Freddie Mac), the Federal Home Loan Banks (FHLB), and the Farm Credit Banks. Technically, GSEs are instrumentalities of the government that exempt them from certain management laws and regulations that would be applicable to other direct government agencies. However, for the purposes of this chapter, GSEs will frequently be referred to as agencies.

Agency debt securities typically are not backed by the full faith and credit of the U.S. government, as is the case with Treasury securities. Agency debt securities are not considered to be risk-free instruments and trade with some credit risk. Nevertheless, agency debt securities have traditionally been considered to be of strong credit quality due to the fundamentals of their underlying businesses and because of their government affiliation.

AGENCY DEBT MARKET OVERVIEW

The market for agency debt securities expanded rapidly during the 1990s, primarily due to increased issuance from housing-related agencies (including Fannie Mae, Freddie Mac, and the FHLB) as they grew their retained portfolios and mortgage-related businesses. The agency debt market has declined off its peak totals to nearly $2 trillion by the second quarter of 2020 largely due to limitations imposed on some housing-related GSEs in the wake of the 2008 financial crisis. See Exhibits 8-1 and 8-2.

Mark Cabana's views expressed in this chapter are his and not necessarily those of Bank of America. Mark would like to thank Ralph Axel, Greg Ingrassia, and Scott Stelmach for very helpful comments and Olivia Lima for data assistance.

Credit Quality of Agency Securities

There is a perception among some market participants that the government implicitly backs agency issues and would be reluctant to let an agency default on its obligations. However, there is no explicit government guarantee for most agency securities and the extent of government backing for agency securities is a source of uncertainty for some investors.

Agency securities are perceived to have a government backing due to their legal characteristics and affiliation with the U.S. government. Agencies are granted authority to issue debt from Congress and many have directors that are appointed by the President of the United States. In addition, most agencies have the authority to borrow directly from the Treasury and some agencies have received direct Treasury financing. Many agency securities are also eligible for standard Federal Reserve open market operations.

Despite their relation to the government, agency securities have historically traded at a slight discount to Treasury securities. The pricing difference between agency and Treasury securities has depended partially on the strength of each agency's underlying business, the perceived strength of their government backing, and the liquidity difference between agencies and Treasuries.

Conservatorship and Credit Quality

Fannie Mae and Freddie Mac were placed in a conservatorship run by the Federal Housing Finance Agency (FHFA) in September 2008. Through the conservatorship, the U.S. Treasury Department and the FHFA established Preferred Stock Purchase Agreements (PSPA). The PSPAs were designed to ensure that Fannie Mae and Freddie Mac (1) provide stability to the financial markets, (2) prevent disruptions in the availability of mortgage finance, and (3) protect the taxpayer. The PSPAs have modified over time and there is an expectation these agencies will eventually be removed from conservatorship.

Even after Fannie Mae and Freddie Mac entered conservatorship in September 2008 the government did not provide an explicit guarantee covering their outstanding debentures, but rather increased direct support to each enterprise. This step strengthened government backing for Fannie Mae and Freddie Mac but did not allay investor concerns sufficient to stop their debt spreads from widening during periods of market stress. In 2008 it took nearly $170 billion in direct purchases from the Federal Reserve to contain sharp spread widening stemming from the financial crisis.

Agency Debt Investors

A variety of market participants invest in agency debt. Many investors are attracted to the relatively high credit quality of agency debt, which offers a slightly higher return when compared with Treasury securities while offering the perception of only modestly more credit risk. In addition, agency issues are also attractive to investors because interest income is exempt from state and local taxation for some issuers (including FHLB and Farm Credit Banks).

The composition of agency debt investors largely depends on the tenor of the debt maturity, though asset managers comprise the largest ownership segment of agency debt. For short-term debt that matures in 12 months or less, investment managers and money market mutual funds are the largest holders. For longer-dated debt outstanding, the largest ownership segments tend to include fund managers, central banks, state and local governments, commercial banks, and pension/insurance funds.

TYPES OF AGENCY DEBT SECURITIES

Agency debt securities are issued in a variety of maturities and types to help manage their business financing needs, mitigate interest-rate risk, and expand their respective investor bases.

Short-Dated Agency Securities

Agencies frequently issue securities with relatively short-term tenors of less than one year, often referred to as discount notes. Discount notes are issued at a discount from par with maturities ranging from 1 to 365 days and are priced similar to Treasury bills. Some of the agencies offer regular and predictable discount note supply through established programs with standard announcement and offering dates, including the Federal Home Loan Bank's discount note auctions. Other discount notes issued by the agencies are offered through reverse inquiries from investors.

Longer-Dated Agency Securities

Agencies also offer a wide variety of longer-dated securities with maturities of between 1 and 30 years. Most agency debt is U.S. dollar denominated, although some agencies have issued debt denominated in foreign currencies. Some longer-dated issues are large in size with fixed-rate coupon offerings issued through established programs, such the Federal Home Loan Bank's Global Debt program, Fannie Mae's Benchmark Notes program, and Freddie Mac's Reference Notes program. These programs were established in the late 1990s to create more regular and standardized types of debt with greater liquidity. The programs were also intended to produce a yield-curve for liquid agency securities and thereby appeal to investors that might otherwise purchase Treasury securities. These fixed-rate coupon offerings typically have semiannual coupon payments with principal redeemed only at the security's stated final maturity date.

In addition to these programs, agencies also offer smaller longer-dated securities with a variety of characteristics that are frequently referred to as medium-term notes. In the past, agencies have offered medium-term notes with a variety of characteristics, including senior and subordinated hierarchies; callable and putable structures; denominations in U.S. dollars or in other currencies; fixed-rate, floating-rate, indexed, and zero coupons. Some agencies also offer variations on fixed-rate callable securities called "step-up notes," in which the issuer will generally have the choice to call a security on a specific date; if it is not called then the investor's interest rate increases or "steps up." In addition, the FHLB Office of Finance offers a TAP issuance program, in which it issues fixed-rate securities at longer-dated maturities and has the option to continually reopen a security for a three-month period based upon investor demand. Some of these longer-dated security types are discussed in greater detail later in this chapter.

Most longer-dated agency securities generally make semiannual coupon payments and are priced similar to Treasury notes, depending on their various characteristics. Some longer-dated agency securities are also eligible for stripping into principal and interest components through the Federal Reserve Book Entry System.

Agencies also tie their floating-rate notes to a number of different indices, including LIBOR, SOFR, fed funds, Treasury bills, or the prime rate. The agencies have been the most active issuer of SOFR-related floating-rate notes and are widely seen as the most proactive adopter of SOFR-related liabilities. At the end of 2019, the agencies had a little over $200 billion of SOFR floating-rate debt outstanding and comprised 77% of all SOFR-related floating-rate debt outstanding. FHLB has the largest amount of SOFR-linked FRNs outstanding, followed by Fannie Mae and Freddie Mac (see Exhibits 8-3 and 8-4).

Callable Securities and Other Tools to Mitigate Interest-Rate Risk

Agencies issue a wide variety of longer-dated securities to better manage the interest-rate and cash-flow risk inherent in their businesses, especially as some relate to securitizing mortgages and purchasing mortgage-backed securities. One of the most notable risks for housing-related GSEs is the unpredictable nature of mortgage prepayment speeds, given that mortgage prepayments tend to vary with the interest-rate environment. Specifically, mortgage prepayment speeds tend to increase in a declining interest-rate environment and decrease in a rising rate environment.

Housing-related agencies partially mitigate this risk by issuing callable debt securities, which have somewhat similar characteristics to mortgage-backed securities. The duration of mortgage-backed and callable debt tends to shorten as interest rates decline due to the increased likelihood that the call options inherent in these structures will be exercised by the mortgage owner or callable debt issuer. By issuing callable debt, GSEs effectively purchase a call option from an investor and compensate the investor by issuing the security at a slightly higher yield when compared to similar noncallable securities.

Callable securities generally have three main characteristics: the maturity date, the lockout period, and the type of call feature. The maturity date is somewhat similar to a noncallable security, which is the latest date on which the security will be retired and principal redeemed assuming the security is not called. The lockout period refers to the amount of time over which a callable security cannot be called by the issuer. For example, a "3 non-call 1-year security" cannot be called for the first year but may be callable at a specific time over the remainder of the security's total three-year life. The call feature is generally one of three types: European-style, in which the call option can only be exercised on a single day at the end of the initial lockout period; Bermudan-style, in which the call option can be exercised on coupon payment dates after the conclusion of the initial lockout period; and, American-style, in which the call option can be exercised at any point after the initial lockout period.

In addition to callable securities, housing-related GSEs also utilize a variety of other tools to help mitigate interest-rate risk, including interest-rate derivatives such as swaps and swaptions. Callable debt and interest-rate derivatives are an important part of housing-related GSE risk management strategies, which have also allowed some GSEs to expand their investor base.

THE PRIMARY MARKET

The agencies use a variety of methods to distribute their securities, including competitive dealer bidding through auctions, issuance allocation to dealers, sales to investors through dealers, and direct sales to investors. The method may differ based on the issuer and the type of debt being offered.

Agencies have a variety of ways to issue short-dated securities, although most offerings are executed through regular discount note auctions or reverse inquiry sales. Housing-related agencies offer programs that provide a regular and predictable supply of short-dated securities to the market through weekly discount note announcements and auctions. Auctions are underwritten by a predetermined group of dealers who participate in the auctions through issuance platforms specific to each of the housing-related agencies. Depending on the agency, these discount note offerings may be conducted through single- or multiple-price auctions.

Agencies also provide discount notes through reverse inquiry offers. In this process, an agency will post rates daily to the public or investor community at which they are willing to issue discount securities. These rates are sometimes referred to as window rates. Dealers will then assist investors in making offers to the issuing agency for a specific amount and tenor near the applicable rate. This process is attractive for both the agency issuer and investor as it allows for a broader range of participants to finance the agencies at short-dated tenors that best meet their investment objectives. However, discount notes issued through the reverse inquiry or window offering process may have nonstandard maturity dates and limited sizes outstanding, which can hinder secondary market liquidity should they be sold by the original investor.

For longer-dated securities, agencies will also use a variety of methods, including syndicated offerings, reopening auctions, or reverse inquiry sales. A common distribution mechanism for agency debt securities is to allocate them among members of a selling group or syndicate of dealers. The syndicate provides market and trading information to the issuing agency before and during the allocation and may support secondary trading in the issue after allocation. In compensation for their services, the syndicate members are offered a concession in the offering or they are able to retain a percentage of the proceeds from the sold securities.

The syndication process is used by some agencies to issue callable and standard fixed-rate coupon offerings. Syndications are most frequently used to issue large fixed-rate coupon offerings such as those issues through the Federal Home Loan Bank's Global Debt program, Fannie Mae's Benchmark Notes program, and Freddie Mac's Reference Notes program. To organize the issuance process among these programs, the U.S. Treasury Department in coordination with the FHFA and the housing-related agencies establish a monthly issuance calendar in which each agency has predetermined days on which it can offer large fixed-rate coupon offerings to investors. The agencies can choose to offer securities on their respective date or pass and wait until their next scheduled issuance date. This monthly calendar coordination ensures that each housing-related agency has the potential to offer coupon securities in relatively large size without interfering with the issuance plans of any other agency. Of note, on these scheduled offering dates, the agencies can also choose to reopen previously issued securities through these established programs. The agencies generally manage the reopening auctions through their internal systems and do not require a dealer syndicate for this process.

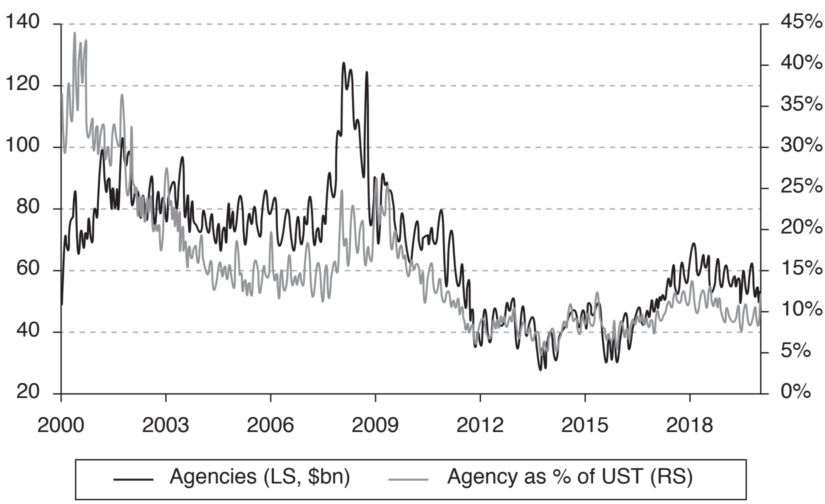
Similar to discount notes, agencies also issue medium-term notes through a reverse inquiry process. Some dealers will post or send daily rates for a variety of security types to underwriting dealers, who then assist investors in making offers to the issuing agency. Agencies frequently issue callable securities through the reverse inquiry process and are able to entertain a wide variety of callable structure reverse inquiries simultaneously, including those with European, American, and Bermudan call options. Agencies will also consider a wide variety of other debt structures through the reverse inquiry process. On any given day, agencies can issue longer-term securities with a variety of different maturities, coupon types, and call features through this process.

THE SECONDARY MARKET

Like Treasury securities, agency securities trade in a multiple-dealer over-the-counter secondary market. Also like Treasury securities, trading among dealers is screen-based, through interdealer brokers. Trading volume is significantly lower than that in the Treasury market, but it is still reasonably high relative to other fixed income markets. Primary dealer trading volumes in agency debt securities averaged 9.5% of U.S. Treasury daily trading volumes from 2010 to 2020 (see Exhibit 8-5).

EXHIBIT 8-5

Agency Debt Trading Volume



Source: Created with data obtained from Federal Reserve.

Secondary market trading activity is also concentrated in agency securities in discount notes. From 2010 to 2020, discount notes averaged 81% of daily primary dealer trading volumes versus longer-term agency securities, which averaged only 19% of such volume. During 2019, daily trading by primary dealers averaged $56 billion per day, with $47 billion in discount notes and $9 billion in longer-dated securities.

AGENCY DEBT ISSUANCE

The quantity of agency debt securities sold in the primary market increased through most of the 1990s and 2000s but has slowly declined since 2008. Agency debt outstanding peaked in 2008 at $3.2 trillion and was only $1.8 trillion at the end of 2019 (see Exhibit 8-1). The decline in agency debt outstanding is related to the conservatorship of Fannie Mae and Freddie Mac, which limits their aggregate indebtedness and required their retained portfolios to decline over time.

Housing-related agencies are the largest issuers of agency debt and total over 80% of all agency-related debt outstanding, including the Federal Home Loan Bank, Freddie Mac, and Fannie Mae. Agency debt outstanding from these three entities totals nearly $1.5 trillion. The FHLB has the largest share of agency debt outstanding at over $1 trillion. The second largest single agency issuer is now Farm Credit and their debt outstanding exceeded that of Fannie Mae and Freddie Mac by the end of 2018.

ISSUING AGENCIES

As mentioned previously, agency securities are direct obligations of federal agencies or GSEs. Federal agencies are entities of the federal government. They include the Export-Import Bank of the United States, the Federal Housing Administration, the Government National Mortgage Association (Ginnie Mae), the TVA, and the Small Business Administration. Historically, a number of federal agencies issued their own debt securities. The TVA still issues its own debt securities and accounts for nearly all the outstanding debt issued directly by federal agencies.

GSEs are privately owned and operated entities chartered by Congress to work toward public policy goals and decrease the cost of funding for certain sectors of the economy. The GSEs are granted certain privileges to help them achieve their public purposes and, in turn, are limited to certain activities. As mentioned, agency debt securities are thought to have an implicit government guarantee and agency security interest income is exempt from state and local taxation for some issuers. The agencies themselves are exempt from state and local income taxes and are also exempt from Securities and Exchange Commission (SEC) registration fees.

The largest GSEs were chartered to provide credit to the housing sector including Fannie Mae, Freddie Mac, and the FHLB. Another set of GSEs was established to provide credit to the agricultural sector, including the Farm Credit Banks, the Farm Credit System Financial Assistance Corporation, and the Federal Agricultural Mortgage Corporation (Farmer Mac).

There are also older GSEs with debt outstanding and other GSEs that have recently been privatized. The Financing Corporation and the Resolution Funding Corporation are GSEs that were established to recapitalize the savings and loan. Another older GSE, the Student Loan Marketing Association (Sallie Mae), was wholly privatized at the end of 2004.

In addition to the agencies and GSEs, there have been some government initiatives that explicitly back types of fixed income securities for public policy purposes. The Temporary Liquidity Guarantee Program (TLGP) was established during the 2008 financial crisis, through which the Federal Deposit Insurance Company (FDIC) guaranteed senior unsecured debt of insured depository institutions issued between October 14, 2008, and June 30, 2009.

The remainder of this section provides a brief overview of each of the agencies, GSEs, and government-backed initiatives that have debt securities outstanding or were recently wound-down. This information is also summarized in Exhibit 8-6.

EXHIBIT 8-6

Summary of Agencies and GSEs

Agency	Purpose	Debt Outstanding ($bn)
FHLB	Provide financial products and services to members and housing associates	1026
Farm Credit	Support rural communities and agriculture with reliable, consistent credit and financial services	294
Freddie Mac	Provide liquidity, stability, and affordability to the U.S. housing market	283
Fannie Mae	Provide liquidity, stability, and affordability to the U.S. housing market	182
TVA	Promote development of Tennessee River and adjacent areas	22
Farmer Mac	Increase the availability and affordability of credit for the benefit of American agriculture and rural communities	19

Source: Created with data obtained from GSE reports.

LARGE, ACTIVE ISSUERS

The largest active issuer today is the Federal Home Loan Bank system. Fannie Mae, Freddie Mac, and the Farm Credit System comprise the next three largest issuers of agency debt.

Federal Home Loan Bank System

The FHLB system was established as a GSE in 1932 to increase credit access for the housing sector by supporting residential mortgage lending and related community investment through its member financial institutions. The FHLB system is composed of 11 regional banks that are privately capitalized and owned as cooperatives by their members. FHLBs provide access to low-cost funding to nearly 7,000 banks, credit unions, insurance companies, and community development financial institutions. FHLBs provide liquidity by raising funds in the global financial markets and then lend that money in the form of "advances" or loans to their member banks and local communities.

The FHFA regulates the FHLB system for mission, as well as safety and soundness issues. Unlike Fannie Mae and Freddie Mac, none of the 11 regional FHLB are in conservatorship.

FHLB debt issuance is conducted through the system's fiscal agent, the Office of Finance. The FHLB Office of Finance sells a variety of debt securities, including discount notes and medium-term notes. Bonds and discount notes issued by the FHLBs are called consolidated obligations. Although each FHLB is primarily liable for its portion of consolidated obligations, each FHLB is also jointly and severally liable with the other FHLBs for the payment of principal and interest on all consolidated obligations.

The FHLBs issue discount notes in maturities ranging from one day to one year, and bonds with maturities of three months to 30 years. The majority of issues are between one and five years. Issue size can range from $10 million to several billion dollars. FHLB debt is sold through a broad, international network of underwriters. Discount notes are offered at fixed tenors of 4, 8, 13, and 26 but can also be offered on reverse inquiry through their discount note window. Consolidated bonds are issued with either fixed-rate coupon payment terms or variable-rate coupon payment terms and can be issued and distributed through directly negotiated or auction formats.

As of year-end 2019, the FHLB Office of Finance had just over $1 trillion in consolidated obligations outstanding. Discount notes outstanding were $404 billion and consolidated bonds outstanding were $622 billion.

Federal National Mortgage Association (Fannie Mae)

Fannie Mae was established in 1938 to develop a secondary market for residential mortgages and was chartered by Congress in 1968 as a private stockholder-owned corporation. Fannie Mae buys home loans from banks and other mortgage lenders in the primary market and holds the mortgages until they mature or issues securities backed by pools of the mortgages. FHFA also regulates Fannie Mae. On September 6, 2008, the Director of the FHFA was appointed conservator of Fannie Mae, at which time the GSE also established the PSPA with the U.S. Treasury Department to ensure the enterprise will maintain a positive net worth.

To finance their businesses, Fannie Mae issues a variety of securities, including discount notes and medium-term notes. Fannie Mae offers benchmark bills with maturities of one year or less that may be auctioned on a weekly basis. Their benchmark note program follows a specific calendar when the issues can be offered typically once or twice a month.

At year-end 2019, Fannie Mae had $182 billion of debt outstanding. Of this debt $27 billion was in short-term debt, $47 billion was in long-term debt maturing within one year, and $108 billion was in longer-term debt beyond one year. Under Fannie Mae's conservatorship their aggregate indebtedness is fixed at $300 billion.

Federal Home Loan Mortgage Corporation (Freddie Mac)

Freddie Mac is a stockholder-owned corporation chartered in 1970 to expand opportunities for homeownership and improve the liquidity of the secondary mortgage market. Freddie Mac purchases mortgage loans from individual lenders and sells securities backed by the mortgages to investors or holds the mortgages until they mature.

FHFA also regulates Freddie Mac. Similar to Fannie Mae, Freddie Mac entered conservatorship overseen by the FHFA in September 2008 and has a PSPA with the U.S. Treasury Department. Under Fannie Mae's conservatorship their aggregate indebtedness is fixed at $300 billion.

Freddie Mac issues a variety of debt securities, including discount notes and medium-term notes. Discount note maturities may range from overnight through one year and are supplemented with reference bills that are auctioned on a predetermined calendar. Medium-term notes are issued in a variety of fixed-rate and variable-rate medium-term notes, including callable and noncallable securities, and zero-coupon securities, with various maturities via an underwriting syndicate of dealers following a yearly issuance calendar.

Freddie Mac had $283 billion of total debt outstanding as of year-end 2019. Of this debt $61 billion was in discount notes, $50 billion was in long-term debt maturing within one year, and $172 billion was in longer-term debt beyond one year.

The Farm Credit System

The Farm Credit System (FCS) is a GSE, established in 1916 to provide credit to the agricultural sector. Farm Credit is a nationwide network of 72 customer-owned financial institutions. Products and services offered by FCS institutions include real estate loans, operating loans, rural home mortgage loans, crop insurance, and various financial services. The FCS and the system's fiscal entity are regulated by the Farm Credit Administration.

The Federal Farm Credit Banks Funding Corporation is the system's fiscal entity, providing funds to system institutions through the issuance of debt securities. The FCS issues discount notes, fixed-rate callable and noncallable securities, and floating-rate notes. In addition, FCS also issues Designated Bonds, which are large, liquid callable and noncallable issues. These bonds are issued through a dealer syndicate and can have 2- to 10-year original maturities.

As of year-end 2019, FCS had $294 billion of debt outstanding. This included $19 billion in discount notes and the remainder in fixed-rate, floating, and designated bonds.

SMALLER, ACTIVE ISSUERS

The Federal Agricultural Mortgage Corporation, and the Tennessee Valley Authority are two other smaller, active issuers.

Federal Agricultural Mortgage Corporation (Farmer Mac)

Farmer Mac is a stockholder-owned corporation chartered in 1988 to promote a liquid secondary market for agricultural real estate and rural housing loans. It does this by buying qualified loans from lenders and grouping the loans into pools against which it issues securities. Farmer Mac thus performs a role for the agricultural mortgage market similar to that performed by Fannie Mae and Freddie Mac for the residential mortgage market. Farmer Mac issues discount notes and medium-term notes, including callable and noncallable securities. As of year-end 2019, Farmer Mac outstanding debt totaled $19 billion with $10 billion in maturities less than one year and $9 billion in tenors greater than one year.

Tennessee Valley Authority

The TVA is a government-owned corporation established in 1933 to promote development of the Tennessee River and adjacent areas. The TVA manages the river system for flood control, navigation, power generation, and other purposes and is the nation's largest public power company.

The TVA issues discount notes as well as longer-term coupon securities, called Power Bonds. Interest and principal on Power Bonds are paid from the proceeds of TVA's power program. TVA outstanding debt included $895 million in short-term debt and over $20 billion in long-term debt as of year-end 2019.

NONACTIVE ISSUERS AND RECENTLY RETIRED GSES

In addition to the issuers discussed above, there are issues outstanding and traded in the market from entities that were previously GSEs and those that are not currently active in the issuance market.

Resolution Funding Corporation

The Resolution Funding Corporation (REFCorp) was established in 1989 as the funding arm of the Resolution Trust Corporation to finance the recapitalization of the savings and loan industry. REFCorp issued $30 billion in debt securities between 1989 and 1991. Interest payments on REFCorp bonds are guaranteed by the U.S. government, and the principal is protected by the purchase of zero-coupon bonds with a face value equal to those of REFCorp bonds. The full $30 billion in issued debt securities was outstanding near the end of 2019.

Financing Corporation

The Financing Corporation (FICO) was established in 1987 to finance the recapitalization of the Federal Savings and Loan Insurance Corporation (FSLIC). Between 1987 and 1989, FICO issued debt obligations with an aggregate principal value of $8.2 billion. Toward the end of 1991, FICO's authority to issue new debt was terminated. The FHLB system provided FICO with initial capital to purchase zero-coupon Treasury securities in order to repay their principal. FICO interest payments are funded by an assessment on FDIC-insured institutions.

FCS Financial Assistance Corporation

The Farm Credit Financial Assistance Corporation was chartered in 1988 to finance the recapitalization of FCS institutions. Between 1988 and 1990, the corporation raised $1.3 billion through the issuance of debt securities, which it provided to system institutions in return for preferred stock. Unlike most GSEs, the debt securities of this corporation were fully guaranteed by the U.S. Treasury. All debt issuance by the corporation has been called or matured, with the last bond maturing in June 2005. The Financial Assistance Corporation's charter was canceled by the FCA as of December 31, 2006.

Student Loan Marketing Association

The Student Loan Marketing Association (Sallie Mae) was a stockholder-owned corporation established in 1972 to increase the availability of student loans. As a GSE, Sallie Mae purchased insured student loans from lenders and made loans to lenders secured by student loans. Sallie Mae was reorganized in 1997 in a step toward privatization and was fully privatized at the end of 2004. As a GSE, Sallie

Mae issued discount notes, medium-term notes, and other debt securities, but no longer has any GSE-related debt outstanding. Sallie Mae was replaced by a publicly held, private sector financial services company named SLM Corporation, which specializes in financing education.

Treasury Liquidity Guarantee Program

The Treasury Liquidity Guarantee Program (TLGP) was announced on October 14, 2008, as an initiative to counter systemic risks in the financial sector by ensuring that financial institutions would be able to roll over maturing wholesale debt. Through the TLGP, the FDIC provided guarantees for a limited amount of newly issued senior unsecured debt of insured depository institutions, most U.S. bank holding companies, and one large nonbank finance company. Debt issued through the TLGP is backed by the full faith and credit of the U.S. government.

Issuers in the TLGP were required to pay a fee to the FDIC that was based on the maturity of the debt and the type of institution that was issuing it. Each participating financial institution was limited to a maximum amount of guaranteed debt that it could issue based on the amount of senior unsecured debt scheduled to expire over a set time period. Guarantees for TLGP-backed senior unsecured debt originally applied to issuance by June 30, 2009, for maturities before June 30, 2012. However, this was extended to issuance by October 31, 2009, for maturities before December 31, 2012.

Issuance through the TLGP was elevated at the start of the program when other forms of corporate debt issuance were limited. During the first six months of the TLGP program $346 billion in term debt was issued from applicable institutions. However, as corporate credit markets improved, credit availability increased, and the FDIC encouraged firms to return to private funding markets, TLGP issuance and amounts outstanding declined. There is limited to no TLGP debt outstanding today.

KEY POINTS

- Agency securities are direct obligations of federal government agencies or GSEs. Agency securities have historically been viewed as having limited credit risk, although they are not risk-free and have at times traded with a notable discount to Treasury securities.
- Agency security issuance and amount outstanding grew in the early 2000s but has declined in recent years due to restrictions from the conservatorship of Fannie Mae and Freddie Mac.
- Federal agencies and GSEs issue a wide variety of debt securities, including discount note securities at tenors less than one year and medium-term notes with numerous structures at maturities greater than one year.

- Agencies use a variety of methods to distribute their securities, including competitive dealer bidding through auctions, issuance allocation to dealers, sales to investors through dealers, and direct sales to investors.
- The vast majority of agency debt issued (mostly concentrated in discount notes) and traded is from the FHLB system, Fannie Mae, Freddie Mac, and Farm Credit.

CHAPTER
NINE

MUNICIPAL BONDS

Sylvan G. Feldstein, Ph.D.
Industry Consultant

Frank J. Fabozzi, Ph.D., CFA, CPA
Professor of Finance
EDHEC Business School

Douglas Gaylor

David Ratner, CFA
Industry Consultant

The U.S. bond market can be divided into two major sectors: the taxable bond market and the tax-exempt bond market. The former sector includes bonds issued by the U.S. government, U.S. government agencies and sponsored enterprises, and corporations. The tax-exempt bond market is one in which the interest from bonds that are issued and sold is exempt from federal income taxation. Interest may or may not be taxable at the state and local levels. The interest on U.S. Treasury securities is exempt from state and local taxes, but the distinction in classifying a bond as tax exempt is the tax treatment at the federal income tax level.

It should be noted that over the years some taxable municipal bonds have been issued. As an example of the largest issuance program, under the Federal Build America Bond (BABS) program, between 2009 and 2010, almost $190 billion of BABS were issued. Interest on these bonds was federally taxable and the federal government pays a portion of the interest payments to the issuer.

The Federal Reserve Board estimates that the overall size of the municipal bond market as of 2020 was $3.8 trillion. The municipal sector is certainly one of the larger components of the domestic bond market, but it is clearly different from the taxable bond market.

The majority of tax-exempt securities are issued by state and local governments and by their creations, such as "authorities" and special districts. Consequently, the terms *municipal market* and *tax-exempt market* are often used interchangeably. Although not all municipal bonds are tax-exempt securities, most are.

The major motivation for investing in tax-exempt municipal bonds is their tax advantage. The primary owners of municipal bonds are individual investors;

the remainder of the investors consists of mutual funds, commercial banks, and property and casualty insurance companies. Although certain institutional investors such as pension funds have no need for tax-advantaged investments, there have been instances in which such institutional investors have crossed into the municipal bond market to take advantage of higher yields. These investors also have purchased municipal bonds when municipal bonds were expected to outperform taxable bonds. Institutional investors who are natural purchasers of taxable bonds but at times purchase municipal debt are known as *crossover buyers*.

The industry has many new buy-side participants. In addition to the traditional bank trust departments, mutual funds, property and casualty insurance companies, and high-net-worth individuals, buyers now include hedge funds, arbitrageurs, life insurance companies, crossover buyers, and foreign banks, among other relative value buyers. There are now municipal bond exchange-traded funds (ETFs) that cater to investors. Additionally, the Tax Cuts and Jobs Act of 2017 (TCJA) reduced their holdings even more by cutting the corporate tax rate to 21% from 35%.

Traditionally, the household sector has owned the largest portion of the tax-exempt municipal bond market. Another substantial owner has been the mutual fund industry. However, examination of Federal Reserve Board data indicates that there have been three major changes among holders. First, the percentage holdings of commercial banks have dropped significantly since 1986. In general, the Tax Reform Act of 1986 reduced the benefits commercial banks received by owning municipal bonds. Commercial banks responded to this change by reducing their municipal bond holdings and investing in assets that provided greater benefits.Additionally, the Tax Cuts and Jobs Act of 2017 (TCJA) reduced their holdings even more by cutting the corporate tax rate to 21% from 35%.

Households accounted for the next ownership change. In 1990, household ownership of municipal bonds reached a peak of 49% for the 20-year period. However, by the end of September 2019, household ownership was at 46%. If commercial banks and households both decreased their holdings, then other groups had to increase their ownership. Federal Reserve Board data indicate that mutual funds, money market funds, closed-ended funds, and exchange-traded funds dramatically increased their holdings. In 1979, they held only 1% of the municipal market; by the end of September 2019, their combined share was 26.2%.

Insurance companies and personal bank trust accounts have had relatively stable ownership of municipal bonds. Insurance companies typically adjust their holdings of municipal bonds according to profitability and the relative value municipal bonds offer compared with taxable bonds. Trust accounts are relatively stable purchasers of municipal bonds. A typical trust account will purchase bonds near par, collect the tax-exempt income, and hold the bonds to maturity.

It should be noted that when municipal bond yields are attractive compared with taxable bonds, traditional bond buyers, hedge funds, and arbitrageurs are active and at times have become significant participants in the municipal market.

In the past, investing in municipal bonds was considered second in safety only to that of U.S. Treasury securities; however, there have now developed among investors ongoing concerns about the credit risks of municipal bonds. This is true regardless of whether or not the bonds are given investment-grade credit ratings by the commercial rating companies. There are several reasons for this: (1) the financial crisis of several major municipal issuers beginning with the City of New York billion-dollar financial crisis in 1975 and the bankruptcy filing in 1994 of Orange County, California; (2) the federal bankruptcy law (which became effective October 1979) that makes it easier for municipal bond issuers to seek protection from bondholders by filing for bankruptcy; (3) the proliferation of innovative financing techniques and legally untested security structures, highlighted by the default of the Washington Public Power Supply System (WPPSS) in the early 1980s; (4) the cutbacks in federal grant and aid programs that will affect the ability of certain municipal issuers to meet their obligations; and (5) fundamental changes in the American economy that may cause economic hardship for municipal issuers in some regions of the country and thus difficulty in meeting their obligations.

Beginning in December of 2007 when the latest recession began, the well-publicized bond defaults of Vallejo, California, and Harrisburg, Pennsylvania, as well as the budgetary stresses of several large states and cities, highlighted credit concerns about municipal bonds. Vallejo utilized Chapter 9 of the U.S. Bankruptcy Code to avoid paying bondholders. And Harrisburg just didn't appropriate debt service. More recently, the default of Detroit and Puerto Rico bonds added to these concerns.

FEATURES OF MUNICIPAL SECURITIES

In Chapter 1, the various features of fixed income securities were described. These include call and refunding provisions, sinking-fund provisions, and put provisions. Such provisions also can be included in municipal securities. In one type of municipal structure discussed below, a revenue bond, there is a special call feature wherein the issuer must call the entire issue if the facility is destroyed.

Coupon Features

The coupon rate on a municipal issue can be fixed throughout the life of the issue, or it can be reset periodically. When the coupon rate is reset periodically, the issue is referred to as a *floating-rate* or *variable-rate* issue. In general form, the coupon reset formula for a floating-rate issue is

$$\text{Percent of reference rate} \pm \text{spread}$$

Typically, when the reference rate is a municipal index, the coupon reset formula is

$$\text{Reference rate} \pm \text{spread}$$

Reference rates that have been used for municipal issues include the Securities Industry and Financial Markets Association (SIFMA), LIBOR, and Treasury bills.

The coupon rate on a floating-rate issue need not change in the same direction as the reference rate. There are derivative municipal bonds whose coupon rate changes in the opposite direction to the change in the reference rate. That is, if the reference rate increases from the previous coupon reset date, the coupon rate on the issue declines. Such issues are referred to as *inverse floating-rate issues.* Some municipal issues have a fixed coupon rate and are issued at a discount from their maturity value. Issues whose original-issue price is less than its maturity value are referred to as *original-issue discount bonds* (OIDs). The difference between the par value and the original-issue price represents tax-exempt interest that the investor realizes by holding the issue to maturity.

Two types of municipal issues do not distribute periodic interest to the investor. The first type is called a *zero-coupon bond.* The coupon rate is zero, and the original issue price is below the maturity value. Zero-coupon bonds are therefore OIDs. The other type of issue that does not distribute periodic interest is one in which a coupon rate is stated but the coupon is not distributed to the investor. Instead, the interest is accrued, and all interest is paid to the investor at the maturity date along with the maturity value. Later in this chapter we will discuss the important aspects an investor should be aware of when considering the purchase of OIDs in the secondary market.

Maturity Date

The maturity date is the date on which the issuer is obligated to pay the par value. Corporate issuers of debt generally schedule their bonds to mature in one or two different years in the future. Municipal issuers, on the other hand, frequently schedule their bonds to mature serially over many years. Such bonds are called *serial bonds.* It is common for a municipal issue to have 10 or more different maturities.

After the last of the serial maturities, some municipal issues lump together large sums of debt into one or two years—much the way corporate bonds are issued. These bonds, called *term bonds,* have become increasingly popular in the municipal market because active secondary markets for them can develop if the term issue is of sufficient size.

The Legal Opinion

Municipal bonds have legal opinions. The relationship of the legal opinion to the safety of municipal bonds for both general obligation and revenue bonds is threefold. First, bond counsel should check to determine if the issuer is indeed legally able to issue the bonds. Second, bond counsel is to see that the issuer has properly prepared for the bond sale by having enacted the various required ordinances, resolutions, and trust indentures and without violating any other laws and regulations. This preparation is particularly important in the highly technical areas of determining if the bond issue is qualified for tax exemption under federal law and if the issue has not been structured in such a way as to violate federal arbitrage regulations. Third, bond counsel is to certify that the security safeguards and remedies provided for the bondholders and pledged either by the bond issuer or third parties, such as banks with letter-of-credit agreements, are actually supported by federal, state, and local government laws and regulations.

The popular notion is that much of the legal work done in a bond issue is boilerplate in nature, but from the bondholder's point of view, the legal opinions and document reviews should be the ultimate security provisions. The reason is that if all else fails, the bondholder may have to go to court to enforce security rights. Therefore, the integrity and competence of the lawyers who review the documents and write the legal opinions that are usually summarized and stated in the official statements are very important.

It should be noted that by 2020, there were thousands of attorneys in the business. They were located throughout the country and listed in the *The Bond Buyer's* "Red Book" Municipal Marketplace directory of municipal bond attorneys. They presented themselves as being experts in municipal finance law and provided various security structure and tax opinions. Sorting out quality distinctions in their work and who is well grounded in the law, and who is not, is challenging.

TYPES OF MUNICIPAL OBLIGATIONS

The number of municipal bond issuers is remarkable. One estimate places the total at approximately 50,000. Even more noteworthy is the number of different issues. As of 2020, the International Exchange (ICE),[1] provides daily prices for over a million individual issues. The Bloomberg Financial Markets' (Bloomberg) database,[2] as of 2020, contained over 5 million CUSIPS (including matured bonds). Of the 941,698 CUSIP numbers still active, Bloomberg updates them on a regular basis.

The number of different issues to choose from is staggering. Considering all the different types of issuers in the market—states, state agencies, cities, airports, colleges and universities, hospitals, continuing care retirement communities (CCRCs), school districts, toll roads and bridges, public power facilities, seaport facilities, water and sewer authorities, solid waste facilities, and other special purpose districts—the investment choices are overwhelming. Some of the issuers are extremely large and issue billions of dollars of debt. Some are extremely small and may only have \$1 to \$2 million in outstanding debt. Obviously, the characteristics

1. ICE is a securities information provider that specializes in data collection and internally authored evaluations. Data are delivered electronically to financial institutions and authorized redistribution vendors. Fixed income coverage encompasses the municipal and taxable bond markets. Another pricing service is Standard & Poor's Securities Evaluation Service.

2. Bloomberg Financial Markets is a multimedia distributor of information services that combines news, data, and analysis for global financial markets and business. The company's core business is a software network that delivers real-time financial information and links the world's financial markets and financial professionals.

of these issuers and their debt are very different, and both require independent and careful analysis. However, municipal bonds can be categorized into two broad security structures. In terms of municipal bond security structures, there are basically two different types. The first type is the general obligation bond, and the second is the revenue bond.

General Obligation Bonds

General obligation bonds are debt instruments issued by states, counties, special districts, cities, towns, and school districts. They are secured by the issuer's general taxing powers. Usually, a general obligation bond is secured by the issuer's unlimited taxing power. For smaller governmental jurisdictions, such as school districts and towns, the only available unlimited taxing power is on property. For larger general obligation bond issuers, such as states and big cities, the tax revenues are more diverse and may include corporate and individual income taxes, sales taxes, and property taxes. The security pledges for these larger issuers such as states sometimes are referred to as being *full faith and credit obligations*.

Additionally, certain general obligation bonds are secured not only by the issuer's general taxing powers to create monies accumulated in the general fund, but also from certain identified fees, grants, and special charges, which provide additional revenues from outside the general fund. Such bonds are known as being *double barreled* in security because of the dual nature of the revenue sources. Also, not all general obligation bonds are secured by unlimited taxing powers. Some have pledged taxes that are limited as to revenue sources and maximum property-tax millage amounts. Such bonds are known as *limited-tax general obligation bonds*.

Revenue Bonds

The second basic type of security structure is found in a revenue bond. Such bonds are issued for either project or enterprise financings in which the bond issuers pledge to the bondholders the revenues generated by the operating projects financed. Below are examples of the specific types of revenue bonds that have been issued over the years.

Airport Revenue Bonds

The revenues securing airport revenue bonds usually come from either traffic-generated sources—such as passenger charges, landing fees, concession fees, and airline apron-use and fueling fees—or lease revenues from one or more airlines for the use of a specific facility such as a terminal or hangar.

Charter School Bonds

These bonds are for publicly funded private schools that offer more institutional and academic flexibility than local public schools. State-aid funding usually follows the student who goes from a traditional public school to a charter school. Bond proceeds go for capital improvements.

College and University Revenue Bonds

The revenues securing college and university revenue bonds usually include dormitory room rental fees, tuition payments, and sometimes the general assets of the college or university as well.

Continuing Care Retirement Community Bonds

Life care or continuing care retirement community (CCRC) bonds are issued to construct long-term residential facilities for older citizens. Revenues usually are derived from initial lump-sum payments made by the residents and operating revenues.

Higher Education Bonds

Debt is often issued by institutions of higher education to finance the costs of building/renovating facilities or purchasing land for expansion. These bonds are secured by revenues of the given project, student charges, and/or a general obligation of the college or university.

Hospital Revenue Bonds

The security for hospital revenue bonds is usually dependent on federal and state reimbursement programs (such as Medicaid and Medicare), third-party commercial payers (such as Blue Cross and private insurance), health maintenance organizations (HMOs), and individual patient payments.

Industrial Development and Pollution Control Revenue Bonds

Bonds have been issued for a variety of industrial and commercial activities that range from manufacturing plants to shopping centers. They usually are secured by payments to be made by the corporations or businesses that use the facilities.

Land-Secured "Dirt" Bonds

Public infrastructure costs associated with new development projects on raw land are often financed by land-secured bonds, also known as "dirt" bonds. Revenue from the additional tax or assessment placed on the properties benefitting from these improvements is the primary security for the bondholders.

Multifamily Revenue Bonds

These revenue bonds usually are issued for multifamily housing projects for senior citizens and low-income families. Some housing revenue bonds are secured by mortgages that are federally insured; others receive federal government operating subsidies, such as under Section 8, or interest-cost subsidies, such as under Section 236; and still others receive only local property-tax reductions as subsidies.

Public Power Revenue Bonds

Public power revenue bonds are secured by revenues to be produced from electrical operating plants and distribution systems. Some bonds are for a single issuer, who constructs and operates power plants and then sells the electricity. Other public power revenue bonds are issued by groups of public and private investor-owned utilities for the joint financing of the construction of one or more power plants. This last arrangement is known as a *joint power* financing structure. During the past several years, this sector started to undergo the most dramatic changes since electricity was invented. In many states the electric utility industry is transforming to a deregulated industry. In a deregulated environment, customers will have the ability to choose an electric provider; therefore, electric providers will face competition. This means that this sector will experience new and different challenges, and investors will need to analyze this sector differently. Additional risk factors include the different energy sources such as coal, nuclear, hydro, natural gas, and solar.

Public-Private Partnerships (PPPs)

Privatization is a form of municipal financing where a private company pays a large payment to operate, and often build or improve, a governmental asset (e.g., usually toll roads). The purchaser issues debt to help finance this large upfront cost, and the operating revenues are pledged to repay bondholders.

Resource Recovery Revenue Bonds

A resource recovery facility converts refuse (solid waste) into commercially salable energy, recoverable products, and a residue to be landfilled. The major revenues for a resource recovery revenue bond usually are (1) the "tipping fees" per ton paid by those who deliver the garbage to the facility for disposal; (2) revenues from steam, electricity, or refuse-derived fuel sold to either an electrical power company or another energy user; and (3) revenues from the sale of recoverable materials such as aluminum and steel scrap.

Seaport Revenue Bonds

The security for seaport revenue bonds can include specific lease agreements with the benefiting companies or pledged marine terminal and cargo tonnage fees.

Sewer Revenue Bonds

Revenues for sewer revenue bonds come from hookup fees and user charges. For many older sewer bond issuers, substantial portions of their construction budgets have been financed with federal grants.

Single-Family Mortgage Revenue Bonds

Single-family mortgage revenue bonds usually are secured by the mortgages and mortgage loan repayments on single-family homes. Security features vary but can include Federal Housing Administration (FHA), Federal Veterans Administration (VA), and private mortgage insurance.

Sports Complex and Convention Center Revenue Bonds

Sports complex and convention center revenue bonds usually receive revenues from sporting or convention events held at the facilities and, in some instances, from earmarked outside revenues such as local motel and hotel room taxes.

Student Loan Revenue Bonds

Student loan revenue bonds usually are issued by state agencies or not-for-profit organizations and are used for purchasing student loans for higher education. Depending on the security structure, bondholders' payment can include student loan repayments and federal payments.

Tax-Allocation Bonds

These bonds are usually issued to finance the construction of office buildings and other new buildings in formerly blighted areas. They are secured by property taxes collected on the improved real estate.

Tobacco Revenue Bonds

Some tobacco bonds are usually solely secured by revenues in the Master Settlement Agreement (MSA) annually paid to states by cigarette companies.

Toll Road and Gas Tax Revenue Bonds

There are generally two types of highway revenue bonds. The bond proceeds of the first type are used to build such specific revenue-producing facilities as toll roads, bridges, and tunnels. For these pure enterprise-type revenue bonds, the pledged revenues usually are the monies collected through the tolls. The second type of highway bond is one in which the bondholders are paid by earmarked revenues outside toll collections, such as gasoline taxes, automobile registration payments, and driver's license fees.

Tribal Casino Bonds

Native American governments in general finance the construction of their casino gaming facilities by issuing debt. Tribal casino bonds derive their revenues from the gaming operations of these facilities.

Water Revenue Bonds

Water revenue bonds are issued to finance the construction of water treatment plants, pumping stations, collection facilities, and distribution systems. Revenues usually come from connection fees and charges paid by the users of the water systems.

Hybrid and Special Bond Securities

Although having certain characteristics of general obligation and revenue bonds, the following types of municipal bonds have more unique security structures as well.

Refunded Bonds

Although originally issued as either revenue or general obligation bonds, municipals are sometimes *refunded.* A refunding usually occurs when the original bonds are escrowed or collateralized either by direct obligations guaranteed by the U.S. government or other types of securities. The maturity schedules of the securities in the escrow fund are such that they pay when due the bond's maturity value, coupon, and premium payments (if any) on the refunded bonds. Once this cash-flow match is in place, the refunded bonds are no longer secured as either general obligation or revenue bonds. The bonds are now supported by the securities held in the escrow fund. Such bonds, if escrowed with securities guaranteed by the U.S. government, have little if any credit risk. They are the safest municipal bond investments available.

Usually, an escrow fund is an irrevocable trust established by the original bond issuer with a commercial bank or state treasurer's office. Government securities are deposited in an escrow fund that will be used to pay debt service on the refunded bonds. A *pure* escrow fund is one in which the deposited securities are solely direct or guaranteed obligations of the U.S. government, whereas a *mixed* escrow fund is one in which the permitted securities, as defined by the trust indenture, are not exclusively limited to direct or guaranteed U.S. government securities. Other securities that could be placed in mixed escrow funds include federal agency bonds, certificates of deposit from banks, other municipal bonds, and even annuity policies from commercial insurance companies. The escrow agreement should indicate what is in the escrow fund and if substitutions of lower-credit-quality investments are permitted.

Still another type of refunded bond is a *crossover refunded bond.* Typically, proceeds from crossover refunding bonds are used to purchase securities that are placed in an escrow account. Usually, the crossover refunding bonds are secured by maturing principal and interest from the escrowed securities *only until the crossover date,* and the bonds to be refunded continue to be secured by the issuer's own revenues until the crossover date, which is usually the first call date of the bonds to be refunded. On that date, the crossover occurs, and the bonds to be refunded are redeemed from maturing securities in the escrow fund, which could include U.S. government securities or other investments, such as certificates of deposit. In turn, the security for the refunding bonds reverts back to the issuer's own revenues.

Here we focus primarily on the pure escrow-backed bonds, not the mixed escrow or crossover bonds. The escrow fund for a refunded municipal bond can be structured so that the refunded bonds are to be called at the first possible date or a subsequent call date established in the original bond indenture. The call price usually includes a premium of from 1% to 3% above par. This type of structure usually is used for those refundings that either reduce the issuer's interest payment expenses or change the debt maturity schedule. Such bonds are known in the industry as *prerefunded* municipal bonds. Prerefunded municipal bonds usually are to be retired at their first or subsequent respective callable dates, but some escrow funds for refunding bonds have been structured differently. In such refundings, the maturity schedules of the securities in the escrow funds match the regular debt-service requirements on the bonds as originally stated in the bond indentures. Such bonds are known as *escrowed-to-maturity,* or ETM, bonds. It should be noted that under the TCJA, such ETM refundings still can be done though not with tax-exempt bonds. In the secondary market there may be ETM refunded municipal bonds outstanding. However, we note that the investor or trader should determine whether all earlier calls have been legally defeased before purchasing an ETM bond.

Dedicated Tax-Backed and Structured Asset-Backed Bonds

More recently, states and local governments have issued increasing amounts of bonds in which the debt service is to be paid from so-called dedicated revenues such as sales taxes, tobacco settlement payments, fees, and penalty payments. Many are structured to mimic the asset-backed bonds that are common in the taxable market. The "assets" providing the security for the municipal bonds are the "dedicated" revenues instead of credit card receivables, home equity loans, and auto loan repayments that are commonly used to secure the taxable asset-backed bonds.

Insured Bonds

Insured bonds, in addition to being secured by the issuer's revenues, are also backed by insurance policies written by commercial insurance companies. The insurance, usually structured as an insurance contract, is supposed to provide prompt payment to the bondholders if a default should occur. These bonds are discussed in more detail later in this chapter.

Lease-Backed Bonds

Lease-backed bonds usually are structured as revenue-type bonds with annual payments. In some instances the payments may come only from earmarked tax revenues, student tuition payments, or patient fees. In other instances the underlying lessee governmental unit makes annual appropriations from its general fund.

Letter of Credit–Backed Bonds

Some municipal bonds, in addition to being secured by the issuer's cash-flow revenues, also are backed by commercial bank letters of credit. In some instances the letters of credit are irrevocable and, if necessary, can be used to pay the bondholders. In other instances the issuers are required to maintain investment-quality worthiness before the letters of credit can be drawn on.

Moral Obligation Bonds

A moral obligation bond is a security structure usually for some state-issued bonds that indicates that if revenues are needed for paying bondholders, the state legislature involved is legally authorized, although not required, to make an appropriation out of general state tax revenues.

Territorial Bonds

These are bonds issued by U.S. territorial possessions such as Puerto Rico, the Virgin Islands, and Guam. The bonds are tax-exempt throughout most of the country. Also, the economies of these issuers may be influenced by positive special features of the U.S. corporate tax codes that are not available to the states.

Troubled City Bailout Bonds

There are certain bonds that are structured to appear as pure revenue bonds but in essence are not. Revenues come from general-purpose taxes and revenues that otherwise would have gone to a state's or city's general fund. Their bond structures were created to bail out underlying general obligation bond issuers from severe budget deficits. The Chicago Sales Tax Securitization Cooperation Bonds are an example.

Money Market Products

Tax-exempt money market products include notes, commercial paper, variable-rate demand obligations, and a hybrid of the last two products.

Notes

Municipal notes include tax anticipation notes (TANs), revenue anticipation notes (RANs), grant anticipation notes (GANs), and bond anticipation notes (BANs). These are temporary borrowings by states, local governments, and special jurisdictions. Usually, notes are issued for a period of 12 months, although it is not uncommon for notes to be issued for periods of as short as three months and for as long as three years. TANs and RANs (also known as TRANs) are issued in anticipation of the collection of taxes or other expected revenues. These are borrowings to even out the cash flows caused by the irregular flows of income into the treasuries of the states and local units of government. BANs are issued in anticipation of the sale of long-term bonds.

Tax-exempt money market products generally have some type of credit support. This may come in the form of an irrevocable letter of credit, a line of credit, municipal bond insurance policy, an escrow agreement, a bond purchase agreement, or a guaranteed investment contract. With a bond purchase agreement, a bank obligates itself to purchase the debt if the remarketing agent cannot resell the instrument or make a timely payment. In the case of a guaranteed investment contract, either an insurance company or a bank invests sufficient proceeds so that the cash flow generated from a portfolio of supporting assets can meet the obligation of the issue.

Commercial Paper

As with commercial paper issued by corporations, tax-exempt commercial paper is used by municipalities to raise funds on a short-term basis ranging from 1 to 270 days. The dealer sets interest rates for various maturity dates, and the investor then selects the desired date. Thus the investor has considerable choice in selecting a maturity to satisfy investment objectives.

Variable-Rate Demand Obligations

Variable-rate demand obligations (VRDOs) are floating-rate obligations that have a nominal long-term maturity but have a coupon rate that is reset either daily or every seven days. The investor has an option to put the issue back to the trustee at any time with seven days' notice or the same day in the case of a daily VRDO. The put price is par plus accrued interest.

Commercial Paper Mode

The commercial paper mode is customized to meet the cash-flow needs of an investor. As with tax-exempt commercial paper, there is flexibility in structuring the maturity because the remarketing agent establishes interest rates for a range of maturities. Although the instrument may have a long nominal maturity, there is a put provision as with a VRDO. Put periods can range from 1 day to more than 360 days. On the put date, the investor can put back the bonds, receiving principal and interest, or the investor can elect to extend the maturity at the new interest rate and put date posted by the remarketing agent at that time. Thus the investor has two choices when initially purchasing this instrument: the interest rate and the put date. Interest generally is paid on the put date if the date is within 180 days. If the put date is more than 180 days forward, interest is paid semiannually. Some commercial paper dealers market these products under a proprietary name, but most do so simply as money market municipals.

Municipal Derivative Securities

In recent years, a number of municipal products have been created from the basic fixed-rate municipal bond. This has been done by splitting up cash flows of newly issued bonds as well as bonds existing in the secondary markets. These products have been created by dividing the coupon interest payments and principal payments into two or more bond classes, or *tranches*. The resulting bond classes may have far different yield and price volatility characteristics than the underlying fixed-rate municipal bond from which they were created. By expanding the risk/return profile available in the municipal marketplace, institutional investors have more flexibility in structuring municipal bond portfolios either to satisfy a specific asset/liability objective or to make an interest rate or yield-curve bet more efficiently.

The name *derivative securities* has been attributed to these bond classes because they derive their value from the underlying fixed-rate municipal bond. Much of the development in this market has paralleled that of the taxable and, specifically, the mortgage-backed securities market. The ability of investment bankers to create these securities has been enhanced by the development of the municipal swap market.

A common type of derivative security is one in which two classes of securities, a *floating-rate security* and an *inverse floating-rate bond,* are created from a fixed-rate bond. Two types of inverse floaters dominated the market: auction rate securities and the later-developed tender option bond (TOB) product. TOB programs, in various forms, have existed since the beginning to middle 1980s. Widespread use did not occur until the 1990s.

In 2008, when failed auctions occurred, new issuance of auction rate securities ended. Functionally, TOBs are similar to the auction rate product. Both derivatives are inverse floaters. Auction rate floaters, however, were sold primarily to corporations and individuals, whereas TOB floaters are sold to money market funds. Tax-exempt money market funds have a continuous need for tax-exempt interest. This demand provided a stable buying base for the TOB floaters. To take advantage of this money market demand, TOBs feature a liquidity facility, which makes these floating-rate derivatives putable and therefore money market eligible. These liquidity facilities typically last 364 days and are provided by highly rated banks or broker-dealers.

TOBs are created through trusts. Given this structure, certain provisions must exist for the unwinding of a TOB. For example, if the remarketing agent fails to sell out the floating-rate class or the underlying bond falls below a minimum collateral value, a mandatory tender event is triggered. When a mandatory tender event occurs, the liquidity provider pays the floater holder par plus accrued interest. The trustee simultaneously terminates the trust and liquidates the bonds. The proceeds from this sale are used to first pay par plus accrued interest to the liquidity provider and then any accrued fees. Finally, the inverse floating-rate investor receives the residual value.

Several proprietary programs have been developed to market and sell plain vanilla TOBs, which are used by mutual bond funds, insurance companies, *and crossover buyers*. Additionally, at times TOBs are used in more exotic combination trades by a few Wall Street structured products areas.

THE COMMERCIAL CREDIT RATING OF MUNICIPAL BONDS

Of the municipal bonds that were rated by a commercial rating company in 1929 and plunged into default in 1932, 78% had been rated double-A or better, and 48% had been rated triple-A. Since then, the ability of rating agencies to assess the creditworthiness of municipal obligations has evolved to a level of general industry acceptance and respectability. In most instances, they adequately describe the financial conditions of the issuers and identify the credit-risk factors. However, a small but significant number of relatively recent instances have caused market participants to reexamine their reliance on the opinions of the rating agencies.

As examples, the troubled bonds of the Washington Public Power Supply System (WPPSS) and Orange County, California, should be mentioned. Two major commercial rating companies, Moody's and Standard & Poor's, gave their highest ratings to the WPPSS bonds in the early 1980s. Moody's gave the WPPSS Projects 1, 2, and 3 bonds its very highest credit rating of Aaa and the Projects 4 and 5 bonds its rating of Al. This latter investment-grade rating is defined as having the strongest investment attributes within the upper medium grade of creditworthiness. Standard & Poor's also had given the WPPSS Projects 1, 2, and 3 bonds its highest rating of AAA and Projects 4 and 5 bonds its rating of A. While these high-quality ratings were in effect, WPPSS sold more than $8 billion in long-term bonds. By 1990, more than $2 billion of these bonds were in default.

Orange County, California, also had very strong credit ratings before its filing for bankruptcy protection on December 6, 1994. This would be the largest municipal bankruptcy filing in U.S. history. The Orange County debacle was unique. The county's problem was not caused by local economic problems, like Philadelphia's crisis in the early 1990s, nor was it caused by budget problems, like New York City's situation in 1975. Orange County's problem was created by the county Treasurer–Tax Collector's investment strategy for the Orange County Investment Pool. The investment pool was highly leveraged and contained a large percentage of inverse floaters. As interest rates rose in 1994, the value of the investments decreased, and the institutions that provided the financial leverage decided to terminate those financial agreements. The problem was that if the investment pool were liquidated, the amount of assets would be insufficient to cover all the loans. Since the pool did not have sufficient assets to cover its debt, the county chose to seek the safety of bankruptcy protection.

The county's voluntary bankruptcy filing was unprecedented. It was a signal to investors that the county did not necessarily intend to repay all its obligations. In most other cases of severe financial hardship, the municipalities tried to meet all their obligations and did not even suggest that they might wish not to fulfill their obligations. What troubled most investors was that Orange County was a vibrant and economically strong area and in all likelihood could fulfill its obligations. This created a different situation for investors and brought the question of an issuer's ability to pay versus its willingness to pay. This was something that municipal investors rarely, if ever, questioned before Orange County.

Another area investors rarely questioned prior to Orange County was the investment strategies that were being used to manage operating fund investments and other state and local investment funds or pools. It was a common perception that state and local government finance officials invested conservatively and followed policies that emphasized safety of principal and maintenance of liquidity. Immediately following the onset of the Orange County debacle, large investors started to question state and local officials on their investment policies and their use of financial leverage and derivative securities. Because Orange County received high-quality credit ratings prior to its problems, investors started to question the reliability of the commercial credit-rating agencies.

The Washington Public Power Supply System and Orange County, California, are the more notable issuers that had high-quality ratings prior to their problems, but they are not isolated instances. In fact, since 1975, all the major municipal defaults in the industry initially had been given investment-grade ratings by Moody's and Standard & Poor's. Of course, it should be noted that in the majority of instances, ratings of the commercial rating companies adequately reflect the condition of the credit. However, unlike 40 years ago, when the commercial rating companies would not rate many kinds of revenue bond issues, today they seem to view themselves as assisting in the capital formation process.

After criticism by some public officials on the federal and state levels, we note that in 2009 the rating agencies recalibrated their ratings upward on many general obligation and essential service revenue bonds. They argued that municipal bond issues should have higher ratings relative to corporate bonds because of historical default rates and recovery levels. This resulted in higher ratings on many municipal bonds.

More recently, highly visible defaults in 2013 and 2014 of $9.5 billion of Detroit's municipal bonds, followed by the defaults in 2014, 2015, and 2016 of $57.2 billion of Puerto Rico municipal bonds, drew increased attention to the reliability of credit ratings on municipal bonds.

Today, many large institutional investors, underwriters, and traders use the ratings of the commercial rating agencies as starting points and rely on their own in-house municipal credit analysts for determining the creditworthiness of municipal bonds. However, other investors do not perform their own credit-risk analysis but instead rely entirely on credit-risk ratings by Moody's, Standard & Poor's, and Fitch. In this section we discuss the rating categories of these three commercial rating companies.

Moody's Investors Service

The municipal bond rating system used by Moody's grades the investment quality of municipal bonds in a nine-symbol system that ranges from the highest investment quality, which is Aaa, to the lowest credit rating, which is C. The respective nine alphabetical ratings and their definitions are found in Exhibit 9-1. Moody's, like the other credit rating agencies, sometimes attaches an "outlook" designation such as "Positive," "Negative," or "Stable" to the bond rating. Moreover, the term "Watch" is designated for a rating change within the next year or so.

Municipal bonds in the top four categories (Aaa, Aa, A, and Baa) are considered to be of investment-grade quality. Speculative or noninvestment grade ratings incorporate the five lower rating grade categories (Ba, B, Caa, Ca, and C). Additionally, bonds in the Aa through Caa categories are refined by numeric modifiers 1, 2, and 3, with 1 indicating the top third of the rating category, 2 the middle third, and 3 the bottom third.

The municipal note rating system used by Moody's is designated by investment-grade categories of Moody's Investment Grade (MIG), and one speculative grade category; SG as shown in Exhibit 9-2.

Moody's also provides credit ratings for tax-exempt commercial paper. These are promissory obligations not having an original maturity in excess of nine months. Moody's uses three designations, all considered to be of investment grade, and one speculative grade category for indicating the relative repayment capacity of the rated issuers, as shown in Exhibit 9-3.

EXHIBIT 9-1

Moody's Municipal Bond Ratings

Rating	Definition
Aaa	Highest quality, minimal credit risk
Aa	High quality, very low credit risk
A	Upper medium grade, low credit risk
Baa	Moderate credit risk
Ba	Speculative elements, substantial credit risk
B	Speculative, high credit risk
Caa	Poor standing, very high credit risk
Ca	Highly speculative, in or near default
C	In default with no recovery expected

EXHIBIT 9-2

Moody's Municipal Note Ratings*

Rating	Definition
MIG 1	Excellent Protection
MIG 2	Strong quality
MIG 3	Acceptable quality
SG	Speculative Grade

*A short issue having a demand feature (i.e., payment relying on external liquidity and usually payable on demand rather than fixed maturity dates) is differentiated by Moody's with the use of the symbols *VMIG1* through *VMIG3*, and *VSG*.

EXHIBIT 9-3

Moody's Tax-Exempt Commercial Paper Ratings

Rating	Definition
Prime 1 (P-1)	Superior capacity for repayment
Prime 2 (P-2)	Strong capacity for repayment
Prime 3 (P-3)	Acceptable capacity for repayment
NP	Not Prime Grade

Standard & Poor's

The municipal bond rating system used by Standard & Poor's grades the investment quality of municipal bonds in a 10-symbol system that ranges from the highest investment quality, which is AAA, to the lowest credit rating, which is D.[3] Bonds within the top four categories (AAA, AA, A, and BBB) are considered by Standard & Poor's as being of investment-grade quality. The respective 10 alphabetical ratings and definitions are shown in Exhibit 9-4.

Standard & Poor's also uses a plus (+) or minus (−) sign to show relative standing within the rating categories ranging from AA to CCC.

The municipal note rating system used by Standard & Poor's grades the investment quality of municipal notes in a four-symbol system that ranges from highest investment quality, SP-1, to the lowest credit rating, D. Notes within the top three categories (i.e., SP-1, SP-2, and SP-3) are considered by Standard & Poor's as being of investment-grade quality. The respective ratings and summarized definitions are shown in Exhibit 9-5.

Standard & Poor's also rates tax-exempt commercial paper. The tax-exempt commercial paper rating categories are shown in Exhibit 9-6.

Fitch

The third rating company is Fitch. The alphabetical ratings and definitions used by Fitch are given in Exhibit 9-7. Plus (+) and minus (−) signs are used with a

EXHIBIT 9-4

Standard & Poor's Municipal Bond Ratings

Rating	Definition
AAA	Highest rating; extremely strong security
AA	Very strong security
A	Somewhat more susceptible to adverse economic effects than two above categories
BBB	Adequate capacity but adverse economic conditions more likely to weaken capacity
BB	Lowest degree of speculation; risk exposure
B	Speculative; risk exposure
CCC	Speculative; major risk exposure
CC	Highly vulnerable to nonpayment
C	Bankruptcy petition may be filed
D	Bonds in default with interest and/or repayment of principal in arrears

3. www.standardandpoors.com. Standard & Poor's Global Ratings, February 25, 2020.

EXHIBIT 9-5

Standard & Poor's Municipal Note Ratings

Rating	Definition
SP-1	Strong capacity to pay principal and interest. Those issues determined to possess overwhelming safety characteristic will be given a plus (+) designation.
SP-2	Satisfactory capacity to pay principal and interest.
SP-3	Speculative capacity to pay principal and interest.
D	Default

EXHIBIT 9-6

Standard & Poor's Tax-Exempt Commercial Paper Ratings

Rating	Definition
A-1+	Extremely strong degree of safety
A-1	Strong degree of safety
A-2	Satisfactory degree of safety
A-3	Adequate degree of safety
B	Speculative capacity for timely payment
C	Doubtful capacity for payment
D	Used when principal or interest payments are not made on the due date

EXHIBIT 9-7

Fitch Municipal Bond Ratings

Rating	Definition
AAA	Highest credit quality
AA	Very high credit quality
A	High credit quality
BBB	Good
BB	Speculative
B	Highly speculative
CCC	Substantial credit risk
CC	Very high levels of credit risk
C	Exceptionally high levels of credit risk
D	Default

rating to indicate the relative position of a credit within the rating category.[4] Plus and minus signs are not used for the AAA category.

Additionally, Fitch assigns ratings for obligations that are due up to 36 months. The rating scale has three investment grade symbols, F1 (the highest), F2, and F3. There are two speculative scales, B and C. There is a rating RD for an entity that has defaulted on one or more of its financial commitments, although it is meeting other financial obligations. Lastly, D indicates a broad-based default event for an entity, or the default of a short-term obligation.

A fourth and smaller rating agency is Kroll Bond Rating Agency (KBRA).

MUNICIPAL BOND INSURANCE

Using municipal bond insurance was considered for many years one way to help reduce credit risk within a portfolio. Because of this, it had great appeal to retail investors. Insurance on a municipal bond was an agreement by an insurance company to pay debt service that is not paid by the bond issuer. Municipal bond insurance contracts insure the payment of debt service on a municipal bond to the bondholder. That is, the insurance company promised to pay the issuer's obligation to the bondholder if the issuer did not do so.

The insurance usually was for the life of the issue. If the trustee or investor had not had his bond paid by the issuer on its due date, he notified the insurer and presented the defaulted bond and coupon. Under the terms of the insurance contract, the insurer generally was obligated to pay sufficient monies to cover the value of the defaulted insured principal and coupon interest when they came due.

Because it was believed that municipal bond insurance reduced the credit risk for the investor, the marketability of certain municipal bonds was greatly expanded. Municipal bonds that benefited most from the insurance would include lower-quality bonds, bonds issued by smaller governmental units not widely known in the financial community, bonds that had a sound although complex and difficult-to-understand security structure, and bonds issued by infrequent local government borrowers who do not have a general market following among investors.

Of course, a major factor for an issuer to obtain bond insurance was that its creditworthiness without the insurance was substantially lower than what it would be with the insurance. That is, the interest cost savings were only of sufficient magnitude to offset the cost of the insurance premium when the underlying creditworthiness of the issuer was lower. The major group of bond insurers are "monoline" companies that were primarily in the business of insuring financial securities, including municipal bonds. Almost all the companies that insured municipal bonds could be characterized as monoline in structure.

While for many years until 2008, the majority of insured bonds were with the monoline insurers—most of whom had AAA ratings from all three major

4. Fitch Ratings Definitions, February 2020.

agencies, and captured 47% of the new issue market—this dramatically changed. With massive defaults in their taxable books of insured bonds, they were rapidly downgraded and faced insolvency. As of 2020, there were mainly two monoline insurers writing business in the financial guaranty insurance sector: Assured Guaranty (rated double A by both Moody's and S&P) and Build America Mutual (BAM) rated double A by S&P. Market share was 6%.

VALUATION METHODS

The traditional method for evaluating municipal bonds is relatively straightforward. First, an investor determines the maturity of the bond, considers the offered price (discount, par, or premium), evaluates any call features or sinking funds, and then considers credit quality. If it is a premium bond and callable, then the investor places more emphasis on the call dates. If the bond is callable and sells at a discount, then the calls are not much of a factor, and the bond is valued using its maturity date. Basically, the investor is determining the relative attractiveness of the bond based on a yield-to-worst calculation. The credit quality is quantified, and the appropriate yield premium for the specific credit quality is added to the base yield-to-worst calculation. Because investors do not perform an option-adjusted spread (OAS) analysis, the yield premium that is applied is a nominal yield premium. The benchmark yields that are used to value the bonds come from a variety of sources, such as yield levels from the primary market, trading levels of similar bonds in the secondary market, and benchmark (triple-A GO, generic sector, state-specific) interest-rate curves.

An investor interested in purchasing a municipal bond must be able to compare the promised yield on a municipal bond with that of a comparable taxable bond. Employing the yield computed with traditional approaches, the following general formula is used to determine the *equivalent taxable yield* for a tax-exempt bond:

$$\text{Equivalent taxable yield} = \frac{\text{tax} - \text{exempt yield}}{(1 - \text{marginal tax rate})}$$

For example, suppose that an investor in the 40% marginal tax bracket is considering the acquisition of a tax-exempt bond that offers a tax-exempt yield of 6%. The equivalent taxable yield is 10%, as shown below:

$$\text{Equivalent taxable yield} = \frac{0.06}{(1 - 0.40)} = 0.10 = 10\%$$

When computing the equivalent taxable yield, the traditionally computed yield-to-maturity is not the tax-exempt yield if the issue is selling below par (i.e., selling at a discount) because only the coupon interest is exempt from federal income taxes. Instead, the yield-to-maturity after an assumed capital gains tax is computed and used in the numerator of the formula.

The yield-to-maturity after an assumed capital gains tax is calculated in the same manner as the traditional yield-to-maturity. However, instead of using the redemption value in the calculation, the net proceeds after an assumed tax on any capital gain are used.

There is a major drawback in employing the equivalent taxable yield formula to compare the relative investment merits of a taxable and tax-exempt bond. Recall from the discussion in Chapter 4 that the yield-to-maturity measure assumes that the entire coupon interest can be reinvested at the computed yield. Consequently, taxable bonds with the same yield-to-maturity cannot be compared because the total dollar returns may differ from the computed yield. The same problem arises when attempting to compare taxable and tax-exempt bonds, especially because only a portion of the coupon interest on taxable bonds can be reinvested, although the entire coupon payment is available for reinvestment in the case of municipal bonds. The total return framework that should be employed to compare taxable and tax-exempt bonds is discussed in Chapter 4.

The traditional method of evaluating a municipal bond leaves much to be desired. The basic problem is that the call risk is not analyzed properly. The yield-to-worst calculation ignores the fact that interest rates can change in the future, and the actual timing of the cash flows may not be the same as what was projected. If an investor evaluates a bond to its maturity date, then this investor will be surprised if the bonds are called several years earlier. Conversely, if the investor evaluates a bond to a specific call date and the bond is not called, then this investor will realize a stream of cash flows that is different from what was anticipated. The result of the traditional methodology is that most callable municipal bonds are priced too richly, and the cost of noncallable bonds with extra convexity is cheap. This is especially true for longer-dated bonds. More information about OAS analysis can be found in Chapter 36.

TAX PROVISIONS AFFECTING MUNICIPALS

Federal tax rate levels affect municipal bond values and strategies employed by investors. There are three provisions in the Internal Revenue Code that investors in municipal securities should recognize. These provisions deal with the tax treatment of OIDs, alternative minimum tax, and the deductibility of interest expense incurred to acquire municipal securities. Moreover, there are state and local taxes about which an investor must be aware.

Tax Treatment of Original-Issue Discount Bonds

When purchasing OIDs in the secondary market, investors should analyze the bond carefully owing to the complex tax treatment of OIDs. Few investors think about tax implications when investing in municipal debt. After all, the interest earned on most municipal bonds is exempt from federal taxes. If investors do think about taxes, they probably think about selling bonds at a higher price than the original tax cost. Most investors believe that this would create a capital gain and absent this situation there should be no tax impact. Sounds straightforward, but the municipal world isn't simplistic. Several years ago the marketplace was introduced to the Revenue Reconciliation Act of 1993, and since then investing in municipals has become more complex. Currently, profit from bonds purchased in the secondary market after April 30, 1993, could be free from any tax implications or taxed at the capital gains rate, ordinary income rate, or a combination of the two rates. To understand this situation, it is essential to understand the rule of de minimus.

In basic terms, the *rule of de minimu*s states that a bond is to be discounted up to 0.25% from the face value for each remaining year of a bond's life before it is affected by ordinary income taxes. This price is commonly referred to as the "market discount cutoff price." If the bond is purchased at a market discount but the price is higher than the market discount cutoff price, then any profits will be taxed at the capital gains rate. If the purchase price is lower than the market discount cutoff price, then any profits may be taxed as ordinary income or a combination of the ordinary income rate and the capital gains rate. The exact tax burden depends on several factors.

The rule of de minimus is especially complicated for OID bonds. For these bonds, a revised issue price must be calculated, as well as the market discount cutoff price. The revised issue price does change over time because the OID must be accreted over the life of the bond. The rule of de minimus does not apply to the OID segment, but it does apply to the market discount segment. The market discount segment is equal to the purchase price (secondary market price) minus the revised issue price. If an OID bond is purchased in the secondary market at a price greater than the revised issue price, the bond is considered to have an acquisition premium, and the rule of de minimus does not apply. If the OID bond is purchased at a price below the revised issue price and above the market discount cutoff price, then the OID bond is purchased at a market discount, and any profits will be taxed at the capital gains rate. Finally, if the purchase price of the OID bond is lower than the market discount cutoff price, then any profits may be taxed as ordinary income or a combination of the ordinary income rate and the capital gains rate. The OID topic is complicated. More specific details can be found in the Internal Revenue Service (IRS) Publications.

Alternative Minimum Tax

Alternative minimum taxable income (AMTI) is a taxpayer's taxable income with certain adjustments for specified tax preferences designed to cause AMTI to approximate economic income. For individuals, a taxpayer's liability is the greater of (1) the tax computed at regular tax rates on taxable income and (2) the tax computed at a lower rate on AMTI. This parallel tax system, the alternative minimum tax (AMT), is designed to prevent taxpayers from avoiding significant tax liability as a result of taking advantage of exclusions from gross income, deductions, and tax credits otherwise allowed under the Internal Revenue Code.

Under TCJA, corporations are not subject to the AMT.

One of the tax preference items that must be included is certain tax-exempt municipal interest. As a result of the AMT, the value of the tax-exempt feature is reduced. However, the interest of some municipal issues is not subject to the AMT. Under the current tax code, tax-exempt interest earned on all private activity bonds issued after August 7, 1986, must be included in AMTI. There are two exceptions. First, interest from bonds that are issued by 501(c)(3) organizations (i.e., not-for-profit organizations) is not subject to AMTI. The second exception is interest from bonds issued for the purpose of refunding if the original bonds were issued before August 7, 1986. The AMT does not apply to interest on governmental or nonprivate activity municipal bonds. An implication is that the issues subjected to the AMT will trade at a higher yield than those exempt from AMT.

Deductibility of Interest Expense Incurred to Acquire Municipals

Some investment strategies involve the borrowing of funds to purchase or carry securities. Ordinarily, interest expense on borrowed funds to purchase or carry investment securities is tax deductible. There is one exception that is relevant to investors in municipal bonds. The IRS specifies that interest paid or accrued on "indebtedness incurred or continued to purchase or carry obligations, the interest on which is wholly exempt from taxes," is not tax deductible. It does not make any difference if any tax-exempt interest is actually received by the taxpayer in the taxable year. In other words, interest is not deductible on funds borrowed to purchase or carry tax-exempt securities.

Special rules apply to commercial banks. At one time, banks were permitted to deduct all the interest expense incurred to purchase or carry municipal securities. Tax legislation subsequently limited the deduction first to 85% of the interest expense and then to 80%. The 1986 tax law eliminated the deductibility of the interest expense for bonds acquired after August 6, 1986. The exception to this nondeductibility of interest expense rule is for *bank-qualified issues*. These are tax-exempt obligations sold by small issuers after August 6, 1986, and purchased by the bank for its investment portfolio.

An issue is bank-qualified if (1) it is a tax-exempt issue other than private activity bonds, but including any bonds issued by 501(c)(3) organizations, and (2) it is designated by the issuer as bank-qualified and the issuer or its subordinate entities reasonably do not intend to issue more than $10 million of such bonds. A nationally recognized and experienced bond attorney should include in the opinion letter for the specific bond issue that the bonds are bank-qualified.

State and Local Taxes

The tax treatment of municipal bonds varies by state. There are three types of taxes that can be imposed: (1) an income tax on coupon income, (2) a tax on realized capital gains, and (3) a personal property tax.

Many states levy an individual income tax. Coupon interest from obligations by in-state issuers is exempt from state individual income taxes in most states. A few states levy individual income taxes on coupon interest whether the issuer is in state or out of state.

State taxation of realized capital gains is often ignored by investors when making investment decisions. In many states, a tax is levied on a base that includes income from capital transactions (i.e., capital gains or losses). In many states in which coupon interest is exempt if the issuer is in state, the same exemption will not apply to capital gains involving municipal bonds.

Some states levy a personal property tax on municipal bonds. The tax resembles more of an income tax than a personal property tax. Before 1995, some state and local governments levied this tax on residents who owned municipal bonds where the issuer of the bond was located outside the investor's home state. While residents owning municipal bonds where the issuer was located within the investor's home state's boundaries were exempt from such tax, this tax was declared unconstitutional by the U.S. Supreme Court because it violated the federal commerce clause by favoring in-state businesses over out-of-state businesses. The determining case was *Fulton Corporation* v. *Janice H. Faulkner, Secretary of Revenue of North Carolina,* No. 94-1239 (U.S. S.C. Feb. 21, 1996). After the court ruled on this case, many state and local governments that levied a similar tax repealed the tax or chose not to collect it.

In determining the effective tax rate imposed by a particular state, an investor must consider the impact of the deductibility of state taxes on federal income taxes. Moreover, in some states, *federal* taxes are deductible in determining state income taxes. It should be noted that under TCJA, the state and local tax deduction was limited to a combination of $10,000 for income, sales, and property taxes.

YIELD RELATIONSHIPS WITHIN THE MUNICIPAL BOND MARKET

In this section, we briefly look at some important yield relationships within the municipal bond market.

Differences Within an Assigned Credit Rating

Bond buyers primarily use the credit ratings assigned by the commercial rating companies, Standard & Poor's, Moody's, and Fitch, as a starting point for pricing an issue. The final market-derived bond price is determined by the assigned credit rating and adjustments by investors to reflect their own analysis of creditworthiness and perception of marketability. For example, insured municipal bonds—when they were a dominant factor in the market—tended to have yields that were substantially higher than noninsured superior-investment-quality municipal bonds, even though most insured bonds were given triple-A ratings by the commercial rating companies. Additionally, many investors have geographic preferences among bonds despite identical credit quality and otherwise comparable investment characteristics.

Differences Between Credit Ratings

With all other factors constant, the greater the credit risk perceived by investors, the higher the return expected by investors. The spread between municipal bonds of different credit quality is not constant over time. Reasons for the change in spreads are (1) the outlook for the economy and its anticipated impact on issuers, (2) federal budget financing needs, and (3) municipal market supply-and-demand factors. During periods of relatively low interest rates, investors sometimes increase their holdings of issues of lower credit quality in order to obtain additional yield. This narrows the spread between high-grade and lower-grade credit issues. During periods in which investors anticipate a poor economic climate, there is often a "flight to quality" as investors pursue a more conservative credit-risk exposure. This widens the spread between high-grade and lower-grade credit issues.

Another factor that causes shifts in the spread between issues of different quality is the temporary oversupply of issues within a market sector. For example, a substantial new issue volume of high-grade state general obligation bonds may tend to decrease the spread between high-grade and lower-grade revenue bonds. In a weak market environment, it is easier for high-grade municipal bonds to come to market than for weaker credits. Therefore, it is not uncommon for high grades to flood weak markets at the same time that there is a relative scarcity of medium- and low-grade municipal bond issues.

Differences Between In-State and General Market

Bonds of municipal issuers located in certain states (e.g., New York, New Jersey, California, Arizona, Maryland, and Pennsylvania) usually yield considerably less than issues of identical credit quality that come from other states that trade in the "general market." There are three reasons for the existence of such spreads. First, states often exempt interest from in-state issues from state and local personal income taxes. Interest from out-of-state issues is generally not exempt. Consequently, in states with high income taxes (e.g., New York and California), strong investor demand for in-state issues will reduce their yields relative to bonds of issues located in states in which state and local income taxes are not important considerations (e.g., Illinois and Wisconsin). Of course, it should be noted that bonds of Puerto Rico and other U.S. territorial governments are also exempt from state and local taxation, and enjoy these yield advantages. Second, in some states, public funds deposited in banks must be collateralized by the bank accepting the deposit. This requirement is referred to as "pledging." Acceptable collateral for pledging typically will include issues of certain in-state issuers. For those qualifying issues, pledging tends to increase demand (particularly for the shorter maturities) and reduce yields relative to nonqualifying comparable issues. The third reason is that investors in some states exhibit extreme reluctance to purchase issues from issuers outside their state or region. In-state parochialism tends to decrease relative yields of issues from states in which investors exhibit this behavior.

Differences Between Maturities

One determinant of the yield on a bond is the number of years remaining to maturity. As explained in Chapter 3, the yield-curve depicts the relationship at a given point in time between yields and maturity for bonds that are identical in every way except maturity. When yields increase with maturity, the yield-curve is said to be *normal* or *have a positive slope.* Therefore, as investors lengthen their maturity, they require a greater yield. It is also possible for the yield-curve to be *inverted,* meaning that long-term yields are less than short-term yields. If short, intermediate, and long-term yields are roughly the same, the yield-curve is said to be *flat*.

In the taxable bond market, it is not unusual to find all three shapes for the yield-curve at different points in the business cycle. However, in the municipal bond market, the yield-curve typically is normal or upward-sloping. Consequently, in the municipal bond market, long-term bonds generally offer higher yields than short- and intermediate-term bonds.

PRIMARY AND SECONDARY MARKETS

The municipal market can be divided into the primary market and the secondary market. The primary market is one in which all new issues of municipal bonds are sold for the first time. The secondary market is the market in which previously issued municipal securities are traded.

Primary Market

A substantial number of municipal obligations are brought to market each week. A state or local government can market its new issue by offering bonds publicly to the investing community or by placing them privately with a small group of investors. When a public offering is selected, the issue usually is underwritten by investment bankers or municipal bond departments of commercial banks. Public offerings may be marketed by either competitive bidding or direct negotiations with underwriters. When an issue is marketed via competitive bidding, the issue is awarded to the bidder submitting the best bid.

Most states mandate that general obligation issues be marketed through competitive bidding, but generally this is not required for revenue bonds. Usually state and local governments require a competitive sale to be announced in a recognized financial publication, such as *The Bond Buyer,* which is the trade publication for the municipal bond industry. *The Bond Buyer* also provides information on upcoming competitive sales and most negotiated sales, as well as the results of previous weeks.

The sale of bonds by issuers, both competitively and through negotiation, has become more efficient and software based. Two companies offer this service for competitive bond sales. One is Ipreo, which also provides a software platform for negotiated bond sales. The other is the Grant Street Group, which focuses on competitive sales in the municipal market.

Secondary Market

Municipal bonds are traded in the over-the-counter markets supported by municipal bond dealers across the country. Markets are maintained on smaller issuers (referred to as *local credits*) by regional brokerage firms, local banks, and some of the larger Wall Street firms. Larger issuers (referred to as *general market names*) are supported by the larger brokerage firms and banks, many of which have investment banking relationships with these issuers. There are brokers who serve as intermediaries in the sale of large blocks of municipal bonds among dealers and large institutional investors. Additionally, beginning in 2000, bonds in the secondary market, as well as some new issue competitive and negotiated bond issues, began to be auctioned and sold over the Internet by large and small broker-dealers to institutional and individual investors.

In the municipal bond markets, an odd lot of bonds is $5,000 or less in par value for retail investors. For institutions, anything below $1 million in par value is considered an odd lot. Dealer spreads depend on several factors. For the retail investor, the spread can range from as low as one-quarter of one point ($12.50 per $5,000 of par value) on large blocks of actively traded bonds to three points ($150 per $5,000 of par value) for odd-lot sales of an inactive issue. For retail investors, the typical commission should be between 1 and 3 points. For institutional investors, the dealer spread rarely exceeds one-half of 1 point ($25 per $5,000 of par value).

The convention for both corporate and Treasury bonds is to quote prices as a percentage of par value, with 100 equal to par. Municipal bonds, however, generally are traded and quoted in terms of yield (yield-to-maturity or yield-to-call). The price of the bond in this case is called a *basis price.* Certain long-maturity revenue bonds are exceptions. A bond traded and quoted in dollar prices (actually, as a percentage of par value) is called a *dollar bond.*

It should be noted that many institutional investors, for trading and bond purchasing purposes, price bonds off the MMD scale. This is a daily index of generic AAA's prices covering the full yield-curve provided by Thomson Municipal Market Data and available to subscribers over the Internet. Also, the Municipal Securities Rulemaking Board (MSRB) in Washington, DC, reports on a daily basis for no charge actual trades and prices of specific bonds in its EMMA site.[5]

5. www.MSRB.org.

BOND INDEXES

The major provider of total return-based indexes to institutional investors is Bloomberg. Investors use the Bloomberg Barclays Municipal Bond index (formerly Barclays and before that the Lehman Brothers Municipal Bond index) to measure relative total return performance and enhance a fund manager's ability to outperform the market. Lehman began publishing municipal indexes in January of 1980 and by 2020 Bloomberg compiles returns and statistics on more than 2,500 benchmarks. They are broad-based performance measures for the tax-exempt bond market. Similar to all bond indexes provided by Bloomberg, the municipal indexes are rules based and market value weighted. As of 2020, the Bloomberg Barclays Municipal Bond Index contained more than 55,000 bonds with a market value of about $1.2 trillion. To be included in the index, bonds must have a minimum credit rating of Baa/BBB. They must have an outstanding par value of at least $7 million and be part of a transaction of $75 million or greater. The bonds must have been issued after December 31, 1990, and have a remaining maturity of at least one year.

In addition to investment-grade indexes, Bloomberg offers total return benchmarks for the noninvestment-grade tax-exempt market. To ensure statistically significant, representative benchmarks for the lower capitalized states, Bloomberg provides state-specific municipal benchmarks with reduced liquidity requirements.

Many investors use Bloomberg indexes as performance measures for a given market or market segment. The benchmarks are also employed to identify and quantify portfolio bets versus the general market and/or a given peer group.

Indexes also are used to identify relative value opportunities as well as a proxy for the outstanding market. Given the consistent methodologies, the Bloomberg indexes are used often when comparing tax-exempt and taxable fixed income markets.

In addition to the Bloomberg indexes, ICE data services publishes a number of the ICE Merrill Lynch municipal bond indexes. Their product is the ICE US Broad Municipal Index which tracks the performance of more than 58,000 investment-grade tax-exempt municipal bonds. *The Bond Buyer,* the trade daily newspaper, publishes weekly yield indexes.

There are also two services that in the afternoon of each trading day make available generic scales for different maturities and credit ratings. As noted, one is provided by Thomson Municipal Market Data, known in the industry as the MMD scale. The other is by Municipal Market Advisors (MMA).

OFFICIAL STATEMENT

An official statement describing the issue and issuer is prepared for new offerings. Often a preliminary official statement is issued prior to the final official statement. These statements are known as the OS and POS. These statements provide potential investors with a wealth of information. The statements contain basic information about the amount of bonds to be issued, maturity dates, coupons, the use of the bond proceeds, the credit ratings, a general statement about the issuer, and the name of the underwriter and members of the selling group. Much of this information can be found on the cover page or the first few pages of the official statement. It also contains detailed information about the security and sources of payments for the bonds, sources and uses of funds, debt-service requirements, relevant risk factors, issuer's financial statements, a summary of the bond indenture, relevant agreements, notice of any known existing or pending litigation, the bond insurance policy specimen (if insured), and the form of opinion of bond counsel. The official statement contains most of the information an investor will need to make an informed and educated investment decision.

REGULATION OF THE MUNICIPAL SECURITIES MARKET

As an outgrowth of abusive stock market practices, Congress passed the Securities Act of 1933 and the Securities Exchange Act of 1934. The 1934 act created the Securities and Exchange Commission (SEC), granting it regulatory authority over the issuance and trading of *corporate* securities. Congress specifically exempted municipal securities from both the registration requirements of the 1933 act and the periodic reporting requirements of the 1934 act. However, antifraud provisions did apply to offerings of or dealings in municipal securities.

The exemption afforded municipal securities appears to have been due to (1) the desire for governmental comity, (2) the absence of recurrent abuses in transactions involving municipal securities, (3) the greater level of sophistication of investors in this segment of the securities markets (i.e., institutional investors dominated the market), and (4) the fact that there were few defaults by municipal issuers. Consequently, from the enactment of the two federal securities acts in the early 1930s to the early 1970s, the municipal securities market can be characterized as relatively free from federal regulation.

In the early 1970s, however, circumstances changed. As incomes rose, individuals participated in the municipal securities market to a much greater extent. As a result, public outcries over selling practices occurred with greater frequency. For example, in the early 1970s, the SEC obtained seven injunctions against 72 defendants for fraudulent municipal trading practices. According to the SEC, the abusive practices involved both disregard by the defendants as to whether the particular municipal bonds offered to individuals were in fact appropriate investment vehicles for the individuals to whom they were offered, and misrepresentation—failure to disclose information necessary for individuals to assess the credit risk of the municipal issuer, especially in the case of revenue bonds. Moreover, the financial problems of some municipal issuers, notably New York City, made market participants aware that municipal issuers have the potential to experience severe and bankruptcy-type financial difficulties.

Congress passed the Securities Act Amendment of 1975 to broaden regulation in the municipals market. The legislation brought brokers and dealers in the municipal securities market, including banks that underwrite and trade municipal securities, within the regulatory scheme of the Securities Exchange Act of 1934. In addition, the legislation mandated that the SEC establish a 15-member (now 21-member) Municipal Securities Rulemaking Board (MSRB) as an independent, self-regulatory agency whose primary responsibility is to develop rules governing the activities of banks, brokers, and dealers in municipal securities. Rules adopted by the MSRB must be approved by the SEC. The MSRB has no enforcement or inspection authority. This authority is vested with the SEC, the National Association of Securities Dealers, and certain regulatory banking agencies such as the Federal Reserve banks. The Securities Act Amendment of 1975 does *not* require that municipal issuers comply with the registration requirement of the 1933 act or the periodic-reporting requirement of the 1934 act. There have been, however, several legislative proposals to mandate financial disclosure. Although none has been passed, there is clearly pressure to improve disclosure. Even in the absence of federal legislation dealing with the regulation of financial disclosure, underwriters began insisting on greater disclosure as it became apparent that the SEC was exercising stricter application of the antifraud provisions. Moreover, underwriters recognized the need for improved disclosure to sell municipal securities to an investing public that has become much more concerned about credit risk by municipal issuers. On June 28, 1989, the SEC formally approved the first bond disclosure rule, effective January 1, 1990. The following paragraphs summarize its contents. The rule applies to all new issue municipal securities offerings of $1 million or more. Exemptions have been added for securities offered in denominations of $100,000 or more, if such securities

- Are sold to no more than 35 "sophisticated investors"
- Have a maturity of nine months or less
- Are variable-rate demand instruments

Before bidding on or purchasing an offering, underwriters must obtain and review official statements that are deemed final by the issuer, with the omission of no more than the following information:

- Offering price
- Interest rate
- Selling compensation
- Aggregate principal amount
- Principal amount per maturity
- Delivery dates
- Other terms or provisions required by an issuer of such a security to be specified in a competitive bid, ratings, other terms of the securities depending on such matters, and the identity of the underwriters

The underwriters shall contract with an issuer or its designated agent to receive copies of a final official statement within seven business days after any final agreement to purchase, offer, or sell any offering and in sufficient time to accompany any confirmation that requests payment from any customer.

Except for competitively bid offerings, the underwriters shall send, no later than the next business day, to any potential customer, on request, a single copy of the most recent preliminary official statement, if any.

Underwriters are required to distribute the final official statement to any potential customer, on request, within 90 days, or 25 days if the final official statement is available from a repository.

The *Dodd-Frank Wall Street Reform and Consumer Protection Act*, signed into law on July 21, 2010, requires that municipal advisers be subject to SEC registration and MSRB oversight.

Material Event Disclosure Under SEC Rule 15c2-12

The first phase of the implementation of amendments to Rule 15c2-12, which took effect on July 3, 1995, required dealers to determine that issuers before issuing new municipal bonds made arrangements to disclose in the future financial information *at least* annually as well as notices of the occurrence of any of 11 "material event notices" as specified in the rule. By the beginning of 2020, the amended rule increased the material event notices to 16. Also by 2020, the annual report and notices of material events are filed with the Municipal Securities Rulemaking Board (MSRB), in an electronic format as prescribed by the MSRB. The MSRB designated its Electronic Municipal Market Access system (EMMA), found at http://emma.msrb.org, as the repository for such disclosure filings.

The second phase went into effect on January 1, 1996, and required dealers to have in-house procedures in place to provide reasonable assurance that they will receive prompt notice of any material event notices that are required to be disclosed by the issuers.

The Governmental Accounting Standards Board

The Governmental Accounting Standards Board (GASB) is a nonprofit organization that sets generally accepted accounting standards (GAAP) for state and local governments. Providing detailed guidelines and established in 1984, for many years it has improved financial reporting standards in reports of state and local governments that are used by analysts, auditors, and other users. By improving the transparency of state and local government accounting, it helps prevent issuers from obfuscating budget deficits and long-term liabilities that in the past had resulted in budgetary disasters and bond defaults. The Web address is http://gasb.org.

The National Federation of Municipal Analysts

The National Federation of Municipal Analysts (NMFA) was established in 1983, and by 2020 had a membership of more than 1,000 municipal professionals, drawing in part from the institutional investors in municipal bonds who advocated increased and timely information for investors. By 2020, its committees have developed detailed disclosure guidelines and risk factors in municipal securities ranging from specific credit sectors to swap structures. They are recommended for municipal bond issuers to use in providing ongoing financial and operating information to investors. The Web address is www.nfma.org.

KEY POINTS

- The majority of tax-exempt securities are issued by state and local governments and by their creations. Most outstanding municipal bonds are tax-exempt securities, meaning that the interest income is exempt from federal income taxes. Consequently, the major motivation for investing in tax-exempt municipal bonds is their tax advantage. The state and local income tax treatment of interest income from municipal bonds varies.
- In terms of municipal bond security structures, there are basically two different types: general obligation bonds (secured by the issuer's general taxing powers) and revenue bonds (issued for either project or enterprise financings in which the bond issuers pledge to the bondholders the revenues generated by the operating projects financed). There are bonds with security structures that have certain characteristics of general obligation and revenue bonds. These hybrid and special bond securities include refunded bonds, dedicated tax-backed and structured asset-backed bonds, insured bonds, lease-backed bonds, letter of credit–backed bonds, moral obligation bonds, and territorial bonds. Municipal money market products include notes, commercial paper, variable-rate demand obligations, and commercial paper mode.
- Municipal bonds are assigned credit ratings by commercial rating agencies (Moody's, Standard & Poor's, and Fitch) just like corporate bonds. Some investors do not perform their own credit-risk analysis, but instead rely entirely on credit-risk ratings assigned. Large institutional investors, underwriters, and traders tend to use ratings as a starting point in evaluating a municipal credit and then rely on their own in-house municipal credit analysts for determining the creditworthiness of municipal bonds.
- As in other sectors of the bond market, yield measures such as yield to maturity and yield to call are computed. In comparing a tax-exempt

municipal bond yield to that of a comparable taxable yield, the taxable equivalent yield is computed.

- Tax considerations in investing in tax-exempt municipal bonds include original issue discount embedded in an issue, the alternative minimum tax, deductibility of interest expense incurred to acquire a municipal bond, and treatment of interest income at the state and local tax levels.
- Bloomberg is the major provider of total return–based municipal bond indexes that are used by institutional investors. The Bloomberg Municipal Bond Index is used to measure relative total return performance. The Bloomberg indexes are available for a given market or market segment within the municipal bond market. Thomson Municipal Market Data and Municipal Market Advisors are two services that in the afternoon of each trading day make available generic scales for different maturities and different credit ratings in the municipal bond market.
- An official statement (OS) describing the issue and the issuer is prepared for new offerings. Typically a preliminary official statement (POS) is issued prior to the final official statement.

CHAPTER
TEN

CORPORATE BONDS

Frank J. Fabozzi, Ph.D., CFA, CPA

Attorney and Founder (retired)
of Covenant Review

In its simplest form, a corporate bond is a debt instrument that obligates the issuer to pay a specified percentage of the bond's par value on designated dates (the coupon payments) and to repay the bond's par or principal value at maturity. Failure to pay the interest and/or principal when due (and to meet other of the debt's provisions) in accordance with the instrument's terms constitutes legal default, and court proceedings can be instituted to enforce the contract. Bondholders as creditors have a prior legal claim over common and preferred shareholders as to both the corporation's income and assets for cash flows due them and may have a prior claim over other creditors if liens and mortgages are involved. This legal priority does not insulate bondholders from financial loss. Indeed, bondholders are fully exposed to the firm's prospects as to the ability to generate cash flow sufficient to pay its obligations.

Corporate bonds usually are issued in denominations of $1,000 and multiples thereof. In common usage, a corporate bond is assumed to have a par value of $1,000 unless otherwise explicitly specified. A security dealer who says that she has five bonds to sell means five bonds each of $1,000 principal amount. If the promised rate of interest (coupon rate) is 6%, the annual amount of interest on each bond is $60, and the semiannual interest is $30.

Although there are technical differences between bonds, notes, and debentures, we will use Wall Street convention and call fixed income debt by the general term—*bonds*. Therefore, practically speaking, it is motivated bond investors who examine covenant compliance and bring alleged violations to the trustee's attention.

THE CORPORATE TRUSTEE

The promises of corporate bond issuers and the rights of investors who buy them are set forth in great detail in contracts generally called *indentures*. If bondholders were handed the complete indenture, some may have trouble understanding the legalese and have even greater difficulty in determining from time to time if the corporate issuer is keeping all the promises made. Further, it may be practically difficult and expensive for any one bondholder to try to enforce the indenture if those promises are not being kept. These problems are solved in part by bringing in a *corporate trustee* as a third party to the contract. The indenture is made out to the corporate trustee as a representative of the interests of bondholders; that is, the trustee acts in a fiduciary capacity for investors who own the bond issue.

A corporate trustee is a bank or trust company with a corporate trust department and officers who are experts in performing the functions of a trustee. The corporate trustee must, at the time of issue, authenticate the bonds issued; that is, keep track of all the bonds sold, and make sure that they do not exceed the principal amount authorized by the indenture. It must obtain and address various certifications and requests from issuers, attorneys, and bondholders about compliance with the covenants of the indenture. These covenants are many and technical, and they must be watched during the entire period that a bond issue is outstanding. We will describe some of these covenants in subsequent pages.

It is very important that corporate trustees be competent and financially responsible. To this end, there is a federal statute known as the Trust Indenture Act that generally requires a corporate trustee for corporate bond offerings in the amount of more than $5 million sold in interstate commerce. The indenture must include adequate requirements for performance of the trustee's duties on behalf of bondholders; there must be no conflict between the trustee's interest as a trustee and any other interest it may have, especially if it is also a creditor of the issuer; and there must be provision for reports by the trustee to bondholders. If a corporate issuer has breached an indenture promise, such as not to borrow additional secured debt, or fails to pay interest or principal, the trustee may declare a default and take such action as may be necessary to protect the rights of bondholders.

However, it must be emphasized that the trustee is paid by the debt issuer and can only do what the indenture provides. The indenture may contain a clause stating that the trustee undertakes to perform such duties and only such duties as are specifically set forth in the indenture, and no implied covenants or obligations shall be read into the indenture against the trustee. Trustees often are not required to take actions such as monitoring corporate balance sheets to determine issuer covenant compliance, and in fact, indentures often expressly allow a trustee to rely upon certifications and opinions from the issuer and its attorneys. The trustee is generally not bound to make investigations into the facts surrounding documents delivered to it, but it may do so if it sees fit. Also, the trustee is usually under no obligation to exercise the rights or powers under the indenture at the request of bondholders unless it has been offered reasonable security or indemnity.

The terms of bond issues set forth in bond indentures are always a compromise between the interests of the bond issuer and those of investors who buy bonds. The issuer always wants to pay the lowest possible rate of interest and wants its actions bound as little as possible with legal covenants. Bondholders want the highest possible interest rate, the best security, and a variety of covenants to restrict the issuer in one way or another. As we discuss the provisions of bond indentures, keep this opposition of interests in mind and see how compromises are worked out in practice. A more detailed description of covenants is provided in Chapter 40 where credit analysis is covered.

SOME BOND FUNDAMENTALS

Bonds can be classified by a number of characteristics, which we will use for ease of organizing this section.

Bonds Classified by Issuer Type

The five broad categories of corporate bonds sold in the United States based on the type of issuer are public utilities, transportations, industrials, banks and finance companies, and international or Yankee issues. Finer breakdowns are often made by market participants to create homogeneous groupings. For example, public utilities are subdivided into telephone or communications, electric companies, gas distribution and transmission companies, and water companies. The transportation industry can be subdivided into airlines, railroads, and trucking companies. Like public utilities, transportation companies often have various degrees of regulation or control by state and/or federal government agencies. Industrials are a catchall class, but even here, finer degrees of distinction may be needed by analysts. The industrial grouping includes manufacturing and mining concerns, retailers, and service-related companies. Even the Yankee or international borrower sector can be more finely tuned. For example, one might classify the issuers into categories such as supranational borrowers (International Bank for Reconstruction and Development and the European Investment Bank), sovereign issuers (Canada, Australia, and the United Kingdom), and foreign municipalities and agencies.

Corporate Debt Maturity

A bond's maturity is the date on which the issuer's obligation to satisfy the terms of the indenture is fulfilled. On that date, the principal is repaid with any premium and accrued interest that may be due. However, as we shall see later when discussing debt redemption, the final maturity date as stated in the issue's title may or may not be the date when the contract terminates. Many issues can be retired prior to maturity. The maturity structure of a particular corporation can be accessed using the Bloomberg function DDIS.

Interest Payment Characteristics

The three main interest payment classifications of domestically issued corporate bonds are straight-coupon bonds, zero-coupon bonds, and floating-rate, or variable-rate, bonds. Floating-rate issues are discussed in Chapter 14, and the other two types are examined below.

However, before we get into interest-rate characteristics, let us briefly discuss bond types. We refer to the interest rate on a bond as the *coupon*. This is technically wrong because bonds issued today do not have coupons attached. Instead, bonds are represented by a certificate, similar to a stock certificate, with a brief description of the terms printed on both sides. These are called *registered bonds*. The principal amount of the bond is noted on the certificate, and the interest-paying agent or trustee has the responsibility of making payment by check to the registered holder on the due date. Years ago bonds were issued in *bearer* or coupon form, with coupons attached for each interest payment. However, the registered form is considered safer and entails less paperwork. As a matter of fact, the registered bond certificate is on its way out as more and more issues are sold in *book-entry* form. This means that only one master or global certificate is issued. It is held by a central securities depository that issues receipts denoting interests in this global certificate.

Straight-coupon bonds have an interest rate set for the life of the issue, however long or short that may be; they are also called *fixed-rate bonds*. Most fixed-rate bonds in the United States pay interest semiannually and at maturity. For example, consider a 4.75% bond due 2033 issued in July 2013. This bond carries a coupon rate of 4.75% and has a par amount of $1,000. Accordingly, this bond requires payments of $23.75 each January 15 and July 15, including the maturity date of July 15, 2033. On the maturity date, the bond's par amount is also paid. Bonds with annual coupon payments are uncommon in the U.S. capital markets but are the norm in continental Europe.

Interest on corporate bonds is based on a year of 360 days made up of twelve 30-day months. The corporate calendar day-count convention is referred to as 30/360.

Most fixed-rate corporate bonds pay interest in a standard fashion. However, there are some variations of which one should be aware. Most domestic bonds pay interest in U.S. dollars. However, starting in the early 1980s, issues were marketed with principal and interest payable in other currencies, such as the Australian, New Zealand, or Canadian dollar or the British pound. Generally, interest and principal payments are converted from the foreign currency to U.S. dollars by the paying agent unless it is otherwise notified. The bondholders bear any costs associated with the dollar conversion. Foreign currency issues provide investors with another way of diversifying a portfolio, but not without risk. The holder bears the currency, or exchange-rate, risk in addition to all the other risks associated with debt instruments.

There are a few issues of bonds that can participate in the fortunes of the issuer over and above the stated coupon rate. These are called *participating* *bonds* because they share in the profits of the issuer or the rise in certain assets over and above certain minimum levels. Another type of bond rarely encountered today is the *income bond.* These bonds promise to pay a stipulated interest rate, but the payment is contingent on sufficient earnings and is in accordance with the definition of available income for interest payments contained in the indenture. Repayment of principal is not contingent. Interest may be cumulative or noncumulative. If payments are cumulative, unpaid interest payments must be made up at some future date. If noncumulative, once the interest payment is past, it does not have to be repaid. Failure to pay interest on income bonds is not an act of default and is not a cause for bankruptcy. Income bonds have been issued by some financially troubled corporations emerging from reorganization proceedings.

Zero-coupon bonds are, just as the name implies, bonds without coupons or an interest rate. Essentially, zero-coupon bonds pay only the principal portion at some future date. These bonds are issued at discounts to par; the difference constitutes the return to the bondholder. The difference between the face amount and the offering price when first issued is called the *original-issue discount* (OID). The rate of return depends on the amount of the discount and the period over which it accretes to par.

Zeros were first publicly issued in the corporate market in the spring of 1981 and were an immediate hit with investors. The rapture lasted only a couple of years because of changes in the income tax laws that made ownership more costly on an after-tax basis. Also, these changes reduced the tax advantages to issuers. However, tax-deferred investors, such as pension funds, could still take advantage of zero-coupon issues. One important risk is eliminated in a zero-coupon investment—the reinvestment risk. Because there is no coupon to reinvest, there isn't any reinvestment risk. Of course, although this is beneficial in declining-interest-rate markets, the reverse is true when interest rates are rising. The investor will not be able to reinvest an income stream at rising reinvestment rates. Investors tend to find zeros less attractive in lower-interest-rate markets because compounding is not as meaningful as when rates are higher. Also, the lower the rates are, the more likely it is that they will rise again, making a zero-coupon investment worth less in the eyes of potential holders.

In bankruptcy, a zero-coupon bond creditor can claim the original offering price plus the accretion that represents accrued and unpaid interest to the date of the bankruptcy filing, but not the principal amount of $1,000. Zero-coupon bonds have been sold at deep discounts, and the liability of the issuer at maturity may be substantial. The accretion of the discount on the corporation's books is not put away in a special fund for debt retirement purposes. There are no sinking funds on most of these issues. One hopes that corporate managers invest the proceeds properly and run the corporation for the benefit of all investors so that there will not be a cash crisis at maturity. The potentially large balloon repayment creates a cause for concern among investors. Thus it is most important to invest in higher-quality issues so as to reduce the risk of a potential problem.

If one wants to speculate in lower-rated bonds, then that investment should throw off some cash return.

Finally, a variation of the zero-coupon bond is the *deferred-interest bond* (DIB). These bonds generally have been subordinated issues of speculative-grade issuers, also known as *junk issuers*. Most of the issues are structured so that they do not pay cash interest for the first five years. At the end of the deferred-interest period, cash interest accrues and is paid semiannually until maturity, unless the bonds are redeemed earlier. The deferred-interest feature allows newly restructured, highly leveraged companies and others with less-than-satisfactory cash flows to defer the payment of cash interest over the early life of the bond. Barring anything untoward, when cash interest payments start, the company will be able to service the debt. If it has made excellent progress in restoring its financial health, the company may be able to redeem or refinance the debt rather than have high interest outlays.

An offshoot of the deferred-interest bond is the *pay-in-kind (PIK) debenture*. With PIKs, cash interest payments are deferred at the issuer's option until some future date. Instead of just accreting the original-issue discount as with DIBs or zeros, the issuer pays out the interest in additional pieces of the same security. The option to pay cash or in-kind interest payments rests with the issuer, but in many cases the issuer has little choice because provisions of other debt instruments often prohibit cash interest payments until certain indenture or loan tests are satisfied. The holder just gets more pieces of paper, but these at least can be sold in the market without giving up one's original investment; PIKs, DIBs, and zeros do not have provisions for the resale of the interest portion of the instrument. An investment in this type of bond, because it is issued by speculative-grade companies, requires careful analysis of the issuer's cash-flow prospects and ability to survive.

SECURITY FOR BONDS

Investors who buy corporate bonds prefer some kind of security underlying the issue. Either real property (using a mortgage) or personal property may be pledged to offer security beyond that of the general credit standing of the issuer. In fact, the kind of security or the absence of a specific pledge of security is usually indicated by the title of a bond issue. However, the best security is a strong general credit that can repay the debt from earnings.

Mortgage Bond

A mortgage bond grants the bondholders a first-mortgage lien on substantially all its properties. This lien provides additional security for the bondholder. As a result, the issuer is able to borrow at a lower rate of interest than if the debt were unsecured. A debenture issue (i.e., unsecured debt) of the same issuer almost surely would carry a higher coupon rate, other things equal. A *lien* is a legal right to sell mortgaged property to satisfy unpaid obligations to bondholders. In practice, foreclosure of a mortgage and sale of mortgaged property are unusual. If a default occurs, there is usually a financial reorganization on the part of the issuer, in which provision is made for settlement of the debt to bondholders. The mortgage lien is important, though, because it gives the mortgage bondholders a very strong bargaining position relative to other creditors in determining the terms of a reorganization.

Often first-mortgage bonds are issued in series with bonds of each series secured equally by the same first mortgage. Many companies, particularly public utilities, have a policy of financing part of their capital requirements continuously by long-term debt. They want some part of their total capitalization in the form of bonds because the cost of such capital is ordinarily less than that of capital raised by sale of stock. Thus, as a principal amount of debt is paid off, they issue another series of bonds under the same mortgage. As they expand and need a greater amount of debt capital, they can add new series of bonds. It is a lot easier and more advantageous to issue a series of bonds under one mortgage and one indenture than it is to create entirely new bond issues with different arrangements for security. This arrangement is called a *blanket mortgage*. When property is sold or released from the lien of the mortgage, additional property or cash may be substituted or bonds may be retired in order to provide adequate security for the debtholders.

When a bond indenture authorizes the issue of additional series of bonds with the same mortgage lien as those already issued, the indenture imposes certain conditions that must be met before an additional series may be issued. Bondholders do not want their security impaired; these conditions are for their benefit. It is common for a first-mortgage bond indenture to specify that property acquired by the issuer subsequent to the granting of the first-mortgage lien shall be subject to the first-mortgage lien. This is termed the *after-acquired clause.* Then the indenture usually permits the issue of additional bonds up to some specified percentage of the value of the after-acquired property, such as 60%. The other 40%, or whatever the percentage may be, must be financed in some other way. This is intended to ensure that there will be additional assets with a value significantly greater than the amount of additional bonds secured by the mortgage. Another customary kind of restriction on the issue of additional series is a requirement that earnings in an immediately preceding period must be equal to some number of times the amount of annual interest on all outstanding mortgage bonds including the new or proposed series (1.5, 2, or some other number). For this purpose, *earnings* usually are defined as earnings before income tax. Still another common provision is that additional bonds may be issued to the extent that earlier series of bonds have been paid off.

One seldom sees a bond issue with the term *second mortgage* in its title. The reason is that this term has a connotation of weakness. Sometimes companies get around that difficulty by using such words as *first and consolidated, first and refunding,* or *general and refunding mortgage bonds.* Usually this language means that a bond issue is secured by a first mortgage on some part of the issuer's property but by a second or even third lien on other parts of its assets. A general and refunding mortgage bond is generally secured by a lien on all the company's property *subject* to the prior lien of first-mortgage bonds, if any are still outstanding.

Collateral Trust Bonds

Some companies do not own fixed assets or other real property and so have nothing on which they can give a mortgage lien to secure bondholders. Instead, they own securities of other companies; they are *holding companies,* and the other companies are *subsidiaries*. To satisfy the desire of bondholders for security, they pledge stocks, notes, bonds, or whatever other kinds of obligations they own. These assets are termed *collateral* (or personal property), and bonds secured by such assets are *collateral trust bonds*. Some companies own both real property and securities. They may use real property to secure mortgage bonds and use securities for collateral trust bonds. As an example, consider the 10.375% Collateral Trust Bonds due 2018 issued by National Rural Utilities. According to the bond's prospectus, the securities deposited with the trustee include mortgage notes, cash, and other permitted investments.

The legal arrangement for collateral trust bonds is much the same as that for mortgage bonds. The issuer delivers to a corporate trustee under a bond indenture the securities pledged, and the trustee holds them for the benefit of the bondholders. When voting common stocks are included in the collateral, the indenture permits the issuer to vote the stocks so long as there is no default on its bonds. This is important to issuers of such bonds because usually the stocks are those of subsidiaries, and the issuer depends on the exercise of voting rights to control the subsidiaries.

Indentures usually provide that, in event of default, the rights to vote stocks included in the collateral are transferred to the trustee. Loss of the voting right would be a serious disadvantage to the issuer because it would mean loss of control of subsidiaries. The trustee also may sell the securities pledged for whatever prices they will bring in the market and apply the proceeds to payment of the claims of collateral trust bondholders. These rather drastic actions, however, usually are not taken immediately on an event of default. The corporate trustee's primary responsibility is to act in the best interests of bondholders, and their interests may be served for a time at least by giving the defaulting issuer a proxy to vote stocks held as collateral and thus preserve the holding company structure. It also may defer the sale of collateral when it seems likely that bondholders would fare better in a financial reorganization than they would by sale of collateral.

Collateral trust indentures contain a number of provisions designed to protect bondholders. Generally, the market or appraised value of the collateral must be maintained at some percentage of the amount of bonds outstanding. If collateral value declines below the minimum percentage, additional collateral must be provided by the issuer. There is almost always provision for withdrawal of some collateral, provided other acceptable collateral is substituted.

Collateral trust bonds may be issued in series in much the same way that mortgage bonds are issued in series. The rules governing additional series of bonds require that adequate collateral must be pledged, and there may be restrictions on the use to which the proceeds of an additional series may be put. All series of bonds are issued under the same indenture and have the same claim on collateral.

Since 2005, an increasing percentage of high-yield bond issues have been secured by some mix of mortgages and other collateral on a first, second, or even third lien basis. These secured high yield bonds have very customized provisions for issuing additional secured debt and there is some debate about whether the purported collateral for these kinds of bonds will provide greater recoveries in bankruptcy than traditional unsecured capital structures over an economic cycle.

Equipment Trust Certificates

The desire of borrowers to pay the lowest possible rate of interest on their obligations generally leads them to offer their best security and to grant lenders the strongest claim on it. Many years ago, the railway companies developed a way of financing purchase of cars and locomotives, called *rolling stock,* that enabled them to borrow at just about the lowest rates in the corporate bond market.

Railway rolling stock has for a long time been regarded by investors as excellent security for debt. This equipment is sufficiently standardized that it can be used by one railway as well as another. And it can be readily moved from the tracks of one railroad to those of another. There is generally a good market for lease or sale of cars and locomotives. The railroads have capitalized on these characteristics of rolling stock by developing a legal arrangement for giving investors a legal claim on it that is different from, and generally better than, a mortgage lien.

The legal arrangement is one that vests legal title to railway equipment in a trustee, which is better from the standpoint of investors than a first-mortgage lien on property. A railway company orders some cars and locomotives from a manufacturer. When the job is finished, the manufacturer transfers the legal title to the equipment to a trustee. The trustee leases it to the railroad that ordered it and at the same time sells *equipment trust certificates* (ETCs) in an amount equal to a large percentage of the purchase price, normally 80%. Money from the sale of certificates is paid to the manufacturer. The railway company makes an initial payment of rent equal to the balance of the purchase price, and the trustee gives that money to the manufacturer. Thus the manufacturer is paid off. The trustee collects lease rental money periodically from the railroad and uses it to pay interest and principal on the certificates. These interest payments are known as dividends. The amounts of lease rental payments are worked out carefully so that they are enough to pay the equipment trust certificates. At the end of some period of time, such as 15 years, the certificates are paid off, the trustee sells the equipment to the railroad for some nominal price, and the lease is terminated.

Railroad ETCs usually are structured in serial form; that is, a certain amount becomes payable at specified dates until the final installment. For example, a $60 million ETC might mature $4 million on each June 15 from 2014 through 2028. Each of the 15 maturities may be priced separately to reflect the shape of the yield curve, investor preference for specific maturities, and supply-and-demand considerations. The advantage of a serial issue from the investor's point of view is that the repayment schedule matches the decline in the value of the equipment used as collateral. Hence principal repayment risk is reduced. From the issuer's side, serial maturities allow for the repayment of the debt periodically over the life of the issue, making less likely a crisis at maturity due to a large repayment coming due at one time.

The beauty of this arrangement from the viewpoint of investors is that the railroad does not legally own the rolling stock until all the certificates are paid. In case the railroad does not make the lease rental payments, there is no big legal hassle about foreclosing a lien. The trustee owns the property and can take it back because failure to pay the rent breaks the lease. The trustee can lease the equipment to another railroad and continue to make payments on the certificates from new lease rentals.

This description emphasizes the legal nature of the arrangement for securing the certificates. In practice, these certificates are regarded as obligations of the railway company that leased the equipment and are shown as liabilities on its balance sheet. In fact, the name of the railway appears in the title of the certificates. In the ordinary course of events, the trustee is just an intermediary who performs the function of holding title, acting as lessor, and collecting the money to pay the certificates. It is significant that even in the worst years of a depression, railways have paid their equipment trust certificates, although they did not pay bonds secured by mortgages. Although railroads have issued the largest amount of equipment trust certificates, airlines also have used this form of financing.

Debenture Bonds

While bondholders prefer to have security underlying their bonds, all else equal, most bonds issued are unsecured. These unsecured bonds are called *debentures.* With the exception of the utilities and structured products, nearly all other corporate bonds issued are unsecured.

Debentures are not secured by a specific pledge of designated property, but this does not mean that they have no claim on the property of issuers or on their earnings. Debenture bondholders have the claim of general creditors on all assets of the issuer not pledged specifically to secure other debt. And they even have a claim on pledged assets to the extent that these assets have value greater than necessary to satisfy secured creditors. In fact, if there are no pledged assets and no secured creditors, debenture bondholders have first claim on all assets along with other general creditors.

These unsecured bonds are sometimes issued by companies that are so strong financially and have such a high credit rating that to offer security would be superfluous. Such companies simply can turn a deaf ear to investors who want security and still sell their debentures at relatively low interest rates. But debentures sometimes are issued by companies that have already sold mortgage bonds and given liens on most of their property. These debentures rank below the mortgage bonds or collateral trust bonds in their claim on assets, and investors may regard them as relatively weak. This is the kind that bears the higher rates of interest.

Even though there is no pledge of security, the indentures for debenture bonds may contain a variety of provisions designed to afford some protection to investors. Sometimes the amount of a debenture bond issue is limited to the amount of the initial issue. This limit is to keep issuers from weakening the position of debenture holders by running up additional unsecured debt. Sometimes additional debentures may be issued a specified number of times in a recent accounting period, provided that the issuer has earned its bond interest on all existing debt plus the additional issue.

If a company has no secured debt, it is customary to provide that debentures will be secured equally with any secured bonds that may be issued in the future. This is known as the *negative-pledge clause.* Some provisions of debenture bond issues are intended to protect bondholders against other issuer actions when they might be too harmful to the creditworthiness of the issuer. For example, some provisions of debenture bond issues may require maintaining some level of net worth, restrict selling major assets, or limit paying dividends in some cases. However, the trend in recent years, at least with investment-grade companies, is away from indenture restrictions.

Subordinated and Convertible Debentures

Many corporations issue *subordinated debenture bonds*. The term *subordinated* means that such an issue ranks after secured debt, after debenture bonds, and often after some general creditors in its claim on assets and earnings. Owners of this kind of bond stand last in line among creditors when an issuer fails financially.

Because subordinated debentures are weaker in their claim on assets, issuers would have to offer a higher rate of interest unless they also offer some special inducement to buy the bonds. The inducement can be an option to convert bonds into stock of the issuer at the discretion of bondholders. If the issuer prospers and the market price of its stock rises substantially in the market, the bondholders can convert bonds to stock worth a great deal more than what they paid for the bonds. This conversion privilege also may be included in the provisions of debentures that are not subordinated. Convertible securities are discussed in Chapters 38 and 39.

The bonds may be convertible into the common stock of a corporation other than that of the issuer. Such issues are called *exchangeable bonds.* There are also issues indexed to a commodity's price or its cash equivalent at the time of maturity or redemption.

Guaranteed Bonds

Sometimes a corporation may guarantee the bonds of another corporation. Such bonds are referred to as *guaranteed bonds.* The guarantee, however, does not mean that these obligations are free of default risk. The safety of a guaranteed bond depends on the financial capability of the guarantor to satisfy the terms of the guarantee, as well as the financial capability of the issuer. The terms of the guarantee may call for the guarantor to guarantee the payment of interest and/or repayment of the principal. A guaranteed bond may have more than one corporate guarantor. Each guarantor may be responsible for not only its pro rata share but also the entire amount guaranteed by the other guarantors.

ALTERNATIVE MECHANISMS TO RETIRE DEBT BEFORE MATURITY

We can partition the alternative mechanisms to retire debt into two broad categories—namely, those mechanisms that must be included in the bond's indenture in order to be used and those mechanisms that can be used without being included in the bond's indenture. Among those debt retirement mechanisms included in a bond's indenture are the following: call and refunding provisions, sinking funds, maintenance and replacement funds, and redemption through sale of assets. Alternatively, some debt retirement mechanisms are not required to be included in the bond indenture (e.g., fixed-spread tender offers).

Call and Refunding Provisions

Many corporate bonds contain an embedded option that gives the issuer the right to buy the bonds back at a fixed price either in whole or in part prior to maturity. The feature is known as a *call provision.* The ability to retire debt before its scheduled maturity date is a valuable option for which bondholders will demand compensation ex-ante. All else equal, bondholders will pay a lower price for a callable bond than an otherwise identical option-free (i.e., straight) bond. The difference between the price of an option-free bond and the callable bond is the value of the embedded call option.

Conventional wisdom suggests that the most compelling reason for corporations to retire their debt prior to maturity is to take advantage of declining borrowing rates. If they are able to do so, firms will substitute new, lower-cost debt for older, higher-cost issues. However, firms retire their debt for other reasons as well. For example, firms retire their debt to eliminate restrictive covenants, to alter their capital structure, to increase shareholder value, or to improve financial/managerial flexibility. There are two types of call provisions included in corporate bonds—a fixed-price call and a make-whole call. We will discuss each in turn.

Fixed-Price Call Provision

With a standard fixed-price call provision, the bond issuer has the option to buy back some or all of the bond issue prior to maturity at a fixed price. The fixed price is termed the *call price*. Normally, the bond's indenture contains a call-price schedule that specifies when the bonds can be called and at what prices. The call prices generally start at a substantial premium over par and decline toward par over time such that in the final years of a bond's life, the call price is usually par.

In some corporate issues, bondholders are afforded some protection against a call in the early years of a bond's life. This protection usually takes one of two forms. First, some callable bonds possess a feature that prohibits a bond call for a certain number of years. Second, some callable bonds prohibit the bond from being refunded for a certain number of years. Such a bond is said to be *nonrefundable*. Prohibition of refunding precludes the redemption of a bond issue if the funds used to repurchase the bonds come from new bonds being issued with a lower coupon than the bonds being redeemed. However, a refunding prohibition does not prevent the redemption of bonds from funds obtained from other sources (e.g., asset sales, the issuance of equity, etc.). Call prohibition provides the bondholder with more protection than a bond that has a refunding prohibition that is otherwise callable.[1]

Make-Whole Call Provision

In contrast to a standard fixed-price call, a make-whole call price is calculated as the present value of the bond's remaining cash flows subject to a floor price equal to par value. The discount rate used to determine the present value is the yield on a comparable-maturity Treasury security plus a contractually specified *make-whole call premium.* These notes are redeemable at any time either in whole or in part at the issuer's option. The redemption price is the greater of (1) 100% of the principal amount plus accrued interest or (2) the make-whole redemption price, which is equal to the sum of the present value of the remaining coupon and principal payments discounted at the Treasury rate plus 10 basis points. The spread of 10 basis points is the aforementioned make-whole call premium. Thus the make-whole call price is essentially a floating call price that moves inversely with the level of interest rates.

1. There are, of course, exceptions to a call prohibition, such as sinking funds and redemption of the debt under certain mandatory provisions.

The Treasury rate is calculated in one of two ways. One method is to use a constant-maturity Treasury (CMT) yield as the Treasury rate. CMT yields are published weekly by the Federal Reserve in its statistical release H.15. The maturity of the CMT yield will match the bond's remaining maturity (rounded to the nearest month). If there is no CMT yield that exactly corresponds with the bond's remaining maturity, a linear interpolation is employed using the yields of the two closest available CMT maturities. Once the CMT yield is determined, the discount rate for the bond's remaining cash flows is simply the CMT yield plus the make-whole call premium specified in the indenture.

Another method of determining the Treasury rate is to select a U.S. Treasury security having a maturity comparable with the remaining maturity of the make-whole call bond in question. This selection is made by a primary U.S. Treasury dealer designated in the bond's indenture. An average price for the selected Treasury security is calculated using the price quotations of multiple primary dealers. The average price is then used to calculate a bond-equivalent yield. This yield is then used as the Treasury rate.

Make-whole call provisions were first introduced in publicly traded corporate bonds in 1995. Bonds with make-whole call provisions are now issued routinely for bonds issued in the investment-grade market, while bonds with fixed-price call provisions are generally used for bonds issued in the high-yield market.

The primary advantage from the firm's perspective of a make-whole call provision relative to a fixed-price call is a lower cost. Since the make-whole call price floats inversely with the level of Treasury rates, the issuer will not exercise the call to buy back the debt merely because its borrowing rates have declined. Simply put, the pure refunding motive is virtually eliminated. This feature will reduce the upfront compensation required by bondholders to hold make-whole call bonds versus fixed-price call bonds.

Sinking-Fund Provision

Term bonds may be paid off by operation of a *sinking fund.* These last two words are often misunderstood to mean that the issuer accumulates a fund in cash, or in assets readily sold for cash, that is used to pay bonds at maturity. It had that meaning many years ago, but too often the money supposed to be in a sinking fund was not all there when it was needed. In modern practice, there is no fund, and *sinking* means that money is applied periodically to redemption of bonds before maturity. Corporate bond indentures require the issuer to retire a specified portion of an issue each year. This kind of provision for repayment of corporate debt may be designed to liquidate all of a bond issue by the maturity date, or it may be arranged to pay only a part of the total by the end of the term.

The issuer may satisfy the sinking-fund requirement in one of two ways. A cash payment of the face amount of the bonds to be retired may be made by the corporate debtor to the trustee. The trustee then calls the bonds pro rata or by lot for redemption. Bonds have serial numbers, and numbers may be selected randomly for redemption. Owners of bonds called in this manner turn them in for redemption; *interest payments stop at the redemption date.* Alternatively, the issuer can deliver to the trustee bonds with a total face value equal to the amount that must be retired. The bonds are purchased by the *issuer* in the open market. This option is elected by the issuer when the bonds are selling below par. A few corporate bond indentures, however, prohibit the open-market purchase of the bonds by the issuer.

Many electric utility bond issues can satisfy the sinking-fund requirement by a third method. Instead of actually retiring bonds, the company may certify to the trustee that it has used unfunded property credits in lieu of the sinking fund. That is, it has made property and plant investments that have not been used for issuing bonded debt. For example, if the sinking-fund requirement is $1 million, it may give the trustee $1 million in cash to call bonds, it may deliver to the trustee $1 million of bonds it purchased in the open market, or it may certify that it made additions to its property and plant in the required amount, normally $1,667 of plant for each $1,000 sinking-fund requirement. In this case it could satisfy the sinking fund with certified property additions of $1,667,000.

The issuer is granted a special call price to satisfy any sinking-fund requirement. Usually, the sinking-fund call price is the par value if the bonds were originally sold at par. When issued at a price in excess of par, the sinking-fund call price generally starts at the issuance price and scales down to par as the issue approaches maturity.

There are two advantages of a sinking-fund requirement from the bondholder's perspective. First, default risk is reduced because of the orderly retirement of the issue before maturity. Second, if bond prices decline as a result of an increase in interest rates, price support may be provided by the issuer or its fiscal agent because it must enter the market on the buy side in order to satisfy the sinking-fund requirement. However, the disadvantage is that the bonds may be called at the special sinking-fund call price at a time when interest rates are lower than rates prevailing at the time of issuance. In that case, the bonds will be selling above par but may be retired by the issuer at the special call price that may be equal to par value.

Usually, the periodic payments required for sinking-fund purposes will be the same for each period. Gas company issues often have increasing sinking-fund requirements. However, a few indentures might permit variable periodic payments, where the periodic payments vary based on prescribed conditions set forth in the indenture. The most common condition is the level of earnings of the issuer. In such cases, the periodic payments vary directly with earnings. An issuer prefers such flexibility; however, an investor may prefer fixed periodic payments because of the greater default risk protection provided under this arrangement.

Many corporate bond indentures include a provision that grants the issuer the option to retire more than the amount stipulated for sinking-fund retirement. This option, referred to as an *accelerated sinking-fund provision,* effectively reduces the bondholder's call protection because, when interest rates decline, the issuer may find it economically advantageous to exercise this option at the special sinking-fund call price to retire a substantial portion of an outstanding issue.

Sinking fund provisions have fallen out of favor for most companies, but they used to be fairly common for public utilities, pipeline issuers, and some industrial issues. Finance issues almost never include a sinking fund provision. There can be a mandatory sinking fund where bonds have to be retired or, as mentioned earlier, a nonmandatory sinking fund in which it may use certain property credits for the sinking-fund requirement. If the sinking fund applies to a particular issue, it is called a *specific sinking fund.* There are also *nonspecific sinking funds* (also known as *funnel, tunnel, blanket,* or *aggregate sinking funds*), where the requirement is based on the total bonded debt outstanding of an issuer. Generally, it might require a sinking-fund payment of 1% of all bonds outstanding as of year-end. The issuer can apply the requirement to one particular issue or to any other issue or issues. Again, the blanket sinking fund may be mandatory (where bonds have to be retired) or nonmandatory (whereby it can use unfunded property additions).

Maintenance and Replacement Funds

Maintenance and replacement fund (M&R) provisions first appeared in bond indentures of electric utilities subject to regulation by the Securities and Exchange Commission (SEC) under the Public Holding Company Act of 1940. It remained in the indentures even when most of the utilities were no longer subject to regulation under the act. The original motivation for their inclusion is straightforward. Property is subject to economic depreciation, and the replacement fund ostensibly helps to maintain the integrity of the property securing the bonds. An M&R differs from a sinking fund in that the M&R only helps to maintain the value of the security backing the debt, whereas a sinking fund is designed to improve the security backing the debt. Although it is more complex, it is similar in spirit to a provision in a home mortgage requiring the homeowner to maintain the home in good repair.

An M&R requires a utility to determine annually the amounts necessary to satisfy the fund and any shortfall. The requirement is based on a formula that is usually some percentage (e.g., 15%) of adjusted gross operating revenues. The difference between what is required and the actual amount expended on maintenance is the shortfall. The shortfall is usually satisfied with unfunded property additions, but it also can be satisfied with cash. The cash can be used for the retirement of debt or withdrawn on the certification of unfunded property credits. While the retirement of debt through M&R provisions is not as common as it once was, M&Rs are still relevant, so bond investors should be cognizant of their presence in an indenture.

Redemption Through the Sale of Assets and Other Means

Because mortgage bonds are secured by property, bondholders want the integrity of the collateral to be maintained. Bondholders would not want a company to sell a plant (which has been pledged as collateral) and then to use the proceeds for a distribution to shareholders. Therefore, release-of-property and substitution-of-property clauses are found in most secured bond indentures.

As an illustration, Texas–New Mexico Power Co. issued \$130 million in first-mortgage bonds in January 1992 that carried a coupon rate of 11.25%. The bonds were callable beginning in January 1997 at a call price of 105. Following the sale of six of its utilities, Texas–New Mexico Power called the bonds at par in October 1995, well before the first call date. As justification for the call, Texas–New Mexico Power stated that it was forced to sell the six utilities by municipalities in northern Texas, and as a result, the bonds were callable under the eminent domain provision in the bond's indenture. The bondholders sued, stating that the bonds were redeemed in violation of the indenture. In April 1997, the court found for the bondholders, and they were awarded damages, as well as lost interest. In the judgment of the court, while the six utilities were under the threat of condemnation, no eminent domain proceedings were initiated.

Tender Offers

In addition to those methods specified in the indenture, firms have other tools for extinguishing debt prior to its stated maturity. At any time a firm may execute a tender offer and announce its desire to buy back specified debt issues. Firms employ tender offers to eliminate restrictive covenants or to refund debt. Usually the tender offer is for "any and all" of the targeted issue, but it also can be for a fixed dollar amount that is less than the outstanding face value. An offering circular is sent to the bondholders of record stating the price the firm is willing to pay and the window of time during which bondholders can sell their bonds back to the firm. If the firm perceives that participation is too low, the firm can increase the tender offer price and extend the tender offer window. When the tender offer expires, all participating bondholders tender their bonds and receive the same cash payment from the firm.

Tender offers have been executed using a fixed spread as opposed to a fixed price.[2] In a fixed-spread tender offer, the tender offer price is equal to the present value of the bond's remaining cash flows either to maturity or the next call date if the bond is callable. The present-value calculation occurs immediately after the tender offer expires. The discount rate used in the calculation is equal to the yield-to-maturity on a comparable-maturity Treasury or the associated CMT yield plus the specified fixed spread. Fixed-spread tender offers eliminate the exposure to interest-rate risk for both bondholders and the firm during the tender offer window.

2. See Steven V. Mann and Eric A. Powers, "Determinants of Bond Tender Premiums and the Percentage Tendered," *Journal of Banking and Finance*, March 2007, pp. 547–566.

CREDIT RISK

All corporate bonds are exposed to credit risk, which includes *credit default risk* and *credit-spread risk.*

Measuring Credit Default Risk

Any bond investment carries with it the uncertainty as to whether the issuer will make timely payments of interest and principal as prescribed by the bond's indenture. This risk is termed *credit default risk* and is the risk that a bond issuer will be unable to meet its financial obligations. Institutional investors have developed tools for analyzing information about both issuers and bond issues that assist them in accessing credit default risk. These techniques are discussed in later chapters. However, most individual bond investors and some institutional bond investors do not perform any elaborate credit analysis. Instead, they rely largely on bond ratings published by the major rating agencies that perform the credit analysis and publish their conclusions in the form of ratings. The three major nationally recognized statistical rating organizations (NRSROs) in the United States are Fitch Ratings, Moody's, and Standard & Poor's. These ratings are used by market participants as a factor in the valuation of securities on account of their independent and unbiased nature.

The ratings systems use similar symbols, as shown in Exhibit 10-1. In addition to the generic rating category, Moody's employs a numerical modifier of 1, 2, or 3 to indicate the relative standing of a particular issue within a rating category. This modifier is called a *notch*. Both Standard & Poor's and Fitch use a plus (+) and a minus (–) to convey the same information. Bonds rated triple B or higher are referred to as *investment-grade bonds.* Bonds rated below triple B are referred to as *non-investment-grade bonds* or, more popularly, *high-yield bonds* or *junk bonds.*

Credit ratings can and do change over time. A *rating transition table,* also called a *rating migration table,* is a table that shows how ratings change over some specified time period. Exhibit 10-2 presents a hypothetical rating transition table for a one-year time horizon. The ratings beside each of the rows are the ratings at the start of the year. The ratings at the head of each column are the ratings at the end of the year. Accordingly, the first cell in the table tells that 93.20% of the issues that were rated AAA at the beginning of the year still had that rating at the end. These tables are published periodically by the three rating agencies and can be used to access changes in credit default risk.

Measuring Credit-Spread Risk

The *credit-spread* is the difference between a corporate bond's yield and the yield on a comparable-maturity benchmark Treasury security or the swap rate. Credit spreads are so named because the presumption is that the difference in yields is due primarily to the corporate bond's exposure to credit risk. This is misleading,

EXHIBIT 10-1

Corporate Bond Credit Ratings

Fitch	Moody's	S&P	Summary Description
			Investment Grade
AAA	Aaa	AAA	Gilt edged, prime, maximum safety, lowest risk, and when sovereign borrower considered "default-free"
AA+	Aa1	AA+	
AA	Aa2	AA	High-grade, high credit quality
AA–	Aa3	AA–	
A+	A1	A+	
A	A2	A	Upper-medium grade
A–	A3	A–	
BBB+	Baa1	BBB+	
BBB	Baa2	BBB	Lower-medium grade
BBB–	Baa3	BBB–	
			Speculative Grade
BB+	Ba1	BB+	
BB	Ba2	BB	Low grade; speculative
BB–	Ba3	BB–	
B+	B1		
B	B	B	Highly speculative
B–	B3		
			Predominantly Speculative, Substantial Risk or in Default
CCC+		CCC+	
CCC	Caa	CCC	Substantial risk, in poor standing
CC	Ca	CC	May be in default, very speculative
C	C	C	Extremely speculative
		CI	Income bonds—no interest being paid
DDD			
DD			Default
D	D	D	

however, because the risk profile of corporate bonds differs from Treasuries on other dimensions; namely, corporate bonds are less liquid and often have embedded options.

Credit-spread risk is the risk of financial loss or the underperformance of a portfolio resulting from changes in the level of credit spreads used in the marking

EXHIBIT 10-2

Hypothetical One-Year Rating Transition Table

Rating at Start of Year	*Rating at End of Year*								
	AAA	**AA**	**A**	**BBB**	**BB**	**B**	**CCC**	**D**	**Total**
AAA	93.20	6.00	0.60	0.12	0.08	0.00	0.00	0.00	100
AA	1.60	92.75	5.07	0.36	0.11	0.07	0.03	0.01	100
A	0.18	2.65	91.91	4.80	0.37	0.02	0.02	0.05	100
BBB	0.04	0.30	5.20	87.70	5.70	0.70	0.16	0.20	100
BB	0.03	0.11	0.61	6.80	81.65	7.10	2.60	1.10	100
B	0.01	0.09	0.55	0.88	7.90	75.67	8.70	6.20	100
CCC	0.00	0.01	0.31	0.84	2.30	8.10	62.54	25.90	100

to market of a fixed income product. Credit spreads are driven by both macro-economic forces and issue-specific factors. Macro-economic forces include such things as the level and slope of the Treasury yield curve, the business cycle, and consumer confidence. Correspondingly, the issue-specific factors include such things as the corporation's financial position and the future prospects of the firm and its industry.

One method used commonly to measure credit-spread risk is *spread duration*. Spread duration is the approximate percentage change in a bond's price for a 100 basis point change in the credit-spread assuming that the Treasury rate is unchanged. For example, if a bond has a spread duration of 3, this indicates that for a 100 basis point change in the credit-spread, the bond's price should change by approximately 3%. Spread duration is discussed in Chapter 53.

EVENT RISK

In recent years, one of the more talked-about topics among corporate bond investors is *event risk*. Over the last couple of decades, corporate bond indentures have become less restrictive, and corporate managements have been given a free rein to do as they please without regard to bondholders. Management's main concern or duty is to enhance shareholder wealth. As for the bondholder, all a company is required to do is to meet the terms of the bond indenture, including the payment of principal and interest. With few restrictions and the optimization of shareholder wealth of paramount importance for corporate managers, it is no wonder that bondholders became concerned when merger mania and other events swept the nation's boardrooms. Events such as decapitalizations, restructurings, recapitalizations, mergers, acquisitions, leveraged buyouts, and share repurchases, among other things, often caused substantial changes in a corporation's capital structure, namely, greatly increased leverage and decreased equity. Bondholders' protection was sharply reduced and debt quality ratings lowered, in many cases to speculative-grade categories. Along with greater risk came lower bond valuations. Shareholders were being enriched at the expense of bondholders. It is important to keep in mind the distinction between event risk and headline risk. Headline risk is the uncertainty engendered by the firm's media coverage that causes investors to alter their perception of the firm's prospects. Headline risk is present regardless of the veracity of the media coverage.

In reaction to the increased activity of leveraged buyouts and strategic mergers and acquisitions, some companies incorporated "poison puts" in their indentures. These are designed to thwart unfriendly takeovers by making the target company unpalatable to the acquirer. The poison put provides that the bondholder can require the company to repurchase the debt under certain circumstances arising out of specific designated events such as a change in control. Poison puts may not deter a proposed acquisition but could make it more expensive. Many times, in addition to a designated event, a rating change to below investment grade must occur within a certain period for the put to be activated. Some issues provide for a higher interest rate instead of a put as a designated event remedy.

At times, event risk has caused some companies to include other special debt-retirement features in their indentures. An example is the *maintenance of net worth clause* included in the indentures of some lower-rated bond issues. In this case, an issuer covenants to maintain its net worth above a stipulated level, and if it fails to do so, it must begin to retire its debt at par. Usually the redemptions affect only part of the issue and continue periodically until the net worth recovers to an amount above the stated figure or the debt is retired. In other cases, the company is required only to *offer to redeem* a required amount. An offer to redeem is not mandatory on the bondholders' part; only those holders who want their bonds redeemed need do so. In a number of instances in which the issuer is required to call bonds, the bondholders may elect not to have bonds redeemed. This is not much different from an offer to redeem. It may protect bondholders from the redemption of the high-coupon debt at lower interest rates. However, if a company's net worth declines to a level low enough to activate such a call, it probably would be prudent to have one's bonds redeemed.

Protecting the value of debt investments against the added risk caused by corporate management activity is not an easy job. Investors should analyze the issuer's fundamentals carefully to determine if the company may be a candidate for restructuring. Attention to news and equity investment reports can make the task easier. Also, the indenture should be reviewed to see if there are any protective covenant features. However, there may be loopholes that can be exploited by sharp legal minds. Of course, large portfolios can reduce risk with broad diversification among industry lines, but price declines do not always affect only the issue at risk; they also can spread across the board and take the innocent down with them. This happened in the fall of 1988 with the leveraged buyout of RJR Nabisco, Inc. The whole industrial bond market suffered as buyers and traders withdrew from the market, new issues were postponed, and secondary market activity came to a standstill. The impact of the initial leveraged buyout bid announcement on yield spreads for RJR Nabisco's debt to a benchmark Treasury increased from about 100 to 350 basis points. The RJR Nabisco transaction showed that size was not an obstacle. Therefore, other large firms that investors previously thought were unlikely candidates for a leveraged buyout were fair game. The spillover effect caused yield spreads to widen for other major corporations. This phenomenon was repeated in the mid-2000s with the buyout of large, investment grade public companies such as Alltel, First Data, and Hilton Hotels.

HIGH-YIELD BONDS

As noted, high-yield bonds are those rated below investment grade by the ratings agencies. These issues are also known as *junk bonds*. Despite the negative connotation of the term *junk,* not all bonds in the high-yield sector are on the verge of default or bankruptcy. Many of these issues are on the fringe of the investment-grade sector.

Types of Issuers

Several types of issuers fall into the less-than-investment-grade high-yield category. These categories are discussed below.

Original Issuers

Original issuers include young, growing concerns lacking the stronger balance sheet and income statement profile of many established corporations but often with lots of promise. Also called *venture-capital situations* or *growth or emerging market companies,* the debt is often sold with a story projecting future financial strength. From this we get the term *story bond.* There are also the established operating firms with financials neither measuring up to the strengths of investment-grade corporations nor possessing the weaknesses of companies on the verge of bankruptcy. Subordinated debt of investment-grade issuers may be included here. A bond rated at the bottom rung of the investment-grade category (Baa and BBB) or at the top end of the speculative-grade category (Ba and BB) is referred to as a "businessman's risk."

Fallen Angels

"Fallen angels" are companies with investment-grade-rated debt that have come on hard times with deteriorating balance sheet and income statement financial parameters. They may be in default or near bankruptcy. In these cases, investors are interested in the workout value of the debt in a reorganization or liquidation, whether within or outside the bankruptcy courts. Some refer to these issues as "special situations." Over the years, they have fallen on hard times; some have recovered, and others have not.

Restructurings and Leveraged Buyouts

These are companies that have deliberately increased their debt burden with a view toward maximizing shareholder value. The shareholders may be the existing public group to which the company pays a special extraordinary dividend, with the funds coming from borrowings and the sale of assets. Cash is paid out, net worth decreased, and leverage increased, and ratings drop on existing debt. Newly issued debt gets junk-bond status because of the company's weakened financial condition.

In a leveraged buyout (LBO), a new and private shareholder group owns and manages the company. The debt issue's purpose may be to retire other debt from commercial and investment banks and institutional investors incurred to finance the LBO. The debt to be retired is called *bridge financing* because it provides a bridge between the initial LBO activity and the more permanent financing.

Unique Features of Some Issues

Often actions taken by management that result in the assignment of a non-investment-grade bond rating result in a heavy interest-payment burden. This places severe cash-flow constraints on the firm. To reduce this burden, firms involved with heavy debt burdens have issued bonds with *deferred coupon structures* that permit the issuer to avoid using cash to make interest payments for a period of three to seven years. There are three types of deferred-coupon structures: (1) deferred-interest bonds, (2) step-up bonds, and (3) payment-in-kind bonds.

Deferred-interest bonds are the most common type of deferred-coupon structure. These bonds sell at a deep discount and do not pay interest for an initial period, typically from three to seven years. (Because no interest is paid for the initial period, these bonds are sometimes referred to as "zero-coupon bonds.") *Step-up bonds* do pay coupon interest, but the coupon rate is low for an initial period and then increases ("steps up") to a higher coupon rate. Finally, *payment-in-kind (PIK) bonds* give the issuers an option to pay cash at a coupon payment date or give the bondholder a similar bond (i.e., a bond with the same coupon rate and a par value equal to the amount of the coupon payment that would have been paid). The period during which the issuer can make this choice varies from five to ten years.

Sometimes an issue will come to market with a structure allowing the issuer to reset the coupon rate so that the bond will trade at a predetermined price.[3] The coupon rate may reset annually or even more frequently, or reset only one time over the life of the bond. Generally, the coupon rate at the reset date will be the average of rates suggested by two investment banking firms. The new rate will then reflect (1) the level of interest rates at the reset date and (2) the credit-spread

3. Most of the bonds have a coupon reset formula that requires the issuer to reset the coupon so that the bond will trade at a price of $101.

the market wants on the issue at the reset date. This structure is called an *extendible reset bond.*

Notice the difference between an extendible reset bond and a typical floating-rate issue. In a floating-rate issue, the coupon rate resets according to a fixed spread over the reference rate, with the index spread specified in the indenture. The amount of the index spread reflects market conditions at the time the issue is offered. The coupon rate on an extendible reset bond, in contrast, is reset based on market conditions (as suggested by several investment banking firms) at the time of the reset date. Moreover, the new coupon rate reflects the new level of interest rates and the new spread that investors seek.

The advantage to investors of extendible reset bonds is that the coupon rate will reset to the market rate—both the level of interest rates and the credit-spread—in principle keeping the issue at par value. In fact, experience with extendible reset bonds has not been favorable during periods of difficulties in the high-yield bond market. The sudden substantial increase in default risk has meant that the rise in the rate needed to keep the issue at par value was so large that it would have insured bankruptcy of the issuer. As a result, the rise in the coupon rate has been insufficient to keep the issue at the stipulated price.

Some speculative-grade bond issues grant the issuer a limited right to redeem a portion of the bonds during the noncall period if the proceeds are from an initial public stock offering. Called "clawback" provisions, they merit careful attention by inquiring bond investors. The provision appears in the vast majority of new speculative-grade bond issues, and sometimes allow even private sales of stock to be used for the clawback. The provision usually allows 35% of the issue to be retired during the first three years after issuance, at a price of par plus one year of coupon. Investors should be forewarned of clawbacks because they can lose bonds at the point in time just when the issuer's finances have been strengthened through access to the equity market. Also, the redemption may reduce the amount of the outstanding bonds to a level at which their liquidity in the aftermarket may suffer.

DEFAULT RATES AND RECOVERY RATES

We now turn our attention to the various aspects of the historical performance of corporate issuers with respect to fulfilling their obligations to bondholders. Specifically, we will look at two aspects of this performance. First, we will look at the default rate of corporate borrowers. From an investment perspective, default rates by themselves are not of paramount significance; it is perfectly possible for a portfolio of bonds to suffer defaults and to outperform Treasuries at the same time, provided the yield spread of the portfolio is sufficiently high to offset the losses from default. Furthermore, because holders of defaulted bonds typically recover some percentage of the face amount of their investment, the *default loss rate* is substantially lower than the default rate. Therefore, it is important to look at default loss rates or, equivalently, *recovery rates.*

Default Rates

A default rate can be measured in different ways. A simple way to define a default rate is to use the issuer as the unit of study. A default rate is then measured as the number of issuers that default divided by the total number of issuers at the beginning of the year. This measure gives no recognition to the amount defaulted nor the total amount of issuance. The rationale for ignoring dollar amounts is that the credit decision of an investor does not increase with the size of the issuer. The second measure is to define the default rate as the par value of all bonds that defaulted in a given calendar year divided by the total par value of all bonds outstanding during the year. Edward Altman, who has performed extensive analyses of default rates for speculative-grade bonds, measures default rates in this way. We will distinguish between the default-rate statistic below by referring to the first as the *issuer default rate* and the second as the *dollar default rate*.

With either default-rate statistic, one can measure the default for a given year or an average annual default rate over a certain number of years. Researchers who have defined dollar default rates in terms of an average annual default rate over a certain number of years have measured it as

$$\frac{\text{Cumulative \$ value of all defaulted bonds}}{\text{Cumulative \$ value of all issuance} \times \text{weighted avg. no. of years outstanding}}$$

Alternatively, some researchers report a cumulative annual default rate. This is done by not normalizing by the number of years. For example, a cumulative annual dollar default rate is calculated as

$$\frac{\text{Cumulative \$ value of all defaulted bonds}}{\text{Cumulative \$ value of all issuance}}$$

There have been several excellent studies of corporate bond default rates. We will not review each of these studies because the findings are similar.

Recovery Rates

There have been several studies that have focused on recovery rates or default loss rates for corporate debt. Measuring the amount recovered is not a simple task. The final distribution to claimants when a default occurs may consist of cash and securities. Often it is difficult to track what was received and then determine the present value of any noncash payments received.

MEDIUM-TERM NOTES

Medium-term notes (MTNs) are debt instruments that differ primarily in how they are sold to investors. Akin to a commercial paper program, they are offered continuously to institutional investors by an agent of the issuer. MTNs are registered with the Securities and Exchange Commission under Rule 415 ("shelf registration") which gives a corporation sufficient flexibility for issuing securities on a continuous basis. MTNs are also issued by non-U.S. corporations, federal agencies, supranational institutions, and sovereign governments.

One would suspect that MTNs would describe securities with intermediate maturities. However, it is a misnomer. MTNs are issued with maturities of 9 months to 30 years or even longer. For example, in 1993, Walt Disney Corporation issued bonds through its medium-term note program with a 100-year maturity, a so-called century bond. MTNs can perhaps be more accurately described as highly flexible debt instruments that can easily be designed to respond to market opportunities and investor preferences.

As noted, MTNs differ in their primary distribution process. Most MTN programs have two to four agents. Through its agents, an issuer of MTNs posts offering rates over a range of maturities: for example, 9 months to one year, one year to 18 months, 18 months to two years, and annually thereafter. Many issuers post rates as a yield spread over a Treasury security of comparable maturity.

Relatively attractive yield spreads are posted for maturities that the issuer desires to raise funds. The investment banks disseminate this offering rate information to their investor clients. When an investor expresses interest in an MTN offering, the agent contacts the issuer to obtain a confirmation of the terms of the transaction. Within a maturity range, the investor has the option of choosing the final maturity of the note sale, subject to agreement by the issuing company. The issuer will lower its posted rates once it raises the desired amount of funds at a given maturity.

Structured medium-term notes or simply *structured notes* are debt instruments coupled with a derivative position (options, forwards, futures, swaps, caps, and floors). For example, structured notes are often created with an underlying swap transaction. This "hedging swap" allows the issuer to create structured notes with interesting risk/return features desired by a swath of fixed income investors.

KEY POINTS

- A bond's indenture includes the promises of corporate bond issuers and the rights of investors. The terms of bond issues set forth in bond indentures are always a compromise between the interests of the bond issuer and those of investors who buy bonds.
- The classification of corporate bonds by type of issuer include public utilities, transportations, industrials, banks and finance companies, and international or Yankee issues.
- The three main interest payment classifications of domestically issued corporate bonds are straight-coupon bonds (fixed-rate bonds), zero-coupon bonds, and floating-rate bonds (variable-rate bonds).

- Either real property (using a mortgage) or personal property may be pledged to offer security beyond that of the general credit standing of the issuer. In fact, the kind of security or the absence of a specific pledge of security is usually indicated by the title of a bond issue. However, the best security is a strong general credit that can repay the debt from earnings.
- A mortgage bond grants the bondholders a first-mortgage lien on substantially all its properties and as a result the issuer is able to borrow at a lower rate of interest than if the debt were unsecured.
- Some companies do not own fixed assets or other real property and so have nothing tangible on which they can give a mortgage lien to secure bondholders. To satisfy the desire of bondholders for security, they pledge stocks, notes, bonds, or whatever other kinds of obligations they own and the resulting issues are referred to as collateral trust bonds.
- Debentures are not secured by a specific pledge of designated property and therefore bondholders have the claim of general creditors on all assets of the issuer not pledged specifically to secure other debt. Moreover, debenture bondholders have a claim on pledged assets to the extent that these assets have value greater than necessary to satisfy secured creditors. In fact, if there are no pledged assets and no secured creditors, debenture bondholders have first claim on all assets along with other general creditors.
- Owners of subordinated debenture bonds stand last in line among debt creditors when an issuer fails financially.
- For a guaranteed bond there is a third party guaranteeing the debt but that does not mean a bond issue is free of default risk. The safety of a guaranteed bond depends on the financial capability of the guarantor to satisfy the terms of the guarantee, as well as the financial capability of the issuer.
- Debt retirement mechanisms included in a bond's indenture are call and refunding provisions, sinking funds, maintenance and replacement funds, redemption through sale of assets, and tender offers.
- All corporate bonds are exposed to credit risk, which includes credit default risk and credit-spread risk.
- Credit ratings can and do change over time and this information is captured in a rating transition table, also called a rating migration table.
- Credit-spread risk is the risk of financial loss or the underperformance of a portfolio resulting from changes in the level of credit spreads used in the marking to market of a fixed income product. One method used commonly to measure credit-spread risk is spread duration which is the approximate percentage change in a bond's price for a 100 basis point change in the credit-spread assuming that the Treasury rate is unchanged.

- The three types of issuers that comprise the less-than-investment-grade high-yield corporate bond category are original issuers, fallen angels, and restructuring and leveraged buyouts.
- Often actions taken by management that result in the assignment of a noninvestment-grade bond rating result in a heavy interest payment burden. To reduce this burden, firms involved with heavy debt burdens have issued bonds with deferred coupon structures that permit the issuer to avoid using cash to make interest payments for a period of three to seven years. There are three types of deferred-coupon structures: deferred-interest bonds, step-up bonds, and payment-in-kind bonds.
- From an investment perspective, default rates by themselves are not of paramount significance because a portfolio of bonds could suffer defaults and still outperform Treasuries at the same time. This can occur if the yield spread of the portfolio is sufficiently high to offset the losses from default. Furthermore, because holders of defaulted bonds typically recover some percentage of the face amount of their investment, the default loss rate is substantially lower than the default rate. Therefore, it is important to look at default loss rates or, equivalently, recovery rates.
- A default rate can be measured in term of the issuer default rate and the dollar default rate.

CHAPTER
ELEVEN

LEVERAGED LOANS

Stephen J. Antczak, CFA

Professor of Finance
EDHEC Business School

Jung Lee
Consultant

A *leveraged loan* is a loan made to a company whose credit rating is speculative grade. That is, the borrower has a credit rating that is below BBB-/Baa3. When reference is made to "loans" by market participants, typically it means (1) loans that are broadly syndicated (to 10 or more bank and nonbank investors), (2) senior secured loans that are at the top-most rank in the borrower's capital structure, and (3) large loans to large companies.

For below investment-grade companies, leveraged loans are a key component of their capital structure. Historically, the typical company raising capital in the leveraged finance space has relied on the loan market for a large portion of their overall funding, with about two-thirds of the total coming from the loan market and about one-third coming from the high-yield bond market. Worth noting, there can be meaningful variations from this two-third/one-third rule of thumb, and these tend to occur during and in the wake of significant market disruptions such as the Global Financial Crisis of 2008–2009.

In terms of the use of proceeds, corporate borrowers utilize the capital from a leveraged loan for various purposes, but by far the two most prevalent uses are to fund mergers and acquisitions and to refinance existing debt. Together these two purposes have accounted for about 80% of leveraged loan usage over time, with close to (although not quite) an even split between these two uses.

With regard to the total par amount of leveraged loans outstanding, the most commonly cited number by market participants is $1.2 trillion, and market outstandings have been hovering at this level in recent years. That said, this figure represents *index-eligible* leveraged loans rather than all leveraged loans outstanding, and to be index-eligible a number of hurdles, such as time until maturity, must be met.

The index-eligible universe is important, as these are the loans that market participants tend to trade, but just as important is that $1.2 trillion underestimates the size of the actual leveraged loan market meaningfully. According to a recent study completed by the Bank of England the size of the leveraged loan market without index constraints is approximately $2.2 trillion, or around 80% larger than the index-eligible universe.[1] Clearly the leveraged loan market is very large and important to issuers.

SYNDICATED BANK LOANS

Leveraged loans have been syndicated and sold to nonbank institutional investors since the late 1980s, but institutional investors only became a meaningful factor in the marketplace in the mid-1990s. Here we describe various facets of the leveraged loan market.

A leveraged loan is one form of a *syndicated loan*. A syndicated loan is a single loan with a single set of terms but multiple lenders, each providing a portion of the funds. The advantage of the syndication of a loan from a borrower's perspective is that (1) it allows a corporation to negotiate loan terms once, while at the same time having access to multiple lenders, and (2) it avoids conflicts in priority from arising that might otherwise occur if the borrower serially negotiated loans. All lenders in the syndicate share equally in rights under the credit agreement.

Typically, a syndicated loan is arranged by a commercial or investment bank—referred to as the *arranger*, also called the *mandated lead arranger*[2]—and that entity advises the borrower on the type of facility (as described later, a revolving line of credit and/or term loan); negotiates the terms of the loan, including pricing; and manages the structuring of the credit agreement. The arranger prepares an information memo or bank book. The document, which is confidential and made available to qualified banks and accredited investors only, provides information about the borrower, the borrower's industry, loan terms, and the borrower's financial projections. For administering the loan on a daily basis, an *agent* is appointed. It is the agent that is responsible for monitoring the borrower to assure compliance with the terms of the loan.

After the credit agreement and a security agreement are finalized, the required documents are filed with the relevant legal jurisdictions. However, the credit agreement may be amended for a variety of reasons. It could be for a minor change, such as a waiver of a specific covenant. Such changes may merely require a majority vote to do so. At the other extreme, it could involve more complex changes such as changes in the interest rate, term of the facility, or the security for the loan. More complex changes may require unanimous consent.

One amendment type worth noting in particular is the "amend-to-extend." The bankruptcy process tends to be very expensive for all stakeholders in a

1. https://www.bankofengland.co.uk/bank-overground/2019/how-large-is-the-leveraged-loan-market
2. Actually, there is often more than one arranger in a transaction despite the reference to a singular party in this chapter.

company, including lenders. In part due to these high costs, modifying the terms of a loan (i.e., amend-to-extend) may be a more beneficial option for all involved (including lenders) than the bankruptcy process. Not surprisingly the number of amend-to-extend and covenant relief amendments tends to rise when business conditions for leveraged loan borrowers soften and the chance of bankruptcy rises.

For example, during the Global Financial Crisis of 2008–2009 and the period immediately following, we saw a multifactor jump in the amount of amend-to-extend and covenant relief amendments when compared to the long-term average. Worth noting is that while there has been an increase in amend-to-extend activity in the wake of the Covid-19 crisis of 2020, there is uncertainty among market participants about the extent to which activity will ultimately rise because there had been more loans with soft covenants (i.e., covenant lite) issued prior to the crisis. Said differently, there simply aren't as many covenants to amend.

Loans may be underwritten or done on a best-efforts basis. In an *underwritten deal*, any portion of the loan that is not subscribed for by other banks or investors the arranger must take onto its books (and thus fund). In contrast, in a *best-efforts deal* the arranger does not guarantee the placement of the entire amount to other banks or investors. Instead, the pricing or the size may be adjusted. A variant of the best-efforts arrangement involves the use of *market flex language* wherein borrowers typically give arrangers the flexibility to adjust loan terms and loan pricing (i.e., increase the spread over the reference benchmark) to ensure that the loan would be fully subscribed. A *reverse market flex*, in contrast, tightens the spread in response to oversubscription or other market conditions.

LOAN STRUCTURE

In practice, there is often not just one loan that is arranged. Instead, a credit agreement often calls for a *revolving line of credit* and one or more term loans (term loan A, term loan B, and so on). In some credit agreements, the revolving line of credit can be drawn upon by the borrower, who is then permitted to convert the amount drawn into a term loan.

Leveraged loans can be classified under the credit agreement as pro rata loans and institutional loans. *Pro rata loans* are distributed to banks, and usually include the revolving line of credit and term loans that mature in three to five years. As the name suggests, *institutional loans* are distributed to nonbank institutional investors and typically include term loans maturing in five to seven years. Institutional loans now represent the significant component of new loan issues. To put the evolution (from banks to nonbank investors) into perspective, it is estimated that a single type of institutional investor—collateralized loan obligations (CLOs)—now have approximately $0.8 trillion of exposure to the leveraged loan market, well in excess of overall bank exposure (estimates range from $0.4 trillion to $0.67 trillion).[3]

3. Bank of England Financial Stability Report, November 2018, Issue No 44; Bank Overground, January 25 2019.

LOAN TERMS

The loan credit agreement sets forth the loan's terms. There are three forms: (1) representations and warranties made by the borrower, (2) affirmative covenants, and (3) negative covenants.

Leveraged loans commonly contain covenants or requirements that must be satisfied by borrowers. The two most common are maintenance requirements and incurrence requirements. These requirements are specified in the form of tests. Basically, *maintenance requirements* are regular reviews of various operating performance measures, such as leverage, interest coverage, and so on. It is not necessary for there to be any particular corporate action in order to "trigger" a review of these operating measures. An *incurrence requirement* is a review of specific operating measures relative to predetermined levels after an issuer has taken an action that triggers a review. Examples of actions that can trigger a review are share repurchases, divestitures, and special dividends. There are five purposes served by this process:[4]

1. *Preservation of collateral:* The borrower represents that the lenders have a legal, valid, and enforceable security interest in the pledged collateral. Typically, this means not only the borrower's existing assets at the time of the loan's closing, but also assets subsequently acquired by the borrower. There are loans where only specific assets are pledged as collateral.
2. *Appropriation of excess cash flow:* In the absence of restrictions, a borrower could take out a loan, sell its assets, distribute the proceeds from the sale of the assets and the proceeds of the loan(s) to the equity holders, and thereby create an empty corporate shell with no assets for the lenders. To prevent this, excess cash flow from the borrower's ordinary and extraordinary business activities—defined as cash flow minus cash expenses, required dividends, debt repayments, capital expenditures, and changes in working capital—is required to be used to prepay loans.
3. *Control of business risk:* Lenders become disadvantaged when a borrower's business becomes riskier and the risk that borrowers will make business decisions to benefit equity holders at the expense of lenders increases.[5] Management of the borrowing firm can increase risk by taking on riskier investment projects, taking on more debt, and acquiring other firms, among other actions. Loan terms are imposed to prevent this practice. In the case of taking on more debt, this may be prohibited even if the priority of the new debt ranking is subordinate to the loan.

4. For a more detailed description, see Chapter 3 in Stephen Antczak, Douglas Lucas, and Frank J. Fabozzi, *Leveraged Finance: Concepts, Methods, and Trading of High-Yield Bonds, Loans, and Derivatives* (Hoboken, NJ: John Wiley & Sons, 2009).

5. Financial economists refer to this as one of the costs of financial distress.

4. *Performance requirements:* Performance measures used by lenders include ratios such as coverage ratios, leverage ratios, and liquidity ratios, as well as dollar amounts, such as tangible net worth, maximum capital expenditures, and cash-flow/net worth requirements. These measures can be calculated based on financial statement items (prepared under generally accepted accounting principles) or lender-specified calculations. If these measures are violated, the loan becomes due and payable immediately.
5. *Reporting requirements:* For purposes of monitoring the borrower, the lender will require that the borrower periodically furnish specified documents and reports. These include not only documents required by government regulatory agencies but also internal reports such as budgets and projections and accounts-receivable analysis, as well as third-party non-filing reports such as appraisals for certain assets.

The pricing of a loan (i.e., the loan's spread) depends in large part on four factors: (1) the credit quality/rating of the borrower, (2) the size of the loan(s), (3) the supply of and demand for new issues in the loan market, and (4) investor risk appetites in general.[6]

Obviously, the lower the borrower's credit rating, the greater the loan's spread all other factors equal. The second factor relates to the balance or imbalance between the amount of loans that are being brought to market and the credit appetite of buyers (i.e., banks and institutional lenders). The size of the loan can result in a higher or lower spread. On the one hand, the larger the loan size, the higher the spread needed to clear the market. On the other hand, for trading purposes a larger loan size can work to decrease the spread because investors believe that larger loans tend to trade better in the secondary market due to greater familiarity with the issuer.[7] Lastly, greater investor risk appetites, even in markets other than the leveraged loan market, tend to lower loan spreads. For example, if spreads in the high-yield bond market decline, loans may appear attractive on a relative basis. Investors may shift funds from the bond market to the loan market as a result.

RECOVERY RATES

The textbook description of the position of a creditor in the case of a bankruptcy is that the priority of creditors as set forth in the original lending agreements will be respected by the courts. However, a good number of empirical studies have clearly demonstrated that in the case of a Chapter 11 bankruptcy, the absolute

6. For other factors influencing a loan's attractiveness, see Chapter 3 in Antczak, Lucas, and Fabozzi, *Leveraged Finance: Concepts, Methods, and Trading of High-Yield Bonds, Loans and Derivatives.*
7. Antczak, Lucas, and Fabozzi, *Leveraged Finance: Concepts, Methods, and Trading of High-Yield Bonds, Loans and Derivatives,* p. 63.

priority rule is typically violated. That is, senior creditors may not be paid in full before junior creditors and even equity owners receive some form of payment. There are a good number of economic reasons as to why the absolute priority rule may be violated. These reasons relate to the direct and indirect costs associated with the negotiations among the creditors and equity claimants. The bottom line, however, is that the recovery rates for the various levels of creditors is an empirical issue.

Fortunately, studies of recovery rates confirm that despite the high risk of a violation of the absolute priority rule in practice, the senior claim of bank loan lenders on the assets of the borrower, as measured by recovery rates, is higher than that for other creditors. In a comprehensive study by Moody's of about 3,500 defaulted loans and bonds issued by more than 700 nonfinancial U.S. corporations, the ultimate recovery rates were higher for loans in comparison to bonds.[8] More specifically Moody's found that the average recovery rate for defaulted loans was 81% of par value; the average recovery rate for defaulted bonds was only 39% of par value. Moreover, the Moody's study reported that loan recovery rates have a right-skewed distribution, while bond recovery rates have a left-skewed distribution.

Another way to look at recovery rates is using post-default trading prices as a proxy for recovery rather than the ultimate recovery levels. Based on a broad sample of issuer-weighted, post-default trading prices, the average recovery for first lien loans is about 70% of par value. In comparison, Moody's found that the average recovery rate for the same time period is about 40% of par value for corporate bonds.

It is important to keep in mind that the previously mentioned ultimate recovery rates are all expressed in percentage terms of par value. As such, loans trading at a discount to par are exposed to relatively muted risk (versus a par-priced loan) in the event of a default. In fact, leveraged loans trading at a discount can actually have a positive return profile in the event of default.

For example, in secondary market trading many leveraged loans were priced in the $60s during the depths of the Global Financial Crisis, and many were trading in the $70s during the more recent Covid-19 crisis (2020). Assume the average 81% recovery rate of par value and the simplified profit calculation (recovery – purchase price + coupon income = profit). Given these assumptions, an investor that purchased a typical loan during the depths of the financial crisis would have made a *minimum profit of 17%* if a default occurred ($81 – $69 + $0 = $12, and $12/$69 = 17%).

8. Moody's *Ultimate Recovery Database: Special Comment*, April 2007. The method for measuring recovering varies from study to study. Some studies use a loan's or bond's post-default trading level as a proxy for its recovery rate. In the Moody's study, the discounted actual amount received by the holder of a given piece of debt at the resolution of a credit event was used.

SECONDARY MARKET

Leveraged loans are private contracts and as a result, prior to 1987, little public information was available about them. This stifled secondary market trading. In 1987 the Loan Pricing Corporation (LPC) began publishing information on global syndicated loans.

In 1995, the Loan Syndication and Trading Association (LSTA) was created as an industry association whose goal was to foster the development of a more liquid and transparent secondary market. It was done so by establishing market practices and procedures for settlement and operations. For example, the LSTA publishes model credit agreement provisions and a document covering the principles for the communications and use of confidential information by loan market participants.

LSTA and Standard & Poor's (S&P) joined forces to create secondary market indexes. Market indexes play an important role for all asset classes for several reasons, such as measuring the performance of an asset class for purposes of making asset allocation decisions and evaluating the performance of managers. In the leverage loan market, the S&P/LSTA U.S. Leveraged Loan 100 is the primary index.[9] This index measures the performance of 100 of the largest institutional leveraged loans (on a market-weighted basis) drawn from term loans included in the S&P/LSTA Leveraged Loan Index (LLI). To be included in the LLI itself the term loan must meet a series of criteria, such as being a senior secured first-lien facility, having a minimum initial term of one year, having a minimum initial spread of 125 basis points over LIBOR, and be denominated in U.S. dollars, among others. The loans included are selected by a set of rules specified by S&P's index committee.

There are two methods by which loans in the secondary market change hands: by assignment or by participation. In the case of an *assignment*, the buyer becomes the lender of record with all related rights and powers. An assignment typically requires the borrower's consent for the exchange to take place. In contrast, if the exchange is accomplished via *participation*, although the buyer receives the right to repayment, the original lender remains the lender of record. It is therefore the responsibility of the lender of record to collect the amount due from the borrower and then pay that amount to the participant. The borrower's consent is usually not required in the case of a participation. However, the buyer bears a greater credit risk in the case of a participation because there is not a contractual link between the borrower and the participant. As a result, if the original lender becomes insolvent, the participant may have no recourse.

As noted earlier the importance of nonbank institutional investors within the leveraged finance market has increased over time. But with the proliferation of exchange-traded funds (ETFs) in recent years a new trend has emerged, and

9. For more details about this index, see "S&P/LSTA U.S. Leveraged Loan 100" published by Standard & Poor's; available at www.SPindices.com.

that is that the leveraged loan investor base has become even more inclusive and now "everyday" individual investors have at least some access to the market.

With regard to the trading characteristics of leveraged loan ETFs, in Exhibit 11-1 we examine select details of a benchmark leveraged loan ETF (ticker BKLN) and compare these details to a benchmark high-yield bond ETF (HYG). First, we see that as of June 2020 the market capitalization of the leveraged loan ETF was $6.5 billion, which represents a fair amount of access to the loan market for everyday investors. With regard to risk and return, the data shows that leveraged loans in ETF format offer less yield than their high-yield bond counterparts (4.98% vs. 5.36%), but are less volatile, have less downside risk, and are less actively traded. Essentially, the ETFs mirror the trading relationships between leveraged loans and high-yield bonds that exist in the cash market.

EXHIBIT 11-1

Trading Profile of Select Leveraged Finance ETFs

Characteristic	BKLN	HYG	Difference
Yield (%)	4.98	5.36	–0.38
Avg. Trading Vol (shares, mm)	8.5	31.2	–22.7
Standard Dev (%)	0.06	0.4	–0.34
Market Cap ($ bn)	6.5	11.8	–5.3
52-Week High ($)	22.92	88.53	–
52-Week Low ($)	17.06	67.52	–

As of June 2020; data from NASDAQ and Invesco and Blackrock manager fact sheets.

KEY POINTS

- A leveraged loan is a loan made to a company whose credit rating is below investment-grade (below BBB-/Baa3). When a reference is made to "loans" by market participants it typically means (1) loans that are broadly syndicated (to 10 or more bank and nonbank investors), (2) senior secured loans that are at the top-most rank in the borrower's capital structure, and (3) larger loans to larger companies.
- A leveraged loan is a syndicated loan with a single set of terms but multiple lenders, each providing a portion of the funds. The advantage of the syndication of a loan from a borrower's perspective is that it (1) allows a corporation to negotiate loan terms only once yet gain access to multiple lenders and (2) avoids possible conflicts in priority if

the borrower serially negotiated loans; all lenders in the syndicate share equal rights under the credit agreement.

- Leveraged loans can be classified as (1) pro rata loans that are distributed to banks and usually include the revolving line of credit and shorter maturity term loans, and (2) institutional loans that are distributed to nonbank institutional investors and typically include longer-maturity term loans.
- Leveraged loans commonly contain covenants or requirements that must be satisfied by borrowers. The two most common are (1) maintenance requirements, or regular reviews of operating measures, and (2) incurrence requirements, a review of specific operating measures after an issuer has taken an action to trigger a review. Purposes of such loan terms include (1) preservation of collateral, (2) appropriation of excess cash flow, (3) control of business risk, (4) performance requirements, and (5) reporting requirements.
- Studies of recovery rates confirm that the senior claim of bank loan lenders on the assets of the borrower, as measured by recovery rates as a percentage of par value, is higher than that for other creditors. It is important to keep in mind that such recovery rates are expressed in percentage terms of par value so that loans trading at par are exposed to greater loss than those trading under par in the event of a default. Worth noting is that recovery rates tend to vary meaningfully by year.
- There are two methods by which loans in the secondary market change hands: (1) by assignment, in which the buyer becomes the lender of record with all related rights and powers and (2) by participation, in which the buyer receives the right to repayment but the original lender remains the lender of record. In the case of a participation, the buyer bears a greater credit risk since there is no contractual link between the borrower and the participant.
- The proliferation of exchange-traded funds (ETFs) in recent years has increased access to the leveraged loan market. When comparing various trading characteristics of benchmark high-yield bond and leveraged loan ETFs we find similar relationships to those that exist in the high-yield and leveraged loan cash markets—loans tend to offer less yield and lower upside potential, but by various metrics tend to have less risk.

STRUCTURED NOTES AND CREDIT-LINKED NOTES

John D. Finnerty, Ph.D.
Professor of Finance
Fordham University
Managing Principal
Finnerty Economic Consulting, LLC

Rachael W. Park
Director
AlixPartners, LLP

Structured notes and credit-linked notes are debt instruments that provide customized interest or principal payments that depend on the performance of a specified reference asset, market price, index, interest rate, or some other market quantity. They enable investors to express a view on the future performance of the reference item as part of their investment management program or protect their other assets against adverse changes in the value of the underlying item as part of their risk management program. A structured note combines a conventional fixed-rate or floating-rate note with an embedded derivative instrument, such as an option or a swap, which links the payments on the note to the reference item. A credit-linked note (CLN) is a particular form of structured note in which the derivative instrument is a credit default swap or some other form of credit derivative.

Structured notes and CLNs provide investors with investment opportunities that they might find difficult or expensive to access in other ways—for example, because of transaction costs, regulatory restrictions, or other market frictions. Generally, any derivative instrument can be structured either as a stand-alone financial instrument, such as a swap or a forward, or it can be attached to a conventional note to form a structured note. Structured notes have been issued regularly at least since the mid-1980s. They emerged as an important instrument in the early 1990s when financial engineers regularly began crafting new forms of structured notes—including, in particular, CLNs—by attaching derivative instruments to medium-term notes in the United States, Europe, and Asia. According to Bloomberg L.P., the average annual volume of structured notes issued between 2015 and 2019 across the globe was $140 billion with 8,258 issues. The new issue volume of structured notes outside the United States accounts for, on average, 75% of the global volume of structured notes issued during the period. Exhibit 12-1 reports the volume of issuance and the number of structured note issues across the globe as well as in the United States between 2010 and 2019.

Data obtained from Bloomberg, L.P.

CLNs have been very popular since the mid-1990s, soon after the credit derivatives market first began to develop. The volume of CLNs issued in the U.S. market increased from $2.5 billion in 2000 to $12.9 billion in 2007, according to Bloomberg L.P. However, the global financial crisis that started in late 2007 caused a significant reduction in the volume of CLN issuance. According to Bloomberg L.P., the average annual volume of CLNs issued between 2015 and 2019 across the globe was $50 billion with 4,155 issues. The new issue volume of CLNs outside the United States accounts for, on average, 99.4% of the global volume of CLNs issued during the period. Exhibit 12-2 reports the volume of issuance and the number of CLN issues across the globe as well as in the United States between 2010 and 2019.

Exhibit 12-2 probably understates the use of CLNs in the United States. CLNs are often used in the U.S. CDS market because they are a form of funded credit derivative, which provides collateral that backs up the CDS protection seller's obligation to pay the protection buyer if a credit event occurs. This usage of the structure is not fully reflected in the issuance statistics in Exhibit 12-2.

STRUCTURED NOTES

A structured note combines a debt security or a certificate of deposit (CD) with a derivative instrument. It is a hybrid security that contains an embedded derivative instrument, which transforms the interest payments or the principal payments (or both) by making at least some of these payments contingent on a specified reference asset, market price, index, interest rate, or some other market quantity. Often, the derivative instrument is designed to provide the investor with financial exposure to a particular underlying asset class, such as equities, commodities, currencies, or interest rates. The term *structured* refers to incorporating a derivative into the structure of the note to give the reconfigured note the desired financial properties. Adding the contingency feature alters the risk/return profile of the (structured) note to suit the investment preferences of investors.

Instead of making the traditional interest payments that are either fixed in amount or tied to a specified floating-rate index, many structured notes pay interest in amounts that are determined by some formula tied to the movement of a stock price or index, a bond or loan price, a commodity price, a foreign exchange rate, or some other financial variable. Some structured notes are designed to have relatively conservative risk/return profiles so as to be useful in reducing portfolio risk, whereas others are designed to have more aggressive risk/return profiles—for example, by leveraging returns so as to provide the possibility for substantial gain or loss. The nature and design of the embedded derivative instrument determines the structured note's risk/return profile.

Characteristics of Structured Notes

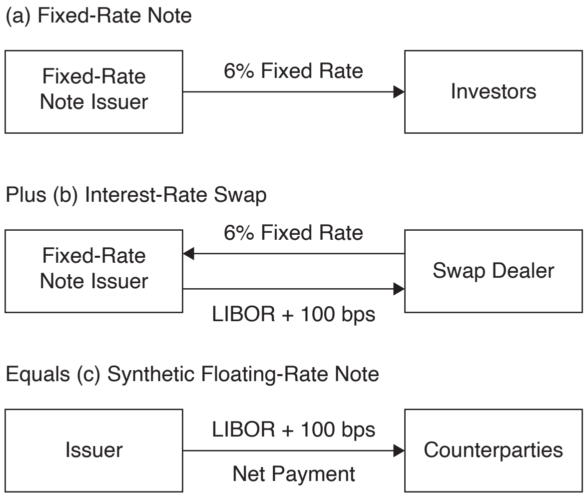
Although a floating-rate note is not considered a structured note, the relationship between a fixed-rate note and a floating-rate note can be used to illustrate the distinguishing characteristic of a structured note, which is the packaging of a derivative with a conventional senior unsecured note or a CD. Start with a 10-year note that pays a 6% fixed rate annually. Add a 10-year fixed-for-floating interest-rate swap in which the note issuer pays LIBOR plus 100 basis points quarterly and receives 6% annually. Exhibit 12-3 illustrates the resulting debt service stream. The package combining the 6% note and the swap is equivalent to a floating-rate note paying LIBOR plus 100 basis points. A floating-rate note could thus be characterized as a structured note that combines a conventional fixed-rate note and a conventional pay-floating-receive-fixed interest-rate swap. (Similarly, this basic relationship implies that a fixed-rate note could be characterized as a conventional floating-rate note plus a conventional pay-fixed-receive-floating interest-rate swap.) This simple intuition underlies all structured notes, which differ in their complexity owing to the nature of the derivative instrument(s) employed in structuring the note.

Most structured notes are issued as medium-term notes (MTNs). MTNs are usually issued under a firm's shelf-registration program, which permits the issuer to register an inventory of securities that may be sold for three years after the registration statement's effective date. Having registered securities available allows the issuer to design and make an offering of previously registered securities in a short period of time without the need to first file a separate registration statement with the SEC. This flexibility allows issuers to respond quickly to changes in market conditions by designing and offering structured notes opportunistically to take advantage of favorable funding opportunities.

Another advantage of MTNs is their flexibility in design, which can benefit both issuers and investors. By combining MTNs with derivatives, issuers can

EXHIBIT 12-3

A Floating-Rate Note Can Be Characterized as a Combination of a Fixed-Rate Note and an Interest-Rate Swap



reduce their financing costs, while investors can satisfy their specific investment needs. Investors seek to satisfy their investment needs through reverse inquiry: They contact an investment bank to request notes with specific characteristics that may not be available currently in the market. Based on an investor's view concerning future market conditions, such as future movements in interest rates, currency exchange rates, commodity prices, or other market variables, investors and issuers can customize structured notes to reflect the investors' specific views on the market. Consequently, structured notes can be issued with a range of embedded options, including call options, put options, swaps, caps, floors, or collars.

Investors prefer to have an MTN issuer of high-investment-grade quality so as not to incur significant credit risk. Structured note investors target specific financial risks they are willing to incur, and they are willing to take on issuer credit risk only if that risk is the specific one they have targeted. CLNs, discussed later in this chapter, are a form of structured note that offers such an opportunity.

The structured note issuer usually is not willing to take on the added financial risk associated with the embedded derivative. When selling a structured note, the issuer typically simultaneously enters into one or more derivative transactions to hedge this risk by transforming the cash flows that the issuer is obligated to make to investors. These derivative transactions allow the issuer to eliminate its exposure to the risks arising from the customization of the structured notes. Returning to our floating-rate note example, the issuer who sells a floating-rate MTN that pays LIBOR plus a premium can simultaneously enter into an interest-rate swap transaction in which it pays a fixed rate of interest and receives LIBOR from a swap counterparty. By combining a floating-rate note and a swap transaction, the issuer is able to create a synthetic fixed-rate note and eliminate its floating-rate risk exposure because the floating-rate payments are offsetting.

Issuing structured notes can enable a firm to reduce its financing costs when the purchasers of the structured notes are willing to pay a premium (accept a reduced yield) in exchange for the investment opportunity. They may be willing to pay a premium when similar investment opportunities are not currently available, possibly due to investment restrictions. For example, suppose an institutional investor that is not permitted to purchase stand-alone non-U.S. currency options has a view that the Australian dollar is going to appreciate significantly relative to the U.S. dollar over the next five years. It cannot buy Australian dollar call options, but it might be able to purchase a structured note that will pay an increased redemption amount at maturity if the Australian dollar has appreciated above some specified threshold. This contingent payment structure embeds a call option on the Australian dollar in the structured note, as illustrated in Exhibit 12-4. The institutional investor is willing to pay for the embedded call option by accepting a lower coupon rate on the structured note than it would require for a plain vanilla fixed-rate note of the same maturity for the same issuer.

Suppose the structured note issuer does not wish to be exposed to Australian dollar foreign exchange risk. It can purchase a matching call option on the Australian dollar from an options dealer (possibly the same dealer who created the structured note) and finance the option premium through the dealer—for example, by paying the dealer 90 basis points per year. If the annual option premium payment is less than the differential in yield between the structured note and an otherwise identical conventional note, then this difference in payments reduces the firm's funding cost, as illustrated in Exhibit 12-5. The issuer saves 10 basis points (6.00% to 5.90%) in this example.

Structured European Medium-Term Notes

When an MTN is issued outside the United States, particularly in the Euromarket, the product is called a Euro-MTN. Euro-MTNs are not subject to national regulations, such as SEC registration requirements. An issuer of Euro-MTNs typically maintains a standardized single document that can be tailored to suit almost any Euro-MTN issue and provides flexibility in the size, currency, and contingent structure of the offering. Similar to MTNs issued in the U.S. market, structured Euro-MTNs can provide an issuer with the opportunity to reduce its funding costs by crafting structured notes opportunistically.

The maturity of Euro-MTNs are typically less than five years, and the ratings on Euro-MTNs are typically higher than MTNs issued in the U.S. market because of the greater credit sensitivity of Euro-MTN investors. The Euro-MTN market is more diverse than the U.S. MTN market, mostly because it has a broader range of currency denominations and a more international mix of borrowers and investors.

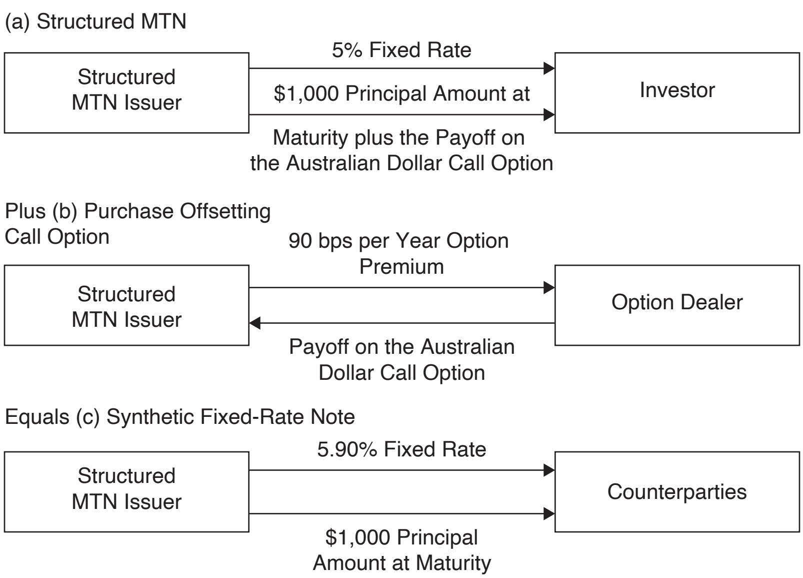
Structured Note Issuer Reduces Its Funding Cost When It Enters into an Offsetting Derivative Transaction That Costs Less Than the Value It Receives for Including the Embedded Call Option in the Structured MTN



Types of Structured Notes

Structured notes have been designed to provide exposure to a wide range of financial risks, such as changes in interest rates, foreign exchange rates, stock prices, the value of market indices, commodity prices, and credit quality. A few examples will illustrate the rich variety of structured MTNs.

Inverse Floating-Rate Notes

A floating-rate note is structured to facilitate taking a view on the future direction of interest rates. Inverse floating-rate notes (IFRNs) reverse the direction of the bet on interest rates. They can also be structured so as to leverage the bet. In particular, IFRNs have a coupon reset formula in which LIBOR is subtracted from a fixed percentage rate. As LIBOR increases (decreases), the coupon payment on an IFRN decreases (increases). By design, investors in IFRNs generally expect interest rates to fall and are therefore bullish on bond prices. For this reason, IFRNs have also become known as *bull floaters*.

If an investor expects interest rates to fall, the investor can approach an investment bank for an opportunity to purchase a structured note, issued by an investment-grade company, with coupon payments that move inversely to LIBOR. The investment bank then communicates this interest to prospective note issuers to whom it proposes an IFRN transaction. If an issuer agrees to the proposed transaction, it would then issue the IFRNs to satisfy the investor's demand.

Exhibit 12-6 provides an example of an IFRN. An IFRN can be created by adding an interest-rate swap to a fixed-rate MTN. For example, if the issuer combines a 7% fixed-rate note and a fixed-for-floating interest-rate swap that pays 7% fixed and receives LIBOR, the resulting structured note pays interest at a rate equal to 14% minus LIBOR. The coupon rate on the IFRN varies inversely with LIBOR.

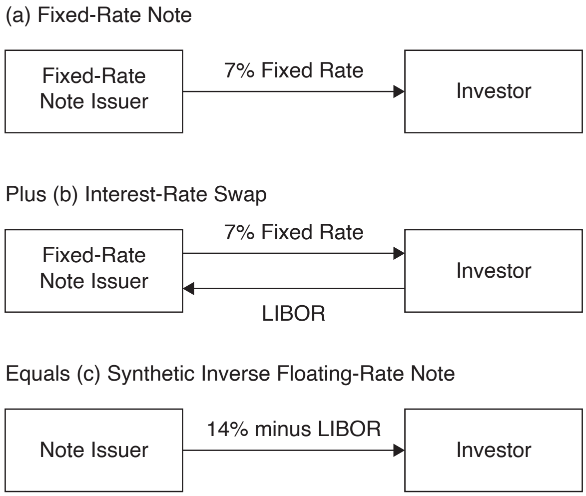
IFRNs have a very long duration. When interest rates drop, the coupon rate on the notes increases and the discount rate at which the stream of debt service payments is valued decreases, which magnifies the price increase. The opposite occurs when interest rates rise. Consequently, the IFRN exhibits much greater price sensitivity in response to interest rate changes than even a conventional fixed-rate note of the same maturity. As Exhibit 12-6 suggests, an IFRN has a duration that is roughly double the duration of a comparable fixed-rate note.

The issuer's objective in issuing structured notes is to reduce its funding cost by satisfying an investor's demand for a particular structure without incurring undue additional risk. If the issuer of IFRNs does not want to pay floating-rate interest, which will fluctuate inversely to market interest rates, but rather, wants to fix its interest payments, then it must hedge this risk. To protect itself against the IFRN's heightened interest-rate risk, the IFRN issuer can simultaneously enter into an offsetting interest-rate swap transaction to pay floating and receive fixed.

Suppose it can issue three-year IFRNs that pay 13.75% minus LIBOR with a semiannual reset. The 25-basis-point saving versus the coupon in Exhibit 12-6 might reflect the reduction in yield purchasers are willing to accept in return for

EXHIBIT 12-6

An Inverse Floating-Rate Note Can Be Characterized as a Combination of a Fixed-Rate Note and an Interest-Rate Swap



the IFRN investment opportunity. An interest rate floor is included in the IFRN to prevent a negative coupon rate if LIBOR rises above 13.75%. The swap does not have such a feature, but the IFRN issuer can offset the IFRN floor by purchasing a cap contract. Thus, the IFRN issuer can hedge its IFRN risk exposure by entering into a swap transaction in which it receives a fixed rate of 7% semiannually for three years and pays LIBOR and simultaneously purchasing a cap contract that pays the excess above the strike rate if LIBOR rises above 13.75%. Suppose the cap contract costs 10 basis points per year. Exhibit 12-7 illustrates the effect of the hedging transactions. As a result of issuing the IFRN and entering into the swap and purchasing the cap contract, the issuer creates a synthetic fixed-rate note paying a 6.85% coupon rate. Its cost of arranging three-year fixed-rate funding is 6.85%, which represents a saving of 15 basis points (6.85% versus 7%).

Leveraged Inverse Floating-Rate Notes

An IFRN can be leveraged by adding another interest-rate swap. This structure results in a coupon rate that is equal to some fixed rate minus some multiple of the reference rate. Exhibit 12-8 illustrates the structure of a leveraged inverse floating-rate note (leveraged IFRN). In this particular example, two interest-rate swaps are embedded in the structured note. As a result, a multiple of two is applied to LIBOR, and the coupon rate of the leveraged IFRN declines twice as fast as the coupon of the IFRN in Exhibit 12-6 as LIBOR rises. The leveraged IFRN pays interest at the rate of 21% minus two times LIBOR.

EXHIBIT 12-7

An Issuer of an Inverse Floating-Rate Note Can Offset Its Interest-Rate Risk by Entering into an Offsetting Interest-Rate Swap and Purchasing a Cap Contract

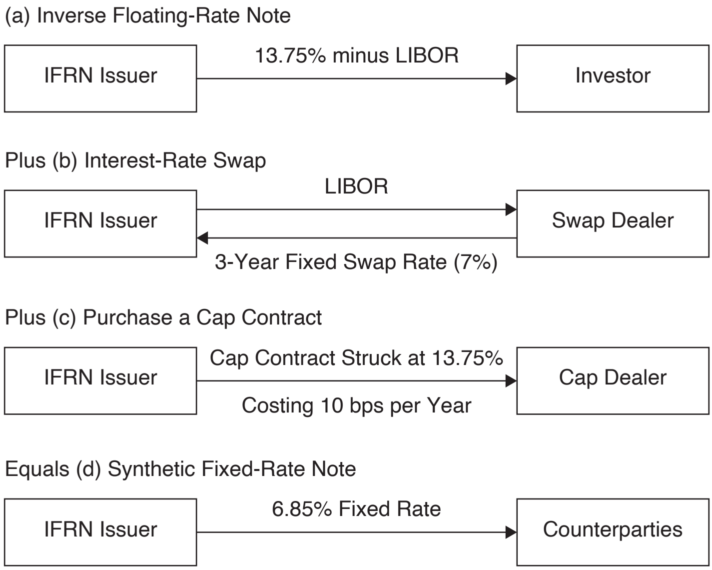


EXHIBIT 12-8

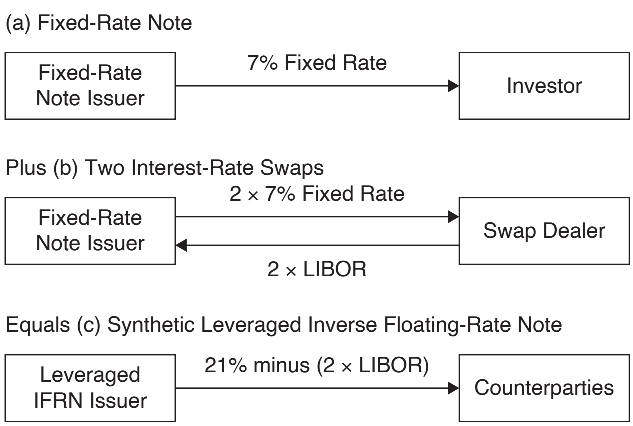
A Leveraged Inverse Floating-Rate Note Created by Combining a Fixed-Rate Note and Two Interest-Rate Swaps



Range Floating-Rate Notes

A range floating-rate note enables the issuer and investors to take a particular view on future interest rate volatility. Range floating-rate notes make interest payments only when the specified interest rate, usually a short-term interest rate such as three-month LIBOR, stays within the stated range. For instance, suppose an issuer sells a range floating-rate note that accrues interest during the first two interest periods at a rate equal to three-month LIBOR plus 100 basis points on those days when three-month LIBOR is between 3% and 4%. The range typically steps up in subsequent periods. If three-month LIBOR is outside the specified range, no interest accrues that day. Therefore, the investor profits if short-term interest rates rise in a gradual and predictable pattern and stay within the specified range. At the same time, the investor bears the risk that LIBOR rises or falls outside of the specified range. In return, the investor is compensated for this risk by receiving a greater spread over LIBOR than a conventional floating-rate note of the same issuer would provide.

An issuer of range floaters could simultaneously enter into an interest-rate swap transaction to hedge its floating interest-rate risk exposure. For example, suppose the issuer enters into an interest-rate swap that pays 6% fixed and receives floating-rate payments that mirror the coupon payments on the structured note, which is three-month LIBOR plus 100 basis points when LIBOR is within the specified range, as in the previous example. As a result of the combined transactions, the issuer of the range floater locks in a financing rate of 6%, which is beneficial if its cost of conventional fixed-rate funding for that maturity exceeds 6%.

Yield Curve Accrual Notes

A yield curve accrual note accrues interest at an above-market fixed annual rate but only when the slope of the yield curve is within a specified range. The slope of the yield curve is defined by the difference between specified long-term and short-term interest rates, such as the difference between the 30-year constant maturity Treasury (CMT) rate and the 2-year CMT rate. No interest accrues on days when the slope is zero or negative; that is, the yield curve is flat or inverted. Often, the notes initially pay the above-market rate for a year or two, and the accrual feature starts at the end of this period. The issuer is usually given the option to redeem the notes prior to maturity or there may be an automatic call. The total rate of return is capped by the fixed annual rate.

A similar structure offers a leveraged play on the slope of the yield curve. Leveraged yield curve–linked notes initially pay interest at an above-market fixed rate for one or two years before switching to paying a floating rate. This floating rate is equal to a multiple, typically between two and five times, of the slope of the yield curve at the beginning of the quarterly interest period. The interest rate is capped, and the minimum rate is zero (if the yield curve is flat or inverted).

Currency-Linked Notes

A currency-linked note is a structured note in which payments are linked to the performance of a specified foreign exchange rate or a basket of currencies. Investors are able to capitalize on their view of the likely movement of the exchange rate. One of the most popular types of currency-linked notes combines a fixed-rate note with an embedded currency call or put option. The issuer pays (receives) an option premium to (from) investors in the form of an enhanced (reduced) coupon rate if it is long (short) the embedded option. At maturity, if the currency option remains out-of-the-money, the issuer repays the par amount to the investor. If the option is in-the-money, the principal repayment amount is enhanced or reduced according to the type of option and its moneyness.

For example, suppose a financial institution wants to issue a structured note that will provide a hedge against a possible fall in the value of the Japanese yen relative to the U.S. dollar. It can sell investors a Japanese-yen-linked U.S. dollar–denominated structured note for \$10 million with an embedded long yen put option that specifies a strike rate set equal to the spot yen–dollar exchange rate of, say, ¥90/\$1 at the time of issue. This put option on yen can be viewed equivalently as a call option on the U.S. dollar. The note pays the par amount in dollars at maturity if the option is out-of-the-money (Japanese yen remains above—equivalently, the U.S. dollar remains below—¥90/\$1). At maturity, if the Japanese yen has weakened (equivalently, the U.S. dollar has strengthened) to ¥95/\$1, then the payment is reduced by \$0.53 million (= \$10 million × (90 – 95)/95). Thus, the financial institution pays—and the investors receive—\$9.47 million. The \$0.53 million saving would offset part of the foreign exchange loss on the assets the financial institution had hedged by issuing the currency-linked note. Conversely, non-U.S. investors who believe that the Japanese yen would strengthen relative to the U.S. dollar—equivalently, that the U.S. dollar might weaken against the Japanese yen—could express that view by taking the other side of the transaction.

As with other structured notes, an issuer of a currency-linked note that is not interested in the currency option for hedging or investment purposes, but is merely acting as a conduit, can hedge itself by taking an offsetting position in the option. If the issuer of the currency-linked note in the preceding example, which is the buyer of a currency put option, were instead merely acting as a conduit, it could hedge itself by selling an identical (or substantially similar) yen put option to neutralize its risk exposure to changes in the yen-dollar exchange rate.

Equity-Linked Notes

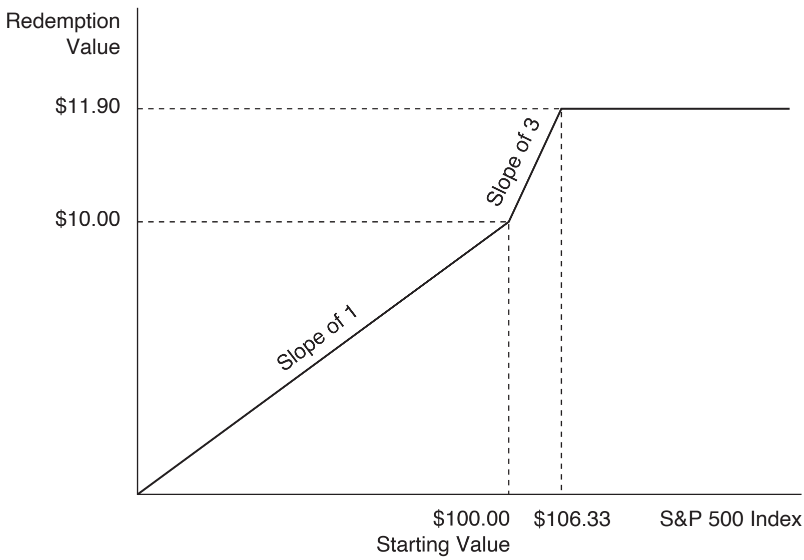
Equity-linked notes are structured by combining a note with an equity derivative. The payments on an equity-linked note are principally determined by the return on the underlying equity derivative, which could be a single stock, a basket of stocks, or an equity index.

One structure combines a non-interest-bearing note and an equity call option. On the maturity date, an investor receives the par value of the note plus a variable return based on the percentage change in the underlying equity derivative. Specifically, the final payout is calculated as the initial investment times the gain or loss in the underlying stock or equity index times a note-specific participation rate. For instance, if the gain on the underlying stock or equity index is 30% during the investment period and the participation rate is 90%, the investor receives 1.27 times the amount she invested. If the note provides principal protection (a floor rate of return of zero) and the underlying equity declines or remains unchanged during the investment period, then the investor simply receives the original amount she invested.

Many equity-linked notes build in leverage by increasing the participation rate to two or three times the percentage change in the benchmark index. For example, suppose a highly rated bank holding company originates accelerated return notes (ARNs) linked to the S&P 500 Index. Its broker-dealer subsidiary will market the notes to its retail customers who want to take a view on the performance of the S&P 500 over the next 14 months. The face amount of each note is $10. The ARNs do not pay interest; the only payment is at maturity. The notes have a 3× participation rate subject to a 19% total return cap. If the ending value of the S&P 500 exceeds the starting value, the ARN holder gets her $10 back plus the product of $10 times the participation rate (3×) times the percentage return on the S&P 500 subject to a cap of $11.90 ($10 plus a 19% return). If the ending value is less than or equal to the starting value, the amount the ARN holder gets back is reduced by the percentage drop in the S&P 500. Exhibit 12-9 shows the payoff on an ARN at maturity. Note that if the S&P 500 fell to zero, so would the payoff on the ARN; the ARN's value would be wiped out.

EXHIBIT 12-9

Payoff on an ARN at Maturity



Equity-linked notes can also be interest-bearing. In that case, the participation rate is reduced to reflect the income provided by the interest payments. As with other structured notes, an issuer of an equity-linked note can hedge its risk exposure—in this case, by simultaneously purchasing an equity call option to hedge its exposure to a rise in the price of the specified stock or equity index. Issuers of equity-linked notes have typically been broker-dealers or highly rated financial institutions with a broker-dealer subsidiary, who can structure these hedges relatively cheaply.

Commodity-Linked Notes

Commodity-linked notes are created by combining a note with a commodity derivative. Commodities that have served as the underlying for such securities include crude oil, natural gas, gasoline, copper, lead, or precious metals. The payments on a commodity-linked note are determined by the performance of the underlying commodity or a specified basket of commodities. Interest or principal payments or both can be commodity-linked.

One structure combines a non-interest-bearing note and a commodity call option. At maturity, an investor receives the par value of the non-interest-bearing note plus a variable return based on the percentage change in the price of the underlying commodity component. If the note provides principal protection and the price of the underlying commodity declines or remains unchanged during the investment period, then the investor simply receives the original amount she invested.

As with equity-linked notes, commodity-linked notes can also be interest-bearing, and the issuer of the notes can hedge its risk exposure by simultaneously entering into an offsetting commodity derivative transaction.

Risks of Structured Notes

Issuers of structured notes and investors face a variety of risks in addition to the risk that is specific to the embedded derivative instrument. These risks are in addition to the risks due to changes in interest rates and price risk due to the remaining time to maturity.

Credit Risk

A structured note is typically a senior unsecured note. An investor does not have a security interest in (or any other access to) the underlying assets. Because a structured note combines an unsecured note and a derivative instrument that an investment bank creates to satisfy an investor's desire for exposure to a specific risk, payments of interest and principal are subject to the note issuer's credit risk. An investor is exposed to the risk of a change in the note issuer's credit ratings or a change in the credit spread of the issuer's senior unsecured notes, which affects the required rate of return on the issuer's conventional notes. An investor bears the risk that the issuer might default on the note. Investors try to control this risk by limiting their structured note purchasers to notes issued by high-grade issuers, such as the parent company of a major bank, a major broker-dealer, or government-sponsored enterprises Freddie Mac and Fannie Mae before they encountered financial distress.

Structured notes are also issued by banking institutions in the form of CD bank deposits. When issued in the United States, their principal (but not any unrealized gain) is insured up to the permitted limit by the Federal Deposit Insurance Corporation, which is an agency of the U.S. government.

It has been more common, however, for investment banks to issue structured notes. Because of the risk of issuer default, it is possible for a structured note to become worthless even when the embedded derivative is in-the-money. This counterparty risk is well illustrated by the collapse of Lehman Brothers in September 2008, which resulted in Lehman Brothers structured notes becoming worthless even when the underlying derivatives had positive returns. In effect, the default risk trumped the risks and returns inherent in the embedded derivative instrument and nullified the specific bet that the issuer and the investors were trying to make when the structured notes were issued.

Market Risk

By design, an investment in a structured note carries additional market risks on top of the risks that a traditional note carries because of the embedded derivative instrument. A structured note is created for investors who are seeking to profit by taking on specific market risks. Depending on future market conditions, such as interest-rate movements, stock price movements, or commodity price movements, losses on a structured note could be magnified. Market risks can be quantified with financial models, such as an interest-rate term structure model or an option pricing model, so that the degree of market risk can be quantified and priced into the structured note price.

The price at which a particular structured note could be sold prior to maturity will depend on several market-related factors that are difficult to assess, which can cause the sale price to be substantially less than the purchase price. These factors include (1) changes in the value of the underlying asset or index, (2) the volatility of the underlying asset or index, and (3) changes in the dividend rate on the underlying asset or index.

The secondary market price of a structured note will also be adversely affected by the inclusion of the issuer's hedging profits and the agent's commissions in the issue price. These transaction costs will not be reflected in the secondary market price. Consequently, the secondary market price will tend to be less, and possibly significantly less, than the purchase price.

Liquidity Risk

The markets for structured notes are generally less liquid than those for conventional senior unsecured notes. There may be no secondary market for a particular structured note. Structured note issuers typically do not commit to make markets in the notes they issue. Most structured notes are rarely traded after issuance. An investor in a structured note should be prepared to hold it to maturity. Due to the limited liquidity, structured notes often have a short maturity between one and three years to compensate.

One of the reasons for the market illiquidity is that because a structured note is customized to satisfy the specific needs of an original investor, there is a smaller number of potential investors who might be willing to buy the structured note (and make the same customized bet) in the secondary market. Another reason for the market illiquidity is that the issue sizes are generally smaller and the transaction costs are usually higher than for standardized notes. Consequently, to value a structured note, one needs to take into account not only the credit risk of the issuer, but also the particular risk/return profile customized to the investor. Pricing accuracy can be another concern with structured notes. Because structured notes are rarely traded after issuance, their prices are usually calculated with a financial model. In that case, the accuracy of the valuation depends to a large extent on whether the underlying derivative is modeled correctly.

As a result, when an investor intends to sell structured notes before they mature, it may not be easy to sell them at a reasonable price within a reasonable time frame. For instance, if interest rates move in the opposite direction to an investor's expectation when he purchased a structured note, the investor may want to sell the structured note but not be able to find a market for it. As another example, when an investor's view on the direction of interest rates proves to be correct but the interest rate underlying the structured note (such as the interest rate in an inverse floater) changed earlier than expected, the investor may want to sell the structured note before the maturity date to take advantage of current market conditions and lock in her profit. Because structured notes are thinly traded securities, the spread between the market bid and ask prices may be wide; the size of the spread would reduce the profit realized on the structured note investment.

Early Redemption Risk

Many structured notes give the issuer the discretion to redeem the notes prior to maturity or automatically redeem the notes early based on the performance of the underlying asset or index. The issuer is likely to use this discretion when interest is accruing faster than on conventional notes of the same maturity and credit rating. The early redemption stops the accrual of interest at the favorable rate and forces the investor to reinvest the redemption proceeds at a less attractive yield.

Systemic Risk

Systemic risk refers to the risk associated with a broad market disruption within the financial market system, as opposed to being limited to an individual security or a particular market segment. By design, structured notes are more exposed to systemic risk than conventional notes because the payments on structured notes are often tied to the conditions in the derivative markets for foreign exchange, equities, or commodities. Any disruptions or problems in the underlying derivative market would magnify the structured note holder's risk exposure to that market and compound her risk exposure to disruptions or problems in the fixed income market. Structured notes typically provide that the calculation of the final payment on the maturity date will be postponed if any of the specified market disruption events occurs on that date.

Why Do Investors Buy Structured Notes?

Investors buy structured notes when the risk/return profile of the security matches their investment needs and the investment opportunity is not otherwise available as cheaply (or at all) in the capital market.

Enhanced Yield

Investors in structured notes typically hope to realize an above-market rate of return. This enhanced yield opportunity might entail an above-market coupon payment if the underlying interest rate moves in the investor's favor in exchange for incurring the risk of receiving interest at a floating rate. This floating rate might be very low or even zero for long periods of time. Alternatively, the potential for enhanced yield might be tied to the performance of a specified benchmark with a single payment at maturity in exchange for foregoing coupon payments and assuming the risk that the payment at maturity might be less than the face amount and possibly even zero. The payoff at maturity is often capped.

Administrative Efficiency

Compared with separate transactions consisting of notes and derivative instruments, which could be complex and costly, purchasing a structured note makes the process simple and reduces administrative costs, such as the cost of maintaining margin or the cost of rolling over shorter-term derivative contracts. At least partially offsetting this benefit, the purchase price usually includes the agent's commission and the issuer's hedging profit, which can increase the investment cost significantly.

Diversification and Hedging

Structured notes facilitate investors diversifying their investment portfolios into new products and new security types and possibly new markets. For example, an investor can diversify his interest rate risk exposure by purchasing a structured note with an embedded derivative based on a different asset class. The embedded derivative can serve a useful hedging purpose, as in the example earlier in the chapter of a financial institution that issued a structured currency-linked note containing a Japanese yen put option to protect against a fall in the value of the Japanese yen relative to the U.S. dollar. Inflation-protection structured notes pay a coupon tied to a benchmark inflation index, which provides the investor with a hedge against inflation.

Customization and Managing Risk Exposure

Because structured notes are customized to conform to investors' views on the interest rate, stock price, exchange rate, or commodity price reflected in the underlying derivative instrument, investors are able to adjust the risk/return profiles of their investment portfolios. Through a reverse inquiry, an investor is able to request notes with specific characteristics, which may not be available currently in the market.

Some structured notes are created to minimize risk exposure by providing principal protection, while others are created to maximize returns with or without principal protection. In any case, the derivative components of the structured notes allow the products to be aligned with any particular investor's market view or economic forecast and to suit the investor's risk tolerance. Moreover, leverage can be built into structured notes, as with leveraged inverse floaters, which can enhance expected returns—but also investment risk—as compared with a direct investment in the underlying assets. Therefore, investors are able to manage risks appropriate to their risk/return profiles in line with their views on the market.

Principal-Protected Structured Notes

A principal-protected structured note (PPN) is a structured note that guarantees the return of at least 100% of invested capital (a floor rate of return of zero), regardless of market conditions, as long as the notes are held to maturity. On the maturity date, barring a default by the issuer, investors receive payments consisting of the original principal amount plus any gains from the underlying assets. Because a PPN is a structured note combined with downside protection, investors in PPNs exchange more certain yet potentially lower returns for more uncertain and potentially larger returns. The return from investing in a PPN depends on the value of the embedded option at maturity. With many PPNs, there is no periodic payment of interest during the investment period, and just a single payment is made at maturity.

Its name suggests that a PPN guarantees the repayment of 100% of invested principal. However, this assurance does not mean that there is zero downside risk, because the issuer might default. Typically, an investment bank or a bank holding company serves as the issuer and is therefore responsible for paying the contingent principal amount at maturity. Therefore, evaluating the financial condition and creditworthiness of the issuer is an important step in deciding whether to purchase a PPN. Credit risk can be significant, which materializes when the issuer defaults. An investor can reduce its principal repayment risk by investing in a structured CD that qualifies for deposit insurance.

The Impact of the Lehman Brothers Bankruptcy

The Lehman Brothers collapse in September 2008 has affected virtually all areas of the financial markets in some way, but particularly the structured products market, because a large number of products were linked to Lehman Brothers' credit. One of the more significant products was the Lehman Brothers PPNs.

The Lehman Brothers PPNs were issued as hybrid financial instruments, constructed from a combination of stocks, bonds, currencies, commodities, and derivatives, which were sold to retail investors as low-risk and safe investments. UBS, one of the largest sellers of structured notes, and other brokerage firms sold Lehman Brothers structured notes to retail investors with principal protection effectively guaranteed by Lehman Brothers. Following the Lehman Brothers bankruptcy in September 2008, however, the guarantee of principal protection became meaningless, and the PPNs became essentially worthless.

Before the Lehman Brothers collapse, investment banks were able to sell PPNs to investors easily because investors were convinced that the PPNs would guarantee principal repayment even when the underlying investments did not produce a positive return. However, the Lehman Brothers bankruptcy rudely awakened retail investors to the risk of possible credit loss and generated a substantial amount of litigation in which investors asserted that the PPN guarantee had been misrepresented because the investors' principal was not truly protected in all events.

This negative experience highlights the need to warn investors properly concerning the risks of investing in structured notes. It also highlights the problem inherent in every derivatives contract: a counterparty default will undermine the upside opportunity or downside protection investors thought they were getting when they purchased the structured notes.

CREDIT-LINKED NOTES

Broadly defined, a CLN is a structured note with at least some of its payments dependent on the occurrence of a defined credit event, such as a specified entity's default, a change in a specified entity's credit rating, or a change in a specified debt instrument's credit spread. CLNs have grown in importance with the development of the market for credit default swaps (CDS) because like CDS, CLNs provide attractive opportunities for managing credit risk exposure. At its simplest, a CLN is a form of collateralized CDS.

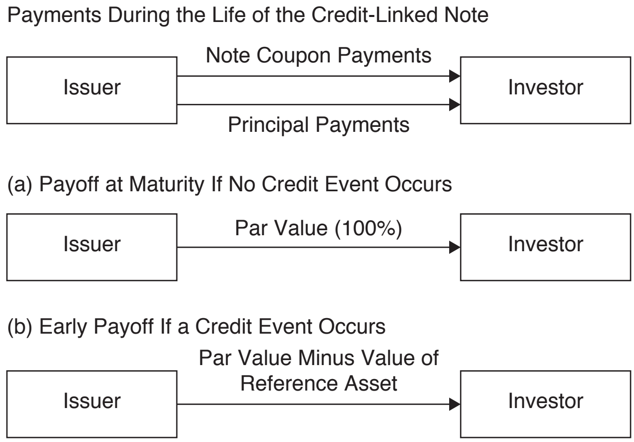
Characteristics of Credit-Linked Notes

Typically, a CLN is a combination of a conventional note and a CDS. A CLN is often issued by either a very strong credit, such as a high-grade bank or a government-sponsored enterprise, or a special-purpose bankruptcy-remote trust that is a counterparty to the CDS. A total return swap or a credit forward contract can also be used in this structure. A CLN allows the issuer to transfer a particular credit risk exposure to the purchaser of the CLN. In this structure, the issuer (seller) of the CLN is the protection buyer, and the investor (purchaser) of the CLN is the protection seller, who ultimately bears the credit risk.

As shown in Exhibit 12-10, if a credit event occurs, the CLN is redeemed early. The redemption amount is reduced below the face amount according to the reduced value of the underlying reference asset, such as a bond or a bank loan that falls in value due to the credit event's occurrence. If no credit event occurs during the life of the CLN, then the full principal amount of the note is paid to the investors at maturity.

EXHIBIT 12-10

Payoffs on a Credit-Linked Note



CLNs are attractive to issuers who want to hedge against a credit default or a rating downgrade, which would adversely affect the value of one of their investments. They are able to customize the terms of the credit protection contract to satisfy their credit risk protection objectives. On the other hand, investors purchase CLNs with the objective of enhancing the yield they receive on their note investment. Investors find CLNs attractive because they are able to gain access to the credit market, which might be unavailable to them otherwise.

A CLN normally adjusts the principal repayment to pay off on the credit derivative instrument embedded within the note. For example, suppose an investor purchased a five-year CLN at a credit spread of 200 basis points that would repay \$1,000 at maturity or \$1,000 minus the payoff if a credit event occurs before the CLN matures. The investor has sold a put option to the issuer of the note and in return receives a higher coupon. Suppose that the reference bond's credit spread is 100 basis points and a credit event occurs that causes the price of the reference asset to fall to 80. The issuer of the CLN pays 100 basis points per year for the put option (200 – 100 basis points). The holder of the CLN would receive \$800 (80% of \$1,000) per \$1,000 face amount following the credit event. The single payment is equivalent to receiving \$1,000 and simultaneously paying off \$200 on the put option.

Funded Credit Derivative

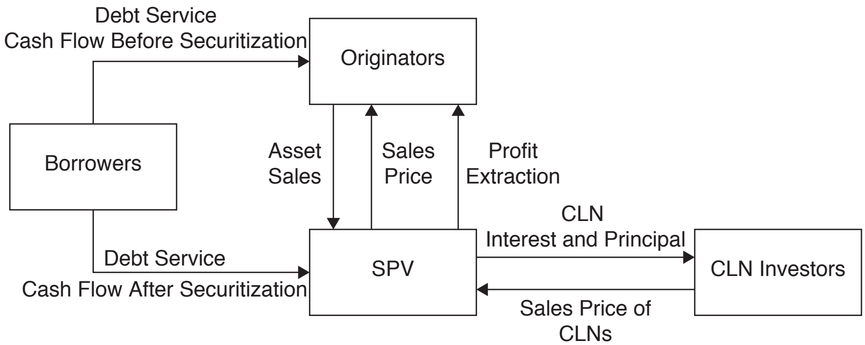
CLNs have gained in popularity because they provide credit protection like CDSs, but entail less risk of contract default. CLNs are a form of funded credit derivative. The investor in the CLN, the protection seller, pays cash to the protection buyer—the full purchase price of the CLN—to purchase the CLN. If a credit event occurs, the protection buyer's repayment obligation decreases, and the protection buyer returns less cash to the protection seller than if no credit event had occurred. In contrast, with CDS, the protection buyer must collect the cash payment from the protection seller, if there is cash settlement, or the protection seller must obtain the bond or loan obligation from the protection buyer and sell it in the market, if there is physical settlement. A CLN thus involves less contract default risk than a CDS written by the same protection seller.

SPV Structure

CLNs have been issued by large financial institutions. This unfunded structure exposes CLN investors to the financial institution's default risk. Alternatively, the CLNs can be issued through a funded structure in which a bankruptcy-remote special-purpose vehicle (SPV) is created to hold high-quality financial assets and issue the CLNs. This structure, which is illustrated in Exhibit 12-11, insulates CLN investors from the risk of issuer default because the SPV's assets are selected so as to generate sufficient cash flows to service the CLNs. The funded CLN structure thus limits the investor's default risk exposure to the reference obligation specified in the CLN, which was the purpose for creating the CLN in the first place.

EXHIBIT 12-11

Structure of a Credit-Linked Note



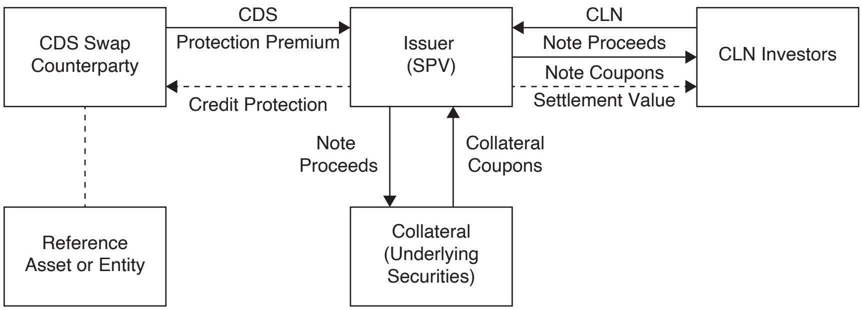
Combining Credit-Linked Notes and Credit Default Swaps

An issuer can design structured products combining CLNs and CDSs to meet both the issuer's and the investors' requirements. Exhibit 12-12 illustrates the combined structure of CLN and CDS, which is designed to fund the CDS obligation and to provide higher returns for an investor who is willing to take on the corresponding credit risk. The CLNs are issued by an SPV, which holds the collateral securities (also known as the *underlying securities*). The SPV uses the proceeds from issuing the CLNs to purchase the pre-agreed collateral securities.

They are normally risk-free securities, such as Treasury bills. The SPV grants a security interest in the collateral to secure the SPV's future performance under the CLN contract. The cash flow from these high-quality securities is used to pay the interest and principal on the CLNs as long as no credit event occurs. In this structure, the SPV buys credit protection on a single reference asset or entity by entering into a CLN and paying the ongoing premium, which is included in the CLN interest rate. The CLN investors sell the credit protection and receive the premium; they have the credit risk exposure to the reference asset or entity.

EXHIBIT 12-12

CLN and CDS Structure on a Single Reference Name



At the same time, the SPV simultaneously enters into a CDS agreement with a highly rated swap counterparty. In this swap agreement, the SPV sells credit protection on the same reference asset or entity underlying the CLNs and, in return, receives the CDS premium. Through the combined CLN and CDS structure, the SPV has a neutral credit risk position with respect to the reference asset or entity.

The coupon rate on the CLN is a spread over LIBOR and is funded by the collateral securities and the fee generated by selling protection in the CDS transaction. The SPV's payment on the CLN is linked to the performance of the reference asset or entity. If a specified credit event[1] involving the reference asset or entity occurs, there are three options to settle the CLN and the CDS. First, under the recovery-linked option, a third party sells the reference assets into the market, and the SPV distributes the realized proceeds to the CLN investors to settle the CLN. At the same time, the third party sells the underlying collateral securities and distributes the proceeds to the swap counterparty to settle the CDS. Second, under the physical delivery option, the CDS swap counterparty delivers the reference assets to the SPV and the SPV delivers them to the CLN investors,

1. Credit events typically include bankruptcy, payment default, repudiation, and restructuring.

and the SPV also delivers the underlying collateral securities to the CDS swap counterparty. Third, under the binary option, a specified cash payment is negotiated among the SPV, the CDS counterparty, and the CLN investors at the outset of the transactions. The SPV makes that cash payment to the CDS counterparty if a credit event occurs. It then deducts it from the principal amount owed to the CLN investors and repays the net amount to the CLN investors.

Reference Obligation Is Emerging Market Sovereign Debt

In the case of CLNs, in which the reference obligation is an emerging market debt obligation, the SPV also may need to enter into an interest-rate swap or a currency swap to reduce interest-rate risk and to tailor the required cash flows of the CLN to the cash flows of the collateral. The resulting package is a CLN that performs similarly to a sovereign bond. Such CLNs are bought by investors who seek an increase in yield as compared with what a comparable sovereign bond would offer and who do not need liquidity during the life of the CLN.

Credit-Sensitive Notes

A conventional corporate bond can be viewed as a package consisting of a long Treasury note and a short position in a CDS, with the credit event defined as an actual default with immediate payment. (Alternatively, one can assume the immediate sale of the note in the event default occurs and ignore the optionality inherent in the flexibility to time the sale of the defaulted note.) In a conventional corporate bond, part of the coupon payment (the credit spread) can be viewed as the CDS premium. The size of the coupon payment depends on the credit quality of the bond at the date of issue, but normally does not change if the credit quality of the bond subsequently changes. Credit-sensitive notes provide for variation in the size of the coupon if the issuing firm's credit quality changes.

A credit-sensitive note is a fixed- or floating-rate note on which the interest rate is adjusted in response to a change in the issuer's credit rating. The coupon rate adjusts inversely to the change in the note's credit rating. If the issuer is downgraded by a credit rating agency, the credit-sensitive note pays a higher coupon rate to compensate investors for the additional credit risk. In this structure, the investors are short a credit spread forward agreement.

Consider the following example with the indicated credit ratings and spreads:

Credit Rating	Credit Spread
AA	100 bps
A	125 bps
BBB	150 bps
BB	200 bps

An investor buys a single-A-rated note paying 125 bps over Treasuries. If the credit rating rises to AA, the investor receives 25 bps less per year in interest. If the credit rating falls to BBB, the investor receives 25 bps more per year in interest. Thus, a credit-sensitive note is a form of structured note, which provides a built-in hedge against changes in the issuer's credit quality. It thus provides protection against the moral hazard risk fixed income investors face.

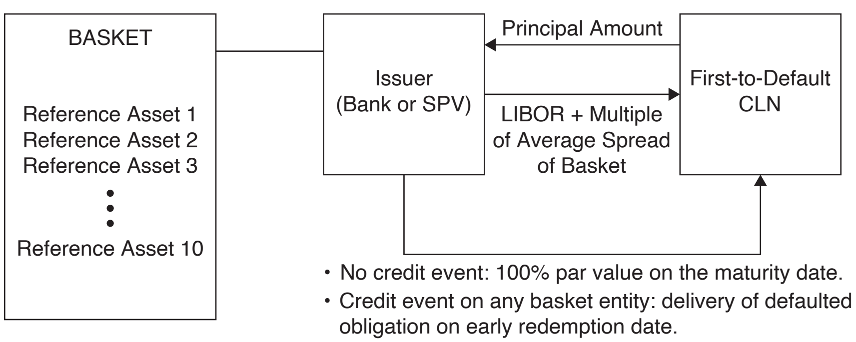
First-to-Default Credit-Linked Notes

A standard CLN is issued with reference to one specific bond or loan. A basket credit-linked note is a CLN that is linked to more than one reference entity. In a first-to-default CLN, an investor sells credit protection on a basket of assets, and the payment occurs upon whichever entity in the basket is the first to default. The coupon payment on the first-to-default CLN is LIBOR plus a multiple of the average spread for the reference entities in the basket of assets. As soon as a credit event occurs on any of the reference assets, the CLN matures.

Exhibit 12-13 illustrates a typical first-to-default CLN structure. Suppose an issuer sells a first-to-default CLN at par with three years to maturity, which is linked to a basket of 10 reference assets with a face value of $10 million. An investor who purchases the note pays $10 million to the issuer at the closing. The issuer will pay interest during the life of the note and will repay the $10 million at maturity, subject to there being no credit event. The CLN investor takes a credit position equal to $10 million notional in each reference entity. The first time a credit event occurs on any asset in the basket, the issuer redeems the CLN by delivering to the CLN investor $10 million face amount of the reference asset that experienced the credit event. Typically, the actual redemption amount is determined by the market value, not by the recovery value, of the reference obligation at the time the credit event is verified.

EXHIBIT 12-13

Structure of a First-to-Default Credit-Linked Note



A first-to-default CLN investor faces the same type of credit risk exposure on default as with a standard CLN, namely, the reduced recovery rate on the defaulted credit. Because a first-to-default CLN involves multiple assets in the basket, rather than a single asset as in a standard CLN, it can reduce the investor's default risk exposure as compared with a single-name CLN through credit risk diversification. The CLN investor obtains default risk exposure to a basket of reference entities, which can be diversified across industries and also across credit rating categories. This diversification benefit is greater the lower are the pairwise correlations among the returns on the reference entities in the basket.

Emerging Market Credit-Linked Notes

Emerging market CLNs are structured notes that are tied to the creditworthiness of a relatively lower-rated sovereign credit. To compensate emerging market CLN investors for taking on greater counterparty credit risk as well as liquidity risk, they are typically paid more than the underlying debt yield. For example, an investment bank issues a $10 million 10-year 9.5% note linked to Turkish government debt when Turkish government bonds of the same maturity pay 9%.

Emerging market CLNs are efficient investment instruments for investors who are not able to trade the underlying bonds of the countries for any reason, such as transaction costs, investment regulations, or other market frictions. They are attractive to emerging market fixed income investors who believe that a particular sovereign credit rating is likely to be upgraded and who want an investment opportunity that enables them to express that view.

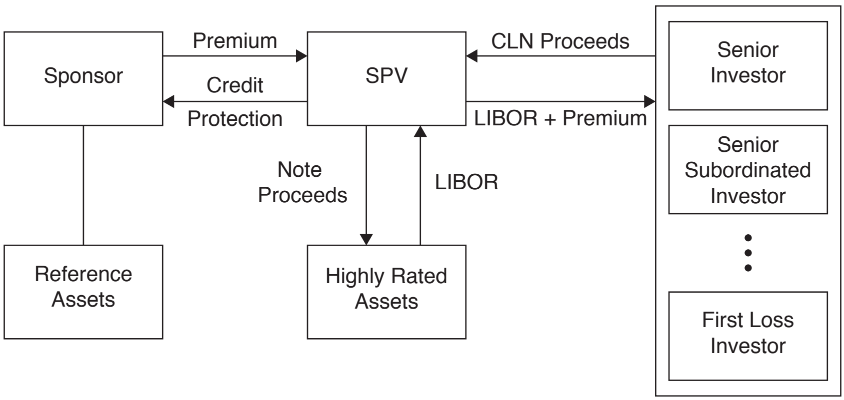
Synthetic CDO Credit-Linked Notes

Synthetic collateralized debt obligations (SCDOs) are a form of CDO that invests in CDSs or other assets to gain exposure to a fixed income portfolio. Unlike a CDS, which typically references a single asset, an SCDO references a portfolio of assets. This portfolio is securitized by issuing notes that are divided into tranches. The SCDO notes are typically prioritized sequentially as to their default risk exposure to the underlying portfolio. They also typically have a sequential amortization structure; the most senior notes are scheduled to be fully repaid first, the next most senior notes are scheduled to be fully repaid next, and so on. Accordingly, when payments are made, they flow first to the most senior notes, thus amortizing them more quickly than the subordinated notes. Investors in the SCDO tranches are able to take on credit risk in accordance with their risk tolerances by purchasing a particular note tranche.

Sponsors may combine SCDOs and CLNs to reduce counterparty risk. Like other CLN structures, an SPV is created to provide a bankruptcy-remote depository for the high-quality assets that are purchased with the CLN proceeds. Exhibit 12-14 illustrates a hybrid structure that combines SCDOs and CLNs in a fully funded structure. The SPV sells credit protection to the sponsor; this credit protection is ultimately provided by the CLN investors. If a credit event occurs involving any of the reference assets, the payments to the CLN investors are reduced according to the repayment priorities of their respective notes. The first loss CLN investors suffer the initial loss up to the full amount of their principal before more senior CLNs are affected.

EXHIBIT 12-14

Funded SCDO: SCDO Combined with CLNs



SCDO transactions can also be structured as a hybrid that blends the funded and unfunded structures. A single, highly rated investor purchases the most senior tranche in the form of an unfunded CDS, whereas the rest of the liability structure is divided into a series of funded CLN tranches, which are purchased by various investors according to their relative risk tolerances. The funded portion of this SCDO structure would mirror the structure illustrated in Exhibit 12-14.

KEY POINTS

- Structured notes and CLNs provide customized interest or principal payments that depend on the performance of a specified reference asset, market price, index, interest rate, foreign exchange rate, commodity price, or some other market quantity.
- A structured note combines a conventional senior unsecured fixed- or floating-rate note with an embedded derivative instrument. A CD can be used in the structure in place of the note to provide principal protection.
- A CLN is a particular form of structured note in which the derivative instrument is a credit default swap or some other form of credit derivative.

- The issuer's objective in issuing structured notes is to reduce its funding cost by satisfying an investor's demand for a particular structure without incurring undue additional risk.
- Investors buy structured notes when the risk/return profile of the security matches their investment needs and the investment opportunity is not otherwise available as cheaply (or at all) in the capital market.

THIRTEEN

COMMERCIAL PAPER

David K. Musto, Ph.D.
Ronald O. Perelman Professor in Finance
Wharton School of the University of Pennsylvania

The trillion-dollar market for commercial paper (CP) is in some ways like the market for Treasury bills. Like a Treasury bill, the typical CP issue is a short-term, unsecured, pure-discount instrument that simply pays its principal amount at maturity. And while CP is a private instrument and therefore not risk-free, the realized default rate has been very low, such that years go by with no defaults at all. So, the securities themselves are similar and have overlapping investor clienteles. However, unlike Treasury bills, CP can be a fragile source of funding, and this fragility necessitates an infrastructure around the CP market that includes the banking system, and occasionally necessitates government intervention as well.

This chapter begins with a description of the security, the relevant regulation and statistics on pricing, and issuance and outstandings over time, followed by a discussion of fragility risk and the infrastructure that addresses it. The chapter ends with an overview of policy interventions that supported the CP market after the sudden contractions in September 2008 and March 2020.

This chapter focuses on the CP market in the United States. Other economies, notably the European Union and Japan, have robust CP markets that operate similarly, though there are some points of departure that are beyond the scope of this chapter.

PAYMENT SCHEDULE AND PRICE QUOTATION

Most CP is issued on a pure discount basis, with only a principal payment at maturity. Pure-discount CP has the same payment schedule as Treasury bills and accordingly is also quoted on a discount-rate basis, so if the price today of CP paying F in n days is P, this is quoted as a discount rate of $d = [(F - P)/F](360/n)$. Coupon-paying CP is generally issued at par, and therefore quoted via its coupon rate, if it is fixed-rate, or its spread over a floating benchmark, if it is floating-rate.

PRIMARY AND SECONDARY MARKETS

CP issuers sell any maturity on any business day, and they do this either directly with their own sales force, or, more likely, indirectly through dealers. This contrasts with the Treasury, whose bills are issued and repaid only on Tuesdays and Thursdays and are placed through auctions. Direct issuers enjoy direct interaction with their investors, which could be useful if, for example, an issuer wants to broaden its investor base, or gauge demand for a different quantity or maturity of its paper, or calm a nervous market. Issuers selling instead through dealers enjoy the low fees prevalent in today's market, and benefit from the dealers' contacts with the investor community.

Once placed, CP is unlikely to come back to the market. If it does, the most likely buyer would be the dealer that placed it, or if the CP was directly placed, the issuer itself. One reason the original seller makes the best market for the paper it places is as a favor to its customers, whose liquidity needs might change. Another is to avoid competing with the investor at selling the same paper. Also, investors shopping around the CP they bought could unnerve the market, potentially sparking a run that the issuer would like to avoid. But because the original seller's goodwill for investors who return the product can run out, and because its capacity to repurchase can shrink in bad times, there is no guarantee of liquidity before maturity.

REGULATORY TREATMENT

The short maturity of CP implies high turnover that amplifies issuance volume. In 2019, for example, the issuance volume supporting the outstanding balance of around $1 trillion was approximately $20 trillion. This means that one basis point of issuance cost is $2 billion per year. CP issuers therefore benefit greatly from low regulatory frictions in general, and from relief from registration requirements in particular. This relief generally comes from one of two sections of the Securities Act of 1933, the sections known as 3(a)(3) and 4(a)(2).

The particular requirements of 3(a)(3) and 4(a)(2), established over the years by enforcement actions and no-action letters, are too extensive to catalog here, but there are a few important highlights. CP issued under 3(a)(3) can finance only "current transactions," so, for example, it can finance inventory but not long-horizon capital projects, and its credit quality has to meet the Federal Reserve's high standards for collateral. It has to be issued in a size and manner that is unfit for the general public, and with no more than nine months to maturity at issuance. CP issued instead under 4(a)(2) does not have to finance current transactions or have credit quality high enough for the Federal Reserve or mature within nine months. The main downside of 4(a)(2) is a tight restriction on resale after issuance. Issuers do not have to choose just one of these two sections, they can, for example, issue paper up to nine months maturity under 3(a)(3) and longer paper under 4(a)(2).

The Federal Reserve's issuance volume statistics show that CP is issued in a size unfit for the general public. In 2019 the average dollar volume of CP issued per day was $79.8 billion, and the average number of transactions underlying this volume was 3,960, implying an average transaction size of $20 million, which is impractical for the general public.

ISSUERS

CP issuers divide into several groups. The issuers of asset-backed commercial paper (ABCP) are the special-purpose vehicles (SPVs) that pay creditors from the cash flows collected from their portfolios of financial assets such as auto loans or trade receivables. The operating companies issuing CP divide on the one hand into financial and nonfinancial issuers, and on the other into domestic and non-U.S. issuers. The domestic issuers subdivide into those with domestic versus non-U.S. parents. Exhibit 13-1 reports the CP outstanding from each group of issuers as of the end of 2019, as reported by the Federal Reserve, and shows only a quarter of all CP, $252 billion in total, coming from nonfinancial issuers, indicating the difficulty an investor might face in diversifying out of the financial industry. In contrast, the $544 billion of CP from non-U.S. issuers and issuers with non-U.S. parents indicates that international diversification may be easier.

EXHIBIT 13-1

CP Outstanding at the End of 2019, by Issuer Type as Reported by the Federal Reserve, in $BB

Issuer Type	CP Outstanding
ABCP	$254.4
Nonfinancial Domestic	$194.4
Nonfinancial Foreign	$57.8
Financial Domestic, U.S. Owned	$50.7
Financial Domestic, Foreign Bank Parent	$119.5
Financial Domestic, Foreign Nonbank Parent	$44.7
Financial Foreign Bank	$183.3
Financial Foreign Other	$139.1

The $255 billion of ABCP outstanding in 2019 is far below its $1,218 billion peak. ABCP was an important part of the "shadow banking system" before the 2007–2009 Global Financial Crisis, financing the warehousing of mortgages before securitization, the securitizations themselves, and portfolios of securities backed by securitizations. Outstanding ABCP grew by $562 billion over the three years ending August 8, 2007, and then shed half that amount in seven weeks as suspicions grew about the collateral. The CP market as a whole shrank by half from its 2007 peak to the end of 2019.

INVESTORS

The short maturity of CP means both low duration and high liquidity. These attributes, combined with the generally high credit quality of CP, make it appealing to short-term investment pools, that is, managed portfolios where investors earn interest while parking their cash. An important class of such portfolios is money-market mutual funds (i.e., money funds), in particular, those that are designated Prime funds because they invest in the whole range of money-market instruments with minimal credit risk, including CP of sufficiently high quality. Historically money funds were the largest bid for CP, holding 46% of the market in 2009. However, their importance shrank in 2016 with the reform that reduced the appeal of prime funds relative to money funds restricted to government securities, in part by requiring prime but not government funds to consider redemption gates and fees during market stress. By the end of 2019, money funds held just 23% of the market, the same percentage held by nonfinancial corporations, which had been the biggest CP clientele before money funds started in the 1970s. One contributor to the reemergence of this clientele is large, cash-rich firms that used to invest in CP indirectly through money funds deciding post-reform to invest directly. Additional important investor types include insurance companies, pension funds, state and local governments, and mutual funds other than money funds.[1]

DEFAULT RISK MEASUREMENT AND REALIZATION

Evaluating the credit risk of CP is akin to evaluating the risk of longer-term debt, though the short maturity can change the focus of the evaluation. Credit-rating agencies, most notably Moody's, S&P, and Fitch, rate CP programs alongside longer-term debt and represent the change of focus with different lettering systems. At S&P the investment-grade CP ratings run from A1 down to A3, at Moody's from P1 to P3, and at Fitch from F1 to F3. CP with the top ratings (i.e., A1/P1/F1) is known as tier one or top tier, and CP one notch down at A2/P2/F2 is known as tier two or second tier. There is little reference to the small amount of CP below second tier.

CP ratings are not as important as they once were. This is because the regulation governing money funds (17 CFR § 270.2a-7 (i.e., *2a-7*)), no longer references credit ratings as it once did. Instead, 2a-7(a)(11)(i) now requires the board of a money fund to determine that a security presents minimal credit risk to the fund. Apropos of the backup credit lines discussed below, 2a-7(a)(11)(i)(B)

1. Statistics on CP ownership by investor clientele are from the Federal Reserve's "Flow of Funds," Table L209.

specifically directs the fund's board to consider the issuer's sources of liquidity when gauging whether the risk of an issuer's CP is minimal.

The credit risk of CP rarely ends in credit loss. In its retrospective on CP defaults through Q2 2017,[2] Moody's reports just nine defaulting issuers since 2000 that were rated at least P2 a year before: five in 2000/1, four in 2008, and none in the 8.5 years that followed. This low rate, which Moody's summarizes as a 0.02% probability of default over a 180-day horizon for P1 paper and 0.03% probability for P2 paper, is often attributed to the "orderly exit" mechanism that benefits from the backup lines.

If default does occur, recovery depends on the CP's place in the capital structure, which in the case of CP issued by an operating company is at the senior unsecured level. In the case of ABCP, recovery depends specifically on the receivables held by the SPV, following the repayment waterfall in the prospectus, as the creditors would generally not have legal recourse back to the entity sponsoring the SPV.

CP RATES

As a short-maturity, privately issued, and unsecured obligation, CP is a close match to interbank lending, so LIBOR is the natural benchmark for CP rates. The average CP rate for a tenor tracks LIBOR for the tenor very closely, outside of market disruptions. Consequently, the morning LIBOR fixing is generally a useful reference for issuers and investors to negotiate pricing. Also, the coupons of floating-rate CP can be defined as a fixed spread relative to the LIBOR tenor that matches the frequency of coupon resets.

Another important benchmark for CP rates is the Overnight Index Swap (OIS) rate. In an OIS transaction, say, for 30 days, one side pays the floating overnight rate, and the other pays a fixed rate for 30 days. Profits and losses are settled along the way with daily margin payments, thereby largely insulating each side of the swap from the other side's credit risk. This insulation distinguishes the OIS rate from the LIBOR rate, which reflects the credit risk of the banking system. Consequently, the OIS rate represents the current funding cost for a given maturity without reference to risks specific to the banking sector.

The main benchmark for risk pricing within the CP market is the credit spread between the two top tiers, which the Federal Reserve reports for nonfinancial issuers. The median spread is around 25 basis points, though it fluctuates over time—for example, falling to single digits in the months before the Global Financial Crisis and then spiking over 600 basis points in the depth of the crisis.

CP trades at a discount to Treasuries that reflects not only the credit-risk difference and the different uses of CP versus Treasury collateral, but also a

2. *Default and Recovery Rates of Corporate Commercial Paper Issuers, 1972–2017 H1*, Moody's Investor Service, April 23, 2018.

taxation difference. Both CP and Treasury interest are taxed at the federal level, but interest from Treasury securities is not taxed at the state level, whereas interest from CP and other private money-market instruments *is* taxed at the state level. The impact of this difference varies with the substantial variation in the applicable tax rates across states.

MATURITY DISTRIBUTION

The Federal Reserve reports the average maturity of outstanding CP to be 60 days, but behind this average is a wide distribution of individual maturities offered on any one day. The Federal Reserve data show that most issuance volume rolls over the shortest maturities, with over 60% of issuance below five days to maturity. The share of very short maturities fluctuates over time and tends to spike at tense moments. Two of the biggest spikes, in September 2008 and March 2020, occasioned the Federal intervention discussed below.

One lesson from the maturity distribution is that the 270-day maturity limit under 3(a)(3) is not particularly binding. Only 8% of all paper is longer than 80 days at issuance. One reason for the scarcity of longer paper is that the Federal Reserve requires CP to be both high quality and no more than 90 days to maturity to be acceptable as collateral, and this acceptability can be important to some CP investors.

BACKUP LINES

Financing with CP resembles financing with a revolving bank line, but it brings a new risk the borrower must address. A revolving line allows borrowing up to a limit, if the borrower stays out of default, and specifies the rate paid on the amount borrowed and the unused line fee paid on the remainder. A borrower can instead go around the bank straight to investors by issuing CP, running a balance by repaying old CP with new CP, and taking the balance down by repaying it from a different source, but by doing so it invites a new risk that economists call *fragility risk*. This is the risk of a sudden and crippling loss of funding due to the same coordination problem that drives bank runs. A CP investor who thinks that other CP investors will not roll their old CP into new CP may easily conclude that he should not roll over either, because the issuer's financial strain from funding the departures could make it a bad risk. The investor could conclude this even if he thinks the issuer is solvent to begin with, due to the damage the strain would cause. All debt finance brings some amount of rollover risk; what's special about CP is that, due to the short maturity, rollover is always imminent, so the capital structure is always fragile unless the issuer finds a way to manage this risk.

CP issuers do not have direct access to banks' defenses against fragility risk, but they can pay for indirect access. Banks have two main lines of defense: deposit insurance and their access to loans from the lender of last resort, the

Federal Reserve System.[3] Deposit insurance discourages runs by showing depositors they will be fine, up to the insurance limit, whether the bank survives or not. Access to the Fed shows depositors that the bank can raise funds through borrowing rather than through solvency-reducing fire sales. CP issuers generally have neither deposit insurance nor access to the Fed, but they can effectively rent access to them by arranging *backup* lines of credit. Before selling CP, the issuer can arrange a credit line that it then takes down only to repay maturing CP when investors will not roll over. By paying the unused line fee on this backup line, the CP issuer rents indirect access to the bank's deposit insurance, since the bank can raise and then loan insured deposits when the issuer's uninsured CP investors leave, and also indirect access to the Fed, since the bank can borrow from the Fed to loan to the issuer.

To perfect this indirect access to defenses against fragility risk, the CP issuer has to stay current with the covenants of its loan contract. The low risk tolerance of CP investors, combined with the short maturity, makes it likely that the issuer will be current when the line is needed. That is, there is little demand for CP with above-minimal credit risk, but an issuer that had minimal risk at issuance can see a rise in its risk and still comply at maturity with the ratio tests and other restrictions in the loan contract. This means the issuer likely still has the line when demand for its CP shrinks, provided its risk does not increase too rapidly. And even if its risk does increase rapidly, loan covenants tend to be written in terms of backward-looking quantities such as realized earnings, rather than forward-looking quantities such as anticipated earnings, so the borrower can be compliant even when its prospects worsen significantly. Banks can limit their exposure to the resulting risk by requiring borrowers to pay down their lines with whatever money they raise next, so that the line is just a bridge to the next source of long-term funding. They can also keep down the term of the line agreement in the first place, and regulatory capital requirements encourage the use of 364-day terms.[4]

The hybrid strategy of issuing CP while retaining an untouched backup line is the industry standard practice.[5] The backup line is sometimes known as a *liquidity facility*, and it will be detailed in the Private Placement Memorandum that lays out the CP program to potential investors. Both investors and rating agencies will likely require the issuer to commit in this memorandum to keep its issuance below the limit of the backup line. Because backup lines have historically allowed issuers to exit CP without default, except in extreme circumstances, they are said to facilitate the "early exit mechanism" that has kept the risk of CP low.

4. The key issue is the credit conversion factor applied to the unused portion of the line. See *Federal Register*, October 11, 2013, pp. 62083, 62091 and 62182.

5. For more analysis of the history and role of backup lines, see Charles Calomiris, "Is the Discount Window Necessary? A Penn-Central Perspective," *Federal Reserve Bank of St. Louis Review* (May 1994), pp. 31–55.

While the backup line has helped keep CP risk low, it is not a credit guarantee. The backup-line provider commits to advance funds for paying down the paper if the issuer is not in default with the loan agreement, but it does not commit to pay down the paper if the issuer fails. A commitment to pay down the paper would be a *letter of credit* (LOC), which is a different product that issuers can buy. The clientele for LOCs includes issuers who are unwilling or unable to publicize the information investors need to do their diligence, but are willing to reveal the information in confidence to an LOC provider. Once an issuer buys an LOC, investors can refocus their diligence on the LOC provider.

REGULATORY RESPONSES TO CRISES

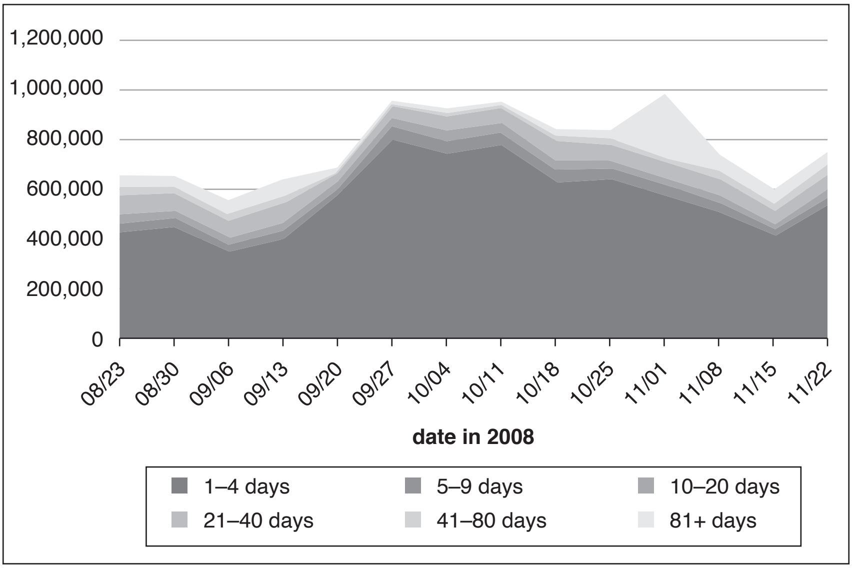
The pressure on the CP market from sudden contractions can be more than the backup-line escape valve can relieve. Banks may be unprepared for many lines to be drawn at once, and the borrowers taking down the lines may have no prospects for paying them down with something else, so that the lines are bridges to nowhere. Furthermore, CP investors may experience contractions of their own, since the economic forces destabilizing investment in CP can destabilize investment in short-term investment pools that buy CP. For these reasons and others, regulators responded to the major market breaks of September 2008 and March 2020 with suites of policy interventions designed to relieve pressure with targeted liquidity. The interventions closest to the CP market are the Commercial Paper Funding Facility (CPFF) in 2008 and 2020, the Asset-Backed Commercial Paper Money Market Mutual Fund Liquidity Facility (AMLF) in 2008, the Money Market Fund Liquidity Facility (MMLF) in 2020, and the Temporary Guarantee Program for Money Market Mutual Funds (the *Temporary Guarantee*) in 2008.

The CPFF is the most direct intervention in the CP market. The Federal Reserve facilitates the purchase of CP directly from issuers, and bears the credit risk, by making loans to an SPV against CP collateral which the SPV buys directly from issuers. In both 2008 and 2020, the Fed targeted the CPFF at the effect of the disruption by limiting purchases from an issuer to the amount the issuer had outstanding before the disruption, and targeted at rollover risk by buying paper at the longer end of CP maturity, with all purchases at 90 days. One difference between the two versions is how the CPFF handled credit risk. The 2008 version bought only top-tier paper, though the pricing distinguished ABCP from other paper. The CPFF bought ABCP at a discount rate equal to the three-month OIS plus 300 basis points, whereas for regular unsecured CP the rate was OIS plus 200 basis points. The later version bought both top-tier paper and second-tier paper, *if* it had been top-tier when the crisis hit, and the discount rates were OIS plus 100 basis points for top tier and OIS plus 200 basis points for second tier.

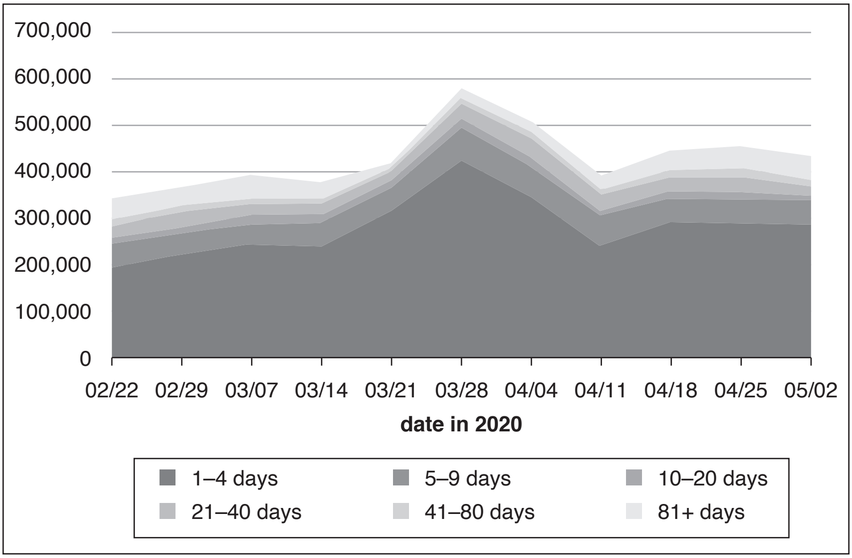
The success of the CPFF at relieving pressure is apparent from the two panels in Exhibit 13-2, which break out CP issuance volume, as reported by the Federal Reserve, by initial maturity in the weeks around the onset of the 2008 (panel a) and 2020 (panel b) crises. In both cases, long-maturity issuance shrinks,

EXHIBIT 13-2

Commercial Paper Volume (in $MM)



Panel A: By Days to Maturity Around Lehman Bankruptcy on 9/15/2008



Panel B: By Days to Maturity Around 2020 Onset of the COVID-19 Pandemic and short-maturity issuance expands as the crisis sets in, and then longer issuance expands rapidly when the CPFF starts buying. In 2008, the CPFF started buying on October 27, and issuance of 81+ day paper grew 686% from the week ending October 25 to the week ending November 1. In 2020, the CPFF started buying on April 14, and issuance of 81+ day CP grew 54% from the week ending April 11 to the week ending April 18.

The AMLF in 2008 and the MMLF in 2020 both offered a liquid secondary market for the CP held by money funds, allowing them to shrink as necessary without the fire sales that can trigger runs, and also allowing them to buy longer-dated securities that they might have to sell to shrink later. The AMLF targeted ABCP holdings in particular, reflecting the prominent role of securitizations in that crisis, whereas the MMLF was open to the whole range of securities in the funds' investible universe. The MMLF launched March 23, 2020, and reached its $54 billion peak holding of money-market securities on April 8. The AMLF launched September 22, 2008, just a week after the Lehman bankruptcy, and reached a peak holding of $146 billion of ABCP on October 8. It worked in tandem with the Temporary Guarantee, which insured money funds' shares and thereby slowed their CP sales by slowing their outflows. The Temporary Guarantee appears to have been very successful slowing outflows, in that over $300 billion flowed out of prime money funds in the five days between the Lehman bankruptcy and the onset of the program, and then flows stabilized when the guarantee began.[6]

KEY POINTS

- Commercial paper is an unsecured, short-term obligation, usually issued in pure-discount form.
- There is little secondary market for commercial paper, outside of selling it back to the dealer or issuer that initially sold it. This may not be a dependable source of liquidity, especially in crisis times.
- Commercial paper issuers face fragility risk, which they manage by arranging backup credit lines for repaying maturing paper when investors do not roll over.
- Commercial paper default has been very rare, due in part to the low risk tolerance of investors and the availability of backup lines.
- In severe market breaks, the federal government has intervened to support the commercial paper market by supporting investors and by buying paper directly from issuers.

Under the rubric of floating-rate securities, or simply *floaters,* there are several different types of securities with an essential feature in common: coupon interest can vary over the instrument's life. Floaters, which were first introduced into the European debt market and issued in the United States in the early 1970s, are now issued in every sector of the bond market—government, agency, corporate, municipal, mortgage, and asset-backed—in the United States and in markets throughout the world. Although a floater's coupon formula may depend on a wide variety of economic variables (e.g., foreign exchange rates or commodity prices), a floater's coupon payments usually depend on the level of a money market interest rate (e.g., the London Interbank Offered Rate, or LIBOR, the Secured Overnight Financing Rate, Treasury bills). A floater's coupon rate can be reset semiannually, quarterly, monthly, or weekly. The term *adjustable rate* or *variable rate* typically refers to securities with coupon rates reset not more than annually or based on a longer-term interest rate. However, this is a distinction without a difference, and we will refer to both floating-rate securities and adjustable-rate securities as "floaters."

In this chapter we will discuss the general features of floaters and present some illustrations of the major product types. Most market participants use "spread" or margin measures (e.g., adjusted simple margin or discount margin) to assess the relative value of a floater. We will briefly describe these measures and note their limitations. Finally, we discuss several popular portfolio strategies that employ floaters.

GENERAL FEATURES OF FLOATERS AND MAJOR PRODUCT TYPES

A floater is a debt security whose coupon rate is reset at designated dates based on the value of some designated reference rate. The coupon formula for a pure floater (i.e., a floater with no embedded options) can be expressed as follows:

$$\text{Coupon rate} = \text{reference rate} \pm \text{quoted margin}$$

The quoted margin is the adjustment (in basis points) that the issuer agrees to make to the reference rate. For example, consider a floating-rate note issued by Ford Motor Credit Co, LLC, April 2018 at a rate of 3-month LIBOR + 123.5 basis points (bps) and a price of par. At the time Ford was rated BBB/Baa1. As of February 2020, Ford is downgraded to BBB-/Ba1 and we expect the discount margin (explained later) to reflect the downgrade. In fact, the February 2020 discount margin is wider than issue (163 bps vs. 123.5). As a result, the new price of the floater is now $98.861, over a 1-point decrease from new issue.

As noted, the reference rate is the interest rate or index that appears in a floater's coupon formula, and it is used to determine the coupon payment on each reset date within the boundaries designated by embedded caps and/or floors. The four most common reference rates are LIBOR, Treasury bill yields, prime rates, and domestic certificate of deposit (CD) rates, and they appear in the coupon formulas of a wide variety of floating-rate products. Other reference rates are used in more specialized markets such as the markets for mortgage-backed securities and the municipal market. For example, the most common reference rates for adjustable-rate mortgages (ARMs) or collateralized mortgage obligation (CMO) floaters include (1) the one-year Constant Maturity Treasury Rate (i.e., one-year CMT), (2) the 11th District Cost of Funds (COFI), (3) the six-month LIBOR, and (4) the National Monthly Median Cost of Funds Index. In the municipal market, the reference rate for floaters is often a Treasury rate or the prime rate. Alternatively, the reference rate could be a municipal index. A popular municipal index is the Bond Buyer 20 bond index. A floater often imposes limits on how much the coupon rate can float. Specifically, a floater may have a restriction on the maximum coupon rate that will be paid on any reset date. This is called a *cap*. Consider a floater issued by Federal Home Bank that matured on October 20, 2006. The coupon formula was three-month LIBOR plus 75 basis points with a cap of 3.75%. If the three-month LIBOR at a coupon date reset was 3.25%, then the coupon formula would suggest the new coupon rate would be 4%. However, the cap restricted the maximum coupon rate to 3.75%. Needless to say, a cap is an unattractive feature from the investor's perspective, but an important one to the borrower.

In contrast, a floater also may specify a minimum coupon rate called a *floor*. Suppose a floater delivers quarterly coupon payments with a coupon formula of the three-month LIBOR plus 12.5 basis points with a floor of 4.25%. Thus, if the three-month LIBOR ever fell below 4.125%, the coupon rate would remain at 4.25%.

A floor is an attractive feature from the investor's perspective. When a floater possesses both a cap and a floor, this feature is referred to as a *collar.* Thus, a collared floater's coupon rate has a maximum value and a minimum value.

While a floater's coupon rate typically moves in the same direction as the reference rate, there are floaters whose coupon rate changes in the opposite direction from the change in the reference rate. These floaters are referred to as *inverse floaters* or *reverse floaters.* A general formula for an inverse floater is

$$K - L \times (\text{reference rate})$$

From the formula, it is easy to see that as the reference rate goes up (down), the coupon rate goes down (up). As an example, consider an inverse floater issued by a large bank. This issue delivered quarterly coupon payments according to the formula

$$18\% - 2.5 \times (\text{three-month LIBOR})$$

In addition, this inverse floater has a floor of 3% and a cap of 15.5%. Note that for this inverse floater, the value for L (called the *coupon leverage*) in the coupon reset formula is 2.5. Assuming that neither the cap rate nor the floor rate is binding, this means that for every one basis point change in the three-month LIBOR, the coupon rate changes by 2.5 basis points in the opposite direction.[1]

There is a wide variety of floaters that have special features that may appeal to certain types of investors. For example, some issues provide for a change in the quoted margin (i.e., the spread added to or subtracted from the reference in the coupon reset formula) at certain intervals over a floater's life. These issues are called *stepped-spread floaters* because the quoted margin can either step to a higher or lower level over time. Consider Abu Dhabi Commercial Bank's floater due in May 2016. From its issuance in May 2006 until May 2011, the coupon formula was three-month LIBOR plus 60 basis points. Thereafter, until maturity, the quote margin "steps up" to 90 basis points.

A *range note* is a floater where the coupon payment depends on the number of days that the specified reference rate stays within a preestablished collar. For instance, Barclay's Bank issued a range note in November 2006 (due in November 2016). For every day during the quarter that the three-month LIBOR was between 3% and 9%, the investor earned the three-month LIBOR plus 155 basis points. Interest would accrue at 0% for each day that the three-month LIBOR was outside this collar.

There are also floaters whose coupon formula contains more than one reference rate. A *dual-indexed floater* is one such example. The coupon rate formula is typically a fixed percentage plus the difference between two reference rates. For example, Swedbank Hypotek issued a floater that matures in August 2015 whose coupon formula is the following:

$$(\text{20-year yen swap rate}) - (\text{2-year yen swap rate}) + 40 \text{ basis points}$$

In addition, the issue has a floor of 0.1%.

1. When L is greater than 1, the security is referred to as a *leveraged inverse floater.*

Although the reference rate for most floaters is an interest rate or an interest rate index, numerous kinds of reference rates appear in coupon formulas. This is especially true for structured notes. Potential reference rates include movements in foreign exchange rates, the price of a commodity (e.g., gold), movements in an equity index (e.g., the Standard & Poor's 500 Index), or an inflation index (e.g., CPI). Financial engineers are capable of structuring floaters with almost any reference rate.

CALL AND PUT PROVISIONS

Just like fixed-rate issues, a floater may be *callable.* The call option gives the issuer the right to buy back the issue prior to the stated maturity date. The call option may have value to the issuer sometime in the future for two basic reasons. First, market interest rates may fall so that the issuer can exercise the option to retire the floater and replace it with a fixed-rate issue. Second, the required margin decreases so that the issuer can call the issue and replace it with a floater with a lower quoted margin.[2] The issuer's call option is a disadvantage to the investor because the proceeds received must be reinvested either at a lower interest rate or a lower margin. Consequently, an issuer who wants to include a call feature when issuing a floater must compensate investors by offering a higher quoted margin.

For amortizing securities (e.g., mortgage-backed and some asset-backed securities) that are backed by loans that have a schedule of principal repayments, individual borrowers typically have the option to pay off all or part of their loan prior to the scheduled date. Any additional principal repayment above the scheduled amount is called a *prepayment.* The right of borrowers to prepay is called the *prepayment option.* Basically, the prepayment option is analogous to a call option. However, unlike a call option, there is not a call price that depends on when the borrower pays off the issue. Typically, the price at which a loan is prepaid is its par value.

Floaters also may include a *put provision* that gives the security holder the option to sell the security back to the issuer at a specified price on designated dates. The specified price is called the *put price.* The put's structure can vary across issues. Some issues permit the holder to require the issuer to redeem the issue on any coupon payment date. Others allow the put to be exercised only when the coupon is adjusted. The time required for prior notification to the issuer or its agent varies from as little as four days to as long as a couple of months. The advantage of the put provision to the holder of the floater is that if after the issue date the margin required by the market for a floater to trade at par rises above the issue's quoted margin, the investor can force the issuer to redeem the

2. The required margin is the spread (either positive or negative) the market requires as compensation for the risks embedded in the issue. If the required margin equals the quoted margin, a floater's price will be at par on coupon reset dates.

floater at the put price and then reinvest the proceeds in a floater with the higher quoted margin.

SPREAD MEASURES

There are several yield spread measures or margins that are used routinely to evaluate floaters. The four margins commonly used are spread for life, adjusted simple margin, adjusted total margin, and discount margin. All these spread measures are available on Bloomberg's Yield Analysis (YA) screen.

Spread for Life

When a floater is selling at a premium/discount to par, a potential buyer of a floater will consider the premium or discount as an additional source of dollar return. *Spread for life* (also called *simple margin*) is a measure of potential return that accounts for the accretion (amortization) of the discount (premium) as well as the constant index spread over the security's remaining life.

Adjusted Simple Margin

The *adjusted simple margin* (also called *effective margin*) is an adjustment to spread for life. This adjustment accounts for a one-time cost-of-carry effect when a floater is purchased with borrowed funds. Suppose that a security dealer has purchased $10 million of a particular floater. Naturally, the dealer has a number of alternative ways to finance the position—borrowing from a bank, repurchase agreement, etc. Regardless of the method selected, the dealer must make a one-time adjustment to the floater's price to account for the cost of carry from the settlement date to next coupon reset date.

Adjusted Total Margin

The *adjusted total margin* (also called *total adjusted margin*) adds one additional refinement to the adjusted simple margin. Specifically, the adjusted total margin is the adjusted simple margin plus the interest earned by investing the difference between the floater's par value and the carry-adjusted price.[3]

Discount Margin

One common method of measuring potential return that employs discounted cash flows is *discount margin.* This measure indicates the average spread or margin over the reference rate the investor can expect to earn over the security's life

3. When the floater's adjusted price is greater than 100, the additional increment is negative and represents the interest foregone.

given a particular assumed path that the reference rate will take to maturity. The assumption that the future levels of the reference rate are equal to today's level is the current market convention. The procedure for calculating the discount margin is as follows:

1. Determine the cash flows assuming that the reference rate does not change over the security's life.
2. Select a margin (i.e., a spread above the reference rate).
3. Discount the cash flows found in (1) by the current value of the reference rate plus the margin selected in (2).
4. Compare the present value of the cash flows as calculated in (3) with the price. If the present value is equal to the security's price, the discount margin is the margin assumed in (2). If the present value is not equal to the security's price, go back to (2) and select a different margin.

For a floater selling at par, the discount margin is simply the quoted margin. Similarly, if the floater is selling at a premium (discount), then the discount margin will be below (above) the quoted margin.

Practitioners use the spread measures presented above to gauge the potential return from holding a floater. Much like conventional yield measures for fixed income securities, the yield or margin measures discussed here are, for the most part, relatively easy to calculate and interpret. However, these measures reflect relative value only under several simplifying assumptions (e.g., reference rates do not change).

One of the key difficulties in using the measures described in this chapter is that they do not recognize the presence of embedded options. As discussed, there are callable/putable floaters and floaters with caps and/or floors. However, the recognition of embedded options is critical to valuing floaters properly. If an issuer can call an issue when presented with the opportunity and refund at a lower spread, the investor must then reinvest at the lower spread. With this background, it should not be surprising that sophisticated practitioners value floaters using arbitrage-free binomial interest rate trees and Monte Carlo simulations. These models are designed to value securities whose cash flows are interest-rate-dependent.

PRICE VOLATILITY CHARACTERISTICS OF FLOATERS

The change in the price of a fixed-rate security when market rates change occurs because the security's coupon rate differs from the prevailing rate for new comparable bonds issued at par. Thus, an investor in a 10-year, 7% coupon bond purchased at par, for example, will find that the bond's price will decline below par if the market requires a yield greater than 7% for bonds with the same risk and maturity. By contrast, a floater's coupon resets periodically, thereby reducing its sensitivity to changes in rates. For this reason, floaters are said to be more "defensive" securities. This does not mean, of course, that a floater's price will not change.

Factors That Affect a Floater's Price

A floater's price will change depending on the following factors:

1. Time remaining to the next coupon reset date
2. Changes in the market's required margin for that specific issuer
3. Whether or not the cap or floor is reached, or is close to being reached

We will discuss the impact of each of these factors in the following sections.

Time Remaining to the Next Coupon Reset Date

The longer the time to the next coupon reset date, the more a floater behaves like a fixed-rate security, and the greater is a floater's potential price fluctuation. Conversely, the shorter the time between coupon reset dates, the smaller is the floater's potential price fluctuation.

To understand why this is so, consider a floater with five years remaining to maturity whose coupon formula is the one-year Treasury rate plus 50 basis points, and the coupon is reset today when the one-year Treasury rate is 5.5%. The coupon rate will remain at 6% for the year. One month hence, an investor in this floater effectively would own an 11-month instrument with a 6% coupon. Suppose that at that time the market requires a 6.2% yield on comparable issues with 11 months to maturity. Then our floater would be offering a below-market rate (6% versus 6.2%). The floater's price must decline below par to compensate the investor for the submarket yield. Similarly, if the yield that the market requires on a comparable instrument with a maturity of 11 months is less than 6%, the floater will trade at a premium. For a floater in which the cap is not binding and for which the market does not demand a margin different from the quoted margin, a floater that resets daily will trade at par.

Changes in the Market's Required Margin

At the initial offering of a floater, the issuer will set the quoted margin based on market conditions so that the security will trade near par. Subsequently, if the market requires a higher/lower margin, the floater's price will decrease/increase to reflect the current margin required. We shall refer to the margin that is demanded by the market as the "required margin." For example, consider a floater whose coupon formula is the one-month LIBOR plus 40 basis points. If market conditions change such that the required margin increases to 50 basis points, this floater would be offering a below-market margin. As a result, the floater's price will decline below par value. By the same token, the floater will trade above its par value if the required margin is less than the quoted margin—less than 40 basis points in our example.

The required margin for a particular issue depends on (1) the margin available in competitive funding markets, (2) the credit quality of the issue, (3) the presence of any embedded call or put options, and (4) the liquidity of the issue. An alternative source of funding to floaters is a syndicated loan. Consequently, the required margin will be driven, in part, by margins available in the syndicated loan market.

The portion of the required margin attributable to credit quality is referred to as the "credit spread." The risk that there will be an increase in the credit spread required by the market is called *credit-spread risk*. The concern for credit-spread risk applies not only to an individual issue but also to a sector or the economy as a whole. For example, credit spreads may increase due to a financial crisis (e.g., a stock market crash) while the individual issuer's condition and prospects remain essentially unchanged.

A portion of the required margin reflects the call risk if the floater is callable. Because the call feature imposes hazards on the investor, the greater the call risk, the higher is the quoted margin at issuance, other things equal. After issuance, depending on how interest rates and required margins change, the perceived call risk and the margin required as compensation for this risk will change accordingly. In contrast to call risk owing to an embedded call option, a put provision provides benefits to the investor. If a floater is putable at par, all else the same, its price should trade at par near the put date.

Finally, a portion of the quoted margin at issuance will reflect the issue's perceived liquidity. *Liquidity risk* is the threat of an increase in the required margin due to a perceived deterioration in an issue's liquidity. Investors in nontraditional floater products are particularly concerned with liquidity risk.

Whether or Not the Cap or Floor Is Reached

For a floater with a cap, once the coupon rate as specified by the coupon formula rises above the cap rate, the floater then offers a below-market coupon rate, and the floater will trade at a discount. The floater will trade more and more like a fixed-rate security the further the capped rate is below the prevailing market rate. Simply put, if a floater's coupon rate does not float, it is effectively a fixed-rate security and will assume the duration risk of a fixed-rate bond. *Cap risk* is the risk that the floater's value will decline because the cap is reached.

The situation is reversed if the floater has a floor. Once the floor is reached, all else equal, the floater will trade either at par value or at a premium to par if the coupon rate is above the prevailing rate offered for comparable issues.

Duration of Floaters

We have just described how a floater's price will respond to a change in the required margin, holding all other factors constant. As explained in Chapter 5, the measure used by market participants to quantify the sensitivity of a security's price to changes in interest rates is called *duration*. A security's duration tells us the approximate percentage change in its price for a 100 basis point change in rates. The procedure of computing a security's duration was explained in Chapter 5.

Two measures are employed to estimate a floater's sensitivity to each component of the coupon formula. *Index duration* is a measure of the floater's price sensitivity to changes in the reference rates holding the quoted margin constant. Correspondingly, *spread duration* measures a floater's price sensitivity to a change in the "quoted margin" or "spread" assuming the reference rate remains unchanged.

Price Volatility of an Inverse Floater

An inverse floater can be created by acquiring a fixed-rate security and splitting it into a floater and an inverse floater. The fixed-rate security from which the floater and inverse floater are created is called the *collateral*. The interest paid to the floater investor and inverse floater investor must be such that it is equal to the interest rate paid on the collateral.

Because valuations are additive (i.e., the value of the collateral is the sum of the floater and inverse floater values), durations (properly weighted) are additive as well. Accordingly, the duration of the inverse floater is related in a particular fashion to the duration of the collateral and the duration of the floater. Specifically, the duration of an inverse floater will be a multiple of the duration of the collateral from which it is created.

To understand this, suppose that a 30-year fixed-rate bond with a market value of \$100 million is split into a floater and an inverse floater with market values of \$80 million and \$20 million, respectively. Assume also that the duration of the collateral (i.e., the 30-year fixed-rate bond) is 8. Given this information, we know that for a 100 basis point change in required yield the collateral's value will change by approximately 8%, or \$8 million (8% times \$100 million). Since the floater and inverse floater are created from the collateral, the combined change in value of the floater and the inverse floater must be \$8 million for a 100 basis point change in required yield. The question becomes how do we partition the change in value between the floater and inverse floater. If the duration of the floater is small, as explained earlier, then the inverse floater must experience the full force of the \$8 million change in value. For this to occur, the duration of the inverse floater must be approximately 40. A duration of 40 will mean a 40% change in the inverse floater's value for a 100 basis point change in required yield and a change in value of approximately \$8 million (40% times \$20 million).

Effectively, the inverse floater is a leveraged position in the collateral. That is, ownership of an inverse floater is equivalent to buying the collateral and funding it on a floating-rate basis, where the reference rate for the borrowing is equal to the reference rate for the inverse floater. Accordingly, the duration of the inverse floater is a multiple of the duration of the collateral.

PORTFOLIO STRATEGIES

Several portfolio strategies have been employed using floaters. These include (1) basic asset/liability management strategies, (2) risk arbitrage strategies, (3) betting on changes in the required margin, and (4) arbitrage between fixed- and floating-rate markets using asset swaps. We will briefly describe each of these strategies in turn.

Asset/liability management strategies can be explained most easily using depository institutions. These institutions typically borrow short term, and their objective is to lock in a spread over their short-term funding costs. Not surprisingly, one obvious way to accomplish this objective is to invest in floating-rate products. Naturally, this strategy is not without risks. The floater's coupon rate likely will be capped, whereas the short-term funding may not be. This is known as *cap risk*. Further, the floater's reference rate may not be the same as the reference rate for funding. If this is the case, the institution is exposed to *basis risk*.

Risk arbitrage strategies using floaters are not arbitrage in the true sense of the term. One example of this type of strategy involves money managers using leverage (via repurchase agreements) to invest in agency adjustable-rate pass-through securities that earn a higher spread over their borrowing rate. Of course, this is not a "risk-free" transaction. Like before, the manager likely will be exposed to cap risk if the floater's coupon is capped while the funding rate is not. The manager also may be exposed to basis risk if the two reference rates are mismatched. Finally, there is *price risk* if the floater's risk changes for the worse, and the floater must be sold prior to maturity. In this case, the quoted margin will no longer compensate the investor for the security's risks, and the floater will sell at a discount to par. No informed investor believes that a risk arbitrage strategy is a reliable source of spread income.

Investors also can speculate on whether a floater's required margin will change. When a floater is issued, the quoted margin contained in the coupon formula will be set so that the floater will be priced at or near par. After the floater enters the secondary market, the quoted margin for a standard floater does not change. Thus, if the floater's risk does not change and the compensation demanded by the market does not change either, the floater's price will be par on every coupon reset date. In this case, the quoted margin offered by the security and quoted margin required by the market (called the *required margin*) are the same. If conditions change such that the required spread is greater than (less than) the quoted margin, the floater will trade at discount (premium) to par. Given this background, one obvious strategy money managers pursue is betting on a change in the required margin for a single issue or a sector.

Lastly, some money managers arbitrage between floaters and fixed-rate securities using a so-called asset swap. An asset-based swap transaction involves the creation of synthetic security via the purchase of an existing security and the simultaneous execution of a swap.

DEMISE OF LIBOR

As a result of the LIBOR scandals that ensued during the Global Financial Crisis, regulators have demanded a move from a survey-based index such as LIBOR to an observable market-based index.

Since the early 1970s, the London Interbank Offered Rate (LIBOR) has served as the benchmark reference rate for government and corporate bonds, mortgages, loans, and other types of financial instruments. While LIBOR has served as an important barometer for global financial markets, the methodology for calculating LIBOR rates is outdated. Each day the Intercontinental Exchange Administration (IBA) receives the funding rates from a group of large banks, called panel banks, and this data is averaged, adjusted, and reported. Of greater concern are the scarcity in underlying transactions and a reduction in the number of panel banks reporting transactions since the Global Financial Crisis in 2008. Consequently, the IBA has relied more heavily on "expert judgment" to determine the appropriate rate, making LIBOR a less reliable benchmark. As a result, in 2014, the Federal Reserve assigned the Alternative Reference Rate Committee (ARCC) the task of recommending an alternative benchmark rate to replace LIBOR.

The ARCC ultimately selected the Secured Overnight Funding Rate (SOFR) as the new benchmark interest rate for all dollar-denominated loans and securities. While LIBOR is partially subject to "expert judgment," SOFR is derived from transactions in the overnight repo markets, making it a daily rate as opposed to LIBOR, which has varying terms ranging from one day to one year. The end of 2021 marks the formal retirement of LIBOR. However, slight differences between the two rates create complexities in the adoption of SOFR that make this deadline subject to change. For one, LIBOR represents the unsecured rate at which banks lend to one another, and as such, it includes a credit-risk premium. SOFR, in contrast, is based on the repo financing of U.S. Treasuries, essentially making it a risk-free rate. Second, SOFR is an overnight rate only, not a rate of multiple maturities. For treasurers who currently borrow at one month, three months, etc., the shift from a fixed LIBOR rate to a daily SOFR rate presents operational challenges.

That said, the transition to SOFR is already underway, with some domestic financial institutions issuing securities and contracts that reference SOFR. Ultimately, the standard use of SOFR by central clearinghouses for derivative products will mark a tipping point in the broader adoption of SOFR as the new benchmark rate.

KEY POINTS

- A floater is a debt security whose coupon rate is reset at designated dates based on the value of some designated reference rate. The coupon formula for a floater with no embedded options is the reference rate plus or minus the quoted margin.

- Typically, a floater imposes a cap or maximum interest coupon rate; a floater also may specify a floor or minimum coupon. A collared floater has both a cap and a floor.
- Inverse floaters or reverse floaters are floaters whose coupon rate moves in the opposite direction from the change in the reference rate.
- The different types of floaters include stepped-spread floaters, range notes, and dual-indexed floaters. Although the reference rate for most floaters is an interest rate or an interest rate index, numerous kinds of reference rates appear in coupon formulas.
- A floater may be callable or prepayment. Floaters also may include a put provision.
- Yield spread measures or margins that are commonly used routinely to evaluate floaters are spread for life, adjusted simple margin, adjusted total margin, and discount margin.
- The price of a floater depends on (1) the time remaining to the next coupon reset date, (2) changes in the market's required margin, and (3) whether or not the cap or floor is reached.
- Index duration is a measure of the floater's price sensitivity to changes in the reference rates holding the quoted margin constant. Spread duration measures a floater's price sensitivity to a change in the "quoted margin" or "spread" assuming the reference rate remains unchanged.
- An inverse floater is effectively a leveraged position in the collateral because the position is economically equivalent to buying the collateral and funding it on a floating-rate basis, where the reference rate for the borrowing is equal to the reference rate for the inverse floater.
- The duration of an inverse floater is a multiple of the duration of the collateral.
- Portfolio strategies using floaters include (1) basic asset/liability management strategies, (2) risk arbitrage strategies, (3) betting on changes in the required margin, and (4) arbitrage between fixed- and floating-rate markets using asset swaps.

CHAPTER

FIFTEEN

INFLATION-LINKED BONDS

John B. Brynjolfsson, CFA
Chief Investment Officer
Armored Wolf Family Holdings, LLC

Inflation is the key driver of investment performance. It determines how much each dollar of return is worth, and it dictates asset returns themselves. Consider the 37-year period from 1983 to 2020, a period marked by falling inflation. Falling raw materials prices allowed corporate margins to expand. Simultaneously, falling interest rates had a positive impact on the price-to-earnings multipliers being applied to those expanded corporate earnings. The result was doubly explosive equity returns. For different reasons, the inflation-adjusted returns of bonds similarly were favorably affected by falling inflation during this period. The opposite happens during bouts of rising inflation. The 17-year inflationary period from 1966 to 1983 represented one of the worst investment climates in modern history for equities and bonds.

In the late 1990s, investors found a weapon that effectively offsets this threat to stable and predictable investment returns—and that weapon and its incorporation into twenty-first-century fixed income markets is the subject matter of this chapter.

Treasury Inflation-Protected Securities (TIPS)[1] are bonds that promise to protect and grow investors' purchasing power. The U.S. Treasury delivers on this promise by adjusting the principal of TIPS based on changes in the consumer price index (CPI).[2] It repays the bondholders' principal in an amount that exactly maintains the purchasing power of their original investment, as

I wish to thank my clients, colleagues, industry contacts, and many friends for their contributions, insight, and support.

1. United States Secretary of the Treasury Robert Rubin coined the term *TIPS* in 1996, before the official launch of "Treasury Inflation-Indexed Securities" (TIIS) in January 1997. Market participants have gravitated to a generic use of the acronym *TIPS* to refer to all forms of inflation-linked bonds, singular and plural. For clarity, this chapter will do the same. Other terms sometimes used to describe this class of bonds include *inflation-linked bonds, IPBS, TIIS, linkers,* and *real-return bonds.*
2. The Bureau of Labor Statistics, a professionally staffed economics-oriented agency of the U.S. Department of Labor, is responsible for gathering and reporting price changes at the consumer level. The CPI series used to calculate TIPS is the non-seasonally adjusted Consumer Price Index for all Urban Consumers (CPI-U) or more simply the non-seasonally adjusted version of the CPI used to calculate "headline inflation." See the discussion about the CPI later in this chapter.

EXHIBIT 15-1

Schematic Cash Flow of TIPS (10-Year)

	Purchase	First Annual Coupon	Interim Annual Coupon	Last Annual Coupon	Principal	Return (per Annum) %
Date	1/15/Year 0	1/15/Year 1	1/15/Year 5	1/15/Year 10	1/15/Year 10	1/15/Year 10
Real $ Cash Flow	(1,000)	20.00	20.00	20.00	1,000	2.00
CPI (Base = 200)	200.0	206.0	231.8	268.7	268.7	3.00
Indexed Principal	1,000	1,030	1,159	1,343	1,343	(na)
Nominal $ Cash Flow	(1,000)	20.60	23.18	26.87	1343.50	5.06

defined by the CPI. In addition, the U.S. Treasury pays interest in an amount that also maintains the purchasing power of the stream of semiannual interest payments by calculating coupon payments based on the CPI-indexed principal amounts. (See Exhibit 15-1.)

The U.S. Treasury launched the TIPS program in 1997, and through the end of the first quarter of 2020 had outstanding over $1,525 billion of the securities according to the Securities Industry and Financial Markets Association (SIMFA). SIIFMA also reports that during the first two months of 2020, an average of $19.65 billion of these securities traded each day. Since the 1940s, at least 15 governments and numerous corporations have issued similarly structured securities. In the United Kingdom, inflation-indexed securities account for more than 20% of government bonds outstanding. For clarity, we will focus our discussion on the U.S. Treasury TIPS and introduce substantive differences of other TIPS where appropriate.

TIPS are best known as a defensive hedge against the fear of inflation, but they offer tactical and strategic advantages as well. Tactically, investors are attracted to the opportunity TIPS afford to speculate on changes in inflation and real interest rates. Strategically, individual and institutional investors with long-term objectives are attracted to TIPS fixed real yield, low correlation to traditional financial assets, and muted volatility. They sense TIPS will help them to achieve their long-term investment goals and reduce risk in the process.

The unique characteristics of TIPS qualify them as a fundamental asset class, as are equities, traditional bonds, and cash. TIPS have relatively high correlation with one-another and modest correlation with other asset classes. As a whole, they form a large, investable, and easily benchmarked universe.

In addition to TIPS' inflation appeal, their novelty and scope, just over two decades after their introduction into the United States, can attest to their importance as an investment instrument. This chapter has two goals; the first and most important is to expose market participants to this important often not well understood investment instrument. The second is to provide portfolio managers with a comprehensive examination of the investment qualities that make TIPS unique.

We begin with the mechanics of TIPS cash flows. We explore real yield and real duration, two measures that are analogous to a nominal bond's yield to maturity and effective duration. The marketplace section narrates a brief history of TIPS, including their trading characteristics. The valuation and performance section presents a framework and evaluates the TIPS market through early 2020 in the context of that framework. The investors section discusses how professional managers and institutions are using TIPS within portfolios and in asset/liability management. The issuers section introduces the suppliers of TIPS and explains why they use the prevailing structures. We then address common investor concerns, specifically on taxes and deflation.

MECHANICS AND MEASUREMENT

How TIPS Work

The merit of TIPS is that while the principal and interest repaid to investors fluctuates based on the level of the CPI, the purchasing power of each payment is fixed. As a consequence, the *real yield* of TIPS (the growth in purchasing power that a hold-to-maturity investor will earn) is fixed. The assumptions corresponding to Exhibit 15-1 are described below:

- Issuance date of January 15 of Year 1
- Issuance price of $100.00
- 10-year maturity
- 2% real coupon paid annually,
- 3% annualized inflation rate, and
- $1000 original face

If the CPI for the TIPS issuance date is 200.0 and the CPI for a coupon date one year later is 206.0, year-over-year inflation would be reported as 3.00%. The TIPS' adjusted principal would be 1.03 times its original value, or $1,030 per $1,000 of "original face."

This indexed principal is used to calculate the coupon paid. In other words, the Treasury calculates the amount of each coupon payment, *after the principal has been adjusted for inflation.* This exhibit shows that the compounding effect of a 2% real annual coupon with a 3% inflation rate results in a *nominal* cash-flow annualized return of 5.06%.

The calculations of actual Treasury TIPS cash flows and returns are only somewhat more complicated. TIPS pay interest semiannually at one-half their stated annual coupon rate. The inflation-indexed principal is accrued daily throughout a month, based on a straight-line interpolation between the two most recent monthly CPI figures reported prior to the settlement month. And lastly, Treasury uses a rather arcane rounding procedure for interim and final calculations.

The Consumer Price Index (CPI)

The specific CPI series used for TIPS indexation is the Non-Seasonally Adjusted, All-Urban Consumer Price Index (NSA CPI-U), and it is reported monthly. Unlike the seasonally adjusted series, the NSA CPI-U is not subject to revision. One consequence of using the NSA CPI-U is that the series includes predictable seasonal fluctuations in inflation. For example, each December when inflation typically is muted by year-end price cutting and inventory liquidations, the NSA CPI-U index tends to fall slightly below its trend growth rate, whereas in certain other months it tends to rise slightly above the underlying trend.

The CPI report that measures the price level in a given month, for example, May, typically is reported on or near the 15th of the following month, in this case June. The two-week hiatus between June 15 and July 1 when the TIPS accruals begin allows for potential delays in the official release of the CPI and eliminates the need to calculate day counts across month-end. The last daily accrual occurs on July 31, about seven weeks after the CPI is reported. Thus the May CPI is fully incorporated into the August 1 TIPS principal.

This relatively quick 15-day turnaround of CPI reports into TIPS indexation is often described as a three-month lag because the May (month 5) CPI is fully incorporated into the TIPS by August 1 (month 8). To calculate the TIPS principal for any settlement date other than the first of a month, for example, July 10, calculate as follows:

1. Find the TIPS principal that applies to July 1; this is based on the April NSA CPI-U report (month 7 – 3 = month 4).
2. Find the TIPS principal that applies to August 1; this is based on the May NSA CPI-U report (month 8 – 3 = month 5).
3. Divide 9, the number of days accrual (the 10th day of the month – the 1st day of the month) by 31 (the number of days in that month).
4. Linearly interpolate by adding 9/31 of the difference between the July 1 and August 1 TIPS' principal values to the July 1 value.

Real Frame of Reference, Real Yield, Nominal Yield, and Break-Even Inflation Rate

Real Frame of Reference

A nominal frame of reference looks at investments in terms of dollars, without regard for any change in purchasing power of those dollars. In contrast, a real frame of reference takes into account the loss of purchasing power due to inflation. Put another way, it calculates how many bushels of wheat, baskets of apples, or more generally, the standard of living to which a given dollar amount corresponds. If it costs 100 "real dollars" to purchase a basket of consumer goods in the Year 0, in Year 20, 100 "real dollars" will still purchase that same "basket."

Any investment can be described from either a *real* or *nominal* frame of reference. To directly compare the expected returns of any two investments, one must choose either a real or a nominal frame of reference. For example, in *Stocks for the Long Run,* 1998, Jeremy Siegel describes equities from 1926 through 1997 as having generated *either* a 7.2% real return *or* a 10.6% nominal return.

Ideally, the frame of reference would be dictated by one's goals, but in practice, the choice is heavily influenced by the characteristics of the investment instrument. For instance, conventional bonds are described easily in a *nominal* frame of reference because they have fixed *nominal* coupons and principal. TIPS, on the other hand, are described more easily within a *real* frame of reference because they have fixed *real* coupons and principal. Not surprisingly, TIPS' *real* yield, *real* duration, and other real characteristics are relatively intuitive and as easy to calculate as a nominal bond's yield to maturity, effective duration, and other nominal characteristics.

Real Yield

The real yield of a TIPS bond represents the annualized growth rate of purchasing power earned by holding the security to maturity. Real yield can be calculated easily on a standard bond calculator by entering the TIPS quoted market price, coupon rate, and maturity date. The calculator does not know the bond is a TIPS or that the price and coupon rate are *real.* It is the user's responsibility to interpret the result as the "real yield."[3]

The *real* yield of a *nominal* bond is more difficult to calculate because it can be precisely determined only with the benefit of hindsight. In practice, when analysts speak of a nominal bond's real yield, they may be (1) referring to its "current" real yield (approximated by subtracting the current year-over-year inflation from the bond's nominal yield), (2) "guesstimating" the nominal bond's "expected" real yield based on expectations of future inflation, or (3) speaking of historical realized real yields on bonds that have matured.

Nominal Yield

The opposite situation occurs with nominal yields. While the nominal yield of a conventional bond is determined easily, the nominal yield of TIPS is more difficult to pin down. The nominal yield realized by holding TIPS to maturity depends on the average level and trajectory of inflation over the bond's lifetime. Ignoring the trajectory of the inflation rate, and focusing only on the average level of inflation, the realized nominal yield can be approximated as

$$\text{TIPS realized nominal yield} = (1 + \text{real yield}) \times (1 + \text{inflation}) - 1$$

3. Two phenomena that could cause a minor difference in TIPS quoted real yield from the TIPS realized real yield are (1) real reinvestment rate of coupon cash flows and (2) the time lag between the applicable date for the CPI and the applicable date for TIPS indexing.

Break-Even Inflation Rate

The break-even inflation rate is the rate that results in the holder of a TIPS "breaking even" with the holder of a nominal bond. Using the preceding equation, the nominal yield of the TIPS can be set to equal the nominal yield of the conventional bond. Solving the equation for the break-even inflation rate gives

$$\text{Break-even inflation rate} \\ = (1 + \text{conventional nominal yield}) / (1 + \text{TIPS real yield}) - 1$$

If the conventional bond's nominal yield is 7% and the TIPS real yield is 4% (both expressed in simple annualized terms), the break-even inflation rate is 2.88%. For most purposes, approximating the preceding equation as the simple difference between the two bonds' yields, 3%, is appropriate—and general industry practice.

The 2008 episode is instructive for a different reason. During this period there was rampant deleveraging of financial balance sheets, a sharp contraction in output, a breakdown of the payment system, and fear that monetary policy would be unsuccessful at managing away deflationary inflation expectations. Though it is common to see graphs of 10-year break-even inflation rates reflect this dramatic drop in inflation expectations toward zero, these rates dramatically understate the actual extent of deflationary expectations. In particular, 10-year TIPS are "newly issued" and as such have a "deflation put," struck at-the-money at time of issuance, embedded within them. It is therefore virtually impossible, regardless of how deflationary the outlook is, to observe negative break-even inflation rates on newly issued 10-year TIPS. Off-the-run TIPS, on the other hand, which may have previous positive inflation accruals included in their market value, can lose this principal, and therefore can be, and were, priced at negative inflation break-evens during late 2008 and early 2009.

Although the break-even inflation rate may be useful to assess market inflation expectations or to gauge break-even requirements for narrowly constrained fixed income investors, it may overstate or understate the risk-adjusted break-even inflation rate applicable to long-term strategies. In particular, the riskier nominal bonds may embody inflation risk premiums. Researchers have estimated the embedded inflation risk premium in nominal bonds to be between 0.50% and 1.0%.[4]

Because TIPS pay in real dollars, exhibit low volatility, and have a low correlation with other assets, at least part of such inflation risk premiums should not be embodied in TIPS yields. Therefore, the risk-adjusted break-even inflation rate for TIPS equals the calculated break-even inflation rate minus the inflation risk

4. Citing the tremendous supply of TIPS, the illiquidity of TIPS, and the substantial exposure that TIPS have to changes in real interest rates, Lucas and Quek suggest that a part of (or the entire) "inflation-risk premium" may be offset. See Gerald Lucas and Timothy Quek, "Valuing and Trading TIPS," Chapter 9 in John Brynjolfsson and Frank J. Fabozzi (eds.), *Handbook of Inflation Indexed Bonds* (New Hope, PA: Frank J. Fabozzi Associates, 1999). For a more detailed discussion of implied break-evens and risk-premiums, see the seminal work on expectations and markets by M. Harrison and D. Kreps, "Martingales and Multiperiod Securities Markets," *Journal of Economic Theory* (1979), pp. 381–408.

premium. This means an investor can advantageously use TIPS even when his expected inflation rate equals the calculated break-even inflation rate. Such an investor will gain by lowering overall portfolio risk or from "reallocating" the risk capacity created into other sectors.

Real and Effective Duration

Real Duration

Duration is the measure of a bond's market-value sensitivity to changes in yields—real *or* nominal. The preceding section describing real and nominal frames of reference and real and nominal yields is pivotal to any discussion of duration. By definition, the *real* duration of TIPS is the percentage change in its market value associated with a 1.0% change in its *real* yield. For example, if the market value (MV) of TIPS is $1,000 and the market values associated with a 0.50% decrease and a 0.50% increase in the TIPS real yield are $1,051 and $951, respectively, the TIPS real duration is 10. In order to center the calculation at current yield levels, the 1.0% change in the definition is applied equally as a 0.50% decrease and a 0.50% increase in yield.

Algebraically, the formula for TIPS real duration is

$$100 \times [\text{MV(real yield} + 0.50\%) - \text{MV(real yield} - 0.50\%)]/\text{MV(real yield)}$$

Not surprisingly, the TIPS duration formula is identical to that of a nominal bond (excepting the frame of reference). It follows that TIPS' duration can be calculated using a standard bond calculator. As with the calculation for real yield, it is the user's responsibility to remember that the result is the TIPS' *real* duration. (Using real duration within a dedicated TIPS portfolio is discussed in a later section.)

As relevant as real duration is to TIPS' portfolio managers, it is critical to understand that TIPS' real duration does not quantify the exposure of TIPS to changes in nominal yields. First, the correlation of real yields with nominal yields historically has tended to be less than 100%—real duration measures sensitivity to phenomena that may affect nominal bonds in an opposite way or not at all. Second, real yields tended to be significantly less volatile than nominal yields—so any given "real duration" tended to correspond with significantly less portfolio volatility than the same "nominal duration." Recently this has not been the case. Perhaps this is due to extremely high levels of confidence in the Federal Reserve's ability to successfully and perpetually target a stable inflation rate near 2%. Correlations between real and nominal yields have been high, and TIPS yield have been almost as, or more volatile than, nominal yields.

Effective Duration

To compare TIPS' risk with that of nominal bonds so that they may be included within a conventional bond portfolio, a manager needs a measure of TIPS' sensitivity to changes in *nominal* interest rates. The method for determining market-value change of TIPS as a function of nominal-yield change is the "effective duration" calculation. The limitation is that since this calculation must infer a change in real yield from the hypothetical change in nominal yield, the measure is statistical rather than deterministic.

Initially, this dilemma caused more than a few managers to conclude that the risk exposure of TIPS could not be managed within the context of a conventional fixed income portfolio. But it was soon realized that in the 1980s, for example, mortgage-backed securities overcame similar concerns. The calculation of effective duration for mortgages calls for an inference that a change in nominal Treasury yield will result in a change in the underlying yield of mortgage cash flows.

Similar to TIPS, yields underlying mortgage pricing are not perfectly correlated with Treasury yields. In fact, during the deflationary scares in the summer of 1998 and fall of 2008, mortgage prices dramatically underperformed what naive calculations of mortgage effective durations would have predicted. For brief periods, as Treasury yields fell, mortgage yields actually rose. Nonetheless, effective duration is used broadly to determine a mortgage's value change as a function of nominal-yield change. It is incumbent on fixed income managers to manage the remaining mortgage basis risk.

Although crude, the best metric we have found for converting TIPS' real yield into "effective duration" is to apply a 75% multiplicative factor to TIPS' real durations. This approach is often described as a "75% yield beta"—a reference to the second coefficient (beta) of a linear regression of change in real yield against a change in nominal yield. Like mortgages, TIPS' effective duration should be used only as a loose metric for nominal interest-rate exposure because substantial risk (basis risk) remains.

Occasionally, nominal yields fall, and TIPS' real yields rise, meaning that TIPS experience negative effective durations. Conversely, occasionally, nominal yields rise, and real yields rise even more, meaning TIPS experience capital losses greater than what their *ex-ante* effective durations predict. It is incumbent on managers, who use TIPS, therefore to manage the basis risk that TIPS embody beyond their modest effective duration.

For example, the regression results of the weekly change in 10-year TIPS' real yield as a function of changes in the 10-year nominal bond's yield for year 2010 had a highly statistically significant slope of 0.56 and an R-squared of 0.47. This slope indicates that historically the "yield beta" over that period, at 56.51%, has been lower than the 75%. The regression result will vary (as a function of the time period chosen to calculate the individual change), the time period included in the study, the securities chosen, and perhaps most important, the economic environment.

TIPS' real duration measures risk as it relates to change in real yield, and TIPS' effective duration measures risk as it relates to changes in nominal yield. Two broader measures of TIPS' risk are volatility and relative volatility. Volatility is simply the standard deviation of TIPS' prices (or returns). It varies over time and across maturities as a function of the calculation period and measurement interval.

Relative volatility is a measure of TIPS' volatility as a fraction of the volatility of another instrument such as a nominal bond having a comparable maturity. In the period leading up to May 2011, the TIPS bond exhibited about one-third the price volatility of a comparable-maturity nominal Treasury bond.

MARKETPLACE

A Brief History of TIPS

TIPS are such a fundamental economic instrument that they predate nominal bonds and even coins. In essence, the buyer of these bonds is simply "storing" (and earning a return on) a current basket of goods she will consume in the future.

In ancient Mesopotamia, warehouse receipts referencing quantities of grains and other goods were traded in a secondary market and were in some ways preferred to the currency of the day.[5] These receipts "were" TIPS. They could be traded, and on maturity, their value would be redeemed in the form of a "real basket" of consumer goods.

In the United States, TIPS date back to the birth of the nation. In 1780, the state of Massachusetts created debt colorfully inscribed as follows:

> Both Principal and Interest to be paid in the then current Money of said State, in a greater or less Sum, according as Five Bushels of CORN, Sixty-eight Pounds and four–seventh Parts of a Pound of BEEF, Ten Pounds of SHEEP'S WOOL, and Sixteen Pounds of SOLE LEATHER shall then cost, more or less than One Hundred Thirty Pounds current money, at the then current Prices of Said Articles.[6]

Since World War II, more than 15 countries have issued TIPS, or, more generally, inflation-linked bonds (ILBs). ILBs are not just issued by countries experiencing runaway inflation. Countries often issue ILBs as they are embarking on successful disinflationary initiatives. For example, in Iceland from 1949 to 1954, inflation averaged over 15% per year. In 1955, the year following the introduction of their ILBs, Iceland's recorded inflation rate fell to zero.[7]

Quotation and Settlement

In the United States, TIPS are quoted on a "real clean" basis—as distinguished from a "nominal dirty" basis. Fractions of a dollar are quoted as units of 1/32.

---

5. Glyn Davies, *A History of Money* (Cardiff: University of Wales Press, 1994).
6. Willard Fisher, "The Tabular Standard in Massachusetts History," *Quarterly Journal of Economics* (May 1913), p. 454.
7. *Statistical Abstract of Iceland,* Table 12.5, p. 150.

In this instance, "real" implies that U.S. TIPS' prices are quoted on the basis of 100 *inflation-adjusted* units of principal. The quoted price 95-20 can be interpreted as 95 and 20/32 real dollars, meaning that the investor is paying 95.625% of the *indexed* principal amount. While this may seem intuitive, it is not the only way to quote TIPS' prices. If prices were quoted on a *nominal* basis, as they are in the U.K. linker market, this same purchase would be quoted as 101.512 (95.625 × 1.06157 = the real price times the index ratio). Similarly, to calculate the clean settlement price, which necessarily is paid in "nominal dollars," multiply the real price by the index ratio.

Clean means that the quoted TIPS' price does not include the accrued-interest amount that the buyer of a TIPS bond owes the seller. Just as with nominal bonds, the TIPS' buyer must compensate the seller for coupon income that has been earned but not yet paid since the last coupon payment. Parties therefore can calculate the settlement proceeds by multiplying real accrued interest by the index ratio and adding the result to the clean settlement price. In practice, a computer algorithm can be used to incorporate prescribed rounding procedures.

Canadian and French TIPS are quoted similarly to U.S. TIPS, except, of course, local inflation indexes are referenced.

The U.K. linker market is quoted on a "nominal clean price" basis, and therefore, some U.K. linkers trade at prices above $200 per $100 original face. This is so because the country's retail price index (RPI) has more than doubled since the Bank of England began issuing these bonds in the early 1980s.

In Australia and New Zealand, ILBs typically are quoted and traded on a "real yield" basis.

Liquidity

The common metrics of liquidity are turnover, bid-ask spread, and transactional size. TIPS are less liquid than conventional coupon Treasuries, but as measured by the bid-ask spread associated with transacting $50 million, they are more liquid than most corporate bonds, nonagency mortgage pass-through bonds, and even some agency debentures. TIPS are significantly more liquid than other inflation hedges such as real estate, precious metal contracts, natural gas partnerships, timberland deeds, and collectable possessions.

VALUATION AND PERFORMANCE DYNAMICS

As with any bond, the holding-period return of a TIPS bond is the sum of its yield and capital gains. For TIPS, changes in real yield determine capital gains. Thus perhaps the most important question for investors evaluating TIPS is: "What direction are real yields heading?"

Over the long term we believe that real yields in the United States should remain at levels below 2.0%. Historically and comparatively, even a 2.0% real return for a riskless instrument is high. Over the past 70 years, long-term Treasury bonds have realized real yields of just above 2% and short-term Treasury bills just below 1%, with both averages concealing significant volatility in real return. During 1999, real yields on long-term nominal Treasuries averaged about 3.5% and Treasury bills 2.5%. Following the 2008 debt crisis "new normal" lower growth dynamics in the developed world depress real yields beyond 2025.

Determinants of Inflation and the Taylor Rule for Real Yields

Professor John Taylor of Stanford University presents a compelling thesis that there is an immutable link between the sustainable real economic growth rate and the sustainable real federal funds rate. "The Taylor rule" argues that over the long term, the real federal funds rate should average the long-term real economic growth rate of the economy, which he estimated to be about 2%. If the monetary authority maintains the real federal funds rate above this for an extended period of time, the inflation rate will diverge toward deflation. If the authority maintains the real federal funds rate below this, the result ultimately will be hyperinflation.[8]

But in 2008 a different risk faced policymakers—the possibility of structural debt deflation. Paraphrasing Fed Chairman Ben Bernanke, we have to be mindful that the risks and costs of deflation may be as great as the risks and costs of inflation.

Despite unprecedented monetary and fiscal stimulus, inflation had been nowhere to be seen through early 2020. This opened the door for residual "Modern Monetary Theory" which delinks monetary policy from inflation, and forces even traditional economists to revisit their assumptions. Regardless, monetary policy should be relatively easy during the next decade. The Fed likely will manage a funds rate that averages at most 2.0% above inflation and substantially less than the 4% above inflation experienced during the 1980s, 1990s, and 2000s. The possibility of negative nominal interest rates in the United States is real, and an actuality elsewhere.

INVESTORS

Tactical Use (Within Fixed Income Portfolios)

There are times when economic fundamentals, financial market dynamics, or simply structure will result in TIPS performing exceptionally well or, as in 1999, less badly relative to other investments. All investors can benefit from understanding how to evaluate and purchase TIPS for tactical gain.

In electing to own TIPS for tactical purposes within a fixed income portfolio, an investor may make a relative valuation assessment by comparing them with debt instruments with similar credit, effective duration, and liquidity. After the investment decision is made, the investor must diligently manage the tracking risk, that is, non–fixed income risk, associated with introducing tactical allocation to TIPS.

8. Taylor's equations suggest that in periods of high inflation, high real rates may be temporarily called for.

International Relative Value Opportunities

The international market for ILBs is currently larger than the U.S. TIPS market. We believe that all global ILBs belong to the same asset class. Tactical opportunities exist in all these markets because no region is immune from ebbs and flows in the global supply and demand for capital. To some extent, ILBs from different countries are interchangeable.

However, there are nuances that differentiate ILBs from one another. International ILBs provide investors with avenues to exploit a variety of currencies, monetary policies, and other local phenomena. These tactical opportunities can be reduced to perspectives regarding absolute global real yield levels, inflation rates, and intercountry differences from these global averages. Exhibit 15-2 reports ancillary data for nine of the larger government issuers of ILBs.

The first and second columns entitled "Market Cap" and "Real Yield" should be of particular interest because they report, respectively, the size and a long-term measure of relative value. Modified duration is simply the sensitivity issues holdings to changes in real yields. Real yield incorporates the return of real principal and the interim real income that an ILBs' holder will earn.

There are potential international risks not included in Exhibit 15-2 that can affect real yields. The first is the credit profile of the particular issuing country. To the extent that government issuers rarely default on debt instruments denominated in their own currencies, credit risk is low. A second factor is issuance. If a country issues more inflation-indexed supply than domestic and global strategic ILBs investors need, yields are likely to rise until sufficient international tactical investors are attracted.

ILBs can be used tactically within equity and cash portfolios as well. Conceptually, the motivation is similar. In the United Kingdom investors often

allocate out of equities into ILBs as a defensive tactic—much as U.S. equity managers reallocate defensively into utility stocks to protect against violent market declines.

Strategic Use

Strategic allocations are more deliberate than tactical ones and ultimately speak to the inherent investment qualities of ILBs. ILBs can play a significant role within such top-down strategic allocations. Enduring investor goals, such as matching liabilities, diversifying risks, controlling downside exposures, and achieving real return objectives, typically drive these strategic allocations. In contrast, bottom-up valuation, market timing, and other opportunistic considerations rarely are important aspects of the strategic decision-making process.

Investors typically make strategic asset allocations among the fundamental asset classes: equities, bonds, cash, and inflation hedges. Unadvisedly, some investors opt for finer gradations using more unwieldy sets of narrowly defined asset classes such as large-capitalization, midcap, small-cap equities, and government bonds at the top-level of their asset allocation framework.

Typically, the thread that holds the elements of an asset class together is that each element's returns are driven primarily by common fundamental phenomena. Simply, correlations between members of the same asset class will be high, whereas correlations between assets that are members of different asset classes will be low.

For ILBs, inflation and real global interest rate are the identifying fundamental phenomena that drive returns. Thus it is reasonable that all ILBs (Treasury, international, agency, and corporate) comprise a distinct asset class, separate from equities, (nominal) bonds, and cash. Real estate, commodities, and certain other "inflation hedges" also fall into this inflation-hedging asset class.

There are three general situations that warrant a strategic reallocation into ILBs. First, portfolio managers looking for higher returns without increased risk may investigate moving out of low-risk assets such as cash. Second, those motivated toward preserving past gains might consider a defensive allocation out of higher-risk assets such as equities or real estate. Importantly, a defensive allocation will tend to decrease or eliminate shortfall probability dramatically. (Shortfall probability is the likelihood that a portfolio will fall below a minimum acceptable threshold.) And third, ILBs can be used strategically in an asset/liability management context.

Asset/Liability Management (ALM)

Asset/liability management is closely related to asset allocation. Traditionally, asset allocation studies do not explicitly incorporate liabilities. They tend to focus on increasing absolute levels of return through allocations to higher-returning assets or through diversification of assets, thereby reducing risk calculated without regard to liabilities.

ALM studies focus on reducing the mismatch between assets and liabilities. Traditionally, researchers have studied ALM in a conventional nominal frame of reference where the exposure of assets and liabilities to conventional yield changes is compared and to some extent matched. Liabilities are assumed to be nominal liabilities even when they are in fact inflation-sensitive.

The large-scale introduction of TIPS by the U.S. Treasury has given asset-liability managers the ability to measure and manage both assets and liabilities that are predominantly real. This is a reprieve for the many investors discussed later.

Investors are not limited to choosing between asset allocation or asset-liability management. The two can be combined into a framework generally termed *surplus management*—optimizing the return and risk of surplus (assets net of liabilities). Although developed at one asset management firm in the 1970s, this framework comes into and out of favor periodically.

Risk/Return Optimization

The novelty of ILBs as an asset class in the United States poses challenges for strategic users of the securities. In particular, to include ILBs in a standard nominal Markowitz mean-variance optimization, the analyst must input appropriate expected return, variance, and correlation data for ILBs as well as other assets (or liabilities) included in the optimization.

Although conceptually inputs for such optimizations are forward-looking, practitioners usually rely heavily on historical data. Since U.S. TIPS have existed since 1997, correlation matrices are built using asset class returns from 1997 forward or from pro forma estimates of TIPS returns prior to 1997. Although most optimization models function in a nominal frame of reference, some practitioners appropriately implement them in a real frame of reference.

Managing Dedicated ILB Portfolios Using Real Duration

After a ILBs allocation has been determined, an implementation strategy must be executed. For this, an investor chooses between active or passive management. In either case, real duration is a useful metric of exposure because it measures the allocation's relative sensitivity to changes (parallel shifts) in the real yield curve.

To construct an ILB portfolio, the practitioner needs first to choose a target "real duration" for the portfolio and then to devise a variety of candidate portfolio structures. The candidate portfolios might include a bulleted portfolio having all its ILBs close to the target duration and a barbell portfolio with a combination of longer and shorter ILBs weighted to achieve the target duration.

To select the most advantageous portfolio structure from those with the same real duration, the practitioner need only concern herself with the exposure to changes in the general real yield curve slope of the various candidate portfolios. This is so because the candidate portfolios have the same real yield duration, so their response to parallel shifts will be very similar.

A recent development in the management of TIPS portfolios is increased demand for "break-even" structuring. Typical TIPS portfolios embody inflation protection by locking in to maturity the real yield of instruments owned. Break-even structuring involves selling similar maturity fixed-rate Treasuries, futures, or paying fixed on interest-rate swaps. This in essence nullifies the real yield and real duration of TIPS, leaving the holder with the inflation indexation of the TIPS held. Of course, realized inflation will need to equal or exceed the inflation which is priced into the nominal market in order to profit from this strategy. In essence this strategy become attractive when (1) real yields are low, so that not much is being given up and (2) the investor believes that inflation will rise more than what the Treasury market has priced in, or that certain risks are associated with inflation that the investor particularly wants to hedge.

Investor Types: Pension Plans, Endowments, Foundations, and Individuals

Defined-benefit pension plans have both retired-lives and active-lives liabilities. Although ILBs as assets may match the active-life portion of these plans extremely well, plan sponsors typically do not rely exclusively on ILBs to back their active-lives liabilities. Instead, they reach for higher expected returns by using other asset classes with higher risk and return qualities. Given that ILBs and the active-lives liabilities are both linked to inflation,[9] sponsors realize that to reach for higher returns, they take on some risk of underperformance in inflationary environments. In addition to generic asset allocations, pension plans may use ILBs to protect a surplus, to offset substantial equity risk exposure, or to reduce the variability of annual funding requirements. Defined-contribution pension plans and their participants also may benefit from the inclusion of ILBs as described separately below.

Endowments, foundations, and other eleemosynary organizations also may have return objectives that are formulated in *real* terms. Typically their goal is to generate a 5% or higher real return on their investment portfolio. (The IRS generally requires that 5% of a charitable foundation's assets be spent on the delivery of charitable services each year—so a 5% real return, net of expenses and contributions, is required to maintain the foundation's inflation-adjusted size.)

Establishing a real-return target for investment performance makes sense for these organizations. Educational or charitable programs, whether they involve physical infrastructure or services, often are budgeted for using inflation-adjusted dollars. Implicitly, such goals, objectives, and plans represent real liabilities.

9. More specifically, active-lives liabilities are tied to increases in wages of employees. The pension plans may prescribe that an employee's retirement benefit is a fixed annuity, with each monthly payment being a fraction of employees' highest annual income. This income level is in turn not explicitly but generally highly correlated with the CPI.

This suggests that eleemosynaries employ ILBs as a core pillar in their investment strategy. ILBs will not generally achieve 5% returns in isolation, but they go a long way toward engineering out much of the downside risk of return distributions. With the downside risk truncated, more aggressive use of a higher-returning (riskier) asset can be used. As of this writing, eleemosynaries generally have used ILBs only at the margin.

Individuals save primarily to provide for retirement needs and secondarily for children's education, bequeathment, and other goals. Younger individuals may be relatively immune to the damage that inflation can cause in the context of such liabilities. They hold a large proportion of their "wealth" in the intangible real asset known as *human capital* (future earning power). As individuals age, the proportion of their real assets typically decrease as their financial assets increase—leaving those in their late 40s and older relatively vulnerable to the inflationary erosion of retirement living standards.

ISSUERS

Although corporations and agencies can and do issue ILBs, governments are by far the largest issuers. By issuing ILBs, government officials make clearer their commitment to maintaining a low level of inflation. A government's willingness to assume the financial risk of inflation is a powerful signal to the marketplace regarding future policy. Donald T. Brash, governor of the Reserve Bank of New Zealand, characterized this attitude in a speech following New Zealand's introduction of these securities:

> The only "cost" to Government is that, by issuing inflation-adjusted bonds, it foregoes the opportunity of reducing, through inflation, the real cost of borrowing . . . Since [the New Zealand] Government has no intention of stealing the money invested by bondholders, foregoing the right to steal through inflation hardly seems a significant penalty.[10]

How can an investment instrument that makes so much sense for investors, as described in preceding sections, also be advantageous to the issuer? Brash's quote provides one example of how investors gain while the issuer forfeits something it considered worthless to begin with. Next we discuss the U.S. Treasury rationale for issuing TIPS.

U.S. Treasury's Rationale

A goal of the Clinton administration was to reduce the future interest burden of the Treasury's debt. Balancing the budget was the main target of this policy, but

10. Donald T. Brash, "Monetary Policy and Inflation-Adjusted Bonds," an address to the New Zealand Society of Actuaries, April 12, 1995.

a secondary objective took aim at "bond market vigilantes." The administration recognized that because of the "maturity premium" inherent in longer-term debt, rolling over a 3-year bond ten times likely would incur less interest cost than issuing a single 30-year bond. One of the most important programs Treasury embarked on during this administration was a deliberate effort to reduce the average maturity of outstanding debt.

TIPS Program

The TIPS program was instituted in this spirit. Like floating-rate debt, TIPS have long *stated* but short *effective* maturities, reducing the "rollover risk" inherent in short-term debt. Additionally, TIPS explicitly provide market-based inflation forecasts for use by the Fed. TIPS reduce the expected cost of financing a government's debt because they are conceptually free of the inflation risk premium built into nominal long-term bond yields. Normally one might conclude that by relieving bond investors of this risk, the Treasury implicitly absorbs a burden or risk equal in magnitude. This is not the case here, however.

By reducing nominal debt and increasing inflation-indexed (real) debt, the Treasury has in effect changed the structure of its liabilities to better match its only asset—its authority to tax. Put another way, the Treasury is the ideal issuer of inflation-indexed debt.

The issuance of TIPS improves taxpayer welfare by eliminating the 0.5% to 1.0% inflation risk premium that researchers believe is embedded in nominal bond yields. At the margin, investors are indifferent to accepting lower yields versus living with the higher risk of nominal debt—so conceptually they are no better or worse off. The elimination of this inflation risk premium is therefore a true welfare gain. In practice, the welfare gains of issuing TIPS have been split between issuers and the investors.

Moral Hazard

The government is both the issuer of TIPS (Department of Treasury) and publisher of the CPI (BLS, Department of Labor). The inherent ambiguity in measuring the CPI creates a moral hazard because the government can directly control the economic value of its liability. Fortunately, several factors mitigate the risk of the government publishing statistics that are not scientifically based.

First, professional integrity, a strong institutional infrastructure, and influential political constituencies combine to preclude the government from manipulating the CPI. Second, any confiscation of value through index distortions would be perceived by the financial community as an erosion of credibility or, if blatant, tantamount to default. Since the issuance process is a repeated game of substantial proportion, such an erosion of credibility would have long-term repercussions on future debt issuance and other government promises that would greatly outweigh any apparent short-term economic or political benefits.

International Issuers

The ILB market in the United Kingdom is large and well developed, comprising about 20% of outstanding debt. Additionally, Canada, Australia, France, Italy, and Sweden have issued ILBs in large enough quantities to ensure reasonable market liquidity as well.

While each of these countries shares the basic inflation-protection concept with their U.S. cousins, differences include market size, trading liquidity, time lag associated with the inflation indexation, taxation, day-count conventions, and quotation conventions. These differences substantially influence both observed quoted real yields and "true" real yields available to investors.

All the ILBs issued by these six governments, together with those issued by the U.S. Treasury, make up a performance benchmark of liquid global inflation bonds known as of April 2011 the *Barclays Capital Global Inflation-Linked Bond Index.*

Corporate Issuers and CPI Floaters

In addition to the U.S. Treasury and non-U.S. government issuers, U.S. corporations, agencies, and municipalities have issued inflation-indexed bonds. Two of the earliest corporate issuers were the Tennessee Valley Authority and Salomon Brothers. Their inflation-indexed bonds were virtually identical in structure to U.S. Treasury TIPS. Other issuers, including Nationsbank, Toyota Motor Credit, the Student Loan Marketing Association (SLMA), and the Federal Home Loan Bank (FHLB), have chosen to structure their bonds as CPI floaters.

A CPI floater is a hybrid between TIPS and a conventional floating-rate note (FRN). Like a TIPS, its return is closely linked to CPI inflation. Like a conventional floating-rate note, its principal is fixed in size. The coupon rate of a CPI floater fluctuates and is typically defined as the CPI inflation rate plus a fixed-percentage margin.

OTHER ISSUES

Taxation

U.S. TIPS are taxed similarly to zero-coupon bonds. They incur a tax liability on phantom income (income earned but not paid). This does not mean that investors in TIPS pay more taxes or that they pay taxes sooner than holders of nominal bonds. In fact, if inflation, nominal yields, and tax rates are constant, the cash-flow profile of taxes paid and payments received on TIPS is comparable with those of nominal bonds (assuming reinvestment of the excess coupon). In practice, many taxpayers hold TIPS in tax-exempt accounts (401(k)s, etc.) or within mutual funds (which are generally required to distribute taxable income).

Deflation Protection

Questions naturally arise regarding how TIPS would behave in a deflationary environment (one where prices are literally falling). Applying CPI indexation, the current adjusted principal value would be less than the prior adjusted principal value. This would affect semiannual interest payments accordingly.

Extending this premise, it is certainly possible for the adjusted principal value to fall below the original principal value—and therefore for coupon payments to be calculated on a shrinking base. Note that they would still be positive and almost equal to their original size. For example, even after 10 years of 1% deflation and a resulting price level that was 10% lower than when it started, the semiannual coupon payments on a $1,000 TIPS would still be about $18 (rather than $20 originally). The final principal repayment would be treated even more favorably.

In particular, *the Treasury has guaranteed that for the maturity payment of principal (and only the maturity payment), the investor will not receive less than the original principal amount.*

In such deflationary circumstances, in order to maintain acceptable nominal returns, the Treasury would in effect be paying a higher real return than initially promised. The Treasury decided that the regulatory, institutional, and psychological benefits of providing this guarantee would facilitate distribution of the bonds to an extent that more than justifies the theoretical contingent cost to the government.

This government guarantee of 100% principal return distinguishes TIPS from all other inflation hedges.

KEY POINTS

- The inflation indexed bond market has existed for centuries in various forms, but blossomed in 1997 when the U.S. Treasury introduced Treasury Inflation-Protected Securities or TIPS, and in years since as investors have adopted them strategically.
- The market real yield on TIPS can be subtracted from the market nominal yield of similar maturity fixed-rate Treasuries to arrive at the “break-even inflation rate.”
- A broad range of investors incorporated TIPS into their asset allocations in order to lock in fixed real yields, while protecting their principal from erosion of purchasing power.
- Investors utilize a “break-even” structure in determining their allocations to TIPS. This involves hedging out the relatively low real yields currently priced by the market in order to profit more directly from a rise in inflation, which may or may not be accompanied by rising real yields.

CHAPTER

SIXTEEN

NON-U.S. SOVEREIGN BONDS

Francesco A. Fabozzi
Managing Editor
Journal of Financial Data Science

Frank J. Fabozzi, Ph.D., CFA, CPA
Professor of Finance

Adam Kobor, Ph.D., CFA
Managing Director of Investments
New York University

Sovereign bonds refer to bonds issued by the central government of a country. In most countries, the sovereign bond sector the largest sector of the bond market and is considered to be the debt within a country that has the lowest default risk because central governments borrow in a currency whose value they control. Central governments can do so by printing more money to satisfy their obligations to bondholders. In this chapter, the market for non-U.S. sovereign bonds and the debt instruments issues are described. The next chapter provides comprehensive coverage of bonds issued by central governments of developing countries.

SIZE OF THE SOVEREIGN BOND MARKET

Exhibit 16-1 shows the amount of central bank debt securities outstanding for 30 countries as of the third quarter of 2018 as reported by the Bank for International Settlement (BIS). The total amount of central bank debt outstanding was almost US$23.9 trillion. For some reason, Japan was not included in the data provided by the BIS. As of early 2019, the BIS did report that the debt was roughly US$12.8 trillion. Therefore, total debt securities issued by the 30 countries was about US$36.7 trillion and the total debt securities issued by the 29 countries excluding the United States was US$23.4 trillion.

Investors can be domiciled in the country where the central government has issued the bond, or they can be foreign investors. Within each of these groups, we distinguish between financial entities (banks, contractual savings entities, and

Parts of this chapter draw from Frank J. Fabozzi and Francesco A. Fabozzi, *Bond Markets, Analysis, and Strategies* (Cambridge, MA: MIT Press, 2021).

collective investment funds) and nonfinancial entities (nonfinancial firms and individual retail investors). Financial entities are key players in the sovereign debt market. Commercial banks invest in government securities for a variety of reasons. They use these securities to meet liquid asset requirements, manage their interest rate risk, and provide collateral for certain transactions (e.g. repurchase agreements). The contractual saving entities include pension funds and life insurance companies. Their mission is to fund a liability structure. Since their liabilities are long-term, they are important buyers of longer-term maturity government securities. Collective investment funds—including bond mutual funds and money market funds—are active participants across the entire yield curve.

TYPES OF SECURITIES ISSUED

Central governments can issue different types of debt instruments. Exhibit 16-1 shows the amount outstanding by type of instrument (fixed rate, floating rate, and inflation linked). Most sovereign borrowers issue bonds with a fairly wide range of maturities. This allows investors to have a benchmark yield that can be used in the pricing of other debt instruments issued in a country. Governments routinely issue two types of securities. The first is a discount security that pays a single cash flow at the maturity date with the difference between the maturity value and the purchase price being the interest the investor receives. Most sovereign debt issued with an original maturity of one year or less are issued as discount securities. The second type is a coupon security that is issued with a stated rate of interest and make interest payments periodically. The interest payments can be made semiannually or annually. In many European countries interest payments are made annually. Sovereign debt with an original maturity of greater than one year is issued generally issued as coupon securities. From Exhibit 16-1, it can be seen that the most common type of instrument is a one that pays a fixed rate.

Sovereigns can also issue two types whose payments are not fixed: floating-rate securities and inflation-adjusted securities. Floating-rate securities are securities whose interest payments change periodically according to a predetermined coupon formula. The coupon formula includes a reference rate (benchmark interest rate) adjusted with a spread.[1]

Inflation-adjusted securities, also referred to as "linkers," adjust the payments (either coupon or principal) to investors for some measure of the country's rate of inflation.[2] There are different designs that can be used for linkers. The reference rate that is a proxy for the inflation rate some consumer price index (CPI). In the United Kingdom, for example, the index used is the Retail Prices Index (All Items), or RPI. In France, there are two linkers with two different indexes: the French CPI (excluding tobacco) and the Eurozone's Harmonised Index of Consumer Prices (HICP) (excluding tobacco). In the United States, it is the

1. Floating-rate securities are discussed in more detail in Chapter 14.
2. Inflation protection securities are discussed in more detail in Chapter 15.

Source: Table C2, *BIS Statistical Bulletin*, Bank for International Settlements, September 2019.

Consumer Price Index—Urban, Non-Seasonally Adjusted (denoted by CPI-U) as calculated by the U.S. Bureau of Labor Statistics.[3]

Given the reference rate, the design of a linker can be such that over time the principal and/or the coupon income are adjusted for inflation between the date of issuance and the payment date of a cash flow. The most commonly used design for a linker today calls for adjusting both the principal and the coupon interest. Before maturity, prices for trades in the secondary market are adjusted similarly. The inflation adjustment is usually done with a lag. This structure is used in the United States for its linker (TIPS) where there is a three-month lag in the CPI-U.

A small part of the central government securities markets is exchange rate-linked government debt, also referred to as principal exchange-rate-linked (PERL) government debt. The structure of this debt instrument is that the principal depends on the exchange rate between the U.S. dollar and some exchange rate, typically the exchange rate between the two exchange rates; one of the rates is that of the issuing country.

The denomination of the payments can in be any currency, not just the local currency. Central governments will assess their local economic conditions and internal political developments in making the decision as to the currency in which they will denominate their bonds. For example, oil-producing countries such as Mexico, Chile, and Columbia facing low oil prices have issued denominated in euros and other non-U.S. dollars.

PRIMARY MARKET FOR SOVEREIGN DEBT

There are a number of distribution methods in use in the primary sovereign debt markets. Typically, central governments are active in the primary market at the beginning of the calendar year.[4] This is the case because the minister of finance of countries begin address their country's funding requirements. During the calendar year, the ministers of finance monitor the global capital markets to identify opportunities to obtain more cost-effective funding.

The three primary distribution methods are (1) auctions, (2) syndications/underwriting, and (3) tap sales. For countries with well-developed markets, the primary distribution method is an auction, which has proven to be more

3. The CPI-U is the most widely followed and perhaps the most understood inflation index among alternative choices such as the Gross Domestic Product (GDP) deflator and the Personal Consumption Expenditure (PCE) deflator. Changes in the CPI-U represent the average change in prices facing urban consumers for a fixed basket of goods and services. This group of urban consumers represents about 87% of the total U.S. population. The Treasury reserves the right to substitute an alternative price index under the following circumstances: (1) the CPI-U is discontinued; (2) the CPI-U is altered materially to the detriment of the investor and/or the security; (3) the CPI-U is altered by legislation or executive order in a manner harmful to the investor and/or the security.

4. Eli Whitney Debevoise II, Neil M. Goodman, and Carlos A. Pelaez, "The Current State of the Sovereign Bond Market," Arnold & Porter, May 2, 2017. Available at https://www.arnoldporter.com/en/perspectives/publications/2017/05/the-current-state-of-the-sovereign-bond-market.

transparent and cost effective than other selling methods. In developing markets, other methods such as syndication, underwriting, and tap sales are used.

Auctions

Many sovereigns use either a single-price auction (also called a uniform price auction) or a multiple price auction (also called a discriminatory auction) for all marketable securities it issues. In a multiple price auction, competitive bidders state the amount of the securities desired and the yields they are willing to accept. The yields are then ranked from lowest to highest (which is equivalent to arranging the bids from the highest price to the lowest price). Starting from the lowest yield bid, all competitive bids are accepted until the amount to be distributed to the competitive bidders is completely allocated. The highest yield accepted by the sovereign is called the "stop yield," and bidders at that yield are awarded a percentage of their total tender offer. The single-price auction proceeds in the same fashion except that all accepted bids are filled at the highest yield of accepted competitive tenders.

The frequency of auctions is a function of the debt management practices of the government and the desire to promote a liquid secondary market. Short-term securities, such as bills, are usually auctioned weekly. In most countries, the day of the week for the auction is fixed. Longer-term coupon securities, such as notes and bonds, are typically auctioned less frequently, usually monthly or quarterly. A well-defined schedule announced in advance it is believed leads to a lower effective borrowing cost.

Syndication

In markets where there are few bidders, the auction method for distributing new issues may not be the best method. In such cases, central governments appoint a group of financial institutions who for a negotiable fee will subscribe to the purchase the bond issue and then resell the bonds to other investors. This process, called syndication, offers the advantage of reducing placement risk when demand for the securities is very uncertain and when the central government seeks to introduce a new debt instrument. Syndication's main disadvantage is the lack of transparency relative to an auction.

An alternative method for selling government securities is via underwriting. With this method for the distribution of new securities, the central government establishes a minimum price for a debt issue to be sold. For a commission, the underwriter subscribes to the entire issue at the minimum price. The underwriter can then retain the portion of the issue it desires and resells the remainder to other investors.

Tap Sales

A *tap sale* is a method of distributing securities that allows issuers to sell additional bonds from past issues. The bonds are sold at their current market price but retain their original face value, coupon rate and maturity. The British and French governments have issued additional securities using this method. Advantages to the issuer include avoiding some of the fixed costs of auctioning off new securities. This method is used for issuing small amounts of securities when the cost of a new issue is prohibitive.

SECONDARY MARKET

In the secondary market, sovereign bonds can be traded directly from investor to investor, or through a broker or primary dealer to facilitate the transaction. The major participants in secondary government bond markets globally are large institutional investors and central banks. The participation of retail investors in secondary market is small. There are two main ways for secondary markets to be structured: as an organized exchange or as an over-the-counter market.

A hallmark of a liquid, well-developed market is how it handles spot transactions (i.e., a transaction for the immediate purchase or sale of a security). An important gauge of a market's efficiency is the amount of time between trade execution and settlement. The shorter the gap, the more cash-like securities become. Settlement is the process that occurs after the trade is made. The bonds are delivered to the buyer for payment is received from the seller. For most developed secondary markets, cash settlement is standard (i.e., when trading and settlement occur the same day). Trades clear within either or both of the two main clearing systems, Euroclear and Clearstream. Settlement occurs by means of a simultaneous exchange of bonds for cash on the books of the clearing system. An electronic bridge connecting Euroclear and Clearstream allows transfer of bonds from one system to the other.

SOVEREIGN CREDIT RISK

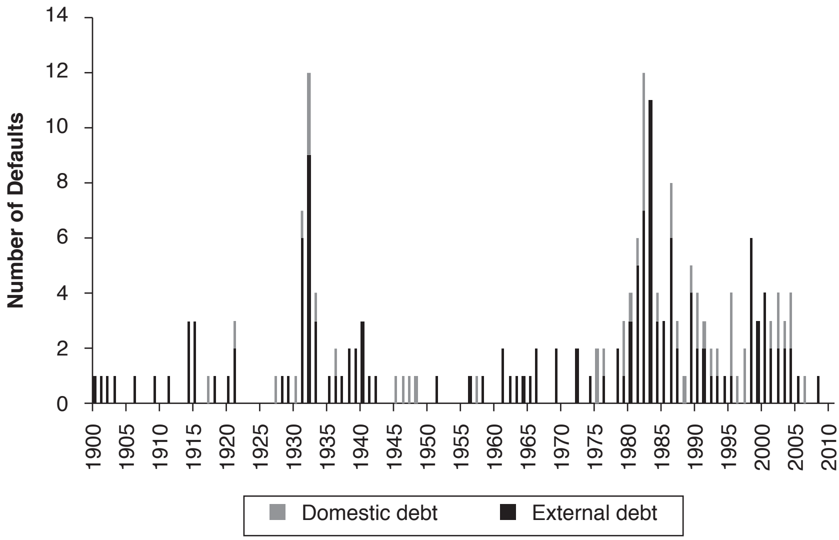
Sovereign debt exposes investors to credit risk. Over history, we could observe several cycles of sovereign debt defaults. These defaults usually came in waves or clusters over time, as Exhibit 16-2 shows based on data collected by Reinhart and Rogoff.[5] It is important to distinguish between domestic and external debt. Domestic debt is issued under national jurisdiction and is typically denominated in the national currency. Domestic debt instruments are usually, but not exclusively, held by residents of the issuing country. External debt, however, is subject to the jurisdiction of foreign creditors or international laws, is typically issued in foreign currency and held by foreign residents. In many cases, it is assumed that domestic debt is not at risk whatsoever, given that the sovereign can always print money to pay its debt back. To service external, foreign currency denominated

5. Carmen M. Reinhart and Kenneth S. Rogoff, *This Time Is Different: Eight Centuries of Financial Folly* (Princeton, NJ: Princeton University Press, 2009).

debt, however, a country needs access to foreign currencies. If the country runs out of foreign reserves and cannot generate sufficient foreign currency inflows by exporting goods or issuing new debt, there is a very obvious technical reason to default.

EXHIBIT 16-2

History of Sovereign Defaults



Authors' construction using data from Carmen M. Reinhart and Kenneth S. Rogoff, *This Time Is Different: Eight Centuries of Financial Folly* (Princeton, NJ: Princeton University Press, 2009).

In reality, domestic debt defaults occurred in the past, although less frequently than external defaults, as shown in the exhibit. Beyond a *de jure* default on domestic debt, we can also consider hyperinflation as a form a default. In such cases, while the government formally pays its obligations back, the purchasing power of the repaid debt is significantly less than when it was borrowed.

Based on historical experience, countries that issue a large portion of their debt with short maturity are usually more prone to face difficulties rolling over their debt during market panics or economic downturns, and thus are more prone to default. From the creditor's perspective, short-maturity debt is a means to force borrowers to follow prudent economic policies, and also is a result of inflation fatigue, as short-maturity debt is much harder to inflate away than long-maturity debt. Nevertheless, even a country with a sustainable debt profile can run into a rollover or debt liquidity crises during recessions and market panics. These types of liquidity crises have been largely reduced by international organizations like the IMF or the World Bank that can provide loans when private lenders would not be able or willing to do so.

Sovereign ratings are credit ratings for countries as assigned by one or more credit rating agency (CRA). The three major CRAs are Moody's Investors Service, Standard & Poor's Ratings Services, and Fitch Ratings. Two CRAs that rate sovereign debt and have the status of a Nationally Recognized Statistical Organization by the U.S. Securities and Exchange Commission are the Japan Credit Rating Agency and DBRS Morningstar. Other CRAs that include Scope Ratings (a German-based CRA) and two Chinese-based CRAs, Dagong Global Credit Rating and China Chengxin Credit Rating Group.

Sovereign ratings are assessments of the relative likelihood that a borrower (i.e., a central government) will default on its obligations. Governments seek these credit ratings to increase their access to international capital markets. Sovereign ratings matter to investors because other things equal investors prefer rated issues to unrated ones. They matter to borrowers as well because the rating agencies are reluctant to assign a credit rating to a lower level of government or corporation that is higher than that of the issuer's home country.

Two sovereign debt ratings are assigned by credit rating agencies, a local currency debt rating and a foreign currency debt rating. The two general categories of risk analyzed in assigning ratings are economic risk and political risk. The former category is an assessment of the ability of a government to satisfy its obligations. Both quantitative and qualitative analyses are used in assessing economic risk. Political risk is an assessment of the willingness of a government to satisfy its obligations. A government may have the ability but may be unwilling to pay. Political risk is assessed based on qualitative analysis of the political factors that influence a government's economic policies.

The reason for distinguishing between local debt ratings and foreign currency debt ratings is that historically, the default frequency differs by the currency denomination of the debt. Specifically, defaults have been greater on foreign currency–denominated debt. The reason for the difference in default rates for local currency debt and foreign currency debt is that if a government is willing to raise taxes and control its domestic financial system, it can generate sufficient local currency to meet its local currency debt obligation. This is not the case with foreign currency-denominated debt. A national government must purchase foreign currency to meet a debt obligation in that foreign currency and therefore has less control with respect to its exchange rate. Thus, a significant depreciation of the local currency relative to a foreign currency in which a debt obligation is denominated will impair a national government's ability to satisfy such obligation. This distinction is not observed with the 17 countries of the European Union's Eurozone, where there is only a single credit rating for a sovereign's issues irrespective of what currency the country is issuing.

A country whose domestic currency is a liquid currency, and which boasts a sizeable domestic institutional savings base, has the capacity to fund its debt in local currency.[6] However where there is a demand for that issuer's name, either

6. By liquid currency, we mean a currency that can be bought or sold quickly and cheaply with a narrow bid-ask spread and without the transaction adversely impacting the exchange rate.

from foreign investors and/or for issues in another currency, a sovereign may also issue in a foreign currency. When this occurs, it will usually swap the proceeds into its local currency. A demand for a particular sovereign name from different investors may cause that issuer to raise debt in a foreign currency; this is common for highly rated borrowers such as Switzerland, Finland, and Sweden, which issue U.S. dollar and euro debt.

The factors analyzed in assessing the creditworthiness of a national government's local currency debt and foreign currency debt will differ to some extent. In assessing the credit quality of local currency debt, for example, Standard & Poor's emphasizes domestic government policies that foster or impede timely debt service.

In assigning a rating for a country's foreign currency debt, credit analysis by S&P focuses on the interaction of domestic and foreign government policies. S&P analyzes a country's balance of payments and the structure of its external balance sheet. The areas of analysis with respect to its external balance sheet are the net public debt, total net external debt, and net external liabilities.

Moody's, another major rating agency, focuses on the following four factors as the foundation of its sovereign bond ratings methodology: (1) economic strength (wealth, size, diversification, and long-term potential), (2) institutional strength (governance, quality of institutions, and policy predictability), (3) government financial strength (ability to deploy resources to face current and expected liabilities), and (4) susceptibility to event risk (risk of sudden risk migration).[7]

SOVEREIGN BOND YIELD SPREADS

There are several studies on the sovereign yield spreads. The focus of most studies is on the importance of a country's fiscal fundamentals on the observed yield spread on sovereign bonds for advanced economies.[8] Several empirical studies for advanced economies find that fiscal fundamentals and default risk are not the key drivers of sovereign yield spreads.

A European Central Bank study by Afonso, Arghyrou, and Kontonikas, however, did find that macroeconomic and expected fiscal fundamentals, international risk, liquidity conditions, and sovereign credit ratings (particularly in the case of a rating downgrade) did have an impact over three time periods: (1) the period preceding the global credit crunch (January 1999–July 2007), (2) the period during which the global credit crunch had not yet transformed into a sovereign debt crisis (August 2007–February 2009), and (3) the period during which the global financial crisis transformed into a sovereign debt crisis (March

8. See Joshua Aizenman, Michael Hutchison, and Yothin Jinjarak, "What Is the Risk of European Sovereign Debt Defaults?" *Journal of International Money and Finance* 34, 2013, pp. 37–59, and Tigran Poghosyan, "Long-Run and Short-Run Determinants of Sovereign Bond Yields in Advanced Economies," IMF Working Paper No. 12/271, 2012.

2009–December 2010).[9] The study looked at 10 euro area countries (Austria, Belgium, Finland, France, Greece, Ireland, Italy, Netherlands, Portugal, and Spain).

Empirical studies do suggest that a key determinant of sovereign yield spread is global market conditions that reflect the risk aversion of global investors rather than conditions specific to a country.[10] This is due to the global financial integration that results in portfolio adjustments by global investors, clearly demonstrated during a financial crisis where there is a flight to countries viewed as a safe haven. Nevertheless, when there is an economic crisis for a specific country, investors become concerned with domestic risk.[11]

There are studies that looked at more than just fiscal variables and default risk in investing observed sovereign yield spreads. These studies look at some proxies for investor expectations about fiscal development for a country. For example, deficit forecasts and potential government liabilities (e.g., the position of the domestic banking sector if it had to be rescued) have been used.[12]

Most of the earlier studied examined observed yield spreads. Since 2013, as a result of data available on forecasts of fiscal variables based on survey forecasts, studies have used forecasts to explain sovereign bond yield spreads. For example, a study by the European Central Bank by Cimadomo, Claeys, and Poplawski-Ribeiro used survey data to investigate how financial institutions forecast sovereign yield spreads.[13] They use monthly survey forecasts for three countries (France, Italy, and the U.K.) between January 1993 and December 2011 to investigate whether survey respondents consider the expected evolution of a country's fiscal balance, as well as other economic fundamentals, are determinants of the expected (as opposed to observed) bond yield spreads over a benchmark German 10-year bond. One-year-ahead forecasts for a country's budget balance, inflation

rate, and GDP are used as a proxy for a country's fiscal development. They find that the expected sovereign yield spread is significantly impacted by the forecasted improvement for a country's fiscal development. Overall, the findings suggest that credible fiscal plans affect expectations of market experts, reducing the pressure on sovereign bond markets.

SOVEREIGN BONDS FROM THE INVESTOR'S PERSPECTIVE

Investors may choose to invest in foreign sovereign bonds for various reasons, and it is also common to bucket foreign sovereign bonds into "developed market" and "emerging market" categories.

From a U.S. investor's perspective, developed market sovereign bonds, as well as bonds issued by supranational organizations like the World Bank, were historically added to investment portfolios to diversify the risk of the U.S. yield curve. Furthermore, return enhancement had been a consideration as well, especially when foreign sovereign yields exceeded U.S. Treasury yields, like 10-year German bund offered higher yield than 10-year U.S. Treasuries in the early 1990s, 2002, or around 2008–2009. As discussed in Chapter 1, many bonds of the highest-rated foreign sovereign issuers currently offer very low or even negative yield, so many investors consider U.S. Treasuries more attractive than those bonds issued by Germany or Switzerland in the present conditions. That said, besides pure diversification, foreign developed market sovereign bonds still play important roles in the market:

- Central banks and other official organizations hold a significant portion of their reserves in the highest-rated sovereign bonds. Based on IMF data,[14] central banks altogether held \$12.2 trillion in assets as of April 2020, and while the U.S. dollar remains the main global reserve currency, about 39% of global central bank reserves[15] is comprised by non-U.S. dollar assets. Foreign reserve currency allocation, and thus allocation to foreign sovereign bonds, is based on various factors, like economic connections with different currency blocks; thus European countries outside the Eurozone would typically have high allocation to euro-denominated bonds.
- Outside of central bank reserve managers, other investors like pension funds may add foreign sovereign bonds to their portfolios on a currency unhedged or hedged basis. If foreign sovereigns are added to on a currency unhedged basis, currency risk (and currency diversification) would be a main contributor to the fixed-income portfolio risk. If, however, foreign sovereign bonds are added on a currency hedged basis, while

14. Total reserves excluding gold: https://data.imf.org/regular.aspx?key=61545869.
15. COFER database: https://data.imf.org/?sk=E6A5F467-C14B-4AA8-9F6D-5A09EC4E62A4.

volatility gets reduced, investors also have to take the cost of hedging into consideration. Based on the covered interest rate parity, a currency with higher interest rates than the same maturity U.S. interest rates would be traded at a discount forward price compared to the spot FX rate, whereas a currency with lower interest rates would have a forward premium versus the U.S. dollar spot rate. For example, while a Japanese government bond offers lower yield than the same maturity U.S. Treasury, if the Japanese short-term interest rate is even more lower than the comparable U.S. interest rate, the carry on the Japanese bonds may be attractive on a currency hedged basis as the investor sells Japanese yen forward at a premium price. When investing in foreign bonds on a currency hedged basis, the difference in the yield curve slopes matter.

Emerging market sovereign bonds are mainly added to the portfolio for return enhancement. J.P. Morgan Global Emerging Market Bond Index, an index comprised of USD-denominated emerging market sovereign and agency bonds, had a spread of 4.63% over U.S. Treasuries at the end of May 2020. Given low yield levels in developed markets, investors may consider the addition of emerging market sovereign bonds as an attractive return enhancer. About 60% of this index is, in fact, comprised of investment-grade bonds, there is no currency risk in this index since all these bonds are USD-denominated, but the duration is high, over seven years, so both yield or spread level increases would adversely impact the index performance. Local currency denominated emerging market bonds have gained importance over the recent decade as well; investors would typically add such bonds on a currency unhedged basis, since hedging high-interest-rate emerging market currencies would have a negative carry based on the logic of the covered interest rate parity.

KEY POINTS

- Sovereign debt refers to the debt issued by the highest level of government in a particular country.
- There are two types of central government securities issued—discount and coupon—and the instruments that can be issued include fixed-rate bonds, floating-rate bonds, and inflation-adjusted bonds
- The three distribution methods used in the primary sovereign debt markets are (1) auctions, (2) syndications/underwriting, and (3) tap sales. For countries with well-developed markets, the primary distribution method is an auction.
- Two sovereign debt ratings are assigned by credit rating agencies (a local currency debt rating and a foreign currency debt rating).
- The two general categories of risk analyzed by credit rating agencies in assigning ratings are economic risk and political risk.

Emerging Market Fixed Income Strategist
BofA Securities

Emerging markets (EMs) comprise nations whose economies are viewed as developing, or emerging, from underdevelopment. These nations usually include almost all of Africa, Central and Eastern Europe, Latin America, Russia, the Middle East, and Asia (excluding Japan). There is no single definition of EMs. Some define them as countries that do not have G10 currencies, though that might classify some AAA-rated countries as EM. EM status is not defined solely by region, nor low credit rating, as many EMs are now investment grade.

Since the early 2000s emerging economies, which had previously depended on foreign currency external debt funding, started focusing on opening their local debt markets to foreign investors, as well. Many of these countries are heavily dependent on commodity exports, whereas others have extensive service and manufacturing sectors.

EM debt includes sovereign bonds and loans issued by governments, as well as fixed-income securities issued by public and private companies domiciled in EM countries. The assets could be denominated in any currency. Many of these countries had defaulted on commercial bank loans in the 1980s and began the 1990s by converting the defaulted loans to restructured sovereign foreign currency bonds, known as *Brady bonds*. While the early to middle 1990s might be thought of as the era when defaulted foreign currency loans were restructured into global bonds, the late 1990s onward will be thought of as the era when defaulted bonds were restructured into new bonds and local markets opened up to foreign investors.

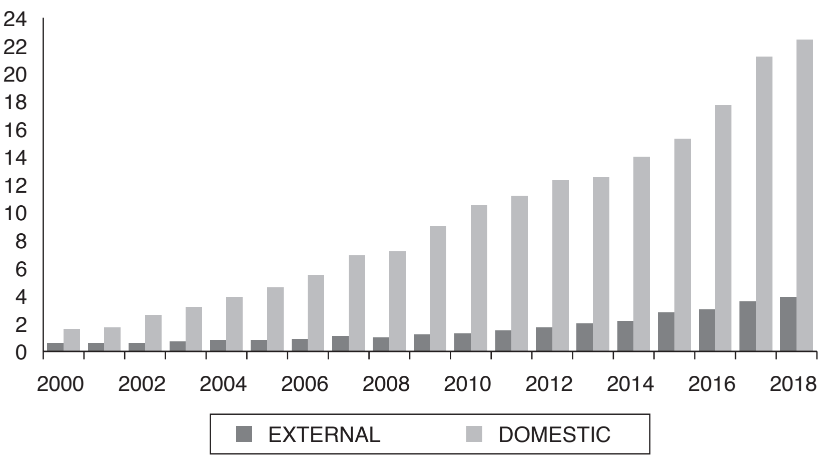
We discuss the market, the evolution of the asset class, the growth of local debt markets, the macro fundamentals that drive sovereign performance, debt sustainability considerations, the compensation provided by spreads, and the issues surrounding defaults, as well as provide a background on selected past defaults and restructurings. The asset class is distinct from the majority of developed market international investing because the largest and most liquid foreign currency bonds are primarily sovereigns bonds, and there is no bankruptcy court for sovereign external debt and countries can institute capital controls that affect all local debt.

THE DEBT UNIVERSE

EMs' tradable debt stock grew almost 1100%, or 15% per year, from 2000 to about US$26 trillion 20 years later. The vast majority of that growth has been in local debt and corporate debt. This is partly due to foreign investment inflows that helped EM countries grow their economies (Exhibit 17-1).

EXHIBIT 17-1

Growth in Domestic versus External Tradable Debt (US$ trillion)



Source: BofA Global Research, Constructed from data obtained from Bank for International Settlement.

Domestic versus External Debt

Domestic debt is issued locally and is governed by the local laws of the issuing country. Domestic debt is usually denominated in local currency and may also be called local debt or local debt markets (LDM).

External debt (EXD) is issued externally and is governed by the laws of a foreign country. It is denominated in foreign currency, primarily U.S. dollars and euros, and may be called foreign currency debt (FC).

Foreign investors initially focused only on *external* debt. The outstanding face value of external EM bonds is close to $3.9 trillion, of which US$2.7 trillion is corporate debt and US$1.2 trillion is sovereign debt. The vast majority of growth in external debt has been through issuance of corporate bonds or sovereign global and Eurobonds, terms that are often used interchangeably.[1] External corporate debt has been growing faster than external sovereign debt.

Domestic debt has become an increasing share of all debt, now over US$22 trillion, or 85% of the total EM tradable debt universe (Exhibit 17-2), up from US$2 trillion in 2000. The lower liquidity, frequent investment restrictions, varied practices, and higher convertibility risk make trading in domestic bonds more difficult for foreign investors than trading in external bonds. However, the potential for significant investment gains due to the decline in local interest rates from highly inflationary and high yielding periods, coupled with currency appreciation, was a driver for significant growth in assets invested in local markets.

Debt Stock by Region

Latin America originally dominated the external tradable debt universe, but with increased issuance in other regions, the breakdown of outstanding external debt has become fairly evenly distributed. Asia now represents 47% of total debt outstanding, with Latin America at 25%, Emerging Europe at 14%, and the Middle East and Africa at 14%. Tradable debt here excludes nontradable debt such as International Monetary Fund (IMF) loans but is not necessarily liquid debt. Tradable debt should not necessarily be considered debt qualifying for benchmark indices, which we describe below, because the latter has an additional requirement of access for foreigners, liquidity for valuation purposes, and other constraining criteria. The growth in debt has been primarily driven by higher issuance of domestic sovereign debt and external corporate bonds, mainly from China.

In local debt, Asia dominates with 78% of the tradable domestic debt, primarily driven by the debt of China and India. China alone has 56% of the domestic debt. Asia is followed by Latin America with 14% of the domestic debt. In the Asian markets, local debt is 90% of all debt in Asia, and in Latin America local debt is 77% of the total debt.

1. A Eurobond is a bond that is issued and sold to international investors and is not subject to registration. A global bond is a bond that is registered in the jurisdictions of the major financial centers.

EXTERNAL DEBT MARKETS

Both the stock of external debt outstanding per country and the number of issuing countries have grown since the early 1990s when countries began to issue foreign currency bonds (Exhibit 17-2).

Size of Market

External debt markets are now dominated by corporate bonds, but sovereign debt still dominates local markets. External debt issuance has been running at around US$600 billion annually, 25% sovereign and 75% corporate, provincial, and quasi-sovereign, compared with US$30 billion during the early 1990s. There is more than US$4 trillion of outstanding tradable external debt in 2020, versus US$1trillion in 2000. Corporate issuance has been increasing in general as corporate borrowers now enjoy wide access to the international capital markets.

Diversification of Issuers

The increase in the number of countries from which sovereign and corporate bonds have been issued has been beneficial to investors seeking diversification and whose investment performance is benchmarked against an index. The larger number of issuers has reduced the concentration of the largest countries in any of the major EM indices.

Major market indices of external debt include outstanding external sovereign debt with sufficient liquidity to provide daily pricing. External bonds have few trading restrictions and historically have been of great interest to the broadest range of foreign investors.

The number of EM countries which issue external debt has increased from 4 in 1991 to close to 80 by 2020. This is a result of large countries with foreign commercial bank loans converting those loans to bonds and smaller countries beginning to tap the external debt markets. The countries with the largest number of bonds in sovereign and corporates are in Exhibits 17-3 and 17-4.

Benchmark EM Sovereign and Corporate Indices

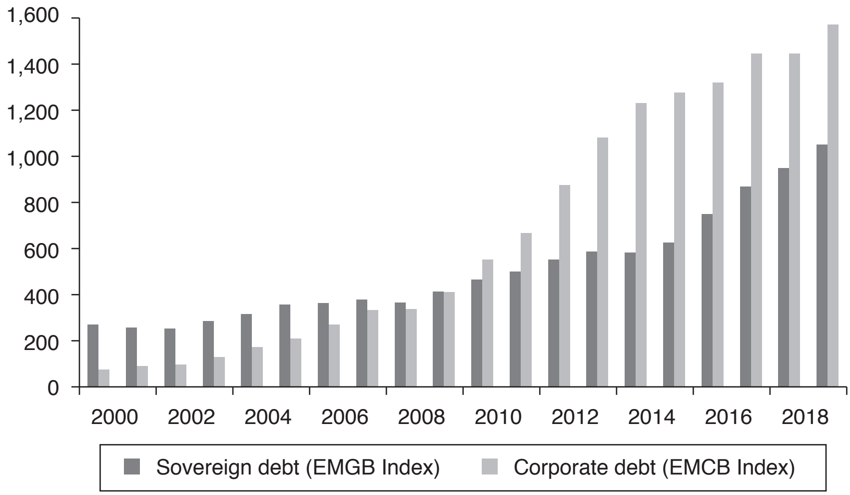
EM sovereign and corporate bonds totaling $2.5–$3 trillion are eligible for inclusion in EM indices. This is larger than the entire US$2.3 trillion market capitalization of the ICE BofA Global High Yield Index.

Sovereigns Are About 40%, Corporates 60% of EM External Debt Indices

The three most frequently used family of benchmark indices are the JPMorgan EMBI Global (EMBIG) index of sovereign and quasi-sovereigns, the Bloomberg Barclays EM Aggregate Index (EMUSTRUU) of USD sovereigns and corporates,

EXHIBIT 17-2

Growth of Sovereign and Corporate USD- and EUR-Denominated Bonds, Many Included in Benchmark Global Indices ($billion)



Source: BofA Global Research, Bloomberg, Constructed from data obtained from ICE Data indices, LLC.

and the ICE BofA EMs External Sovereign Index (EMGB) of EUR and USD bonds. Each of those indices have a sovereign market value near $1 trillion as of 2020. A majority of investors use modified indices that limit the size of the largest countries, so that a credit problem with one issuer does not have an excessively adverse impact on index or portfolio performance.

While there is no unique definition, most investors consider a company to be a "quasi-sovereign" if the government owns more than 50% of its equity. Often, such *quasis* are of such strategic government importance that investors expect them to have an implicit government guarantee, if needed. Quasi sectors are mainly in oil and gas, but also in metals and mining, utilities, and finance.

The JPM index includes USD sovereign and quasi sovereigns that are 100% owned by the government, such as Pemex. The ICE BofA index includes only sovereign issuers, not quasi sovereign, from countries that do not issue a G-10 currency. The ICE BofA index includes also EUR-denominated debt. The five largest countries comprise about 30% of the indices today compared to 98% of the index at inception in 1993.

Corporate Debt Growth

The EM corporate bond market is one of the fastest growing asset classes globally, at $1.6 trillion index eligible debt in 2020 from just $74 billion 20 years earlier. In each corporate index family, about two-thirds of the market capitalization is comprised of investment grade bonds.

EXHIBIT 17-3

Over the last three decades, Eastern European, African, Middle Eastern, and Asian markets have gained market share. Asia dominates the market capitalization, mainly from China's large issuance of quasi-sovereign bonds after 2010. This has left Latin America with only 26% of the market capitalization of external debt qualifying for index inclusion, compared to 98% at inception of the indices.

The most frequently used indices that include corporates are the USD JPMorgan CEMBI ($1.1 trillion), the Bloomberg Barclays EM Aggregate Index that includes USD-, EUR-, and GBP-denominated sovereign, quasi-sovereign, and corporate debt from EM issuers ($2.5 trillion LG20TRUU of which $2.2 trillion is in USD) and the ICE BofA Emerging Markets EM corporate index ($1.7 trillion, EMCB).

EM countries are home to Vale, the largest iron ore company; Codelco, the largest copper company; Bimbo, the largest baker; JBS, the largest meat packer; and Gazprom, the largest gas company, to name a few. The Mexican telecommunications company, America Movil, is one of the largest in the world. The Industrial and Commercial Bank of China is the largest bank in the world. Mexico's Pemex has issued some of the most actively traded bonds in the world, including among developed market corporate bonds.

At one time, rating agencies would not rate an EM corporate higher than the rating of its sovereign (this was termed a "sovereign ceiling"), expecting that in a crisis, a government could appropriate the foreign exchange of the corporate or prevent it from converting local currency into foreign currency. But that criterion has been relaxed. Although credit analysts at one time viewed corporate bond valuations primarily based on the sovereign, increasingly, analysts consider a company's global peer group when determining value, in addition to geographic location.

Credit Quality of EM Countries

EMs have improved in credit quality as an asset class. This is now a diverse asset class ranging from investment-grade credits to defaulted debt. The asset class was created from weak economies struggling to improve after the 1980s. Many countries have pursued macroeconomic policies that allow them to better weather external shocks and reduce their sensitivity to changes in capital flows, and their credit quality has improved as a result. During some periods, EM economies have even been the growth drivers of the global economy.

Despite the difficulties surrounding the 1997 Asian debt crisis and 1998 Russian default, there have been many more positive than negative ratings actions since then. Thus the percentage of investment-grade bonds in the major benchmark indices has risen from under 10% in the mid-1990s to close to 60–70% 25 years later. Credit quality also rose by three notches from BB–/Ba3 to BBB–/Baa3, when considering the rating of the index weighted by market capitalization.

LOCAL DEBT MARKETS

In the 1980s, country fundamentals across EMs were weak with twin fiscal and current account deficits, high inflation, large external debt stocks, currency crises, and in some cases institutional uncertainty. At that point, financing needs were normally covered by external debt, denominated in a G10 currency and governed by New York, London, or Tokyo laws. However, fundamentals started to change in the 1990s as countries implemented macroeconomic stabilization programs, adopted a more responsible fiscal stance, and moved away from fixed-exchange rate regimes toward floating ones. In several cases, monetary policy started to be managed using inflation targeting regimes.

This process led to a gradual improvement in economic fundamentals. Inflation declined and currencies became more stable. Under this new backdrop, investors gained confidence in buying debt denominated in local currency issued by countries and corporations in EM world. Most local debt was bought by local investors, but foreign investors have become an increasing share of holders of local debt. In some countries, foreigners now hold close to 50% of local government fixed-rate bonds.

Investing in local EM debt is similar to investing in any international foreign currency denominated bond; returns have two main sources: local yields and local currency returns. Because holders also incur currency risk, convertibility risk and other capital controls risks, local market bond yields are normally higher than those for external debt. In addition, local yields of EM countries have traditionally been more volatile than those of developed markets, consistent with higher volatility in inflation. That said, in the last two decades we saw a significant decline in local yields responding to better fundamentals, higher credibility, and/or to lower global yields.

Capital Controls

Capital control is a policy device that a government uses to regulate the foreign currency flows into and out of the country, usually used to restrict volatile movements of capital due to investor speculation. Controls on inflows typically respond to the macroeconomic implications of the increasing size and volatility of capital inflows, such as currency appreciation, loss of competitiveness, and credit booms. Controls on outflows are used to limit the downward pressure on their currencies and foreign reserves, a significant risk to a local bond investment.

The implementation of capital controls is a key risk for foreign investors holding, or planning to hold, local debt. Most EM countries have some form of capital controls that can be increased as needed. Even countries with free convertibility of their currencies could institute capital controls if deemed necessary. Capital controls normally can take the form of transaction taxes, transfer taxes, withholding taxes, reserve requirements, unremunerated reserve requirements, multiple exchange rate systems, and/or limitations in terms of the amount of assets to be held, caps on volume permitted, controls on the international sale or purchase of various financial assets, and sometimes even limits on the amount of money a private citizen is allowed to take out of the country. As the IMF discussed,[2] the most common experiences in using capital controls are capital controls to limit short-term inflows, capital outflow controls during financial crises, and extensive exchange controls during financial crises.

Convertibility Risk

Convertibility, or transfer, risk is the risk that a government will restrict the conversion of local currency into foreign currency or restrict the transfer of foreign currency out of the country. In other words, it is the risk that an investor will not be able to repatriate the cash flows of the investment, normally due to exchange restrictions imposed by a government. Drastic measures may occur during crises. Several such examples are:

- **Korea, 1997**: Daily currency move was limited to 5% and the FX market would shut down after that level was reached.
- **Russia, 1998**: Banks froze dollar withdrawals and the central bank terminated the fixing of the currency in the Moscow International Currency Exchange auctions.
- **Argentina, 2001 and 2019**: Authorities limited domestic residents' access to dollars and required exporters to sell dollar proceeds promptly after collection.
- **Venezuela, 2003:** Limited ability of locals and foreign companies to convert bolivars into U.S. dollars.
- **Brazil, 2008–2013**: The government adopted an IOF tax on foreign inflows for specific financial transactions, but the tax moved back to zero in 2013.

Investing in Local Debt Markets

As discussed above, investors can gain exposure to local currency returns by buying a local currency instrument in a particular market. To do so, an investor would have to send funds to the country, convert it into local currency, and then buy a local debt instrument. While this process appears simple, there are several nuances that need to be managed.

Countries have different regulations, laws, and limits for foreign investment, typically including the need to set up a local account, hire a local custodian, report activity to the local regulator, and pay taxes if applicable. Also, each country has its own requirements: some countries limit the amount and/or the type of

2. International Monetary Fund, "Capital Controls: Country Experiences with Their Use and Liberalization," Occasional Paper 190 (2000).

bonds that foreign investors can hold; others impose taxes on capital inflows, have minimum holding periods, or intervene heavily in the foreign exchange market, and so on. In some cases, local trading conventions differ from the international ones, adding an additional layer of caution when trading a local debt instrument.

Holders of Domestic Debt

Although foreign investors have significantly increased their percentage ownership of assets in emerging local debt markets, and in a few markets they hold close to 50% of the sovereign fixed-rate bonds, local investors are still the main holders of local debt.

Banks are a key player among local investors, but so are other local institutional investors (pension funds, mutual funds, and insurance companies). When risk aversion picks up globally, local institutional investors with a longer investing horizon have been able to step in to buy bonds, cushioning the price and yield movements.

Types of Local Bonds

Local bond types issued by EM countries are no different in nature than those issued by developed markets. While calculating conventions may differ, foreign investors normally have access to several debt instruments denominated in local currency. The most common instruments are fixed-rate bonds (coupon bonds), fixed-rate notes or bills (zero-coupon bonds sold at discount), inflation-linked bonds, floating bonds (linked to the reference interest rate or to a market rate close to the reference interest rate), and in some cases foreign exchange linked bonds (linked to a hard currency but payable in local currency) or fixed-rate local bonds with debt service payable in U.S. dollars at the then-prevailing foreign exchange rate.

THE FOREIGN INVESTOR BASE

The profile of the EMs' sovereign investor base has become more diverse due to the growth of EM debt and excess historical returns. Ownership was once concentrated in the hands of a few creditor banks and dealers, but now is distributed more widely through actively traded global and local bonds.

In the 1980s, EM debt was mostly in the form of U.S. dollar-denominated loans to EM governments from foreign commercial banks. Intermarket dealers traded participations in those loans. Originally, the principal nonbank investors were high-net-worth individuals from EM countries. They were the first to realize that these countries had begun to "turn the corner," and in the late 1980s began to repatriate their funds by buying distressed assets. This, in turn, triggered a steady recovery in asset values, which was further supported by the subsequent issuance of Brady bonds.

Rise in Credit Quality of the Asset Class Led to Changes in the Investor Base

In 1996, Poland became the first EM sovereign to achieve an investment-grade rating, but not the last, as currently 32% of EM sovereigns are investment grade. This opened the door for demand from high-grade investors for investment-grade EM bonds. Higher returns have played a key role as well, attracting more investors.

To reduce concentration risk, investors usually construct diverse portfolios with a diversified benchmark that caps representation of large countries. This approach lends confidence that an idiosyncratic shock by a single distressed country would not cause excessive deterioration in portfolio performance. Capping corrects for the risk that distressed countries often increase issuance and thus increase uncapped portfolio weight prior to default.

Low Global Yields Boosted Interest in Emerging Markets

As U.S. interest rates have remained low since the 2008 financial crisis, demand for EM assets continues to grow. The high returns on EM bonds increasingly attracted institutional investors. A broader range of insurance companies and pension funds, in search of higher yields and diversification, now invest in EMs. With relatively low financing costs and many newly formed hedge funds offering the potential of levered returns, the demand for assets continues to grow.

The investor base is broad, with a large percentage being dedicated EM managers of mutual funds, pension funds, insurance companies, and sovereign wealth funds. Other participants are hedge funds, including those with macro, credit, or distressed strategies. Finally, there are "crossover" investors from developed high-grade or high-yield bond markets who view EMs as an asset class to include in their portfolios. Notably, EMs are an increasing portion of the global bond funds, partly due to the opening of many local markets to foreigners.

EM DEBT PERFORMANCE

High yields, high returns, and high Sharpe ratios have made EM debt an appealing asset class. Exhibit 17-5 shows the EM sovereign spread widened less than U.S. high-yield spreads during severe market stresses from 2000 to 2020.

Historical Returns

EM external debt has produced one of the highest returns among major asset classes. Exhibit 17-6 shows the performance of the J.P. Morgan EMBI Global Diversified Composite Index (JPEIDIVR) since inception in December 1993.

For almost three decades, returns for the asset class have exceeded other major fixed-income markets, with a cumulative return of over 800%, far above the average cumulative returns of under 500% for U.S. high-yield bonds or

Morgan EMBI Global Diversified Composite Index, ICE Data indices, LLC.

around 300% for U.S. Treasuries over the same period. Over that period, EM debt has provided an 8.7% annualized return compared with 6.9% for the U.S. high-yield market. In comparison, cumulative returns of EM equities posted a 260% return, less than the approximately 1000% of U.S. equities.

EM sovereigns tend to issue long maturity foreign currency bonds, mainly 10 to 30 years, while EM corporates, especially lower quality corporates issue shorter bonds. Sovereign bonds thus have an average life of around 12 years, compared to an average life of 7 years for corporates. As a result, sovereign bonds have higher sensitivity to interest rates. Due to the downward trend in U.S. interest rates, the higher interest rate sensitivity has benefited holders of sovereign bonds, which have outperformed EM corporates and Global High Yield. However, if U.S. interest rates rise, the higher interest rate sensitivity would be a disadvantage.

A small part of the historical return of EM external sovereign debt is due to the lower Treasury yields. From inception of the indices in the early 1990s to 2020, U.S. Treasury rates declined by 500 basis points, or an average of 20 basis points per year. This accounts for about 1% of the historical annual return.[32] The remainder of the return can be attributed to the coupon income, price appreciation due to spread tightening, and the steady aging of low-priced bonds as they accrete to par. The end of this period came with Treasury yields reaching historical lows and EM spreads simultaneously touching historically tight levels, providing annualized returns that would be difficult to replicate over the next 25 years.

Volatility and Sharpe Ratios

Periodic crises in EMs have brought volatility along with high returns.

Over the past 10 years, while EM external debt has provided an annualized 7% return, it has come with a 6% annualized volatility (see Exhibits 17-7 and 17-8). Higher risk should come with a higher return. A risk-adjusted return measure, the Sharpe ratio, is used to compare equity investments. It is measured as the ratio of the return in excess of the risk-free rate divided by the volatility.

From 2010–2020, the Sharpe ratio in EM external debt has been higher than that of U.S. Treasuries, with higher annualized returns offsetting higher volatility (Exhibit 17-8). The S&P equity index had the highest Sharpe ratio in the past 10 years. From a Sharpe ratio perspective, EM external debt would have been a better investment than European or EM equity, as both had higher volatility and lower returns than that of EM external debt.

Correlation with Other Asset Classes

EM external debt returns are weakly correlated with the returns of U.S. Treasury bonds (0.27, see Exhibit 17-9). The correlations are higher with U.S. investment

3. A spread tightening of 20 basis points would increase the index value by 1.6%.

grade corporates (0.72), U.S. high yield corporates (0.69), EM Equities (0.67), and Global Governments (0.58). Low correlations can give EMs an important diversification role in a global portfolio.

EM local debt is equally highly correlated with EM equity as with EM external debt because both local debt and local equity returns have a currency component and local and external debt is increasing managed together by a similar investor base.

Liquidity

Many investment-grade and high-yield bond portfolios include some EM debt, and thus high-yield managers represent an important source of "crossover" investors. Crossover investors include EM debt because these bonds may be included in their global credit or bond indices. In addition, valuations can be better at times than in developed market debt and liquidity can be better.

Compared to EM Corporates and U.S. high-yield indices, average EM sovereign issues are twice as large, making sovereign pricing more transparent and bid-ask spreads narrower. Thus, EM debt plays a key role in high-yield portfolios by offering greater liquidity when needed.

Some EM corporate bonds are as liquid as most U.S. corporate bonds. Over 419 corporate issues in the ICE Emerging Market Corporate indices have outstanding face value of at least US$1 billion, in addition to 531 sovereign issues in the sovereign index. This is more than the 402 bonds in the ICE BofA Global High Yield Index that are over US$1 billion.

Average trading volume of EM debt recorded by the Emerging Markets Traders Association is usually about US$15 billion per day, of which $10 billion is local debt. These volumes can decline by 20–40% following market crises or periods of low risk appetite. Corporate bonds have smaller issue sizes and trade about 30% less frequently than sovereigns, despite the larger stock of corporate bonds compared to external sovereign bonds.

EM Fundamentals That Contribute to Returns

EM debt investors monitor economic indicators to allocate their investments across countries and such reallocations can affect relative spreads. Many of the indicators are important for analyzing debt sustainability (a concept described in the next section).

Important economic indicators include: real gross domestic product (GDP) growth, consumer price index (CPI) inflation, current account/GDP, fiscal balance/GDP, public debt/GDP, net external position/GDP, foreign exchange (FX) reserves/short-term external debt, current account balance/GDP, net foreign direct investment/GDP, private credit/GDP, bank loans/deposits, nonperforming loans as a percentage of bank portfolios, and external debt/exports of goods and services.

Political and institutional stability is always taken into account as well. Many investors increasingly look at Environmental, Social, and Governance (ESG) indicators to complement their economic analysis.

SOVEREIGN DEBT SUSTAINABILITY

Sovereign spreads are closely linked to investor's perception about a country's probability of default and the sustainability of its debt. There are many dimensions to understanding a country's debt sustainability. We focus on three steps: (1) debt dynamics, (2) debt structure, and (3) gross financing needs.

Step 1: Debt Dynamics

The first step to understanding debt sustainability is calculating how a country's debt-to-GDP ratio will change over time. Investors monitor the debt-to-GDP ratio, instead of the nominal stock of debt, because a country's capacity to service its debt is proportional to the size of its economy (tax revenue is proportional to nominal GDP).

Fiscal policy and automatic debt dynamics: Contributions to changes in the debt-to-GDP ratio can be grouped into two categories: (1) fiscal policy and (2) automatic debt dynamics.

- **Fiscal policy:** Contribution from the current year's fiscal primary balance (revenues minus non-interest expenses)
- **Automatic debt dynamics:** Contributions of macroeconomic variables (growth, interest rates, inflation, currency fluctuation) and pre-existing debt-to-GDP ratio

Fiscal policy is not set in a vacuum from the variables that contribute to automatic debt dynamics. Tax revenues are impacted by growth and many EM governments receive significant revenues from commodity exports, such as oil and metals. In addition, many expenses are mandated by laws or constitutional rights, limiting the government's discretion to reduce spending.

Debt-stabilizing primary balance: The debt-stabilizing primary balance is the fiscal primary balance that the government needs to maintain so that its debt-to-GDP ratio remains unchanged from one year to the next. If a country's fiscal primary balance is lower (higher) than the debt-stabilizing primary balance, then debt-to-GDP will rise (fall) from one year to the next.

Note that the debt-stabilizing primary balance may be a surplus or a deficit, depending on the country's macroeconomic variables. The debt-stabilizing primary balance will typically be a surplus if growth is lower than real interest rates. The debt-stabilizing primary balance will typically be a deficit if growth is higher than real interest rates.

The debt-stabilizing primary balance is an important concept for debt sustainability because political constraints limit the feasibility of fiscal adjustments within a short period of time. If a country is far away from its debt-stabilizing primary balance and fiscal policy is adjusted only gradually, then the country's debt ratio may continue to rise for several years.

How economic variables affect a country's debt-to-GDP ratio: The year-over-year change in a country's debt-to-GDP ratio is affected by the following variables:

- **Fiscal primary balance** (revenues minus noninterest expenses): A fiscal primary *deficit* will *increase* the country's debt-to-GDP ratio and a primary fiscal *surplus* will *reduce* the country's debt-to-GDP ratio.
- **Growth**: Higher real growth will *lower* the country's debt-to-GDP ratio, since it will increase the denominator of the debt-to-GDP ratio.
- **Debt-to-GDP ratio in prior year:** Higher pre-existing debt-to-GDP ratio will *increase* the debt-to-GDP ratio by increasing the interest payments due on the pre-existing stock of debt.
- **Interest rates:** Higher effective interest rates will *increase* the debt-to-GDP ratio by increasing interest payments.
- **Inflation:** Higher inflation will *decrease* the debt-to-GDP ratio by reducing the real cost of interest service and increasing the nominal size of GDP (however, note that higher inflation is not a panacea because inflation can increase the interest rate demanded by investors and can also lead to currency depreciation).
- **Exchange rate:** A depreciation of the domestic currency will *increase* the debt-to-GDP ratio by increasing the local currency value of the foreign currency debt.
- **Proportion of foreign currency debt:** A higher proportion of debt denominated in foreign currency increases the sensitivity of the debt-to-GDP ratio to exchange rate fluctuations.

Calculating the change in debt-to-GDP ratio: The intuition behind the formula for calculating the change in the debt ratio is the following: the debt-to-GDP ratio increases (decreases) by the primary deficit (surplus) plus the contribution of the automatic debt dynamics due to growth, the pre-existing debt stock, inflation, interest rates, and currency depreciation.

The change in a country's debt-to-GDP ratio can be calculated as follows:

$$D_t - D_{t-1} = -pb + \left[\frac{i - \pi(1+g) - g + \alpha e\left(1+i^f\right)}{1+g+\pi+g\pi} * D_{t-1} \right] \tag{17-1}$$

where D_t is the current year's debt-to-GDP ratio, D_{t-1} is the prior year's debt-to-GDP ratio, pb is the fiscal primary balance (revenues minus non-interest expenses), g is the real GDP growth rate, i is the nominal effective interest rate (weighted average of domestic and foreign nominal interest rates), i^f is the nominal interest rate on foreign currency debt, π is the inflation rate (growth rate of GDP deflator), α is the proportion of debt denominated in foreign currency in year $t-1$, and e is the nominal exchange rate depreciation (percentage increase in local currency value of one U.S. dollar). Unless noted otherwise, variables refer to their values in year t.

Calculating the debt-stabilizing primary balance: The debt-stabilizing primary balance (pb^*) can be calculated by setting the change in the debt-to-GDP ratio ($D_t - D_{t-1}$) equal to zero and then re-arranging as in the following equation:

$$pb^* = \left[\frac{i - \pi(1+g) - g + \alpha e(1+i^f)}{1+g+\pi+g\pi} * D_{t-1} \right] \tag{17-2}$$

Note that the debt-stabilizing primary balance is reached when the government's primary fiscal balance exactly offsets the contributions from automatic debt dynamics.

Step 2: Debt Structure

In addition to a country's debt-to-GDP ratio, characteristics of a country's debt structure may also expose the country to higher or lower vulnerability to macroeconomic shocks.

Currency denomination: Countries with large shares of debt denominated in foreign currency are more vulnerable to an increase in the debt-to-GDP ratio due to a depreciation of domestic currency. Sharp currency depreciations usually accompany EM crises and can make the country's foreign currency debt unaffordable.

Fixed vs. floating rates: A country's effective interest rate is more sensitive to fluctuations in interest rates if the country has a high proportion of floating-rate debt. Fixed-rate debt protects the country from spikes in interest rates (historically, EM central banks have hiked interest rates during crises to protect against a currency depreciation). On the other hand, fixed-rate debt reduces the transmission of declining interest rates.

Maturity profile: Debt with a short maturity profile is more vulnerable to a decline in refinancing rates because a short maturity profile means that a larger proportion of debt is coming due each year. To reduce this vulnerability, many countries perform liability management operations where they buy back short-term debt prior to maturity (this is typically financed by simultaneously issuing long-term debt).

Ownership: If debt is primarily owned by a captive group of investors, then it may be less vulnerable to a decline in refinancing rates during a crisis. Generally, domestic institutional investors are more captive than foreign investors, since the former often need to own government securities to meet regulatory requirements and domestic investors often have a home bias.

Governing law: It is generally easier for a country to restructure its debt if the debt is governed by domestic law rather than foreign law, such as New York or English law. Restructurings typically result in significant losses for bondholders.

Step 3: Gross Financing Needs

GFN = Primary Deficit + Debt Service: Gross financing needs (GFNs) refers to the debt that a country needs to issue to cover its fiscal primary deficit and to cover its debt service (interest expense plus principal amortizations), as follows:

$$\text{Gross Financing Needs} = \begin{array}{l}\text{Fiscal Primary Deficit + Debt Service} \\ \text{(Interest and Amortizations)}\end{array} \tag{17-3}$$

Gross financing needs are typically expressed as a percentage of GDP and are often distinguished between domestic currency needs and foreign currency needs. Note that if the country has a fiscal primary surplus, then the gross financing needs are reduced by the surplus.

Gross financing needs are subject to two important risks:

- **Interest rate risk:** Risk that investors demand higher interest rates to purchase new debt. Higher interest rates could make a debt stock that was affordable with lower interest rates no longer affordable.
- **Rollover risk:** Risk that investors fail to purchase new debt to refinance maturing debt. If refinancing rates drop significantly, a country is said to have lost market access.

Refinancing rates decline when investors fear default: Investors often reduce their purchases of sovereign debt when they believe that a sovereign can no longer afford to pay the coupons and principal on its debt. When refinancing rates decline and a country loses access to debt markets, countries must cover debt service by drawing down on assets, such as savings or international reserves, or by printing money that can push up inflation. Loss of market access is often accompanied by capital flight by both residents and nonresidents, leading to currency depreciation and depletion of international reserves. Countries may impose capital controls to preserve their international reserves, but the controls may not be sufficient.

Depletion of assets can trigger default: If investor confidence is not restored, the depletion of assets due to loss of market access can force a country to stop paying its debts, leading to a moratorium and an eventual debt restructuring. For this reason, external debt investors monitor closely the country's stock of international reserves and exchange rate developments.

High GFNs increase vulnerability to investor sentiment: Countries with high gross financing needs are therefore more vulnerable to changes in investor sentiment that could lead to higher interest rates or lower refinancing rates. Lack of appetite for debt issuance can force a country to enact fiscal austerity to reduce its fiscal deficit (reducing financing needs) or may lead to a debt crisis if it cannot find resources, like an International Monetary Fund (IMF) loan, to refinance maturing debt.

Domestic ownership of debt can mitigate risks of high GFNs: It may be easier for countries with a deeper pool of domestic institutional investors to sustain higher gross financing needs. Otherwise, countries must rely on foreign investors to fill their financing gaps. Foreign investors are usually more sensitive to changes in global liquidity conditions and may reduce rollover rates during periods of global uncertainty.

Example: Comparing Debt Sustainability

In Exhibit 17-10, we compare the debt-stabilizing primary balances of three hypothetical countries (Country A, Country B, and Country C), calculated with the formula presented earlier. To simplify the comparison, all countries have the same growth rate, inflation rate, and have no foreign currency debt.

EXHIBIT 17-10

Example of Debt Sustainability Comparison

	Country A	Country B	Country C
Debt/GDP Ratio, t-1	80%	40%	80%
Effective Interest Rate, Nominal	7.0%	9.0%	9.0%
Growth Rate, Real	3.0%	3.0%	3.0%
Inflation Rate	2.0%	2.0%	2.0%
Share of Foreign Currency Debt	0.0%	0.0%	0.0%
Debt-Stabilizing Primary Balance (pb*), % of GDP	**1.5%**	**1.5%**	**3.0%**

Source: BofA Global Research.

Countries A & B: Different debt ratios, same debt-stabilizing primary balances: Note that both Country A and Country B have the same debt-stabilizing primary balance of 1.5% of GDP. Country A has twice the debt ratio (80%) as Country B (40%). However, Country A's interest rate is 2pp lower (7% for Country A and 9% for Country B). As a result, Country A needs to run a 1.5% primary surplus to keep its debt ratio unchanged at 80%. Country B needs to run the same 1.5% primary surplus to keep its debt ratio unchanged at the lower rate of 40%.

Country A probably more vulnerable to shocks than Country B: Although both Country A and Country B need to keep their fiscal balances at the same level to stabilize their debt ratios, Country A is probably more vulnerable to a debt crisis than Country B due to Country A's higher debt ratio. A high debt ratio usually implies high gross financing needs, subjecting Country A to higher interest rate risks and rollover risks. Policymakers cannot control the interest rates demanded by investors to refinance debt nor can they control the demand for new debt issuance. A spike in interest rates could make Country A's debt service less affordable, as illustrated with Country C.

Country C shows how higher interest rates can make debt unaffordable: Country C illustrates the risks that higher interest rates could make debt unaffordable. Country C combines Country A's 80% debt ratio with Country B's 9% interest rate. Country C's debt-stabilizing primary balance is 3% of GDP, twice as large as the 1.5% debt-stabilizing primary balances of Countries A and B. It is therefore much harder for Country C to stabilize its already high debt ratio than it is for Country A or B. The pace at which a country's effective interest rates could increase depends on the country's debt structure (fixed vs. floating rates and maturity profile) and gross financing needs.

WHAT DO EM SPREADS COMPENSATE FOR?

Probability of Default and Risk Premium

Sovereign external debt investors require compensation for both default and nondefault risks. Despite the focus that sovereign investors place on debt sustainability, it is likely that a large proportion of the sovereign spread can be attributed to risk premiums that compensate for uncertainty, price volatility, liquidity, and correlations with risky assets, among others. The risks that sovereign external debt investors face include:

Default: Risk that interest and principal payments are not made on full and on time. After defaults, sovereigns typically restructure and extend maturities, reduce coupon rates, or reduce principal amounts. These modifications often result in significant losses for bondholders. The historical rate of default over five years for foreign-currency, foreign law bonds are low for investment-grade countries (around 2%), but higher for high-yield countries (5% for BB-rated countries and 12% for B-rated countries).

Uncertainty in assessment of creditworthiness: To evaluate creditworthiness, investors must make assumptions about fiscal policy and macroeconomic variables in the long term. All of these assumptions are subject to uncertainty, particularly in countries where polices can change dramatically after elections. In addition, although credit ratings signal potential risk, rating agencies are often slow to adjust their assessments, particularly when fundamentals are deteriorating quickly.

Price volatility risk: Spreads widen during periods of risk aversion as investors re-price bonds lower to protect themselves against larger-than-typical price adjustments. Higher volatility regimes can persist, and it is difficult for investors to predict how long the higher volatility will last.

Liquidity risk: Risk that bid-offer spreads will widen during periods of uncertainty and risk aversion, increasing transaction costs.

Correlations with selloffs in other risky assets: EM assets tend to perform poorly when global risk aversion increases. When global liquidity conditions are loose and risky assets are favored by investors, EM spreads tend to compress slowly while investors search for yield and accept lower risk premiums. But when global conditions deteriorate, EM spreads can widen quickly, especially for lower-rated countries.

Weak Link Between Asset Class Spreads and Defaults

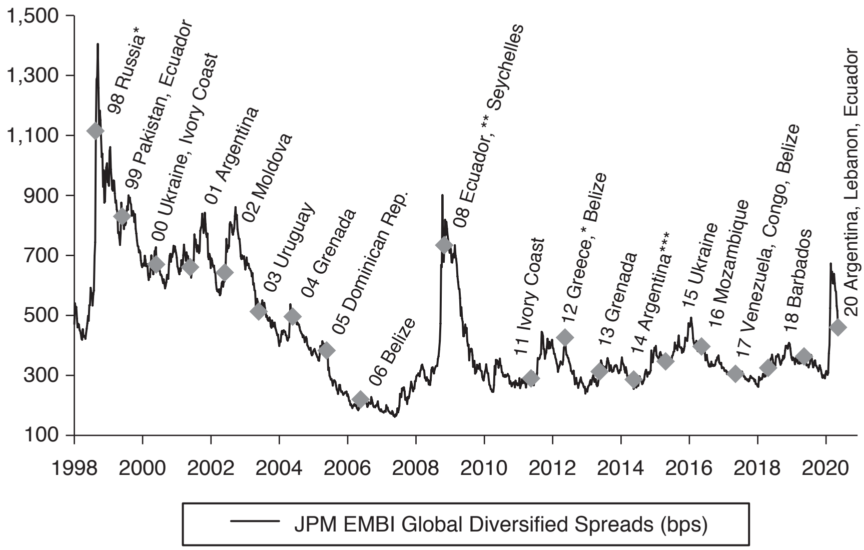
Wider spreads for the asset class have not been strongly linked to higher default rates since 2000 (Exhibit 17-11). Default frequency has not increased during periods of higher overall EM spreads and defaults have still occurred while EM spreads were compressing.

Sovereign defaults by large countries on foreign currency bonds issued under foreign law are historically rare. On the other hand, defaults by small economies, particularly island nations, have been more common. But losses from defaults by small countries are typically immaterial for diversified foreign investors, given the small weights of such countries in typical portfolios.

Over the past 20 years, defaults on foreign currency, foreign law bonds by large issuers were limited to just two countries: Argentina (2001, 2014, and 2020) and Venezuela (2017). And though prominent, defaults by Russia and Greece were actually primarily against domestic law bonds.

EXHIBIT 17-11

Sovereign Defaults on Foreign Currency, Foreign Law Bonds Through Three Financial Crises—Not Concentrated in One Point of a Credit Cycle



Source: BofA Global Research, Constructed from data obtained from Bloomberg, Moody's.

Note: *Denotes default that is primarily on domestic law bonds and included in the exhibit for context. **Default due to unwillingness to pay, rather than inability to pay. ***Technical default related to court decision.

Remarkably, the 2008 financial crisis did not unleash a wave of defaults. That year, Ecuador selectively defaulted on its foreign bonds, but this default resulted from an unwillingness rather than inability to pay. Several sovereign defaults occurred in 2020 in the context of the COVID-19 pandemic, including Lebanon, Ecuador, and Argentina. However, those economies entered the pandemic with pre-existing vulnerabilities.

At the same time, a longer time horizon would show evidence of clustering of defaults, such as during the mid-1980s. However, during that time external debt was primarily contracted via bank loans rather than bonds. Moreover, the 1980s are less comparable to today due to structural shifts in EMs. These shifts include flexible exchange rates and inflation targeting, accumulation of foreign reserves, and reduced reliance on foreign currency financing.

Wider asset class spreads: Higher risk premiums that can accelerate crises: During periods of higher-risk aversion, the spreads of all countries typically widen. The spread widening is typically proportional to the perceived strength of the country's fundamentals (countries with weaker fundamentals widen more).

For countries with stronger fundamentals, it is probable that wider spreads primarily reflect larger risk premiums, rather than a higher probability of default. Investors can usually expect risk premiums to recede once the period of heightened risk aversion ends and volatility subsides.

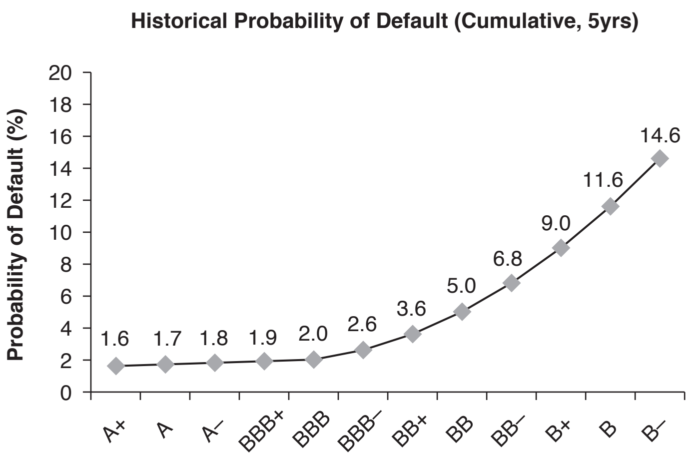
For countries with weaker fundamentals, higher spreads due to global risk aversion could hasten the onset of a crisis. Higher interest rates increase interest expense and can lead to a self-fulfilling bad equilibrium. Persistently higher interest rates increase the risk of default, which increases the interest rate demanded by investors, which in turn increases the risk of default, and so on. Without a circuit breaker, this cycle can lead to a debt crisis.

Historical probabilities of default by rating: Exhibit 17-12 shows the historical rate of default on foreign currency debt by rating published by rating agencies. The historical probability of default over five years is around 2% for BBB-rated countries and similar for countries with higher ratings. In contrast, the probability of default for high-yield countries increases significantly as credit quality declines, reaching 5% for BB-rated countries and 12% for B-rated countries.

Though these historical estimates are useful benchmarks, they should be treated with caution. In contrast to the large sample size of corporate defaults, sovereign default rates are based on a small sample of sovereigns, very few of which have defaulted.

EXHIBIT 17-12

Historical Probability of Default on Foreign Currency Debt—Only 2% for BBB-Rated Countries, but Rises Significantly for High-Yield Countries



Source: BofA Global Research, Constructed from data obtained from Moody's, S&P, Fitch. Note: Probabilities of default are averaged by rating bucket (A/BBB/BB/B), as published by Moody's (1983-2019), Fitch (1995-2019), and S&P (1975-2019). For intermediate rating notches, a linear trend is used to interpolate ratings above BBB and a quadratic trend is used to interpolate ratings below BBB.

Compensation for default risk: Exhibit 17-13 shows the five-year spreads required to compensate for the historical probability of default given a country's rating. For investment-grade countries, five-year spreads of about 25–40 bps would be required to compensate for the historical probability of default. For high-yield sovereigns, downgrades imply large increases in the spread required to compensate for the incremental risk of historical default. For example, a downgrade from BB to B would increase the required spread from about 80 bps to 185 bps.

Exhibit 17-14 compares the sovereign CDS spread (as of June 2020) against the spread required to compensate for the historical probability of default. The difference between the CDS spread and the spread required to compensate for the historical risk of default likely reflects risk premiums for nondefault risks (the gap may also reflect different assessments about the relative creditworthiness of countries or the future probability of default). Note that the gap is smaller for investment-grade countries and wider for lower-rated countries such as Brazil, South Africa, and Turkey.

SOVEREIGN RESTRUCTURINGS

The goal of a debt restructuring is to provide the sovereign with some debt service relief, particularly in short-term, so that the sovereign can eventually regain market access. This can be done by lowering the coupon rates, extending maturities, reducing the face value of existing debt, or some combination of the three measures.

If the debt exchange sufficiently lowers the country's debt burden, then spreads could tighten to reflect a lower probability of default on the new cash flows, supporting post-restructuring bond prices. This should in turn create a positive feedback loop supporting bond prices. An orderly pre-default exchange would be in the interest of investors, the issuing country, and third parties such as the International Monetary Fund (IMF). Outright defaults can result in a deepening of the financial crisis that can reduce the payment capacity of the country.

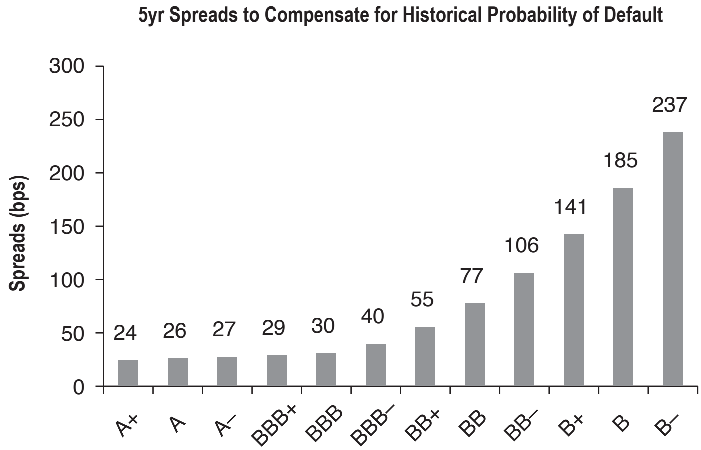
There have been successful pre-default voluntary exchanges in EMs. Addressing "holdout" investors has become an increasingly difficult issue. Holdouts are funds that buy distressed debt at a low price, decline to participate in a debt exchange, and then litigate to collect par for the defaulted assets. In this section, we discuss the role of third-party support, New York law documentation, and collective action clauses (CACs) intended to mitigate the problem of holdouts in sovereign debt restructurings. We follow with details of some exchanges that took place in the past as guides for future exchanges, both inside and outside of EM debt.

Third-Party Support, the Role of the IMF

The Western nations established the International Monetary Fund (IMF) and the World Bank after World War II as "permanent machinery" to anchor the Bretton Woods system. When developing countries began experiencing debt problems in

EXHIBIT 17-13

Spread of Only 30 bps Needed to Compensate for Historical Probability of Default of BBB-Rated Countries



Source: BofA Global Research. Note: Required spread calculated with simplified formula: Spread = [-(1-RR)/T]*[ln(1-PD)], where RR=Recovery Rate (in percent) and PD=Probability of Default (in percent). Calculation uses 25% Recovery Rate.

EXHIBIT 17-14

Difference Between CDS Spread and Spread Required to Compensate for Historical Probability of Default Likely Reflects Risk Premium for Nondefault Risks

CN=China, CL=Chile, SA=Saudi Arabia, MY=Malaysia, PE=Peru, PA=Panama, PH=Philippines, ID=Indonesia, MX=Mexico, RU=Russia, CO=Colombia, ZA=South Africa, BR=Brazil, TR=Turkey, CDS spreads as of June 2020 the late 1960s, the Paris Club was formed to restructure debt from export credit agencies. A decade later, the London Club was formed to deal with workouts of foreign commercial bank debt. When countries had a significant amount of outstanding bonds rather than loans in the 1990s, restructuring defaulted debt required a new process.

The IMF and the U.S. Treasury have played significant roles in proposing a permanent mechanism to deal with defaulted debt. More recently, however, the IMF also started to play a key role in providing funding for developed economies.

In past programs, the IMF would typically lend enough money for the sovereign to service its debt, so long as it stuck to a plan, including extensive supervision and review by the IMF. Some distressed countries have presented greater challenges when foreign reserves declined rapidly or when a sovereign could not, or would not, print money to cover local debt service (Argentina pegged to USD, Russia chose to default).

Historically, the condition for receiving IMF support is that a sovereign must not only adhere to IMF targets for inflation, fiscal deficits, and exchange rate controls, but also that the sovereign must repay the IMF loan in full. There has never been IMF debt forgiveness, except in the case of some Highly Indebted Poor Countries (HIPC), an initiative launched in 1996 by the IMF and World Bank, with the aim of ensuring that no poor country faces a debt burden that it cannot manage. Thirty-two countries, mostly in Africa, benefited with full debt relief. More recently, the IMF created the flexible credit line (FCL) with less conditionality but for countries with stronger fundamentals. Although IMF debt is not typically forgiven, maturing payments can sometimes be refinanced with new loans.

Distressed Debt International Litigation

There is no bankruptcy court for sovereign defaults, like exists for corporate defaults. Therefore, the outcome of most of sovereign defaults is either the resumption of payments or, in most cases, a distressed debt exchange.

No bankruptcy court: The absence of a formal bankruptcy process clouds sovereign debt restructuring. There is a debate on reforming the international financial system, with a primary focus on the need for a sovereign debt restructuring process that would limit the risk that litigation could disrupt or delay a debt restructuring. Yet in many cases, progress is impeded by interference from "holdout" investors.

Holdout investors do not participate in the restructuring but will demand payment on the original contractual agreement or negotiate a preferred settlement for themselves through litigation. Typically, these investors are distressed debt funds that have large enough positions and the means to engage attorneys to sue the sovereign and then to attach assets. Furthermore, no restructuring would be possible if too many creditors did not participate.

So, there is a need to make the sovereign debt restructuring process swift and orderly, reducing the holdout risk. Without a process in place, there is a fear that concerned investors would be inclined to sell their bonds before the event of default, thus actually speeding the decline and preventing the sovereign from constructing a solution.

Sovereign immunity: Investors have won judgments against sovereign issuers in default. However, in contrast to corporate defaults, it is very difficult to attach the assets of a sovereign. There is a more favorable legal climate for attaching assets in Continental European law than in Britain and the United States. In Continental Europe, successful litigators attached the assets of the central bank of the sovereign whose claims they were holding.[4] In addition, central banks that are incorporated separately for commercial purposes do not have immunity; only the sovereign does.

The Foreign Sovereign Immunities Act of 1976 precludes a waiver of immunity of prejudgment attachment of the accounts of a foreign central bank. Since then, a number of common law countries have adopted similar legislation on sovereign immunity. During one litigation case, Deutsche Bundesbank considered amending the law (via Parliament) on the non-immunity provided to a sovereign whose assets were deposited with a German bank.[5]

These laws have an impact on non-participants in distressed exchanges. Another avenue open to non-participants involves wire transfers. In the United States, an attachment order can only reach a wire transfer either before it is initiated or after payment is made complete. However, Europe does not have an equivalent law. A distressed investor is able to intercept payments from a sovereign on restructured debt to bondholders in Europe.[6]

Changing the provisions of a bond: To deal with the holdout problem and encourage maximum participation in an exchange, all contractual proposals seek to change the restructuring process by changing the provisions found in sovereign debt contracts, allowing a supermajority to vote on restructuring terms.

New York law documentation: A standard New York law contract on pre-2003 bonds requires the unanimous consent of all creditors to change "key financial terms" (such as payment dates and amounts). Typically, all other terms can be amended with the support of one-half or two-thirds of the outstanding bondholders. Some New York law bonds also require that 25% of the bondholders agree before litigation can be initiated.

4. Cardinal vs. Yemen and Leucadia vs. Nicaragua.
5. Cardinal vs. Yemen.
6. Elliot vs. Peru.

English law documentation: A standard English law contract allows a supermajority of bondholders (typically 75%) present at a meeting that meets quorum requirements to amend all of the bond's terms, including the bond's payment dates and amounts. Many English law bonds also have provisions that make it difficult for an individual bondholder to initiate litigation.

Collective action clauses: A collective action clause (CAC) defines how many bondholders are needed to agree on a change in the repayment terms of a bond, in order to effect the change and make it applicable for all bondholders. The CACs were introduced to deal with rogue creditors. CACs have long been present in bonds sold under UK law. Under New York law, these clauses began to be included in many bonds since Mexico introduced it in 2003.

With CACs, the bond terms specify lower percentages required to change both financial and nonfinancial terms of the bonds. The typical structure allows 75–85% of bondholders to amend a bond's financial terms, as long as no more than 10% of the bondholders object. Financial terms could include payment dates and amounts. The remaining nonfinancial terms might be amended only with the support of 66% of the bondholders. Also, certain provisions that relate to the ability of creditors to sue to collect on their bonds previously cannot be amended at all.[7]

Initially, these collective action clauses applied to each bond series individually, reducing the likelihood of holdouts getting better terms on a specific bond. However, these single series CACs were thought to be insufficient to prevent a small number of bondholders from purchasing enough bonds to reach a voting block that could obstruct the whole-debt restructuring process in one or more bond series.

In 2014, most sovereign bonds were also issued with additional aggregated CACs, which allow bondholders to vote on a restructuring or re-profiling proposal applied to multiple series of notes (in aggregate), provided that they all contain the necessary contractual provisions. For example, they may require a 66⅔% threshold for each individual series plus an 85% threshold in aggregate for several series, versus an individual 75% threshold under series-by-series CACs. Nevertheless, creditors may still obtain a blocking position with respect to a particular series.

Because these CACs have evolved over time to offer greater issuer protection from creditors, prices of specific distressed sovereign bonds tend to be higher when the voting thresholds are lower.

7. Issuers use only a few jurisdictions for international bond issuance. New York is the largest jurisdiction by far, followed by England and Germany. German law bonds traditionally have also lacked clauses, but German law is being used less in new issuance following the introduction of the euro.

Successful Debt Exchanges

Since 2000, several exchanges were successful, which we define as one in which the exchange offer is made, at the latest, before the end of the debt service payment grace period, there is high creditor participation, and one in which the issuer does not default during the following five years.

Any exchange in an EM can set a precedent for future exchanges. This includes distressed debt, prior to and averting a default, as well as defaulted debt exchanges. Issuers in distressed global bond restructurings tend to expect that bondholders should get the same or less favorable treatment than the restructurings before it. Bondholders, on the other hand, tend to look back at the exchanges with modest haircuts and where bond prices then rallied, exemplified in the 2003 Uruguay exchange and the 2015 Ukraine exchange, viewing those as ideal restructurings for the next exchange, because it would be most beneficial to them.

Successful distressed debt exchanges: We highlight some aspects of the US$4.9 billion 2003 Uruguay exchange, because it was relatively large at the time and included several important features that could be considered in the future global debt restructuring discussions.

Successful exchanges have several commonalities. The most important is that every communication, from the economic statistics to the political speeches, shows that the sovereign is nearing default. Regardless of any IMF or other support, investors would understand that this issuer is highly likely to default without the exchange. This is clear when the issuer misses a coupon payment and pays during the grace period or offers an exchange during the grace period. It is also clear when officials stop short of declaring a moratorium but announce that they expect to miss the next debt service payment.

With that as a backdrop, the second commonality is that prices need to collapse, as investors realize that the only choices are restructuring or default. If bond prices remain in the US$80–90 range, the issuer has not communicated that there will be no more payments without a reduction in debt service.

There also needs to be some subtle coercion in the exchange offer, so that bondholders that do not participate in the exchange are not paid in full while other bondholders accept a haircut or write-off. This holdout issue has been addressed through collective action clauses, by conditioning the exchange on some minimum participation threshold with the perception that insufficient participation would result in a default, and through exit consents.

Exit consents are created when holders accept new bonds in the exchange, but in the process provide their consent to amend the nonpayment terms of the old bond. Exit consents can destroy value by impairing the liquidity and litigation prospects as they change such features as cross-default, listing, and acceleration clauses. Typically, these changes can be undertaken without a unanimous vote from bondholders.

Recovery values: Recovery values have been diverse, each credit with its own features at default. There are two values that are both referred to as "recovery values." One is the settlement price in a credit default swap (CDS) auction, which indicates the price of the cheapest bond around 30 days after default. The other is the eventual value of the original debt after an exchange has taken place.

Following the eight large EM defaults since 2008, that had outstanding CDS swap contracts, almost all prices were in the \$20–\$40 range (Exhibit 17-15). Moody's also provides a list of foreign currency and local currency defaults and distressed debt exchanges with recovery rates around 30 days after default, including defaults, missed payments and distressed exchanges (Exhibit 17-16).

EXHIBIT 17-15

Credit Default Swap Auction Prices, Typically Taking Place About 30 Days After Default

Date	Country	Bonds Avg Price
Jan-08	Ecuador	31.375
Mar-12	Greece	21.500
Sep-14	Argentina	39.500
Oct-15	Ukraine	80.625
Dec-17	Venezuela	24.500
Apr-20	Lebanon	14.125
May-20	Ecuador	34.875
Jun-20	Argentina	31.500

Source: BofA Global Research

Note: First CDS auction was Ecuador in 2008

Uruguay, 2003—orderly exchange, avoided default: Uruguay was among the first large market-friendly distressed sovereign debt restructurings, seen as beneficial for both issuer and investors. It serves as a model for other countries. Over 95% of the \$4.9 billion eligible bonds were exchanged for new securities that matured later and paid lower interest, stretching out debt payments. However, to call it successful, one must appreciate how distressed the situation was for Uruguay at that time.

Distress: Uruguay had an investment-grade rating before Argentina defaulted on US\$95 billion of debt in 2001. Uruguay was current on its debt service prior to its 2003 voluntary exchange, but there was great concern that the spillover effect from the contraction in neighboring Argentina was making it impossible for Uruguay

Source: Moody's Investors Service; Note: Prices (Moody's calls them recovery rates) are % of the par value of the bond at the time of the initial default event, 30-day post-default for missed payments or around the close of an exchange for distressed debt exchanges. When the trading price is not available, Moody's calculates an equivalent measure estimating the recovery as the ratio of the present value of the cash flows of the new debt instruments received as a result of the distressed exchange versus the outstanding face value of those initially promised, discounted by an approximated market yield at the time of default. For Arg, the trading price-based recovery rate at the time of default in ´14 was 68%. The ultimate recovery as of the time of default resolution in ´16 was about 97% as the missed interest payments were repaid in full., For Barbados, the recovery rate was based on the trading price of its defaulted FC bonds. Arg defaulted on short-term debt in Aug ´19 and on long-term debt in Feb ´20. Only included the recovery rate of the defaulted long-term debt in Feb ´20.

to maintain its fiscal accounts, as its primary trading partner was Argentina and Argentines held a sizable amount of the deposits in Uruguayan banks.

In June 2002, the Uruguayan government lifted the currency bands it had in place and allowed the peso to trade freely. By August 2002, there was a run on the banks, the government froze some deposits, and bonds had plummeted to US$30 from US$100 at the end of 2001.

Uruguay's banking system was heavily dollarized, and neither the banks nor the government held enough liquid dollar assets to back those deposits. Thus, the bank run in Uruguay was due to an increasing recognition by depositors that the central bank's foreign reserves totaled less than the amount of dollar deposits in the system.

Golden gloves: Banks were not able to reopen until the United States pledged $1.5 billion to bolster the financial system (through a bridge loan from the U.S. Treasury's Exchange Stabilization Fund). The IMF pledged $2.8 billion in assistance to Uruguay and asked Uruguay to propose a debt exchange before failing to make a payment on its debt. The objective was to try to avoid the type of crisis that took place in Argentina. The exchange gave Uruguay a fiscal surplus by reducing interest payments and enabled it to draw on IMF loans, regaining investor confidence in its ability to pay debts, and revive the economy. The IMF provided Uruguay an initial $303 million payment on the loan pledge in March 2003, and the exchange was offered a month later.

Uruguayan external support worked because the $1.5 billion loan from the IMF, World Bank, and U.S. Treasury was used to give a 100% guarantee on the dollar checking and savings deposits, while rescheduling the time deposits and the loan brought back depositors' confidence. The resolution demonstrated that a voluntary mechanism and collective action clauses in its bonds were a good way to restructure debt and that there is a need for greater accountability and transparency.

The government had warned that, without a successful exchange, it might not be able to make all its debt payments, even in 2003. The exchange was successful because most investors realized the risks of not participating were high.

Holdouts were a concern of creditors, as well as the government: The government took the following steps to deal with holdouts:

1. It required at least 80% participation to complete the exchange.
2. If resources were insufficient, it would pay on the new bonds first.
3. New bonds would be liquid and be included in benchmark indices; old bonds would not be.
4. Those exchanging international bonds were asked to approve exit consents that reduced the old bonds' liquidity and their holders' ability to enforce debt-service payments.

5. New bonds paid debt service into a trust, which would distribute the payments to bondholders, reducing the attachment risk by holders of the old bonds. Notification was made that the old bonds would be treated less favorably by bank and pension fund regulators because of their future illiquidity.

S&P and credit default swap market considered it a default: Standard & Poor's called the swap a default and rated the nation's long-term foreign currency debt at about five levels below investment grade after investors received the new bonds. The rationale was that the new bonds, with both a longer maturity and lower coupon, were worth less than the old bonds in net present value terms.

A rating agency default rating is not a "credit event" criterion for triggering a credit default swap (CDS). Because this was a voluntary exchange of USD debt, the USD exchange did not trigger CDS. However, the yen Brady bond included a collective action clause, in which 50% of the bondholders could vote to change the material payment terms of the bond; the new terms would apply to 100% of the bondholders.

The holders of the yen bonds at a bondholders' meeting agreed to amend the terms to extend the maturity and this extension would be effective for 100% of the yen bondholders. This was, in effect, a forced restructuring for some percentage of these bondholders, and this yen rescheduling alone actually triggered CDS in every currency.

A month later, S&P raised its Uruguay rating to B– from selective default, stating that the exchange "significantly reduces the sovereign's debt amortization burden through 2007" and alleviates near-term funding pressures.

Unsuccessful Exchange, Argentina 2001

The government of Argentina conducted two large voluntary exchanges of debt in an effort to reduce near-term debt service by extending maturities and lowering cash coupon rates, but these were not ultimately sufficient to avert default.

Argentina June 2001 exchange failed, defaulted in six months: In the year preceding its December 2001 default, Argentina was in the midst of a deep recession. The peso was fixed one-for-one with the U.S. dollar by law and Argentina had limited monetary policy tools to be competitive. As a result, it borrowed too heavily from the global capital markets and was sinking in debt, with roughly 90% of Argentina's sovereign debt denominated in dollars. Banks were in a difficult position with most of their assets in pesos and liabilities denominated in dollars. Government bonds represented more than 20% of their assets.

In June 2001, the government conducted its "mega swap," exchanging close to US$30 billion of local, external global, and external Brady debt, which was about one-third of the outstanding external debt, much of it coming due in the near future. It swapped that debt for four liquid external bonds, most of which paid no cash coupon initially, but instead capitalized at a 12% per annum rate for five years before paying a high 12% cash coupon on a larger capitalized face amount. There was no coercion and it was a fair market level. Some investors, mostly local, hailed the exchange as the solution to Argentina's debt problem. Others were less optimistic and feared that the country's borrowing costs would soar after 2006.

Argentine local banks and pension funds were active participants in that exchange. The attractive feature for Argentina was that it significantly reduced debt service for close to five years. However, investor confidence did not increase sufficiently, and Argentina's funding needs could not be sustained.

The situation had deteriorated further by November, and a second "voluntary" exchange of Brady and Eurobond debt for local loans was offered. This exchange was originally only open to local investors, but participant restriction was eventually relaxed. The exchange was viewed as coercive by S&P, who downgraded all eligible bonds to a default rating of "D."

Simultaneously, there was a run on the banks, forcing the government to set limits on bank withdrawals. Within a month, the sovereign declared a moratorium on the payments of US$95 billion of external debt, which at the time was by far the largest sovereign default in history. The government also broke the currency peg, converted deposits to pesos, and had to bail out the banks, which were heavily dollarized. The government froze and then "pesified" the dollar deposits, effectively wiping out all of the banking system's existing capital. But it then issued new bonds to the banks to offset those losses.

Argentina default—large, complex, equitable: The Argentine restructuring from the 2001 default was much more complex and unique than any that had preceded it:

- The size and disparity were enormous—US$95 billion total face defaulted external debt obligations covered over 80 individual external bond issues in eight legal jurisdictions and in multiple currencies.
- There were many more different parties with their own agendas coming to the negotiating table. Many of the investors were original or early holders that wanted to reduce the losses on their investments.
- There were large blocks of bonds held by distressed debt funds with teams of litigators to bring them top recovery value. An active market for defaulted bonds over the next 10 years allowed such funds to accumulate sizeable holdings.

Exchange proposal came three years after default: In early 2005, Argentina proposed a relatively balanced exchange to all holders after Argentina declared a moratorium on December 24, 2001. Rather than extend maturities or discount all bonds by the same yield, Argentina determined the amount of accrued but unpaid interest through December 31, 2001, and added that to the face; this was the factor applied to a par claim for each bond.

For each Argentine claim, investors received a principal bond, with the Discount option requiring a 66.3% haircut or the Par option requiring no haircut, past-due interest in cash accruing from December 2003, and a GDP warrant giving investors the right to receive additional payments based on GDP growth in the event that the economy recovered. The concept of GDP warrants was promoted by the IMF, which expected this to be a beneficial solution to volatile economies in distress. The principal bonds had no Treasury collateral and over 50% of the coupon on the Discount bond was capitalizing (i.e., it was not paid in cash but added to the bond's face value). Only about $63 billion was exchanged in 2005.

In 2010, Argentina offered another exchange, less favorable to investors than the prior one. This exchange added another $20 billion in participation, for a total participation rate since the default of 92%, which still left close to $6 billion outstanding.

Litigation: Several lawsuits prevented Argentina from being able to issue in the international markets without resolving its disputes with holdouts. For the first time, many disparate foreign bondholders united in an organized committee in the United States and Europe, with strong objections to the framework proposed by Argentina. The most vocal large distressed hedge funds had claims and won judgments against Argentina that totaled more than $2.3 billion from U.S. court suits.

During the litigation, it was up to a U.S. judge to determine if Argentina had shown enough fairness and effort in these multiple exchange offers to keep these funds from exercising those judgments. Although the court ruled in favor of the distressed bondholders in October 2012, Argentina refused to pay.

Applying the *pari passu* clause in the defaulted bonds, a federal judge ruled that if Argentina made any more payments on the exchange bonds issued during the restructuring, then it had to pay what it owed to the holdouts. Appeals to higher courts over several years failed to overturn the decision, and in June 2014 the U.S. Supreme Court refused to hear Argentina's appeal on this case. In addition, the remedy included in the ruling instructed financial intermediaries not to help Argentina pay the exchange bonds if it did not also pay the holdouts.

Argentina chose to default on the June 30 payment of the 2005 and 2010 exchange bonds rather than negotiate a settlement with the holdouts. CDS was triggered in July 2014. Prices had been volatile on both foreign and local law foreign currency bonds from 2013 to 2016, affected by the judicial process and expectations regarding a settlement with the holdouts. It took a total of 15 years for the holdouts to resolve their claims.

Repeat Defaulters

Restructuring, even after a default, does not assure future timely payments, not even for a year or two. Some countries have repeatedly defaulted, including Russia, Ecuador, Ivory Coast, and Argentina.

In 2000, both Russia and Ecuador restructured their US$40 billion defaulted debt into US$27 billion of Eurobonds. When Ivory Coast defaulted, creditors did not vote to accelerate the bonds, likely because the size was small, as was their current ability to pay.

Russia's 1997 restructuring then 1998 default on Soviet era debt: In 1997, Russia restructured US$32 billion of debt obligations from the Soviet era, which Russia had agreed to honor long after the breakup of the Soviet Union. The debt did not cross-default to Russian Federation external bonds. That exchange had no principal collateral, no interest collateral, and no haircut. In addition, the defaulted loans were repackaged into new loans rather than bonds.

That restructuring was not sufficient. In 1998, there was no consensus view on how Russia would be able to solve its debt crisis, as reserves were collapsing. Russia defaulted on local debt and the US$32 billion of Soviet-era restructured loans. Russia did not default on any of its Russian-issued Eurobonds. The defaulted loans traded as low as $6 in 1998–1999. Russia restructured again in 2000, and by 2003 Moody's rated Russia investment grade.

Ecuador—unfair treatment, no willingness: Ecuador was the first country to default on Brady bonds and the first to give differential treatment to its bondholders, both in 1999 and in 2008. Ecuador defaulted in 1999, restructured in 2000, then selectively defaulted in 2008. In 2008, the government in power claimed that the restructured 2012s and 2030s were illegally issued by a prior administration. The government defaulted selectively on those, but not on the 2015 Eurobond that had later been issued under the current government in 2005.

Ivory Coast default—willing, but not able: Ivory Coast had more French Franc Bradys than USD Bradys. It defaulted in 2000 on US$3.5 billion for failure to make a complete payment. This was the only country that has made a partial payment on time. The government had expected to pay the rest after the grace period, but was not able to make the payment. Investors did not vote to accelerate the bonds, likely because the size was small, as was their ability to pay. The bonds were restructured in June 2010 and a political stalemate by December 2010 caused a disruption in government functioning and another default on the bonds.

DERIVATIVES

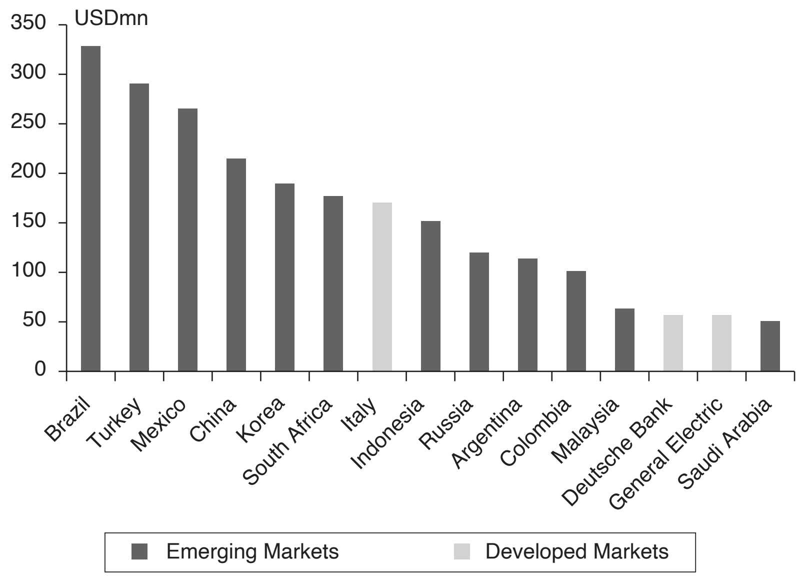
In addition to cash bonds, institutional investors also transact in derivative markets on Eurobonds. Derivatives have given institutional investors leverage and enhanced opportunities to hedge a corporate or sovereign position, express a directional view, or take advantage of relative mispricings in the market.

Credit default swaps (CDS): EM sovereign credit default swaps are among the most liquid and actively traded CDS in the world. Twelve out of 15 of the most actively traded CDS in the world are based on EM sovereigns, according to DTCC data. Therefore, several EM sovereign CDS are more actively traded than most developed market corporate CDS. (Exhibit 17-17). EM credit derivatives evolved alongside the rapid growth of the global corporate credit derivatives markets. CDS have grown to play a major role in emerging-markets investing and hedging.

CDS exposure is similar to the exposure of a floating-rate note investment. Both bond spreads and CDS spreads relate to credit default risk. A CDS offers investors an alternative way of going long or short a particular credit. Brazil, Turkey, Mexico, China, Korea, and South Africa are the most actively traded credits in the world. In addition, there are CDS indices, such as CDX.EM. The index is a basket of 17 global EM sovereign credits, with the largest weights assigned to Brazil, China, Turkey, Mexico, South Africa, and Indonesia.

EXHIBIT 17-17

CDS Credits with Highest Average Daily Notional Trading Volume in 2019 ($mn), Including Emerging Markets, Developed Markets, Sovereign and Corporate Credits



Source: BofA Global Research, Constructed from data obtained from DTCC 2019 CDS average daily traded notional ($mn).

Companies with foreign direct investments or with equities in emerging countries have used the sovereign CDS market extensively to hedge the overall sovereign risk, or to determine what return they should target when lending to various private projects or valuing the purchase of a local asset.

Exchange traded funds (ETFs): A number of ETFs have been created that mirror the overall market and replicate an index similar to those used as common benchmarks. The market capitalization of the largest EMs ETF, EMB, was about 30% as large as the largest high-yield ETF, HYG, in 2015 but five years later it had grown to 80% of the largest high-yield ETF. As with other ETFs, it is also used as a vehicle for taking a long or short market view, as well as for hedging.

KEY POINTS

- The Brady restructurings of the 1990s transformed illiquid commercial bank loans into liquid, globally traded bonds. The issuance of Brady bonds transformed EM debt into an asset class in its own right. As the asset class has evolved, defaults have occurred on external bonds since 1999, and the restructurings of those defaulted bonds have allowed sovereigns to reduce debt service going forward, which provides the sovereign an opportunity to rebuild its economy.
- EM debt has evolved into a sophisticated market with global investors ranging from pension funds and hedge funds to mutual funds and individual investors. It has grown tremendously over the last three decades as it has opened its doors to international investment, not only in international bonds but in local debt markets as well.
- Although EM debt has had well-known market shocks, it has weathered them as investors return to the market for its generous returns compared with other asset classes.
- EM debt has taken its place as a viable asset class, with product choices as extensive as those in some developed debt markets. The ongoing improvement in economic fundamentals may continue to attract investors to this asset class.

CHAPTER

EIGHTEEN

FIXED INCOME EXCHANGE TRADED FUNDS

Matthew Tucker, CFA
Managing Director
BlackRock

Stephen Laipply
Managing Director
BlackRock

Fixed income exchange traded funds (ETFs) have transformed bond markets since their introduction in the United States in 2002. The significance of their impact is largely due to the combination of features that they offer. Like a traditional mutual fund, a fixed income ETF is advised by an asset management firm that manages and rebalances the portfolio in accordance with stated investment guidelines. And like a listed equity or futures contract, a fixed income ETF provides investors with exposure that can be traded throughout the day on an exchange. As of April 30, 2020, there were $1.2 trillion in fixed income ETF assets under management across 1,475 funds globally and $857 billion in assets under management across 399 funds in the United States.[1]

Fixed income ETFs possess three key attributes:

- *Exchange listing provides transparent, intraday liquidity*. This is in stark contrast to the underlying over-the-counter (OTC) bond market, which is less transparent and less liquid.
- *A mechanism for creating and redeeming new fund shares*. The number of outstanding shares adjusts to market supply and demand. This differs from closed-end ETFs, which have a fixed number of shares. As a result, fixed income ETFs avoid some of the premium and discount volatility experienced by traditional closed-end funds.
- *Targeted market exposure*. ETF managers rebalance the funds and manage cash flows with the objective of providing risk and return characteristics that track (in the case of an index ETF) or seek to outperform (in the case of an active ETF) a published market index.

In this chapter, we discuss the characteristics of fixed income ETFs and how they compare to other fixed income instruments. We will then explore

1. Source: BlackRock, Bloomberg as of 4/30/2020.

various investment applications of fixed income ETFs for individual investors, advisors and institutions. Finally, we examine the structure and management of these funds as well as their trading behavior.

INVESTMENT CHARACTERISTICS

Exchange traded funds provide several key benefits:

- *Low investment management fees*. Fixed income ETFs generally have lower fees than open- and closed-end mutual funds. The average management fee is 30 basis points (bps) for a fixed income ETF versus 89 bps for the average fixed income mutual fund.[2]
- *Transparency*. Holdings of most fixed income ETFs are published on a daily basis. This gives investors regular access to the funds' assets and risk exposures.
- *Intraday liquidity*. The ability to trade fixed income ETFs throughout the trading day provides investors with greater visibility into portfolio valuation, even during periods of volatility and illiquidity. This intraday liquidity is particularly important and valuable during stressed market periods such as the COVID-19 crisis of 2020.
- *Tax efficiency*. The ETF creation/redemption mechanism makes ETFs more tax efficient than traditional mutual funds. When ETF shares are redeemed, the fund delivers securities in-kind (meaning that the underlying securities, rather than cash, are distributed). This in-kind distribution is not considered a taxable event for capital gains purposes. Mutual funds and other vehicles that distribute cash for redemptions must sell securities to raise the cash; in doing so, they potentially realize capital gains (or losses), which are paid to investors in the form of capital gains distributions.
- *Investment breadth*. ETFs provide exposure to a wide array of sectors for which futures and other exchange-traded vehicles do not exist.
- *Risk control*. Because they are exchange traded, and because each fund's underlying securities are held in a separate custodial account, fixed income ETFs have minimal counterparty risk.[3]

Exhibit 18-1 outlines the characteristics of ETFs along with other commonly used fixed income exposure vehicles: individual fixed income securities, futures, and swaps.

2. Source: Morningstar as of 4/30/2020.
3. There are ETFs that rely on uncleared OTC swaps to gain market exposure and, therefore, have a higher degree of counterparty risk relative to ETFs, which solely hold cash bond positions to achieve their exposures.

EXHIBIT 18-1

Key Characteristics of Bonds, ETFs, Futures, and Swaps

	Bonds	ETFs	Futures	Swaps
Advantages	Highly customizable; can target exposure to any asset sector	Priced, traded, and settled like stocks; broad or targeted exposure	Standardization of contracts and electronic trading enable large trading volumes and generally low transaction costs	Standardized exist but also bespoke; can target exposure to multiple sectors
Legal Structure	Security	1940 Act Fund	Derivative	Derivative
Round-Trip Execution Costs	Bid/offer spreads	Bid/offer spreads, commissions	Bid/offer spreads, commissions	Bid/offer spreads, possible early termination and other fees
Holding Costs	Minimal	Expense ratios	Embedded financing and contract roll costs	Embedded financing costs
Transparency of Costs	Low	High	High	Low
Notional Investment	100%	100%	Margin	Collateral (variable amount)
Tracking Error	Potentially high, varies by asset class	Generally low	Lower if a single deliverable exists; higher for basket of deliverables (cheapest to deliver option)	Low
Minimum Investment Size	Single security	Single share	Single contract	Customized (may be based upon minimum volume criteria)
Expiration	Stated maturity	Perpetual and stated end-date liquidation structures exist	Quarterly (usually)	Fixed expiration agreed upon at initiation
Liquidity Sources	OTC; multi-dealer model	Exchange; multi-dealer model	Exchange; multi-dealer model	OTC; multi-dealer model
Counterparty Risk	Minimal	Minimal	Minimal	Significant; can be reduced via collateral arrangements

Fixed income ETFs are used by both retail and institutional investors to obtain fixed income exposure across a broad asset class or a specific sector. Retail investors utilize these funds primarily for both core and custom portfolio exposure. Institutional investors utilize the funds primarily as liquid fixed income access vehicles.

Retail Investors and Financial Intermediaries

Retail investors and financial intermediaries use fixed income ETFs alongside traditional vehicles such as open- and closed-end mutual funds and separately managed accounts, primarily through these strategies:

- *Core exposure*. As with traditional types of funds, fixed income ETFs can be used for core fixed income exposure. A core holding typically provides an investor with broad market exposure. Around this core, exposure to various sectors can be added to satisfy specific risk/return targets. The wide selection of fixed income ETFs enables investors to construct core fixed income exposure either with a single broad market ETF (such as an ETF that is benchmarked to the Bloomberg Barclays U.S. Aggregate Bond Index) or with multiple ETFs that track various government and credit sectors which, when combined, provide broad market exposure.
- *Custom exposure*. Fixed income ETFs can provide targeted exposure to a specific market or sector, allowing investors to tailor portfolios for a variety of investment objectives or constraints. This application is widely used by individuals and is especially popular among investment advisors, because it allows them to customize fixed income exposures for large numbers of individual clients in a scalable way. As an example, an investor who holds a core position in an aggregate bond ETF may wish to periodically overweight exposure to investment-grade credit. The investor may accomplish this by augmenting their core exposure with a tactical allocation to an investment-grade credit ETF. Similarly, an investor may wish to shorten or lengthen the U.S. Treasury duration exposure of their core holding and may do so by blending in shorter or longer duration U.S. Treasury ETFs. The granularity and flexibility of fixed income ETFs have resulted in the creation of fixed income ETF "models," which are portfolios of fixed income ETFs constructed by advisory firms to target specific risk objectives. It is estimated that approximately $60 billion in assets are allocated to fixed income ETF models as of March 31, 2020.[4]
- *Market access.* The ability to target specific fixed income markets with a low-cost, liquid investment vehicle allows investors to gain exposure

4. Source: BlackRock as of 3/31/2020.

to sectors such as high-yield or emerging markets that can be challenging to access through the underlying bond market. As an example, an individual investor may find implementing a broad emerging market bond allocation difficult (if not impossible) through individual bond issues. However, there are a number of large, liquid ETFs in the market today that allow investors to gain access to this challenging fixed income sector instantaneously through an exchange.

- *Leveraged exposure.* There are a growing number of exchange traded products that provide investors with the ability to gain leveraged long and short exposure to fixed income markets. These funds have attracted interest from investors who seek to implement short-term tactical strategies on the direction of the targeted fixed income sector and who are comfortable with the mechanics and implications of leverage. These funds typically achieve their target exposure and leverage synthetically through OTC total return swaps or exchange traded futures.

  Investors considering these investments should be aware that the majority of leveraged and inverse funds reset leverage to a target level on a daily basis. Since the benchmark itself is not levered, the use of fund leverage, coupled with the impact of market path dependency and return compounding, can potentially distort fund returns relative to levered benchmark returns over longer periods of time.

Institutional Investors

Institutional investors rely on ETFs' liquidity, transparency, flexibility, and relatively low-cost structure to implement the following commonly used investment strategies:

- *Liquidity management.* Cash "equitization" (a term borrowed from equity markets) involves short-term investments of excess cash to maintain market exposure. Futures are commonly used for cash equitization due to their liquidity and ease of trading. Cash is invested in a money market account, and the futures position serves as an overlay to obtain the desired market exposure. The challenge with futures is that they generally offer only exposure to money markets or U.S. Treasuries (although credit index futures now exist[5]). Over-the-counter swaps (e.g., index total return swaps) may provide precise, customized exposure to a variety of fixed income sectors, but may exhibit less liquidity and potentially result in higher transaction costs relative to exchange-traded instruments, are subject to counterparty risk, and can be opaque and operationally intensive. Conversely, fixed income ETFs cover a wide range of fixed income sectors through an exchange traded format.

5. CBOE iBoxx iShares Corporate Bond Futures (www.cboe.com/products/futures/corpbondfutures).

As an example, a manager benchmarked to a broad index—such as the Bloomberg Barclays U.S. Aggregate Bond Index—would ideally employ a cash equitization instrument to maintain exposure to the index. While U.S. Treasury futures are liquid, they have a very high tracking error versus the Aggregate index, due to the differences in sector exposure and the presence of the delivery option in the futures contract. A number of fixed income ETFs exist that would allow the manager to invest excess cash efficiently and cost effectively without significantly increasing portfolio tracking error. In cases where a more cash-like exposure is desired, there are now a number of ETFs that offer money market-like exposure but still trade on exchange.

The liquidity management strategy can be implemented with ETFs across asset classes, as with a pension fund that uses fixed income ETFs as part of a core liquidity component within a broader portfolio. The ETF investment represents a portion of the exposure to each asset class. In this way, it complements, rather than replaces, the core holdings. The ETF portfolio provides a "liquidity sleeve" around the overall portfolio that can be accessed as needed to effect rebalancing. This approach allows the pension fund to maintain a strategic asset allocation without the need to continuously trade the less-liquid portions of their portfolio. It is especially valuable in fixed income markets where bid/offer spreads on individual securities can be significant and liquidity can be discontinuous.

- *Portfolio transitions*. When investors restructure their portfolios (e.g., due to changes in their manager profile or strategic asset allocation), they risk significant performance gaps and excessive costs. There is a tradeoff to be managed with respect to moving assets quickly and potentially incurring higher trading costs, and moving assets more slowly, which can result in performance differences relative to the target exposure. As an example, a pension plan that is moving a significant amount of money into the corporate bond market may find that it takes days or weeks to build the desired exposure through individual bonds. While the bond portfolio is being constructed, the plan is underexposed to any market movements that may occur in the corporate bond market. Futures and OTC swaps can be utilized to quickly obtain market exposure, but the tradeoffs discussed previously would still apply. The pension plan could instead purchase a fixed income ETF to rapidly establish and maintain corporate bond market exposure while it assembles the target bond portfolio.
- *Portfolio trades*. In these transactions, investors buy or sell large portfolios of bonds instantaneously at one price from a broker-dealer. Broker-dealers use fixed income ETFs to either hedge or facilitate these transactions by exchanging bonds for shares and vice versa using the creation/redemption mechanism (to be discussed in a later section).

- *Tactical allocations*. To take advantage of a market opportunity, a tactical investor must be able to move in and out of the market quickly. Individual bonds can provide targeted exposure but are generally difficult to trade in a large, diversified basket format. Futures and OTC swaps can be utilized, but the tradeoffs discussed previously apply.

  Fixed income ETFs combine the liquidity of futures and the diversified exposure of index total return swaps. For example, an investor favoring the wide level of credit spreads observed during the 2008–2009 Global Financial Crisis or the 2020 COVID-19-driven market volatility could have purchased a corporate bond ETF far more quickly and efficiently than buying an equivalent portfolio of individual securities. Investment advisors and hedge fund managers often use fixed income ETFs for tactical plays across large numbers of client accounts as they may implement market views more rapidly and cost effectively than could otherwise be accomplished through the underlying bond market.
- *Strategic asset allocation.* For decades, bond portfolio managers have constructed portfolios at the individual security level. Many actively managed portfolios consist of hundreds or thousands of individual bonds. While these bonds may have been selected on their individual merit, in aggregate their idiosyncratic properties may cancel, leaving what is, in effect, beta and factor exposure. As a result, there is significant opportunity to reduce line items, lower the trading costs associated with individual bonds, and increase liquidity through a combination of ETFs that provide similar beta and factor exposure. As an example, many "core plus" managers often have a return profile similar to a combination of a broad, investment-grade bond index (e.g., the Bloomberg Barclays U.S. Aggregate Bond Index) and a high-yield index (e.g., the ICE BofA US High Yield Index). This combination is essentially a core beta exposure plus a credit tilt or credit factor exposure. Such managers could use a combination of low-cost broad market and high-yield ETFs to create these core beta and factor exposures, while using individual securities and derivatives for higher conviction, uncorrelated positioning.

Advanced Applications: Derivative Substitute/Complement

In addition to the more conventional applications discussed in the preceding sections, tactical investors may also employ fixed income ETFs in more advanced strategies involving options, short selling, and vehicles that contain packaged leverage.

- *Options*. As the market for fixed income ETFs has grown and developed, options have been listed on many funds. For listed options on U.S. fixed income ETFs, there is currently over $70 billion in contract notional value outstanding and nearly $6 billion of trading activity per day on average.[6] Because they are listed, options on fixed income ETFs may be attractive relative to OTC fixed income options in terms of cost, transparency, and operational ease. Trading strategies using these options can be structured in a similar manner to those employed in futures options or OTC fixed income options. Options on fixed income ETFs allow investors to access leveraged market exposure and pursue a variety of strategies such as call or put spreads, directional volatility bets through straddles, etc. Credit ETF options have become especially popular and trade hundreds of millions of dollars a day in notional equivalent exposure. They have become a viable alternative to credit index default swap (CDX) swaptions given their high correlation with actual cash bond portfolios.

- *Short selling.* Investors who wish to short a specific fixed income sector may find that such a strategy is easier to implement through a fixed income ETF rather than through the underlying bond markets. Like equities, shares in fixed income ETFs may be borrowed and sold short. The cost varies with supply/demand conditions in the market for the ETF and helps shape an investor's decision on whether to use the ETF or an alternative strategy to short the market. Additionally, dislocations in the cost to borrow a fixed income ETF can create investment opportunities.

  As an example, a relative value hedge fund may find that the borrow cost in a particular high-yield ETF has increased from 1% to 5%, due to a significant level of short interest. The hedge fund may choose to take advantage of this situation by purchasing the high-yield ETF and lending it out at a rate of 5% (less any bid/ask differential). This would allow the hedge fund to achieve the return of the high-yield ETF plus 5%. Furthermore, the hedge fund may find that the high-yield beta exposure can be hedged by shorting a similar basket of correlated securities, CDX, or a credit index total return swap (e.g., a swap based on the iBoxx $ Liquid High Yield Index). If the cost of shorting the correlated exposure is less than 5%, then the hedge fund earns a spread for as long as the dislocation persists. In this example, the hedge fund must also price in the potential basis risk between the ETF and the correlated basket or swap.

FIXED INCOME ETF MANAGEMENT

Because fixed income ETFs are managed funds, an investment advisor is charged with overseeing the portfolio and delivering on its investment objective in accordance with a published prospectus and Statement of Additional Information (SAI). The manager has full investment control of the positions and transactions

6. Source: Bloomberg as of 4/30/2020.

in the portfolio. There are two primary types of funds in the marketplace—index funds and active funds.

Index ETFs

The majority of fixed income ETFs are index funds, which seek to match the performance of a published benchmark. Many fixed income securities have discontinuous liquidity, making it virtually impossible to fully replicate a broad market benchmark. For this reason, most fixed income index ETFs employ a set of techniques to sample from the broad market. These approaches, the most common of which are optimization and stratified sampling, involve creating a portfolio that contains a subset of the securities from an index that match the major risk characteristics of that index. In constructing and maintaining a portfolio, the manager must balance available security liquidity and transaction costs with the objective of creating a diversified portfolio to reduce idiosyncratic risk and better track benchmark performance.

Active ETFs

In 2008, the first active fixed income ETF was launched, and as of March 31, 2020, there are over 100 active fixed income ETFs[7] in the market. Like their index counterparts, active ETFs also have a stated benchmark. But unlike index funds, their objective is to outperform the benchmark. Active ETFs are not typically used by investors as liquid exposure vehicles in the same way that index ETFs have been used, as an active ETF's portfolio exposure will vary through time. What active ETFs do offer is a managed alpha vehicle that can be accessed and traded throughout the day.

Managers of active fixed income ETFs employ an array of investment strategies to achieve outperformance, including security selection, asset allocation, and duration management, similar to traditional open-end or closed-end mutual funds.

As with index ETFs, active fixed income ETF providers publish their holdings on a daily basis, which creates challenges for a portfolio manager holding concentrated positions or investing in illiquid markets. For this reason, most of the active fixed income ETFs that have come to market are those that invest in more liquid asset classes or that hold securities until their maturity. This minimizes the chances of the manager being taken advantage of due to the transparency of their posted holdings.

FIXED INCOME ETF CHARACTERISTICS AND MECHANICS

Fixed income ETFs typically provide daily transparency of holdings and pay income through monthly distributions. The liquidity provided by fixed income

7. Source: BlackRock, Bloomberg as of 3/31/2020.

ETFs is supported by two complementary markets—the primary market, in which fund shares are created and redeemed, and the secondary market, in which existing shares are traded throughout the day on an exchange.

Holdings Transparency

A differentiating factor of fixed income ETFs is that their holdings are disclosed more frequently than mutual funds. The majority of fixed income ETF providers publish holdings on a daily basis, providing investors with continual transparency into the fund's risk profile. The exceptions are ETFs that represent share classes of mutual funds, as well as those ETFs that have received specific regulatory exemptions.

Fund Distributions

As 1940 Act mutual funds, fixed income ETFs are required to distribute earned income to investors. This income reflects accrued interest earned by the fund and includes the amortization and accretion of securities purchased at a price other than par, as well as securities lending income and fund management expenses. Typically, fixed income ETFs distribute income monthly. Earned income may be generally defined as

$$\text{Earned Income} = \text{Accrued interest} + \text{discount accretion} - \text{premium amortization} + \text{securities lending income} - \text{fund expenses}$$

It is important to note that income is earned at the fund level but distributed at the share level. As a result, changes in the number of shares outstanding in a given month can result in a change in the size of the distribution on a per share basis paid to investors. Value is neither created nor destroyed, however. Any perceived surplus/deficit in per share distributions is offset directly in the net asset value (NAV). For established funds with moderate flows, this tends to result in small shifts in distributed income on a monthly basis; for smaller funds and those that experience extreme flows, the impact can be greater. Note that this income distribution mechanism is not unique to ETFs; it also applies to other mutual fund structures.

Fixed income ETF distributions are an important attribute for investors who invest in bonds for income purposes. Distributions create a future stream of cash flows that an ETF holder will receive, in much the same way that an individual bond provides a future stream of coupon payments.

The Primary Market: Creation and Redemption of Fund Shares

Broker-dealers who create or redeem ETF shares are known as authorized participants (APs). Authorized participants generally work with both investors and ETF providers to maintain liquidity in the market.

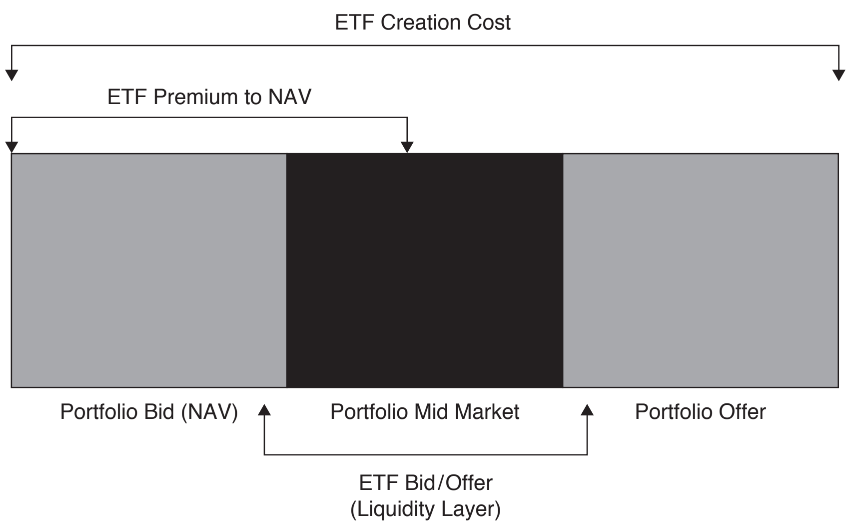
Investors purchase and sell shares of ETFs on an exchange, trading them in exactly the same way as a listed stock. Each share represents partial ownership of the portfolio of securities held by the fund, much like shares in a traditional open-end mutual fund represent partial interest in the underlying fund holdings. What differs is the ETF's creation/redemption mechanism.

On a daily basis, the ETF provider publishes the holdings of the ETF along with the lists of securities that can be delivered for the creation or redemption of shares. During periods of strong demand for an ETF, the price of the shares is bid up in the market as the supply of shares is depleted. If the ETF price is sufficiently higher than the value of the underlying securities held within the ETF, an arbitrage opportunity may exist. Authorized participants could purchase the underlying fixed income securities, deliver them to the ETF provider in exchange for the creation of new ETF shares, and then sell the newly created ETF shares in the market for a profit. This same dynamic occurs in markets with strong selling pressure that results in an excess supply of shares and falling prices. If the ETF trades significantly or persistently below the value of the securities in the fund, APs could purchase the ETF shares in the open market (at a discount), deliver them to the ETF provider in exchange for the underlying bond holdings (i.e., redeem these shares), and then sell these bond holdings at a net profit.

Arbitrage pressure keeps the ETF price in line with the value of the underlying securities. Exhibit 18-2 illustrates the arbitrage boundaries for fixed income ETFs in terms of the bid/ask spread of the underlying securities.

EXHIBIT 18-2

Fixed Income ETF Arbitrage Boundaries



Note that one need not be an AP in order to close an arbitrage opportunity in an ETF. As an example, if an ETF is trading at a discount relative to the value of its underlying securities, then a market participant (such as a hedge fund) may act to close a valuation gap by buying the ETF and selling short against it a group of correlated securities or derivatives. The correlated securities basket could consist of individual bonds, interest rate derivatives, or credit derivatives. The hedge fund would wait for the values of the ETF and the correlated basket of securities to converge. At that time, all positions would be unwound for a net profit.

All ETF creations and redemptions must be done at a value equal to the fund's NAV. This ensures that the value of the securities passing into or out of the fixed income ETF matches the value of the shares issued by or taken back by the fund. In this way, existing shareholders of fixed income ETFs are protected from any potential transfers of wealth during the share creation/redemption process.

Additionally, investors buying or selling the fund transact at the *market price* of the fund, as opposed to the NAV. Market price execution is an important point of differentiation for a fixed income ETF relative to traditional open-end fund structures. In an ETF that utilizes the in-kind creation/redemption process, each investor incurs the transaction costs created by their specific transaction through the market price of the ETF (i.e., the market price should reflect the cost of share creation) and existing investors are unaffected. Conversely, in a mutual fund structure, investors enter and leave the fund at the fund's net asset value, as opposed to market price, and transaction costs are shared by all investors in the fund. Note that it is customary to value fixed income securities on the *bid* side of the underlying bond market for NAV calculation purposes, while investors typically purchase fixed income securities on the offered side of the market. As a result, a new investor may enter a mutual fund at the NAV, but the securities purchased as a result of this investor's entry may ultimately cost more than the bid-side prices that were implied by the NAV. This differential is paid for by existing investors in the fund.

Such a dynamic is generally beneficial for the transacting investor but not the existing investors. An investor's choice of whether to use an ETF or a mutual fund depends, in part, on their desire to incur isolated or mutually shared costs.

The Secondary Market: The Exchange Liquidity Layer

One of the characteristics that differentiate fixed income ETFs from other managed vehicles is that the shares are listed and traded on a stock exchange. Unlike the OTC bond market, the exchange format provides for a high level of visibility into trading volumes, two-sided market levels (both bid and offer), and transaction costs. It also provides investors with the ability to control market execution by using equity trading strategies such as limit orders and stop loss orders, and to employ shorting strategies by borrowing ETF shares and selling them into the market.

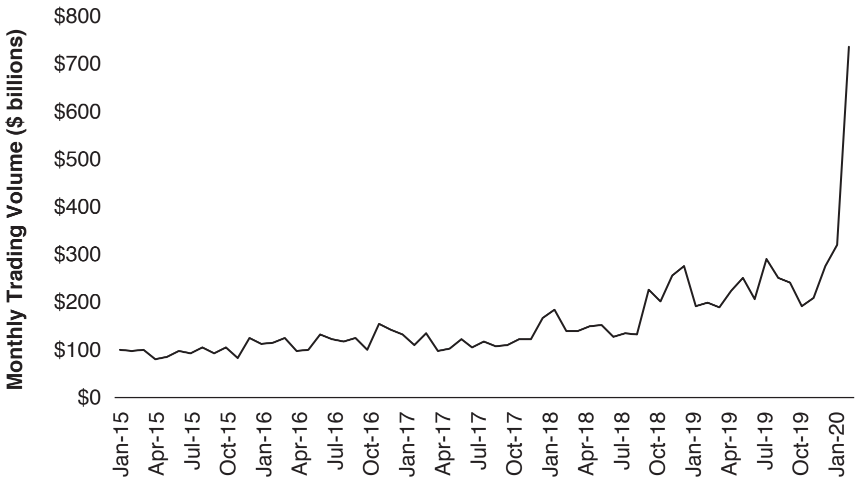
The level of intraday liquidity and market visibility offered by ETFs is in sharp contrast to the underlying OTC bond market, where trades are negotiated directly between parties by phone, e-mail, or other medium. The OTC market creates a number of challenges for an investor. First, it is difficult to determine best execution. An investor can solicit market bids or offers from a selection of dealers, but that investor has no way of knowing whether they executed at the best available price in the market. Second, OTC markets generally provide either the bid or offer price for a transaction, whereas two-sided markets allow the investor to explicitly observe their transaction costs through the spread between the bid-side and offer-side prices.

One of the central benefits of ETFs is that they develop their own independent exchange liquidity layer through the secondary market as trading volume and shares outstanding grow. Secondary market activity accounts for the majority of trading volume, as most ETF transactions occur without the need to create/redeem shares and access the underlying market. Under normal market conditions, secondary trading activity is roughly five times that of primary (creation/redemption) activity. In periods of market stress and volatility, this ratio can move above 20 as primary activity falls due to illiquidity in the underlying bond market and more trading moves to the exchange.[8]

This exchange liquidity can be substantial. As an example, during the first quarter of 2020 when the COVID-19 crisis was gripping markets, fixed income ETFs traded between $25 billion and $35 billion per day, two to three times the average of $11 billion observed in 2019.[9] Exhibit 18-3 illustrates monthly fixed income ETF volumes from January 2015 through March 2020.

EXHIBIT 18-3

Monthly Trading Volumes for U.S. Fixed Income ETFs



8. Source: BlackRock as of 3/31/2020.
9. Source: BlackRock, Bloomberg as of 3/31/2020.

Secondary market liquidity is a key benefit of ETFs in general and fixed income ETFs in particular. The liquidity layer essentially decouples the ETF liquidity from that of the underlying OTC bond market and allows investors to trade in the ETF without having to create or redeem shares. The ability to trade a fixed income ETF within the exchange liquidity layer can result in the ETF trading at a much tighter bid/offer spread than the underlying bond market. When trading demand outstrips available exchange liquidity, the market price action of the fixed income ETF may motivate dealers to access the underlying bond market in order to square orders with inventory.

Accordingly, the level of liquidity available for a fixed income ETF is not driven by the level of observable exchange liquidity alone. A large purchase or sale in a fixed income ETF may potentially absorb the existing level of exchange liquidity, which would then necessitate the creation or redemption of shares by an AP in order to balance the market. The AP would do this by accessing the underlying bond market (i.e., purchasing bonds to facilitate share creation or selling bonds to facilitate share redemption). Therefore, the total available liquidity of a fixed income ETF is a function of not only the observable exchange liquidity but also the liquidity of the underlying bond market (which is substantial in most fixed income sectors).

A fixed income ETF's total available liquidity may be thought of as the sum of the following:

1. Observable exchange liquidity (i.e., the average daily volume)
2. Contingent exchange liquidity that may be unlocked through the use of limit orders, etc. (which is provided by existing fund shareholders who are willing to transact at a price that is more favorable to them than what is currently available in the market)
3. Underlying bond market liquidity that may be accessed through the creation/redemption process

Through careful execution designed to maximize observable and contingent exchange liquidity, market participants are often able to transact in fixed income ETFs in excess of the average daily volume with minimal market impact. Exhibit 18-4 illustrates the layers of liquidity of fixed income ETFs.

Exhibit 18-5 presents observed bid/offer spreads for trades on some of the largest fixed income ETFs relative to spreads in the respective underlying market. Note that, because of the robust exchange liquidity in these ETFs, their bid/offer spreads are a fraction of the underlying bond market bid/offer spreads. This is particularly pronounced in the more esoteric sectors such as high yield and emerging markets.

EXHIBIT 18-4

Fixed Income ETF Liquidity Layers

Morgan USD Emerging Markets Bond ETF (EMB), Invesco Emerging Markets Sovereign Debt ETF (PCY), iShares Core U.S. Aggregate Bond ETF (AGG), and Vanguard Total Bond Market ETF (BND).

TRADING BEHAVIOR: A CLOSER LOOK AT PREMIUMS, DISCOUNTS, AND PRICE DISCOVERY

The price at which an ETF trades is primarily a function of the value of the underlying securities in the portfolio (i.e., the NAV), and is also influenced by market flows, liquidity, and market volatility.[10]

When an ETF trades at a price above the NAV, it is said to be trading at a premium; when the ETF is trading below the NAV, it is said to be trading at a discount. Because the convention in fixed income markets is to value securities using bid-side prices, the NAV of a fixed income ETF is calculated using the bid side of the underlying bond market. Under most market conditions, a fixed income ETF will trade at a premium to this bid-side NAV. Under normal market conditions, the maximum premium should be the full bid/ask spread of the underlying portfolio, otherwise an arbitrage would be possible as discussed previously.

The level of premium or discount for a fixed income ETF is a function of the bid/offer spread of the underlying bond market, the balance of ETF flows, and the level of market volatility and execution risk that a market participant takes on in executing the creation/redemption or arbitrage activity.[11]

In periods of high volatility and market dislocation, the market price of the fixed income ETF can often lead the underlying market, creating the appearance of large discounts or premiums. These larger deviations reflect the fact that many of the underlying bonds held by the ETF may not be trading on a given day. As an example, only about 25% to 35% of bonds trade on a given day in the corporate bond indexes that the larger, more liquid bond ETFs track.[12]

Accordingly, a substantial amount of the NAV may be based on estimates of value calculated by bond pricing services, rather than actual trades. In fast-moving markets, these estimates can lag the price changes that are occurring in the bonds, ETFs, and other securities that are trading. The ETF price is in effect a real-time indicator of the value of the bond portfolio on exchange. The price discovery properties of ETFs are well known,[13] and are particularly pronounced for fixed income ETFs.[14]

To illustrate this point, Exhibit 18-6 shows the market price of the largest corporate bond ETF versus its NAV from February 19, 2020, through March 24, 2020, the peak of COVID-19-induced market volatility. Exhibit 18-7 shows the market price of this ETF versus the prices of its top five holdings over this same period. While this ETF traded at up to a 5% discount to NAV, Exhibit 18-7

illustrates that its price was very much in context with bonds that were trading. Note that this ETF traded tens of thousands of times on exchange daily, while the top five underlying holdings traded less than three dozen times each day on average over the same period.

Accordingly, fixed income ETFs can provide both valuable information content on real-time market conditions as well as a readily tradeable instrument when underlying bond market liquidity conditions are challenged.

KEY POINTS

- Fixed income ETFs combine many of the attributes of individual bonds and bond portfolios, mutual funds, swaps, and futures to provide transparent, liquid, and efficient exposure for investors.
- Retail and intermediary investors use fixed income ETFs primarily for core or custom exposure, market access, and model portfolios. Institutional investors use fixed income ETFs for cash equitization and liquidity management, portfolio transitions, tactical and strategic allocations, and as a substitute or complement to derivative instruments for investment and risk management purposes.
- In the primary market for fixed income ETFs, Authorized participants help maintain liquidity by increasing shares of the ETF (when demand increases) or decreasing shares of the ETF (when demand decreases) through an exchange of bonds for shares. Arbitrage pressure helps to keep the ETF price in line with the value of the underlying fixed income securities.
- In the secondary market, investors trade ETF shares on equity exchanges. This added liquidity layer can be substantial and may provide significantly tighter bid/offer spreads relative to those observed in the underlying bond market.
- Fixed income ETF pricing behavior is driven primarily by movements in the underlying bond market, ETF fund flows, and the level of market volatility.
- Fixed income ETFs provide price discovery and serve as an actionable vehicle and real-time window into market conditions, particularly when the underlying bond market is stressed.

NONCONVERTIBLE PREFERRED STOCK

Steven V. Mann, Ph.D.
Distinguished Professor Emeritus
Moore School of Business
University of South Carolina

Preferred stock is a hybrid security that combines features of both common stocks and corporate bonds. While preferred stock possesses some debtlike features, it is considered to be an equity security. Preferred stockholders have a claim on the cash dividends paid by the issuing corporation, and their claim is senior to that of common shareholders. Furthermore, cash dividends paid to preferred stockholders are almost always fixed by contract (e.g., a specified dollar amount or percentage of their face value). Accordingly, "plain vanilla" preferred stock is, in essence, a perpetuity. The specified percentage is called the *dividend rate,* which may be fixed or floating. Almost all preferred stock issued today limits the payments to be received by the security holder to a specified amount with the proviso that the cash flows received will never exceed those specified in the contract and may be less.

Failure to make preferred stock dividend payments cannot force the issuer into bankruptcy. If the issuer fails to make the preferred dividend payments as specified in the contract, then depending on the terms of the issue, one of two things can occur. If the issue is *cumulative,* the dividend payment accrues until it is fully paid. Conversely, if the issue is *noncumulative,* missed dividend payments simply are forgone. Failure to make dividend payments also may trigger certain restrictions on the issuer's management. As an example, if dividend payments are in arrears, preferred shareholders may be granted voting rights to elect some members to the issuer's board of directors. This feature is called *contingent voting* because the voting rights are contingent on a missed dividend payment.[1]

Cumulative preferred stock has some debtlike features, namely (1) the cash flows promised to preferred stockholders are fixed by contract and (2) preferred stockholders have priority over common stockholders with respect to dividend payments and distribution of the assets in case of bankruptcy.[2] However, on a balance

1. By contrast, *blank check* preferred stock contains a provision that gives voting rights to approved preferred shareholders as protection against a hostile takeover attempt.
2. The position of noncumulative preferred stock is considerably weaker.

sheet, preferred stock is classified as equity. When there is more than one class of preferred stockholders, the claims of preferred stockholders to the issuer's assets differ in the event of bankruptcy. For example, *first* preferred stock's claim to dividends and assets has priority over other preferred stock. Correspondingly, *second* preferred stock ranks below at least one other issue of preferred stock.

Almost all preferred stock has a sinking-fund provision, and such provisions usually are structured similarly to those used with corporate bonds. A sinking fund is a provision allowing for a preferred stock's periodic retirement over its life span. Most sinking funds require a specific number of shares or a certain percentage of the original issue to be retired periodically, usually on an annual basis. Sinking-fund payments can be satisfied by either paying cash and calling the required number of shares or delivering shares purchased in the open market. Most sinking funds give the issuer a noncumulative option to retire an additional amount of preferred stock equal to the mandatory requirement. This is called a *double-up option*. Preferred shares acquired to satisfy a sinking-fund requirement usually are called using a random selection process.

Preferred shares offer investors two distinct advantages over debt and other equity investments. Preferred shares offer higher yields on average than bonds or common stock. Moreover, preferred shares provide good diversification benefits owing to their low correlation with stocks and bonds. In order to obtain these benefits, investors in preferred stocks must contend with the risk characteristics of these securities. Preferred shares possess limited potential for price appreciation. The reason is that the lion's share of the total return is due to the stream of dividend payments. Naturally this raises the specter of default risk, meaning a breach in the contract with the preferred stockholder like omission of a dividend. Some preferred shares are callable, which exposes the investor to reinvestment risk. Finally, preferred stocks tend to be less liquid than common stocks.

PREFERRED STOCK ISSUANCE

Corporations use three types of securities—debt, common stock, and preferred stock—to finance their operations. In terms of total dollars issued, preferred stock ranks third by a large margin. There have been two fundamental shifts in the issuance pattern of preferred stock since the early 1980s. Since the mid-1980s, the major issuers of preferred stock are financial institutions and insurance companies, whereas before this time, public utilities issued a majority of preferred stock. Second, most of the preferred stock issued today carries an adjustable-rate dividend. Traditionally, almost all preferred stock paid a fixed dividend.

Types of Preferred Stock

There are three types of preferred stock: (1) fixed-rate preferred stock, (2) adjustable-rate preferred stock, and (3) auction-rate and remarketed preferred stock.

Fixed-Rate Preferred Stock

Prior to 1982, all publicly issued preferred stock paid a fixed dividend rate.

Adjustable-Rate Preferred Stock

For *adjustable-rate preferred stock* (ARPS), the dividend rate is reset quarterly based on a predetermined spread from the highest of three points on the Treasury yield curve. The predetermined spread is called the *dividend reset spread*. The dividend reset spread is added to or subtracted from the *benchmark rate* determined from the yield curve. The three points on the yield curve are the highest of (1) the 3-month Treasury bill rate, (2) the 10-year Treasury rate, or (3) the 30-year Treasury rate. It is often the case that the dividend reset spread is expressed as a certain percentage of the benchmark rate.

Auction-Rate and Remarketed Preferred Stock

Most ARPS is perpetual, with a cap and floor on the dividend rate. Because most ARPS is not putable, however, ARPS can trade below par value after issuance if the spread demanded by the market as compensation for the risk of the security is greater than the dividend reset spread. The popularity of ARPS declined when these instruments began trading below their par value. This occurs because when an issuer's credit risk deteriorates, the dividend-rate formula remains unchanged and the preferred stock's value will decline. In 1984, a new type of preferred stock was issued to overcome this problem—*auction-rate preferred stock*. This innovation was particularly well received by corporate investors who sought tax-advantaged short-term instruments to invest excess funds. The dividend rate on auction-rate preferred stock is reset periodically, but the dividend rate is established through a Dutch auction process. Participants in the auction consist of current preferred shareholders as well as potential buyers. The dividend rate that participants are willing to accept reflects current market conditions. Commercial paper rates typically serve as benchmarks.

In the case of *remarketed* preferred stock, the dividend rate is determined periodically by a remarketing agent, who resets the dividend rate so that any preferred stock can be tendered at par and be resold (remarketed) at the original offering price. An investor has the choice of dividend resets every 7 days or every 49 days.

TRUST PREFERRED

Trust preferred securities are hybrid securities primarily issued by financial institutions with features of both debt and equity. They are treated as debt for tax purposes such that dividend payments are tax deductible and may be deferred up to five years. Conversely, they are treated as Tier I capital for trust preferred securities are senior to both preferred and common stock but subordinate to all debt. These securities possess 30-year maturities allowing for early redemption at the behest of the issuer. Trust preferred shares generally deliver quarterly dividend payments.

In the aftermath of the financial crisis of 2007–08, regulators lamented financial institutions were too highly levered and that more regulation was paramount. These changes in regulation were delivered in two packages—Basel III and the Dodd-Frank Act. Endorsed by the G-20, the Basel III banking standards are to be enacted by member nations through either regulation or statue by January 1, 2013. The Dodd-Frank Act was signed into law and represents the most significant U.S. financial reform since the Depression. Both packages of regulation raise capital standards and phase out trust preferred from Tier 1 capital. Basel III generally gives a much longer phase-out period than the three years stipulated by Dodd-Frank. The other important difference in the treatment of trust preferred stock is that Dodd-Frank exempts small banks from the phaseout. Basel III contains no such exemption.

PREFERRED STOCK RATINGS

Preferred stock is rated just like corporate bonds. A preferred stock rating is an assessment of the issuer's ability to make timely dividend payments and fulfill any other contractually specified obligations (e.g., sinking-fund payments). The three nationally recognized statistical rating organizations (NRSROs) that rate corporate bonds also rate preferred stock. The NRSROs are Fitch Ratings, Moody's Investors Service, Inc., and Standard & Poor's Ratings Group. Symbols used by the NRSROs for rating preferred stock are the same as those used for rating corporate long-term debt. It is important to note that the rating applies to the security issue in question and not to the issuer per se. Two different securities issued by the same firm could have different ratings. Standard & Poor's attaches +*s* and –*s*, which are called *notches,* to denote an issue's relative standing within the major ratings categories.[3]

TAX TREATMENT OF DIVIDENDS

Dividend payments made to preferred stockholders are treated as a distribution of earnings. This means that they are not tax deductible to the corporation under the current tax code.[4] Interest payments are tax deductible, not dividend payments. While this raises the after-tax cost of funds if a corporation issues preferred stock rather than borrowing, there is a factor that reduces the cost differential: a provision in the tax code exempts 70% of qualified dividends from federal income taxation if the recipient is a qualified corporation. For example, if corporation A owns the preferred stock of corporation B, for each $100 of dividends received

3. Moody's attaches 1s, 2s, and 3s to indicate the same information.
4. An exception to this statement is trust-preferred securities.

by A, only $30 will be taxed at A's marginal tax rate. The purpose of this provision is to mitigate the effect of double taxation of corporate earnings.

The tax treatment of preferred stock also differs depending on whether it is classified as *old money, new money,* or *partial money*. Old money refers to preferred stock issued before October 1, 1942. For old money preferred stock, the dividend-received deduction is only 42%. Partial money refers to a very small new set of issues that were classified as both old and new money. Old and partial money comprise only a tiny fraction of the preferred stock outstanding today. In other words, virtually all preferred stock outstanding today is new money.

There are two implications of this tax treatment of preferred stock dividends. First, the major buyers of preferred stock are corporations seeking tax-advantaged investments. Indeed, very few individual investors hold preferred stock in their portfolios. Second, the cost of preferred stock issuance is lower than it would be in the absence of the tax provision because the tax benefits are passed through to the issuer by the willingness of corporate investors to accept a lower dividend rate.

KEY POINTS

- Preferred stock is a hybrid security that combines elements of debt and equity.
- Preferred shares offer higher yields on average than bonds or common stock and provide good diversification benefits owing to their low correlation with stocks and bonds.
- Preferred share possess limited potential for price appreciation and are exposed to default risk.
- There are three types of preferred stock: (1) fixed-rate; (2) adjustable-rate; and (3) auction-rate.
- Trust preferred securities are hybrid securities primarily issued by financial institutions with features of both debt and equity. They are treated as debt for tax purposes such that dividend payments are tax deductible and may be deferred up to five years.

CHAPTER
TWENTY

PRIVATE INFRASTRUCTURE DEBT

Frédéric Blanc-Brude, Ph.D.
Director
EDHEC Infrastructure Institute

This chapter discusses the characteristics, pricing, and credit risk of private infrastructure project debt instruments. Long the preserve of banks, private infrastructure debt has become an increasingly common asset class in institutional portfolios of alternative credit. Infrastructure debt is originated with the aim of financing long-term capital projects with limited alternative uses, which makes it different from other forms of corporate debt securities.

INFRASTRUCTURE BORROWERS

The economic literature has identified a number of fundamental economic characteristics of infrastructure companies (and borrowers), which sets them apart from other types of investments.[1] In the TICCS taxonomy of infrastructure companies, these characteristics can be summarized thus:[2]

1. *Single-use investment:* Infrastructure assets can be described as "relationship-specific," that is, the investment required only makes sense in the context of a "relationship"—typically, a contract, license, or concession, which justifies the demand or usefulness of the investment.
2. *Sunk or irreversible capital investment:* This relationship must exist for infrastructure investment to take place because the initial capital expenditure is "sunk," that is, irreversibly invested and unusable for any other purpose than the one originally intended.

1. See, for example, Jose Gomez-Ibanez, *Regulating Infrastructure*: *Monopoly, Contracts and Discretion.* Harvard University Press, 2003.
2. EDHECinfra, *The Infrastructure Company Classification Standard (TICCS®)*, EDHEC Infrastructure Institute, 2020 (url: https://docs.edhecinfra.com/display/TICCS).

3. *Large size requiring a long repayment period:* Infrastructure investments are sizable in absolute terms, making the repayment period necessarily long (multiple decades) and potential losses large as well.
4. *Inflexible total cost structure:* Operating infrastructure at its design capacity implies predictable fixed (operating, maintenance, and capital) costs and low variable costs, resulting in an inflexible cost structure. In turn, investing in infrastructure requires a higher degree of certainty in future revenue streams, which underpins the requirement for long-term contracts, especially since infrastructure assets have little to no alternative uses.
5. *Infrastructure as a service:* Infrastructure companies have value because their assets provide a useful service to its users, the demand for which is the sole justification for the investment. Thus, despite consisting mainly of large tangible, immobile assets, the value of infrastructure assets is determined by their providing a service.
6. *Not a store of value:* It follows that, unlike other "real" assets such as land, building, commodities, or art, infrastructure investment are not a store of value. Instead, infrastructure assets must be useful for them to have (social, economic, and financial) value.

The firms that invest in infrastructure assets can be very similar to other large industrial firms. One speaks then of "infrastructure corporates." In this case, "infrastructure debt" is found to be very similar in form, pricing, and quality to investment-grade corporate bonds, and there may not be much of an infrastructure debt asset class to speak of.[3]

However, the economic characteristics listed above also allow infrastructure investments to be structured in a way that reflects the long-term value and unique purpose of the individual infrastructure assets, thus optimizing leverage and the tenor of debt instruments. This use of "project finance" is very common in the infrastructure sector: about 70% of all infrastructure debt borrowers worldwide are project finance vehicles. The official definition of project finance was put forward by the Bank of International Settlement in a report to the Basel Committee:

> Project finance is a method of funding in which investors look primarily to the revenues generated by a single project, both as the source of repayment and as security for the exposure. In such transactions, investors are usually paid solely or almost exclusively out of the money generated by the contracts for the facility's output. The borrower is usually a Special Purpose Entity (SPE) that is not

3. See Frederic Blanc-Brude and Jing-Lis Yim, "The Pricing of Private Infrastructure Debt: A Dynamic Approach," in *EDHEC Infrastructure Institute Publications* (2019), for a discussion and empirical tests.

> permitted to perform any function other than developing, owning, and operating the installation. The consequence is that repayment depends primarily on the project's cash flow and on the collateral value of the project's assets.[4]

The practice of project financing infrastructure assets is the primary source of new private infrastructure debt instruments. These instruments are 7- to 25-year term loans in their immense majority, as well as the some privately placed and very few publicly traded bonds. Since 2000, global origination of new infrastructure project finance debt typically ranges in the 300 to 400 billion U.S. dollars a year. In what follows, we review the key characteristics of private infrastructure project debt, what factors tend to determine their pricing (credit spread). and how to approach credit risk in an asset class that is designed to avoid hard defaults.

CHARACTERISTICS

Limited Recourse

Project financing amounts to investing in a single-project firm or Special Purpose Entity (SPE) with a predefined lifespan. Before the financing decision can be taken, this SPE has to demonstrate its financial viability with a high degree of probability.

Creditors have no substantial sponsor guarantees (limited recourse) or any tangible assets collateral (relationship-specific capital investment). The only source of value of the SPE is its future free cash flow, that is the cash flow available once the various tasks that the SPE has contractually committed to accomplish in each period (e.g., to build, maintain, and operate an infrastructure project) have been executed.

In project financing, the free cash flow of the firm is thus the sole determinant of asset value. At any time t during the SPE's finite life, the firm's value is simply the sum of expected cash flow available for debt service, or CFADS, discounted at the appropriate rate. This value is the only quantity against which the SPE may initially borrow (and later restructure or refinance) any debt.

In the majority of cases, the project SPE raising the debt in question does not own any tangible assets,[5] or owns assets that are so *relationship-specific* that they have little or no value outside of the contractual framework that determines the future CFADS stream, and justifies the investment in the first place.

4. BIS, *Basel II: International Convergence of Capital Measurement and Capital Standards: A Revised Framework*, technical report, Bank of International Settlements, 2005.

5. In the most frequent case of public infrastructure projects financed through a so-called public–private partnership contract, the ownership of the tangible infrastructure also assets remains in the public domain.

Project financing also means that the owners of the SPE provide very little, if any, collateral to secure its debt. Contracts must suffice to create enforceable and valuable claims and to define expected cash flows with reasonable accuracy.[6]

The only form of collateral available to infrastructure project lenders is the "share-pledge" made by the project owners. In the event of default, lenders can try and maximize recovery by securing a larger share of the project future CFADS, including the debt's "tail," that is, the SPE's cash flow beyond the original maturity of the debt and over which lenders have control rights in states of the world embodied by certain covenant breaches. As is the case during the life of the loan, free cash flow in the tail is determined by the contractual arrangements that led to the SPE's creation—for example, the right to collect a toll. There is no terminal value.

Hence, unlike traditional firms, the value of the total assets of an SPE can be observed. This makes structural credit risk models, which derive a firm's credit risk from its total asset value, a natural and more suitable choice than reduced form models, which approach default as a pure hazard rate. We return to this point in more detail below.

The CFADS thus plays a central role in our approach to value infrastructure debt: it is the risky (stochastic) *underlying process* driving value in project finance debt securities, not dissimilar to the stochastic processes referred to in the design of option pricing formulas.

In this context, an important feature of project finance is the role of *initial* financial leverage (agreed at financial close). The ratio of senior debt to total investment in infrastructure project finance typically averages 75%, irrespective of the business or credit cycle, and can be as high as 90% for certain categories of projects with a the most predictable free cash flow.[7]

It can be argued that the high leverage typically observed in project finance should be interpreted as a sign of *low* asset risk,[8] that is, lenders agree to provide most of the funds necessary to carry out the planned investment without further recourse or security because the probability of timely repayment is considered to be very high.

Beyond the predictability of the SPE's business model and therefore its ability to meet the base case debt service agreed at financial close, lenders agree to extend the majority of the necessary funds because of the covenants and embedded options that are found in project finance debt and that create unique state-dependent control rights for them, of the sort that are not found in traditional corporate debt.

Covenants and Embedded Options

Because project finance SPEs typically have a high degree of initial leverage, debt contracts often contain covenants to protect debt holders. These covenants can vary from one loan to another, depending on the bank's relationship with the counterparty and the bank's assessment of the project's risk.

Nevertheless, covenants and embedded options commonly found in project finance debt include:[9]

- *Minimum Debt Service Coverage Ratio (DSCR) requirement:* In order to mitigate credit risk, debt covenants often require the borrower to maintain at least a minimum level of the debt service coverage ratio—the ratio of the free cash flow of the SPE to the current period's scheduled debt payment. If the DSCR falls below a pre-agreed threshold, equity dividends can be "locked-up" to create a supplementary cash buffer for debt holders, as well as to create incentives for equity investors to resolve the problems that have led to lower than expected free cash flow (to the extent that it is in their power).
- *Nonfinancial default triggers:* In addition to covenants that trigger default due to financial weakness (missed debt payment, or a decrease in the DSCR below the minimum stipulated level), default can also be triggered by nonfinancial or operational events. For example, events such as the revocation of the SPE's license to perform a business, the failure to complete construction in time, or the default of a counterparty to the SPE, can lead to an event of default. Once this has occurred, the project cannot be managed without lenders' involvement.[10]
- *Step-in option:* Thus, financial and nonfinancial default triggers give lenders an option to "step in," which, in turn, should impact the debt value. In case of a breach of a debt covenant, debt owners have the right to get involved in the management of the project company. In this context, debt holders can put in a "cash sweep" to accelerate debt payments, or reschedule debt payments to gain more financial flexibility to resolve outstanding issues.
- *Cash sweeps:* Cash sweeps are a form of compulsory prepayment. After an agreed-upon distribution to shareholders, which can be zero, any remaining CFADS balance is used to prepay the debt. This is to minimize the effects of substantial fluctuations in cash flows on credit risk and to use the excess cash generated in good periods to reduce outstanding debt and protect against periods with lower than expected cash flows. Of course, cash sweeps introduce prepayment risk for investors.

9. See E R Yescombe, *Principles of Project Finance*, Academic Press, 2002.
10. See Yescombe, *Principles of Project Finance*, section 13.11.

- *Cash claw-back:* Under a claw-back provision, equity investors agree that if problems occur with future cash flows, they will repay or lend to the project company up to the amount they have received in dividends or other distributions over a set period of time.
- *Reserve accounts:* Reserve accounts are established to reserve cash during periods of higher earnings to service debt payments during periods of lower earnings. These accounts provide security for lenders against short-term cash problems, and can also be set up to fund future expenditures. Reserve accounts may also segregate funds based on their use. For example, debt service reserve account (DSRA) contains funds to service next period's debt payment (principal + interest), and tax reserve accounts contain funds to pay tax liabilities that have been incurred but would be paid in the future.
- *Prepayment option:* Project loans often allow prepayments at little to no cost. If the project does well, the SPE may take advantage of this prepayment option to refinance at lower rates. However, with the development of institutional investors' involvement in lending to infrastructure projects, prepayment may become more penalizing for SPEs since these investors tend to be looking for instruments with a known duration.

Note that traditional capital budgeting methods would fail to take into account the effects of these covenants and embedded options. Structural credit models, on the other hand, can incorporate the effects of these covenants through their effect on the cash flows to debt holders.

Default Triggers

Default mechanisms in project finance have two important dimensions: first, the default point is more straightforwardly known than in standard corporate finance; and second, the presence of debt covenants that impose other obligations on the borrower in addition to the debt repayment means that *technical* defaults are a prevalent form of credit event.

In structural models of standard corporate debt, default is generally modeled as crossing a threshold point below which the total value of the firm's assets is less than its short- and medium-term liabilities. This is because as long as the total value of the firm is higher than its near term liabilities, equity holders can raise more cash by issuing new equity or debt and satisfy their current debt obligations. For infrastructure SPEs, this is not the case because equity holders are constrained in their ability to raise more cash by issuing new debt or equity to preserve the value of existing debt holders' security.[11] The non-recourse nature of the equity investment and the inability of the firm to increase its borrowing make default easier to predict than in standard corporate finance.

11. See Yescombe, *Principles of Project Finance*, sections 13.7 and 13.10.

In project finance, the relationship between the firm's free cash flow or cash flow available for debt service (CFADS) and the expected senior debt service, that is, the ability of a given SPE to service its senior debt obligation, is captured by a debt service cover ratio (DSCR), which is routinely monitored by project finance lenders for each SPE. The DSCR at time t is written as

$$\mathrm{DSCR}_t = \frac{\mathrm{CFADS}_t}{\mathrm{DS}_t^{\mathrm{BC}}} \tag{20-1}$$

in each period $t = 1, 2, \ldots T$ for a project financing of maturity T; $\mathrm{DS}^{\mathrm{BC}}$ is the base case debt service. As a function of the CFADS, that is, the distribution of the DSCR at time t (DSCR_t) in project finance can capture both the firm's asset value and its volatility. Moreover, the DSCR provides an *unambiguous* definition of default.[12]

Thus, a "hard" default of the SPE (a default of payment) can be defined in terms of the *ex post* CFADS at time t as

$$\mathrm{Default}_t \Longleftrightarrow \mathrm{CFADS}_t < \mathrm{DS}_t^{\mathrm{BC}} \tag{20-2}$$

which can be expressed in terms of *ex post* $DSCR_t$ as

$$\mathrm{Default}_t \Longleftrightarrow \mathrm{DSCR}_t = \frac{\mathrm{CFADS}_t}{\mathrm{DS}_t^{\mathrm{BC}}} < 1 \tag{20-3}$$

By definition, if DSCR_t equals unity, the SPE is just able to service its senior debt during the relevant period, and if it falls below unity, the borrower can unambiguously be considered in default.[13]

Credit events may also be defined more loosely. For example, in the Basel II framework, project finance default is defined as "*past-due more than 90 days on any material credit obligation to the banking group.*"[14]

Thus, unlike standard corporate debt where covenants typically only relate to the financial state of the firm, project finance SPEs can also experience *soft* or *technical* defaults; for example, a low *ex post* DSCR may constitute a breach of the loan's covenants and also be considered an event of default.

The formulation of the default point above suggests that credit events can be very finely defined in project finance and that lenders may consider an SPE to be in default and take remedial action long before it has become unable to repay its debt.

Ex ante, that is, at the time of financial close, lenders typically require the DSCR to be significantly higher than unity in order to create a credit-risk

12. Frédéric Blanc-Brude and Majid Hasan, *Infrastructure Valuation*, London: PEI Media, March 2015.

13. Moody's defines project finance default as "a missed or delayed disbursement of interest and/or principal." Moody's, *Default and Recovery Rates for Project Finance Bank Loans 1983–2011*, technical report (London, U.K.: Moody's Investor Service), Feb. 2013, is congruent with this view.

14. BIS, *Basel II: International Convergence of Capital Measurement and Capital Standards: A Revised Framework.*

buffer and also so that equity/junior distributions can be made once senior debt obligations have been met. *Ex post*, if DSCR_t is too low, it can trigger one of the covenants described above.

Hence, the default point in project finance at time t can be defined as

$$\text{DSCR}_t = 1.x \text{ with } x \geq 0$$

And since the DSCR provides an unambiguous default point of infrastructure project finance debt, its probability of default at time t can be written as

$$p_t = \Pr(\text{DSCR}_t < 1.x \mid \min_{j<t} \text{DSCR}j \geq 1.x)$$

which is the probability that the DSCR reaches the default point, conditional on there having been no default until that time.

Hence, knowledge of the distribution of DSCR_t for a category of project financing and of the DSCR-related covenants of a given loan is sufficient to identify and predict default in project finance. We also show that knowledge of the first two moments of the distribution of DSCR_t is sufficient to derive the SPE's distance to default, which is instrumental in our valuation model.

Restructurings

Restructurings are the result of the embedded options discussed above. We use the term restructurings or "workouts" to refer to any change in the SPE's capital structure or debt service schedule (face value, maturity, and seniority) from the base case scenario. Such workouts are very common in project finance.[15]

SPEs are restructured both during financial distress (to avoid bankruptcy), and when the firm's free cash flow is sufficiently high (to take advantage of a lower credit risk to refinance at lower rates). The suitability of refinancing depends on the maturity of existing debt, debt covenants that may penalize refinancing, and external market conditions. If the debt covenants allow refinancing at little to no cost, as is usually the case with bank loans,[16] and demand for infrastructure projects is high, an SPE may be able to refinance at lower costs. However, if the existing debt is expiring soon and the demand for infrastructure debt is low, refinancing can be costly. Long-term investors' greater aversion to refinancing, which can significantly reduce the duration of their fixed income portfolio may lead to the more frequent introduction of prepayment charges and to fewer refinancings.

Such workouts can change the SPE's debt service schedule and hence its default threshold can also deviate from the base-case scenario.

Crucially, in the case of workouts triggered by financial distress, the period between the maturity of the debt and the maturity of the project, the so-called the "tail" of the loan, can allow for debt service restructurings that leave the value of

15. See Yescombe, *Principles of Project Finance*, sections 7.7 and 13.6.
16. See Yescombe, *Principles of Project Finance*, section 13.6.

the initial debt quasi- or completely intact. It allows debt holders to restructure debt schedule and recover any losses suffered during the original maturity of the debt.[17]

Next, we look at the determinants of credit spreads in infrastructure debt.

PRICING DETERMINANTS

Despite project finance being a subset of corporate debt, existing research suggests that the drivers of corporate debt spreads do not necessarily impact project finance credit spreads in the same ways, and vice versa. Here, we summarize some of the key findings of the existing academic literature on the determinants of credit spreads in infrastructure debt.

The literature on corporate finance acknowledges that credit spreads should have multiple determinants.[18] For example, Churm and Panigirtzoglou identify three components of credit spreads: expected default, credit risk (uncertainty about probability of default), and non-credit risk, which is highly correlated to swap spreads[19] for investment-grade debt. The noncredit-risk component, attributed to liquidity, tax, or regulatory effects, increases as the credit-risk component increases, consistent with the empirical evidence that lower-quality credits have higher credit default swap bid-ask spreads and that a small proportion of swap spreads is due to credit risk.

Likewise, existing research about the determinants of infrastructure project finance debt credit spreads suggests a range of potential factors:

- *Maturity:* Unlike in traditional corporate finance, a longer tenor may not equate to greater risk and larger spreads for lenders.[20] Consistent with the inference that high leverage signals low asset risk in project finance, longer maturities can signal greater lender confidence. Previous researchers have found that the credit spread term structure in project finance, unlike other types of debt, is *hump-shaped*—beyond a certain maturity, longer-term projects are cheaper than short-term ones.[21] The authors attribute this to the dependence of project finance debt repayments on project cash flows, which makes longer tenors beneficial. Additionally, time-idiosyncratic risks like construction risk dissipate

with longer maturities.[22] However, Blanc-Brude and Strange suggest that this may be a dynamic effect due to changing market conditions rather than evidence of a nonlinear term structure.[23] In a panel regression of spreads, year and country effects were found to be much stronger drivers of the spreads in project loans. Similarly, Gatti and colleagues do not find a statistically significant relationship between maturity and spread.[24]

- *Leverage:* Spreads are found to have a positive relationship with leverage, signaling a tradeoff between cheaper credit and reduced equity contribution.[25]
- *Size:* Loan size and project finance credit spreads have a negative relationship.[26] However, the effect in project loans is three to four times smaller than in the corporate debt control groups.[27] Kleimeier and Megginson found the relationship to be statistically insignificant.[28]
- *Syndicate size:* The hypothesis that the number of creditors has an impact on spreads is not overwhelmingly supported by empirical evidence. While Etsy and Megginson[29] found that loan pricing is positively related to the number of arranging banks and the shares held by them,[30] they did not find a significant relationship between syndicate size and spreads.
- *Ratings:* Likewise, the impact of credit ratings is not clear-cut. Gattti and colleagues find that rated project debt has higher spreads and argues the very decision to rate project debt signals higher *ex ante* project risk.[31] Most project finance debt is, however, unrated.

- *Debt seniority:* In general mezzanine or subordinated debt is found to have higher spreads, reflecting a higher degree of risk for creditors who are not senior in the cash-flow waterfall.[32]
- *Guarantees:* Guarantees extended by multilateral banks are generally found to reduce average spreads.[33] Kleimeier and Megginson find also find that among all forms of corporate debt, project finance loans display the greatest sensitivity to third-party guarantees, with a higher reduction in average spreads.[34] The same effect is found by Kleimeier and Megginson.[35]
- *Business risk:* The uncertainty inherent in the business model of the borrower is another proxy for credit risk. Infrastructure projects that have a long-term, contracted revenue stream can raise debt that is systematically cheaper than those whose revenues are exposed to demand risk.[36]
- *Refinancing:* Blanc-Brude and Strange find that refinanced loans tend to have lower spreads by up to 50 bps.[37] In a number of cases, credit spreads are planned to increase post-construction to encourage debt refinancings.[38]

In a recent study, Coelho considers and recomputes the results of most of the studies above and confirms these findings with a more recent. [39] Thus, the research literature suggest that project finance debt is priced quite differently than corporate debt.

However, these studies suffer from a number of limitations. For the purpose of explaining the determinants of credit spreads, existing studies all use linear regression techniques, implying that the determinants of credit spreads do not fundamentally change over time but instead that risk pricing tends to revert to a long-term mean.

Most studies use data sets that generally predate the 2008 credit crisis, which resulted in a step change in the level of credit spreads in private debt as a result of a shock to creditors' cost of funds, followed by the evolution of the

average creditor's risk preferences, partly due to new regulation of the banking sector and partly to the entry of new types of creditors in the private debt sector.

Even though more recent papers[40] do take into account the 2008–2009 credit market dislocation event, they fail to capture the evolution of individual risk premia over time. Instead, they fit a static linear model through a time series with nonlinear, non-stationary characteristics.

Moreover, existing studies solely relying on observable spreads over time. Hence, if certain types of private infrastructure debt become less likely to be originated over a period, though such assets are still held on the balance sheet of an investor at that time, they may not be adequately valued using current market spreads.

In a more recent study,[41] Blanc-Brude and Yim develop a dynamic model of the determinants of credit spreads to estimate the evolution over time of the individual risk-factor premia and determine their *unbiased* effects on spreads over time.

They show that infrastructure and corporate credit spreads are determined by a combination of common factors that can be grouped into four categories:

- *Credit market beta:* The largest effect driving credit spreads in infrastructure debt is a time-varying trend factor that captures the state of the credit market over time. This effect is not explained by loan or borrower characteristics. In the case of infrastructure debt, this effect is mostly constant over time but exhibits "regime shifts," especially in 2008 (up) and 2014 (down).
- *Credit risk:* This only explains part of the level of credit spreads.
    - Infrastructure borrowers that are exposed to *merchant risk* (See TICCS® Taxonomy) are required to pay a time-varying premium from 20–40% above the market average at the time.
    - Size has no effect on average corporate spreads but is a driver of lower risk premium in infrastructure debt. In effect, larger loans can be interpreted as a signal of lower credit risk in infrastructure finance.
    - Industrial sectors can be considered a partial proxy for credit risk but are mostly not significant, except for social infrastructure and, among corporate borrowers, infrastructure corporates, which have come to benefit from a substantial discount relative to average market spreads in recent years.

40. Blanc-Brude and Ismail, "Who Is Afraid of Construction Risk? Portfolio Construction with Infrastructure Debt"; Coelho, "The Term Structure of Credit Spreads in Syndicated Loans."
41. Blanc-Brude and Yim, "The Pricing of Private Infrastructure Debt: A Dynamic Approach."

- *Liquidity:* Other drivers of spreads are proxies of the cost of liquidity for creditors.
    - *Maturity:* While it is difficult to capture in static models, maturity is found to be a significant and time-varying driver of spreads.
    - While the effect of size is primarily a matter of credit risk, in periods of limited creditor liquidity (2008), even infrastructure debt becomes more expensive as a function of size. However, this effect is not strong enough to create a persistent "size premium."
    - Refinancings, which are not a significant driver of spreads in normal times, are shown to be more expensive in times of credit-market stress.

- *Cost of funds:* The benchmark against which floating-rate debt is priced is a factor explaining the level of credit spreads.
    - Base rates are inversely related to spread, that is, higher rates imply lower spreads, but this effect is shown to have all but vanished since 2008. Since then, the level of credit spreads and that of base interest rates has become completely uncorrelated.
    - *Market segments:* Taking base rates into account, some markets are cheaper than others as a result of the well-documented segmentation of credit markets. This is the case when comparing LIBOR- versus Euribor-priced loans, but also the different geographic areas in which different lenders operate. Again, since 2008, these differences have tended to disappear.

The dynamic modeling of illiquid debt spreads in Blanc-Brude and Yim allows overcoming structural limitations in the data: observable spreads are biased due to the segmentation and low liquidity of the private credit market, but *unbiased* factor prices (premia) can be estimated from observable spreads and used to determine the factor-implied spreads for any instrument at any time.

The time-varying nature of individual risk premia implies that repricing individual instruments over time can be material and is required if such investments are to be evaluated on a *fair-value* basis.

One of the most important requirements of the IFRS framework is to *calibrate valuations to observable market prices*, thus ensuring that estimated spreads represent current investor preferences at the measurement time. While fair value is not always required for debt instruments, which tend to be booked at cost (outstanding face value) unless they become impaired, the requirement to evaluate assets on a like-for-like basis only grows as the private debt asset class becomes a more significant part of investors' portfolios.

Next, we look at how to approach credit risk in private infrastructure debt.

CREDIT RISK

The extensive control rights of lenders of infrastructure debt are central to understanding its credit risk profile: infrastructure debt is designed to avoid default of payment events, or hard defaults, because these instruments are the object of continuous and extensive monitoring, any material degradation of the credit risk profile of the borrower (e.g., delays, cost overruns, low DSCR, etc.) can trigger a lender-driven restructuring in order to mitigate credit risk and avoid a hard default.

As a result, actual hard defaults can be very rare, sometimes unheard of in certain infrastructure debt portfolios. Of course, the absence or rarity of hard defaults does not mean that credit risk is negligible in infrastructure debt. Rather, with project finance debt credit risk is managed on an ongoing basis. This has two important implications:

1. Infrastructure project debt requires costly monitoring.
2. Because credit risk is dynamic (and endogenous), the usual reduced-form models of default risk are not adequate to measure or model the credit risk of infrastructure debt instruments.

Reduced Form Approach

The limits of reduced form credit risk models is well illustrated by the empirical default studies conducted by rating agencies, which consists of measuring the number of defaults observed within a population of loans at a given point in time and in each loan's life cycle. These studies all imply a reduced form approach because rely on observing discreet events of default, i.e., they derive an implicit "hazard rate" from observed hard defaults, which is the common approach when estimating corporate debt default frequencies.[42]

Several stylized facts are frequently abstracted from these reports:

- On average, the available sample of project finance loans exhibits marginally decreasing cumulative default rates in time, which is the result of a decreasing annual probability of default as project loans mature.
- As a consequence, project finance debt exhibits continuous default risk transitions over a period of approximately 10 years, from a triple-B equivalent to a single-A equivalent. The observed probability of default in available samples trends from around 2% around the time of financial close to near zero after 10 years.

However, observed hard defaults in project finance debt are also clustered in time and space: in sector or countries which experienced a market shock

42. See, for example, Edward I. Altman and Heather J. Suggitt, "Default Rates in the Syndicated Bank Loan Market: A Mortality Analysis," *Journal of Banking and Finance* 24(1–2), pp. 229–253.

(merchant power in the the United States in the early 2000s) or a sector-wide policy reversal (retroactive changes in solar power subsidies in Spain in the early 2010s) or went through a brief moment of over-optimism and "covenant-light" deals (the toll road sector in Spain or Australia in the mid-2000s), defaults of payment can be hard to avoid even with the protection and step-in rights that are available to lenders.

Moreover, if projects are financed that are fundamentally uneconomic or face a shock that makes them durably so, lenders may have little interest in "working-out" the best financial structure going forward and can decide to "wipe out" the project owners instead and sell the project to distressed asset investors to minimize their loss. Evidence suggests that in this rare case, lender haircuts are significant.[43]

In the majority of cases, workouts do take place after a "soft" or technical default, and hard defaults never materialize. Again, this should not be understood to mean that the risk of hard default is low. Rather it is conditionally low, if the adequate monitoring is in place and effective and successful workouts are possible. If these conditions are not met in some projects, then the probability of hard default may be quite high.

As a result, reduced forms approaches to infrastructure debt credit risk are likely to provide very biased results since very few defaults are observable and they are unlikely to be representative of the credit risk that characterizes different types of infrastructure borrowers.

Structural Approach

Unlike reduced form models that specify a default process exogenously, structural models postulate the existence of a default triggering mechanism, that is, a discrete event at the threshold between two states (default vs. no default), the probability of which is determined endogenously. In other words, default events do not occur randomly but are linked to a firm's assets and liabilities. Structural models assume a link between the firm's fundamentals (assets and liabilities) and its credit risk variables and predicts credit events from the change in these fundamentals.

In Merton's classic model of valuation of corporate debt, the value of the company follows a stochastic process (Vt).[44] The company is financed from debt and equity, its debt is a single obligation and resembles a zero-coupon bond with face value B and maturity T. At time t, the value of the firm is the sum of its equity St and debt Bt ($Vt = Bt + St$, for $0 < t < T$). In this model, the firm does not pay any dividends nor issues any new debt. If at maturity the value of the firm

43. See also Majid Hasan and Frédéric Blanc-Brude, "You Can Work It Out! Valuation and Recovery of Private Debt with a Renegotiable Default Threshold," *Journal of Fixed Income* 26 (2017), pp. 113–127, for a game theoretic model of debt restructuring in project finance.

44. Robert C Merton. "On the Pricing of Corporate Debt: The Risk Structure of Interest Rates," *Journal of Finance* 29 (1974), pp. 449–470.

is less than its liabilities ($VT < B$), the firm is considered to be in default. The equity holders then choose not to provide any new equity capital as an expression of their "limited liability option" and hand over the firm to the debt holder, which liquidates the remaining assets and receive the proceeds $B_T = V_T$. If there is no default, the debt holder receives the payoff B, and equity holders receive the remainder of the firm's value $V_T - B$.

The original Merton model has been criticized for making a number of strong assumptions, including a simplistic capital structure (the firm borrows once and subsequently deleverages) and the idea that the default point is not only known unambiguously, but the firm must default exactly when this point is reached, neither of which is self-evident empirically for corporate credits.

However, the Merton model is rather well-suited to project financing: SPEs borrow once and subsequently deleverage, default is unambiguously known and actively monitored, and the underlying process driving asset value (CFADS) can be captured by the distribution of the DSCR.

Indeed, given the definition of DSCRt given above, the CFADS for a given period is simply obtained as

$$\text{CFADS} = \text{DSCR}_t \times \text{DS}_t^{\text{BC}} \tag{20-4}$$

with DS_t^{BC}, the debt service. The same relationship holds in expectation. Hence, as long as the base case debt service is known, we can reduce the question of modeling the free cash flow of the firm in project finance to that of the dynamics of DSCRt and its determinants.

Furthermore structural models have been further developed to extend the original Merton model and address most of the issues found in the asset pricing literature. These include models that incorporate complex capital structures[45] and endogenous default thresholds.[46]

Structural models are thus the most suitable choice for infrastructure project debt, as the primary input of these models is the value of the firm's assets and loan covenants, which we know can be observed in the case of SPEs, and because they can incorporate the endogenous credit risk dimension.

Blanc-Brude and Hasan demonstrate how the standard distance to default metric can be derived for infrastructure debt using only the first two moments of the DSCR distribution.[47]

In the KMV model, Crosbie and Bohn[48] posit that the "distance to default" is a sufficient statistic to arrive at a rank ordering of default risk. The firm's distance to default can be approximated as

$$\text{Distance to Default} = \frac{[\text{MV}] - [\text{DT}]}{[\text{MV}]\ .\ [\text{Vol}]} \tag{20-5}$$

where MV is the market value of assets, DT is the default threshold, and Vol is the standard deviation of the annual percentage change in the asset value.[49] The numerator expresses the firm's financial leverage, or *financial risk*, while the denominator reflects its *business risk*. In other words, KMV assumes that differences between the credit risk of different companies are reflected in the value and volatility of their assets, as well as their capital structure, which are all present in the distance to default measure.

Following the definition of default in infrastructure project finance given above, distance to default at time t can be defined as

$$\text{DD}t = \frac{\text{CFADS}_t - \text{DS}_t}{\sigma_{\text{CFADS}_t}\,\text{CFADS}_t} \tag{20-6}$$

with CFADSt, the cash flow available for debt service, and DSt, the debt service at time t.

Using the definition of DSCRt above, the above expression can be written as a sole function of the DSCR:[50]

$$\text{DD}t = \frac{1}{\sigma_{\text{DSCR}_t}}\,\frac{\text{DS}^{\text{BC}}_{t-1}}{\text{DS}^{\text{BC}}_t}\left(1 - \frac{1}{\text{DSCR}_t}\right) \tag{20-7}$$

where σ_{DSCR_t} is the standard deviation of the annual percentage change in the DSCR value. Hence, the first two moments of the distribution of DSCR$_t$ together with the debt repayment profile (the growth rate of the debt service defined by DS$_t$ – 1/DS$_t$) are sufficient inputs to estimate the distance to default of project finance debt instruments.

Empirical Validation

Blanc-Brude, Hasan, and Whittaker[51] propose a Bayesian estimation of the DSCR process in different types of infrastructure projects and derive unbiased measures of credit risk in private infrastructure debt using a data set of the financials of hundreds of private infrastructure borrowers.[52]

The left panel of Exhibit 20-1 shows the unconditional probability that DSCR*t* falls below the hard default threshold at each point in the life cycle of projects. Only the first default of payment is counted, which is consistent with Moody's definition of default (missing one payment) and computation of marginal default frequencies.[53]

Consistent with rating agencies results, project finance borrowers tend to de-risk over time. However, at the aggregate level (black line), marginal default frequencies are higher than in the reports produced by Moody's.[54] This is because a structural model measures all potential defaults, as opposed to a biased sample of actual credit events. After 10 years, conditional on no default until that time, default risk in infrastructure debt is typically not equal to zero, in contrast with the conclusion of reduced form approaches but more in line with actual credit ratings.

In calendar time (right panel of Exhibit 20-1), the aggregate default risk follows the business cycle, decreasing from the early 2000s until the 2008 financial crisis and increasing again from 2009 onward. This is consistent with previously reported evidence. Here, the default risk of "merchant" projects that have a business model more exposed to the economic cycle (e.g., toll roads) also tends to increase more markedly at bad times in the economic cycle, as illustrated by the blue line on Exhibit 20-1. Infrastructure projects that have very predictable cash flows (and the resulting higher leverage) like PFI projects[55] have very low default rates at all times and countries where such projects are more commonly found (e.g., the U.K.) and also exhibit lower default risk than the average infrastructure borrower.

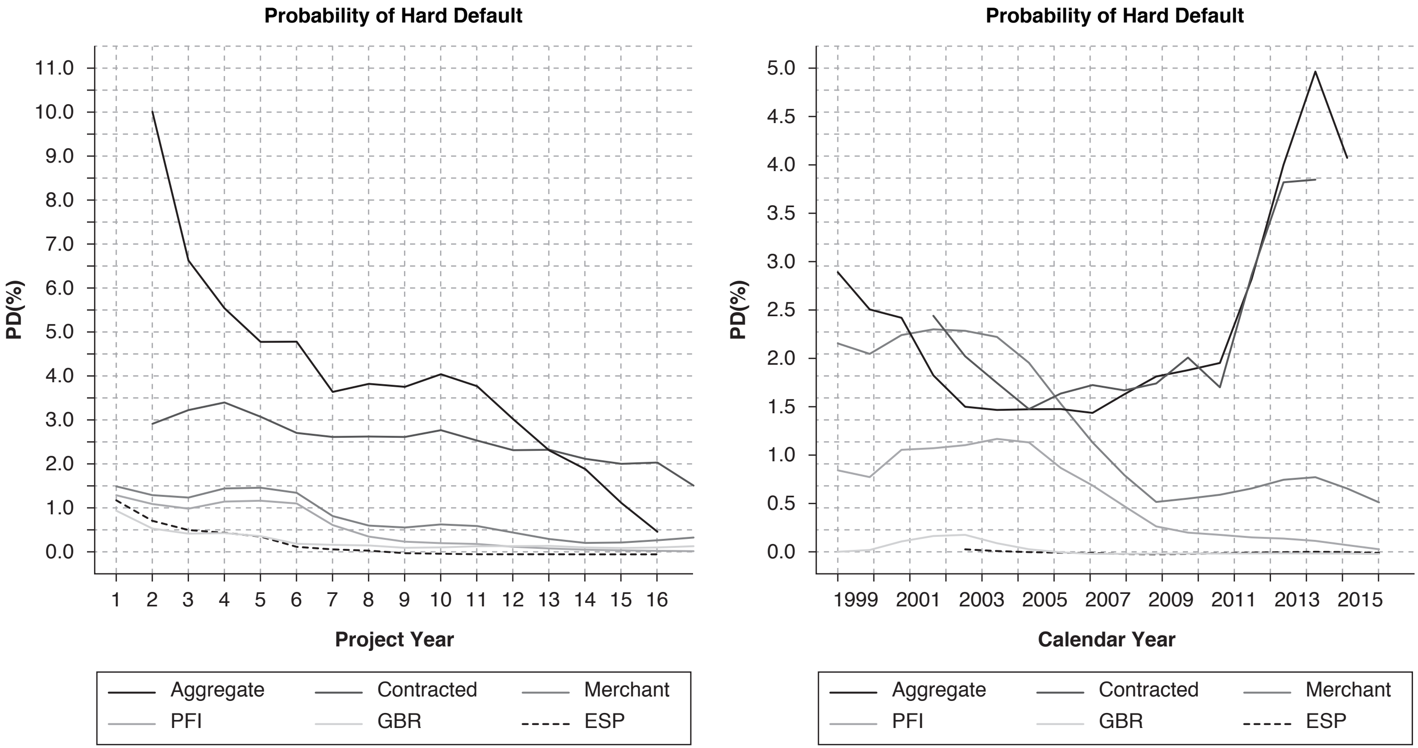
EXHIBIT 20-1

Probabilities of Hard Default over Time, Computed as the Probabilities of DSCR*t* Falling Below 1.0



KEY POINTS

- Both theory and empirical evidence suggest that private infrastructure debt is different from other forms of corporate debt.
- The determinants of its pricing are different and its credit risk profile is in great part determined by the monitoring, control rights, and resulting embedded options that can be exercised by creditors in order to manage credit risk on an ongoing basis, mitigate default risk, and maximize recovery.
- The requirement to monitor infrastructure project borrowers also implies higher servicing costs and the credit quality of these instruments must then be closely related to the quality of the monitoring.
- Credit risk management requires advanced modeling to overcome the paucity of default event data, which may be a challenge for smaller investors and complicates the prudential treatment of this asset class.

CHAPTER

TWENTY-ONE

AN OVERVIEW OF MORTGAGES AND THE MORTGAGE MARKET

Anand K. Bhattacharya, Ph.D.
Professor of Practice
Department of Finance
Arizona State University

Bill Berliner
Managing Director, Research and Fixed Income Investor Relations
PennyMac

Over the last few decades, the mortgage market in the United States has emerged as one of the largest financial asset classes. As of the third quarter of 2019, the total face value of one- to four-family residential mortgage debt outstanding was approximately $11 trillion, with more than $8 trillion having been securitized into a variety of investment vehicles. As a point of comparison, at the same point in time, the outstanding amount of marketable U.S. Treasury notes and bonds totaled roughly $12 trillion. For a variety of reasons, such as product innovation, technological and regulatory changes, and evolving consumer and lender preferences, the composition of the primary mortgage market continues to evolve on a fairly dynamic basis. The mortgage lending paradigm has undergone a number of profound changes over the past two decades. Between 2002 and mid-2007, there was a proliferation of product offerings designed to both appeal to changing consumer preferences and broaden the range of borrowers that could qualify for mortgage loans. While this had the effect of increasing the home ownership rate in the United States, it eventually led to a disastrous combination of relaxed underwriting standards and inflated values for residential real estate. The subsequent financial crisis led to the collapse of numerous large financial firms and lenders, as well as Freddie Mac and Fannie Mae, which were placed into conservatorship in 2008. While underwriting and lending practices have subsequently evolved to comply with a new regulatory framework, at this writing many aspects of the mortgage market and housing finance, including the form that Freddie Mac and Fannie Mae will ultimately take, remain unclear and the subject of intense debate and speculation.

The purpose of this chapter is to outline fundamental aspects of the mortgage markets in the context of the post-crisis industry and regulatory environment. We will define the terminology and metrics associated with various mortgage products, describe the process by which lenders compute their loan pricing, and discuss the different risks associated with mortgage products.

PRODUCT DEFINITION AND TERMS

In general, a mortgage is a loan that is secured by the underlying real estate that can be repossessed in the event of default. For the purposes of this chapter, a mortgage is defined as a loan made to the owner of a one- to four-family residential dwelling and secured by the underlying property. Standard product offerings are level-pay "fully amortizing" mortgages, indicating that the obligor's monthly payments are calculated in equal increments to pay off the loan over the stated term. There are, however, a number of key characteristics that are considered critical in understanding the instruments, and they are differentiated along the following attributes.

Lien Status

The lien status dictates a loan's seniority in the event of the forced liquidation of the property owing to default by the obligor. The preponderance of mortgage loans originated have first-lien status, implying that a creditor would have first call on the proceeds of liquidation of the property if it were to be repossessed. Borrowers have often used second-lien loans as a means of liquefying the equity a home for the purpose of expenditures (such as medical bills or college tuition) or investments (such as home improvements). A second-lien loan also may be originated simultaneously with the first lien in order to maintain the first-lien loan-to-value (LTV) ratio below a certain level. A fairly common practice prior to mid-2007, this allows the obligor to avoid the need for mortgage insurance, which is required for loans with LTVs greater than 80%.

Original Loan Term

The majority of mortgages are originated with a 30-year term and amortize on a monthly basis. Loans with stated shorter terms of 10, 15, and 20 years also are utilized by borrowers who are motivated by the desire to own their home earlier. Among these mortgages, where the monthly mortgage payment is inversely related to the term of the loan, the 15-year mortgage is the most common instrument. Small numbers of loans are also structured to have so-called balloon payments. The loan amortizes over a 30-year term; however, at a preset point in time (the "balloon date," generally five or seven years after issuance) the borrower must pay the balance of the loan in full.

Interest-Rate Type (Fixed vs. Adjustable Rate)

As is indicated by the nomenclature, fixed-rate mortgages have an interest rate that is set at the closing of the loan (or, more accurately, when the rate is "locked" by the borrower) and is constant for the loan's term. Based on the loan balance, interest rate, and term, a payment schedule effective over the life of the loan is calculated to amortize the principal balance. Note that while the monthly payment is constant over the life of the loan, the allocation of the payment into interest and principal changes over time, as we will demonstrate later in this chapter. During the earlier years of the loan, the level-pay mortgage consists mainly of interest, whereas the constant payment is composed mainly of principal in the later years of the life of the loan.

Adjustable-rate mortgages (ARMs) have note rates that change over the life of the loan. The note rate is based on both the movement of an underlying rate (the index) and the spread over the index (the margin) required for the particular loan program. A number of different indexes, such as the one-year Constant Maturity Treasury (CMT) and the London Interbank Offered Rate (LIBOR) can be used to determine the reference rate. (As LIBOR is scheduled to be discontinued after 2021, other rates, such as the Secured Overnight Financing Rate [SOFR], are being contemplated as replacement indices for ARMs.) ARMs typically adjust or reset annually, although instruments with alternative reset frequencies are originated. Owing to competitive considerations, the initial rate is often somewhat lower than the so-called fully indexed rate. In this case, the initial rate is referred to as a "teaser rate." In any case, the note rate is subject to a series of caps and floors that limit how much the note rate can change at the reset. Structurally, the caps serve to protect the consumer from the payment shock that might occur in a regime of rising rates, whereas the floor acts to protect the interests of the holder of the loan by preventing the note rate from dropping below predefined levels. The vast majority of adjustable-rate loans have 30-year terms.

The most commonly originated type of ARM is the fixed-period or hybrid ARM. These loans have fixed rates that are effective for longer periods of time (3, 5, 7, and 10 years) after funding. At the end of the period, the loans reset in a fashion very similar to that of more traditional ARM loans. Hybrid ARMs appeal to borrowers who desire a loan with lower initial payments (because ARM rates generally are lower than rates for 30-year fixed-rate loans) but without as much payment uncertainty and exposure to changes in interest rates as ARMs without the fixed-rate period.

Amortization Schemes

As noted, mortgages traditionally have been originated as fully amortizing instruments, meaning that some portion of all payments is dedicated toward reducing the loan's balance. Alternative amortization patterns that grew increasingly popular prior to 2007, particularly in the ARM market, were interest-only loans. The product's payments are divided into two stages. During the interest-only phase, the borrower's monthly payments consist only of interest, and are calculated as a simple function of the loan's note rate and balance. When the interest-only period ends, the loan is recast (i.e., its payments are recalculated) to reflect the loan's remaining term. This means that the loan's payments increase at some point after origination; this phenomenon, called payment shock, caused financial problems for borrowers that were unable to make the higher post-recast payments. A simple example at this point will be helpful. A loan with a balance of \$100,000 and a 6% note rate would have a monthly payment of \$600 calculated over the normal 360-month term. The same loan with a 10-year interest-only period would have an initial payment of \$500 per month for the first 120 months.

In month 121, the loan would recast and require a new monthly payment (calculated at 6% over a 240-month remaining term) of \$716. The borrower is therefore allowed to make a lower payment for the first 10 years of the loan, but accepts the facts that the loan is not being amortized during the interest-only period, along with the commitment to a larger future payment once the loan is recast.

Another variation that had a brief burst in popularity was the payment-option or negative-amortization loan. Although the terms of these products were often quite complex, the product basically allowed for payments that were less than the amount required to make the loan's full monthly interest payment. If the payment made was less than the interest amount due in any month, the shortfall was added to the loan's balance, causing its balance to increase and creating the "negative amortization" in the product's name. For a variety of reasons, the product was discredited and, in some states, outlawed entirely.

Credit Guarantees

While our discussion has centered on the basics of mortgage loans, one of the considerations that also distinguishes various mortgages is the form of the eventual credit support required to enhance the liquidity of the loan. While a complete discussion of secondary markets is beyond the scope of this chapter, the ability of mortgage lenders to continually originate mortgages is heavily dependent on their ability to create fungible assets from a disparate group of loans made to a multitude of individual obligors. Therefore, mortgage loans can be further classified based on whether the eventual credit guaranty associated with the loan is provided directly by the federal government, indirectly through quasi-governmental agencies, or by various alternative entities and practices.

One of the dimensions into which loans can be classified is based on the degree of support received from the Federal government. As part of housing policy considerations, the Department of Housing and Urban Development (HUD) oversees two agencies, the Federal Housing Administration (FHA) and the Department of Veterans Affairs (VA), that support housing credit for qualifying borrowers. The FHA provides loan guarantees for borrowers who can afford only a low down payment and generally also have relatively low levels of income. The VA guarantees loans made to veterans, allowing them to receive favorable loan terms. These guarantees are backed by the U.S. Treasury, which provides these loans with the "full faith and credit" of the U.S. government. These loans are referred to under the generic term of *government loans*. Government loans are securitized largely through the aegis of the Government National Mortgage Association (Ginnie Mae, or GNMA), an agency also overseen by HUD.

Loans that are not associated with government guarantees are classified as *conventional loans*. Conventional loans can be securitized either as so-called private label structures or as pools guaranteed by the two government-sponsored enterprises (GSEs), namely, Freddie Mac and Fannie Mae. The GSEs are shareholder-owned corporations that were created by Congress to support housing activity. Both Fannie Mae and Freddie Mac were placed into conservatorship by the U.S. Treasury in August 2008. By the end of 2010, the GSEs had received a combined total of more than $150 billion in support from the government, in exchange for preferred stock owned by the Treasury (and for which the two firms paid a 10% dividend rate). The terms were revised at the end of 2012 to eliminate the dividend but pay virtually all of their earnings to the Treasury, a clause known as the *net worth sweep*. The very existence of the GSEs, as well as their form and function, remains quite uncertain at this writing; in any case, however, it is likely that they will play a smaller role in housing finance in the future. For as long as they continue to exist, however, the actual choice of the vehicle (GSE versus private label) used to securitize a particular loan depends on a number of factors, such as conformance of obligor credit attributes and property features with GSE loan requirements, the cost of credit enhancement, and loan balance.[1]

Loan Balance (Conforming vs. Nonconforming)

As noted earlier, a mortgage's balance often determines the investment vehicle into which it can be securitized. This is due to the fact that the agencies have limits on the loan balance that can be included in agency-guaranteed pools. The maximum loan sizes for one- to four-family homes effective for the following calendar year are recalculated every November. The year-over-year percentage change in the limits is based on the October-to-October change in the average home price (for both new and existing homes) published by the Federal Housing Finance Agency, the GSEs' regulator since 2008. Since their inception, Freddie Mac and Fannie Mae pools have had identical loan limits because the limits are dictated by the same statute. The effective conforming balance for any individual loan was complicated by the financial crisis that erupted in 2007. The statutory limit rose to $417,000 for a single-family loan in 2006. The Housing and Economic Recovery Act of 2008 (HERA) effectively increased the conforming limit in high-cost areas, based on the area's median home price, to a maximum of $625,500 (or 150% of the statutory limit) for loans on single-family homes.

1. A note with respect to terminology: throughout this chapter, we will use the term agencies to refer to Freddie Mac, Fannie Mae, and Ginnie Mae; the term GSEs refers to Freddie Mac and Fannie Mae only.

The Economic Stimulus Act of 2008 (ESA) temporarily increased the ceiling in high-cost areas to $729,750, subject to annual renewal. (As of October 2011, the limit in high-cost areas was reduced to the HERA limit in effect for that year.) The statutory limit remained at $417,000 from 2006 through 2016; for 2020 the conforming limit was $510,400 (and $765,600 in high-cost areas).

Loans larger than the conforming limit (and thus ineligible for inclusion in agency pools) are classified as jumbo loans and are securitized in private-label transactions (along with loans, conforming balance or otherwise, that do not meet the GSEs' required credit or documentation standards). While the size of the private-label sector is significant, it has long been dwarfed by the agency market. Despite the GSEs' difficulties, the market share for loans being securitized as agency MBS has been, through 2020, in excess of 90%, largely due to regulations and expenses associated with the issuance of non-agency MBS transactions.

Loan Credit and Documentation Characteristics

Mortgage lending traditionally has focused on borrowers of strong credit quality who were able (or willing) to provide extensive documentation of their income and assets. These loans are generically referenced as prime loans. As we noted in the introduction, the period between 2002 and mid 2007 was characterized by the rapid expansion of product offerings to consumers who had been outside of the traditional credit paradigm. Loans made to borrowers with demonstrably weaker credit are classified as *subprime* loans. This sector grew rapidly between 2003 and 2006; at its peak, it comprised roughly 20% of all issuance, by loan amount, in the United States before declining precipitously after the beginning of 2007.

A category between prime and subprime loans is was comprised of so-called alternative-A or *alt-A* loans. This category historically consisted of loans with nontraditional attributes, such as relaxed documentation and occupancy requirements. By 2007, however, the sector effectively became the middle ground for loans that could not be easily categorized as prime or subprime. As a result, its credit profile and performance were wildly uneven, and issuance of loans under the alt-A rubric also dropped dramatically as the product fell out of favor.

The primary factor that enabled the growth of subprime and alt-A lending was the degree of investor acceptance of securities collateralized by these loans. In particular, subprime loans were almost never held in lenders' loan portfolios, making their issuance particularly dependent on securitization as the means of monetizing their production. As a result, the collapse in investor demand for investment products backed by such loans was a primary factor in the demise of these products, as well as many lenders that specialized in their production.

Mechanics of Mortgage Loans

As discussed previously, most mortgage loans are structured as immediately and fully amortizing instruments, where the principal balance is paid off over the life of the loan. As noted previously, fixed-rate loans generally have a monthly payment that is fixed for the life of the loan, based on loan balance, term, and interest rate. A fixed-rate loan's monthly payment can be calculated using the following formula:

$$\text{Monthly payment} = \text{Original balance} \times \frac{\text{interest rate} \times (1 + \text{interest rate})^{\text{loan term}}}{(1 + \text{interest rate})^{\text{loan term}} - 1}$$

Note that the interest rate as used in the formula is a monthly rate calculated by dividing the loan's rate by 12.

Using this formulation, the allocation of the level payment into principal and interest over time provides insights regarding the buildup of owner equity in the property. As an example, Exhibit 21-1 shows the total payment and the allocation of principal and interest for a $100,000 loan with a 5.5% interest rate (or *note rate,* as it is often called) for the first 60 months.

EXHIBIT 21-1

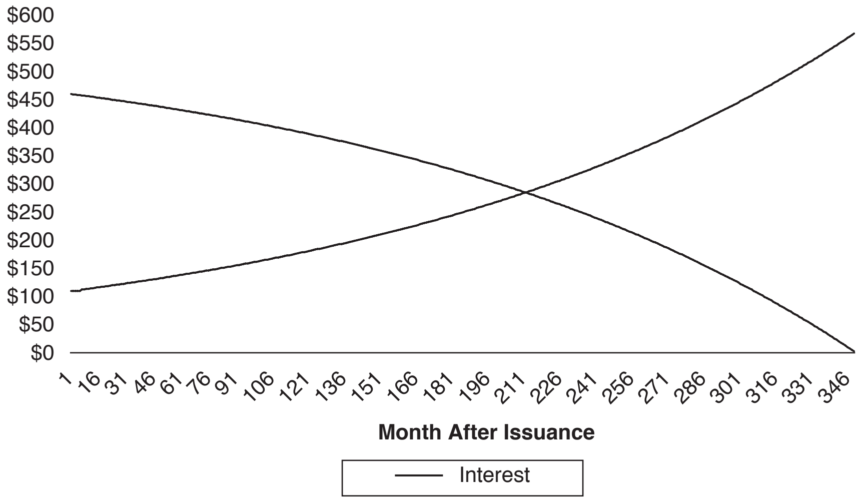
47	$567.79	$432.71	$135.08	$94,273.98
48	$567.79	$432.09	$135.70	$94,138.28
49	$567.79	$431.47	$136.32	$94,001.96
50	$567.79	$430.84	$136.95	$93,865.01
51	$567.79	$430.21	$137.58	$93,727.43
52	$567.79	$429.58	$138.21	$93,589.23
53	$567.79	$428.95	$138.84	$93,450.39
54	$567.79	$428.31	$139.48	$93,310.91
55	$567.79	$427.68	$140.12	$93,170.80
56	$567.79	$427.03	$140.76	$93,030.04
57	$567.79	$426.39	$141.40	$92,888.64
58	$567.79	$425.74	$142.05	$92,746.59
59	$567.79	$425.09	$142.70	$92,603.88
60	$567.79	$424.43	$143.36	$92,460.53

The exhibit shows that the payment consists mostly of interest in the early period of the loan. Since interest is calculated from a progressively declining balance and the aggregate payment is fixed, the amount of interest paid steadily declines; conversely, the principal component consequently increases over time. In fact, the exhibit shows that the unpaid principal balance in month 60 is $92,460, which means that of the $34,067 in payments made by the borrower to that point, only $7,539 was composed of principal payments. However, as the loan ages, the payment is increasingly allocated to principal. The crossover point in the example (i.e., where the principal and interest components of the payment are equal) comes in month 210. A graphic representation of principal and interest payments, along with the balance of the loan, is shown in Exhibit 21-2.

EXHIBIT 21-2

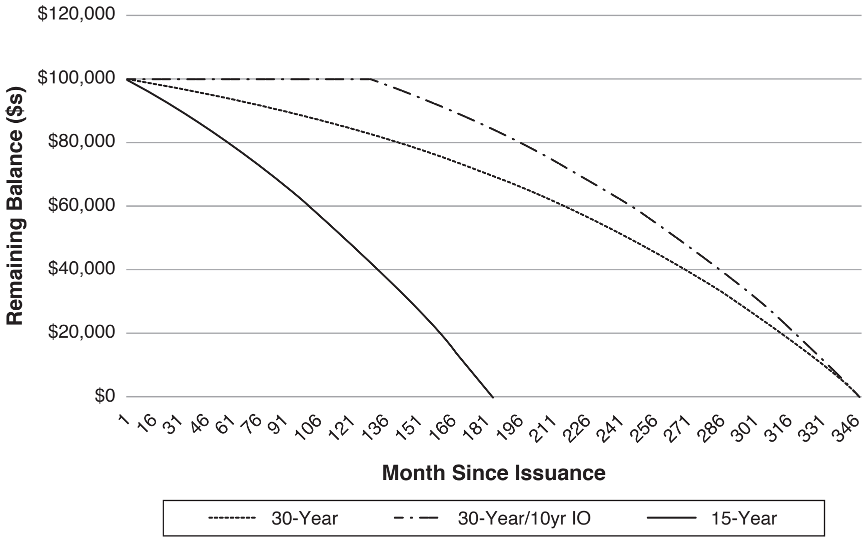
Allocations of Principal and Interest Payments for a $100,000 30-Year Fixed-Rate Loan with 5.5% Note Rate (Total Monthly Payment of $567.79)



Loans with shorter amortization schedules (e.g., 15-year loans) allow the buildup of equity in the home at a much faster rate. Exhibit 21-3 shows the outstanding balance of a $100,000 loan with a 5.5% note rate using 30- and 15-year amortization terms. Note that while 50% of the 30-year loan balance is paid off in month 246, the halfway mark is reached in month 151 with a 20-year term and month 107 with a 15-year loan. The chart also shows the outstanding balance for a 30-year loan with a 10-year interest-only period. In the case of balloon loans, the monthly payments are calculated to amortize the principal balance over a 360-month term. The balloon payment occurs at either month 60 (for a five-year balloon) or month 84 (for a seven-year balloon) and refers to the unpaid principal balance at the balloon date.

EXHIBIT 21-3

Unpaid Principal Balance for a $100,000 Fixed-Rate Loan at 5.5% for Different Loan Terms and Amortization Schemes



For an amortizing ARM loan, the payment is calculated at the initial note rate for the full 360-month term. At the first reset and at every subsequent adjustment, the loan is "recast," and the monthly payment schedule is recalculated using the new note rate and the remaining term of the loan. For example, the payments on a three-year hybrid ARM with a 4.5% note rate initially would be calculated as a 4.5% loan with a 360-month term. If the loan resets to a 5.5% rate after three years, the payment is calculated using a 5.5% note rate and a 324-month term. The following year, the payment would be recalculated again using the prevailing rate (depending on the performance of the index referenced by the loan) and a 312-month term.

In general, mortgage loans can be prepaid at the option of the borrower. When a loan is prepaid, the holder of the loan (either in the form of a loan in portfolio or as part of a mortgage-backed security) receives the prepaid principal at face value. *Prepayments* take place for a variety of reasons. They may occur when a borrower "refinances" the loan, sells the underlying property, or defaults on the loan. Prepayments (especially those due to refinancing) hurt the holder of the mortgage by calling away the asset and forcing the holder to reinvest the proceeds at lower interest rates. The causes and implications of prepayments are discussed in more depth below.

THE MORTGAGE INDUSTRY

Within the mortgage market, there are a number of different types of financial institutions involved, either directly or indirectly, in the business of making mortgage loans. A number of different classification schemes can be used to distinguish businesses and functions.

Direct vs. Third-Party Originations

The Fannie Mae Selling Guide defines *third-party originations* (TPOs) as "any loan that is completely or partially originated, processed, underwritten, packaged, funded, or closed by an entity other than the seller . . . that sells the loan to Fannie Mae." TPOs are often originated through mortgage brokers that represent clients but do not make underwriting decisions or actually fund loans. In addition, loans are often originated by a *correspondent lender* but sold to a larger entity (the *correspondent investor*), which in turn either holds or securitizes the loans. *Direct lenders*, as the nomenclature indicates, deal directly with borrowers, and also underwrite and fund their loans. Many large lenders are involved in multiple business lines, divide their operations into units or "channels" that deal with TPOs (generally called the *wholesale channel*) along with those that work directly with borrowers (the *retail channel*). These distinctions are necessary partly because the different channels have differing cost structures, necessitating alternative pricing.

As indicated by the nomenclature, a direct lender actually underwrites and funds loans. Conversely, a mortgage broker represents clients and typically works through multiple lenders to obtain financing for borrowers. The broker does not, however, either make the underwriting decision or fund the loan in such "third-party" originations or TPOs, but rather serves as an agent linking borrowers and lenders. The Fannie Mae Selling Guide defines third-party originations (TPOs) as "any loan that is completely or partially originated, processed, underwritten, packaged, funded, or closed by an entity other than the seller . . . that sells the loan to Fannie Mae." TPOs are often originated through mortgage brokers that represent clients but do not make underwriting decisions or actually fund loans. In addition, loans are often originated by a correspondent lender but sold to a larger entity (the correspondent investor), which in turn either holds or securitizes the loans. Direct lenders, as the nomenclature indicates, deal directly with borrowers, and also underwrite and fund their loans. Many large lenders involved in multiple business lines divide their operations into units or "channels" that deal with TPOs (generally called the wholesale channel) along with those that work directly with borrowers (the retail channel). These distinctions are necessary partly because the different channels have differing cost structures, necessitating alternative pricing.

Depository vs. Nondepository

Depository institutions (which include banks, savings and loans, and credit unions) collect deposits from both wholesale and retail sources and use the deposits to fund their lending activities. Since depositories have portfolios (for both loans and securities), they have the option of either holding their loan production as a balance sheet asset or selling the securitized loans into the capital markets in the form of *mortgage-backed securities* (MBS). (In addition, there is a market for nonsecuritized mortgage portfolios among depositories because there are accounting advantages to holding loans on their books instead of securities.) *Nondepository lenders* (mainly so-called *mortgage bankers*) do not have loan portfolios; virtually all their loan production is sold to investors through the capital markets. (This is sometimes referenced as the "loans-to-bonds" business model.) Depositories that can hold mortgages or MBS in portfolio sometimes can be more aggressive in how they price different products, especially products they wish to accumulate in their loan or investment portfolios (most frequently short-duration assets such as adjustable rate loans). By contrast, mortgage bankers must price all their production based on capital markets execution. This means that mortgage bankers are at a competitive disadvantage in issuing products for which capital market demand is either weak or nonexistent; they may also find it difficult at times to compete in some product sectors targeted aggressively by banks.

Originators vs. Servicers

Loan originators underwrite and fund loan production. However, once a loan is closed, an infrastructure is required for collecting and accounting for principal and interest payments, remitting property taxes, dealing with delinquent borrowers, and managing the process of foreclosing on nonperforming loans. Entities that provide these functions are called *servicers*. For providing these services, such entities receive a fee, which generally is part of the monthly interest payment. Servicing as a business is both labor- and data-intensive. As a result, large servicing operations reap the benefit of economies of scale under normal industry conditions (i.e., when delinquencies are relatively low), However, such large servicers are often poorly prepared to deal with large numbers of seriously delinquent loans. In the wake of the financial crisis, this led to a serious backlog in the handling of nonperforming loans, as well as controversy surrounding the practices and activities of a number of large servicers.

Servicing as an asset may be classified along several dimensions. Required, or *base*, servicing is compensation for undertaking the activities described earlier, and is either dictated by industry guidelines or (in the case of nonagency securities or loans) conditional on the product. For example, as of this writing, lenders must hold 25 basis points (bps) of base servicing for fixed-rate loans being securitized into GSE-eligible pools, whereas Ginnie Mae requires either 19 or 44 bps (depending on the securitization vehicle) for similar loans. The ownership of base servicing also provides the servicer with ancillary benefits, including interest float on insurance and tax escrow accounts, along with the ability to cross-sell other products using the database of borrower information. *Excess* servicing is any additional servicing over the base amount and is merely a strip of interest payments held by the servicer that allows the loan to be securitized with an "even" coupon, as demonstrated later in the section on execution dynamics. Excess servicing neither requires any activity on the part of the servicer nor does it convey any benefits; it is strictly a by-product of the securitization process.

THE LOAN UNDERWRITING PROCESS

After the application for a loan is filed, it is considered to be part of the "pipeline," which suggests that there is a planned sequence of activities that must be completed before the loan is funded. At application, the borrower can either lock the rate of the loan or let it float until some point before the closing. From the perspective of the lender, there is no interest-rate risk associated with the loan until it is locked. However, after the loan is locked, the lender is exposed to risk in the same fashion as any fixed-rate asset. Lenders typically track locked loans and floating liabilities separately; they are referred to as the "committed" versus the "uncommitted" pipeline.

There are two essential and separate components of the underwriting process:

- Evaluation of the ability and willingness on the part of the borrower to repay the loan in a timely fashion
- Ensuring the integrity of the property and whether it can be sold in the event of a default to pay off the balance of the loan

There are several factors that are considered important in the evaluation of the creditworthiness of a potential borrower.

Credit Scores

Several firms collect data on the payment histories of individuals from lending institutions and use sophisticated models to evaluate and quantify individual creditworthiness. The process results in a credit score, which is essentially a numerical grade of the credit history of the borrower. There are three different credit reporting firms that compile credit data—namely, Experian, Transunion, and Equifax. The data are provided to *FICO* (originally Fair, Isaac and Company), which calculates a set of credit scores used as proxies for borrower creditworthiness. While the various scores have different underlying methodologies, the scores generically are referred to as *FICO scores*. Lenders attempt to obtain more than one score in order to minimize the impact of variations in credit scores across providers. In such cases, if the lender obtains all three scores, generally the middle score is used, whereas the convention is to use the lower value in the case of the availability of only two scores.

Credit scores are useful in quantifying the potential borrower's credit history. The general rule of thumb has traditionally been that a score in excess of 700 represents a "strong" borrower. The problems associated with the financial crisis led to a reassessment of this threshold; a 730 or higher score is typically considered necessary for borrowers to receive the best rates and offerings from lenders.

Loan-to-Value Ratio

The *loan-to-value ratio* (LTV) is an indicator of a borrower's leverage at the point when the loan application is filed. The LTV calculation compares the value of the desired loan to the market value of the property. By definition, in a purchase transaction a loan's LTV is a function of the down payment and the purchase price of the property (subject to an appraisal). In a refinancing, it depends on the requested balance of the new loan and the appraised market value of the property.[2] LTV is important for a number of reasons. First, it is an indicator of the amount that can be recovered from a loan in the event of a default, especially if the value of the property declines. It also has an impact on the expected payment performance of the obligor because high LTVs may indicate a greater likelihood of default on the loan. While loans can be originated with very high LTVs, borrowers seeking a loan with an LTV greater than 80% generally must obtain insurance for the portion of the loan that exceeds 80%. As an example, if the borrower applies for a $90,000 loan in order to buy a property for $100,000, he or she must obtain so-called mortgage insurance (MI) on $10,000 of the balance. Mortgage insurance is a monthly premium that is added to the loan payment and can be eliminated if the borrower's home appreciates (or the loan is paid down) to the point where the loan has an LTV below 80%. (Borrowers seeking loans with very high LTVs often utilize government loans issued by entities such as the FHA, which requires only a 3.5% down payment on a purchase loan.)

Another measure used by underwriters is the combined LTV (CLTV), which accounts for the existence of any second liens. A $100,000 property with an $80,000 first lien and a $10,000 second lien will have an LTV of 80% but a CLTV of 90%. For the purposes of underwriting a loan, CLTVs are more indicative of the borrower's credit standing and indebtedness than LTVs and therefore a better gauge of the creditworthiness of the loan.[3]

---

2. If the new loan is larger than the original loan, the transaction is referred to as a "cash-out refinancing." Otherwise, the transaction is described as a "rate-and-term refinancing."

3. This, of course, assumes that the lender is aware of all loans made on the property; a loan made against a property carrying an unknown or "silent" second lien likely would result in an overly leveraged loan and a higher probability of ultimate principal loss.

Income Ratios

In order to ensure that borrowers' obligations are consistent with income, lenders calculate debt-to-income (DTI) ratios that compare the potential monthly payment on the loan to the borrower's monthly income. The most common measures are *Debt-to-Income* ratios (DTIs). Two forms of DTIs are typically used by underwriters. The *front-end ratio* (sometimes also referenced as the *housing ratio*) is calculated by dividing the total monthly payments on the home, including principal, interest, property taxes, homeowners' insurance, and HOA fees, by the borrower's pretax monthly income. The *back-end ratio* is similar but includes other debt payments and obligations (including auto loan and credit card payments) to the total payments. The traditional maximum ratios, which remain in force for many loan programs, are 28% and 36%, respectively. However, the maximum back-end ratio that will allow a loan to be considered a QM loan is 43%, as discussed below.

Documentation

Lenders traditionally have required potential borrowers to provide data on their financial status and to support the data with documentation. Loan officers typically require applicants to report and document income, employment status, and financial resources (including the source of the down payment for the transaction). Part of the application process routinely involves compiling documents such as tax returns and bank statements for use in the underwriting process. In the period between 2000 and 2007, however, documentation standards were progressively relaxed, leading to the proliferation of limited- and no-documentation loan programs. Popular options included "stated income" loans (which required borrowers to supply an income figure but did not require supporting documentation) as well as programs that required no disclosures of incomes, assets, or employment. (These programs were often labeled "no income/no asset"—"NINA"—loans.)

The trend began in the mid-1990s with programs targeted to borrowers whose credit was sound but who had income streams that were either variable or, in the case of self-employed borrowers, difficult to document. This eventually led to the widespread marketing of loans to wage earners who often used the absence of formal documentation to inflate their incomes and evade DTI analysis.

One result of the financial crisis that began in 2007 was the return of rigorous underwriting standards, with full income and asset documentation a key requirement. While this certainly strengthened the credit quality of loans issued under this regime, it unfortunately also served to shut many otherwise strong borrowers out of the mortgage and housing markets due to difficulties in documenting their incomes.

A key reason for the change in how documentation is treated by lenders was the passing of the Dodd-Frank Act of 2010. Commonly referenced as the DFA, the law fundamentally altered the way mortgages are originated and securitized while also creating a new regulatory entity, the Consumer Financial Protection Bureau (CFPB). A key provision of the DFA was the requirement that mortgage lenders must verify an applicant's ability to repay a loan under an expanded set of criteria as part of the underwriting process. Failure to make a good-faith effort to ensure that the borrower can reasonably be expected to repay a loan (the *ATR requirement*) may allow the borrower to recoup fees and finance charges paid to the lender, as well as serve as a defense in a foreclosure action. The law states that a loan is presumed to meet the ATR requirement if (1) it is underwritten to certain standards (including a maximum 43% DTI), (2) the borrower's income or assets are verified and documented, (3) the loan is not considered a "higher-priced" loan, and (4) the loan does not include features such as negative amortization, interest-only payments, or a balloon payment. Such loans are classified as Qualified Mortgages (QMs). Loans that do not meet these criteria are considered Non-Qualified Mortgages (Non-QMs). Non-QM loans cannot be placed into agency-issued pools and must be securitized through private-label transactions. In order to meet the ATR standards without standard forms of income documentation, underwriters often use documents such as bank statements to estimate the applicant's income.

GENERATION OF MORTGAGE LENDING RATES

While it may appear simple on the surface, the determination of mortgage lending rates is a complex interplay between levels in the secondary market for loans (or, more typically, MBS), the value of servicing, the cost of credit enhancement, and the costs associated with generating the loan. In this process, the pricing of different MBS (quoted directly and through the mechanism of inter-coupon spreads) is very important in determining the eventual disposition of loans. The MBS market serves to institutionalize the intermediation function by allowing providers of funds (investors) and users of funds (lenders) to interact at the national level. Using the MBS market, lenders make loans, package them into securities, sell them into the capital markets, and use the proceeds to make new loans. While certain lenders may hold some loans and products in loan portfolios (e.g., banks tend to hold short-duration products such as ARMs), the bulk of production is sold into the capital markets either directly or indirectly, using correspondent investors and/or the GSEs.

While a complete discussion of the MBS market is beyond the scope of this chapter, it is instructive to review the process involved in securitizing loans because of the importance of this process in the determination of lending rates. For the sake of simplicity, the following discussion focuses on fixed-rate conforming loans securitized through the GSE programs. The coupons on such pools (or *pass-throughs*, because they pass principal and interest through to the investor) generally are created in 1/2 percentage point increments (e.g., 3.5%, 4.0%, etc.). Loans, by contrast, generally are issued in 1/8 percentage point increments. The creation of pools to be traded as MBS involves the aggregation of loans with similar characteristics, including note rates that are higher than the coupon rate but within a specified rate, depending on the agency and program. The weighted average of the note rates of the loans in the pool is referred to as the pool's *weighted average coupon* (WAC). The spread between a pool's WAC and its coupon rate (or pass-through rate) is allocated to three sources:

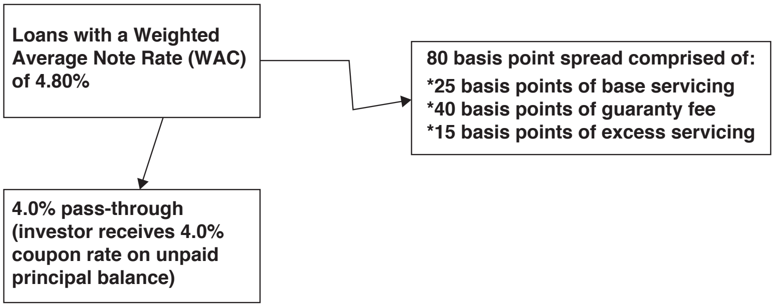
- *Required or base servicing*, which refers to a portion of the loan's note rate that is required to be held by the servicer of the loan. As noted previously, this entity collects payments from mortgagors, makes tax and insurance payments for the borrowers, and remits payments to investors. The amount of base servicing required differs depending on the agency and program.
- *Guaranty fees ("g-fees")* are fees paid to the agencies to insure the loan. Since these fees essentially represent the price of credit risk insurance, there is variation across loan types. In the conventional universe, loans that are perceived to be riskier typically require a higher g-fee for securitization. For Ginnie Mae pools, the guaranty fee is almost always 6 bps. Note that for Fannie Mae and Freddie Mac securities, g-fees can be capitalized and paid as an upfront fee in order to facilitate certain execution options, as discussed below.
- *Excess servicing* is the remaining amount of the note rate that would reduce the interest rate of the loan to the desired coupon. This asset is often capitalized and held by the servicer. Nonetheless, secondary markets exist for trading servicing in the form of either raw mortgage servicing rights or securities created from excess servicing.

Pooling practices for conventional loans changed dramatically in 2019. Prior to June of that year, Freddie Mac and Fannie Mae each issued pool under its own rubric which traded separately in the forward market. The two pooling programs were similar in that they passed through principal and interest paid by the borrowers to investors; aside from the issuer, the primary difference between the programs was the timing of cash-flow payments. (Fannie Mae pools paid principal and interest monthly on the 25th day of the month following each record date, while Freddie Mae made payments on the 15th day of the month.) In June 2019 both Fannie and Freddie embarked on the *Single Security Initiative* (SSI) and began issuing pools through the *Common Securitization Platform* (CSP), an entity that coordinating issuing pools for both Fannie Mae and Freddie Mac. The new pools are known as *Universal Mortgage-Backed Securities* (UMBS), and trade to the same standards and conventions to which Fannie pools traded before the transition. (Pre-existing Freddie Mac pools can be exchanged for UMBS pools.)

A schematic showing how a typical UMBS pool allocates cash flows is shown in Exhibit 21-4.

EXHIBIT 21-4

Cash-Flow Allocation for a UMBS 4.0% Pool with a 4.80% WAC



A common misconception is that lenders quote rate levels to consumers. In actuality, lenders calculate "discount points" (i.e., an up-front fee paid at closing) for a broad range of note rates. Note that these rate levels can be associated with both positive and negative points. (Negative points can be thought of as a rebate to the borrower in exchange for paying a higher rate.) The process for other products is similar in concept, if not identical in process. Exhibit 21-5 shows a hypothetical matrix of rates and points for 30-year conforming fixed-rate loans, with the zero-point (or *par*) rate highlighted.

EXHIBIT 21-5

Hypothetical Rates/Points Matrix for 30-Year Conventional Loans

Rates	Points
3.250%	3.000
3.375%	2.625
3.500%	2.250
3.625%	1.875
3.750%	1.500
3.875%	1.125
4.000%	0.750
4.125%	0.375
4.250%	**0.000**
4.375%	–0.375
4.500%	–0.750
4.625%	–1.125
4.750%	–1.500
4.875%	–1.875

Given existing market conditions, the process of generating points involves two steps:

- Determining the optimal execution for each note rate
- Calculating the appropriate price and amount of points for each note rate

Loans can be securitized in pools with a range of coupons, although pooling rules changed in 2019 to help facilitate the SSI. To maximize their proceeds, the optimal execution is calculated regularly by the originator and is a function of the levels of pass-through prices, servicing valuations, and guaranty fee buydown costs.[4] Exhibit 21-6 shows two possible execution scenarios for a loan with a 4.125% note rate. Note that execution economics and securitization rules generally dictate that loans are pooled with coupons between 25 and 100 bps lower than the note rates, although the maximum spread under new pooling rules is 112.5 bps. In the example, securitizing the loan in the 3.5% pool is the best execution option because it provides the greatest proceeds to the lender.

EXHIBIT 21-6

Pooling Options for a 4.125% Conventional Loan Using Hypothetical Levels
Assumes 40 Bps Guaranty Fee, 25 Bps Base Servicing

	UM30 3.0%	UM30 3.5%	Comments
Pass-through Prices	99.25	101.50	
Base Servicing	1.00	1.00	25 bps (priced at 4x)*
Guaranty Fee	0.40	0.40	
Excess Servicing/G-Fee Shortfall	0.475	–0.025	
Excess/G-Fee Buydown**	1.90	–0.10	Both assumed 4x*
Gross Proceeds	**102.15**	**102.40**	
Costs and Margin	–3.00	–3.00	Same for both execution options
Net Proceeds	**99.15**	**99.40**	

*For simplicity's sake, the multiple used for base and excess servicing, as well as the g-fee buydown, were assumed to be the same.

**Since g-fee buydowns represent a payment made to the GSE, it is shown here as a negative value.

4. Guaranty fee buydowns are the monetized value of the guaranty fee. They are paid by the originator as a fee at the time of funding.

Once the optimal execution is determined for each note rate strata, the associated points are then calculated. As with the execution calculation, the calculation of points is based on market prices for pass-throughs and prevailing valuations for servicing and g-fee buydowns. Exhibit 21-7 shows a hypothetical calculation of points for loans with rates from 4.125% to 4.5%, assuming that the best execution for all rates would be into pools with a 3.5% coupon rate. The calculated points are shown at the bottom as the difference between the net value of the loan after pricing all components and its par value. While the example does not show it, points generally are rounded to the nearest one-eighth. In practice, points are calculated simultaneously for many rate levels and are subsequently posted in a rates/point matrix similar to the one shown in Exhibit 21-7.

Note also that the costs shown in Exhibit 21-7 include an allocation for the lender's targeted profit margin. Margin requirements change in line with market conditions, most notably based on the levels of lending volumes and the industry's price competitiveness at that time.

In the event that the loan is perceived to be riskier as a result of factors that may include a lower credit score, less documentation, and/or a higher LTV, it might be assigned a higher guaranty fee by the GSE. As a result, the loan would be more costly to the borrower. As an example, assume that the 4.125% note rate loan shown in Exhibit 21-7 was assigned a 50 bps guaranty fee. At the 4× multiple, the guaranty fee buydown costs an extra 0.4 points. The incremental cost of credit enhancement means that the loan's net value is 99.4; the 4.125% loan would be priced to have 1 point. Therefore, the lending paradigm called *risk-based pricing* means that the higher costs (in the form of points at a given note rate strata) associated with riskier loans represent greater credit enhancement costs that are being passed on to the borrower.

As mentioned, the examples show the calculation for a loan that is eligible to be securitized in a pool issued as a UMBS by one of the GSEs. If the loan were ineligible for such securitization, the cost of the guarantee fee is replaced by the cost of alternative credit enhancement needed to securitize the loan. The most common form of credit support in nonagency transactions is called *subordination*. Briefly, this means that bonds created within the deal are prioritized with respect to how they will receive principal and interest cash flows, as well as how they will accrue losses suffered by the transaction's collateral pool. (Higher-priority or more senior bonds have the highest priority for receiving cash flows, and are the last to suffer writedowns.) As a result, the cost of credit enhancement to the transaction is a function of two elements:

- The relative size of the subordinate or junior classes of bonds
- The price at which they can be sold to investors

The size of the subordinate classes has traditionally been assigned by the rating agencies. Their primary role is to determine how large the subordinates need to be in order for the senior bonds to receive a triple-A rating. In turn, the size of the subordinate classes is a function of the perceived riskiness of the loans

EXHIBIT 21-7

Sample Calculation of Points for Different Note Rates All Loans Assumed to Best-Execute into UMBS 3.5s

	4.125%	4.250%	4.375%	4.500%	Comments
Pass-through Price	101.5	101.5	101.5	101.5	
Base Servicing	1	1	1	1	25 basis points, Assuming 4x multiple
Excess Servicing/G-Fee Shortfall	–0.025	0.100	0.225	0.350	Assumes 40 bp g-fee
Excess Servicing Value		0.40	0.90	1.40	Assumes 4x multiple
G-fee Buydown Value	–0.10				Assumes 4x multiple
Gross Proceeds	**102.40**	**102.90**	**103.40**	**103.90**	
Costs and Margin	–3.00	–3.00	–3.00	–3.00	Includes allocated costs and profit margin
Net Proceeds	**99.40**	**99.90**	**100.40**	**100.90**	
Points	0.60	0.10	–0.40	–0.90	
Rounded Points	***0.50***	***0.00***	***–0.50***	***–1.00***	Rounded to nearest 1/8th

backing the transaction. The level at which the subordinates trade in the new-issue market is dictated by the price at which investors feel they can garner attractive risk-adjusted returns. Subordinates typically trade at large price discounts to the more senior bonds in order to account for their greater risks and/or reduced protection from losses.

Therefore, the cost of credit support in nonagency or private-label transactions is expressed by the weighted average price at which the subordinate classes can be sold. Riskier collateral thus has higher credit enhancement costs since the amount of subordination is higher and/or the overall price at which the subordinates can be sold is lower.

Risk-based pricing is accomplished in two ways. Lenders might create separate loan programs that reflect a set of attributes, and price the program based on the loans' credit enhancement costs. This was reflected in the proliferation of different lending programs prior to the financial crisis. In cases where creating a separate program is inefficient or undesirable, attributes are priced using "add-ons," or points added to the discount points calculated in the manner described previously. Add-ons (often called loan-level price adjustments, or *LLPAs*) are fees calculated to account for the incremental cost of credit enhancement for a loan. Similar to discount points, such fees are quoted as percentage points of the loan's face value. For example, a 30-year fixed-rate conforming-balance loan with a 4% note rate may be associated with 0.75 points. However, a borrower may seek a loan with an LTV higher than that specified by the program's guidelines. If the add-on in this case is 1.5 points, the loan then becomes a 4% loan with 2.625 points.

However, the disinclination of many borrowers to paying large amounts of money at closing necessitates a recalculation of the rate, given some targeted amount of points and the rate/point structure prevailing at that time. In the preceding example, suppose that the borrower only wishes to pay 1/2 point after the effect of the add-ons. Referring to Exhibit 21-5, note that a loan with 1.125 points is associated with a 3.875% note rate, whereas a loan with negative 0.375 points has a note rate of 4.375%. Therefore, the borrower in the example could obtain a loan with a rate of 4.375% with 0.75 points. This methodology indicates how the expense (calculated in terms of points) of "alternative" loans is translated into incrementally higher note rates.

RISKS ASSOCIATED WITH MORTGAGE PRODUCTS

Holders of fixed income investments ordinarily deal with interest-rate risk, which is the risk that changes in the level of market interest rates will cause fluctuations in the market value of such investments. Mortgages and associated mortgage-backed securities, however, have additional risks associated with them that are unique to the products and require additional analysis. (In the following discussions, mortgages and MBS are collectively referred to as pools for the sake of clarity.)

Prepayment Risk

In a previous section we noted that obligors generally have the ability to prepay their loans before they mature. For the holder of a mortgage asset, the borrower's prepayment option creates a unique form of risk. In cases where the obligor refinances the loan in order to capitalize on a drop in market rates, the investor has a high-yielding asset payoff, and it can be replaced only with an asset carrying a lower yield. Prepayment risk is analogous to "call risk" for corporate and municipal bonds in terms of its impact on returns, and it also creates uncertainty with respect to the timing of investors' cash flows. In addition, changing prepayment "speeds" owing to interest-rate moves cause variations in the cash flows of mortgage pools, strongly influencing their relative performance.

The importance of prepayments to the mortgage sector has created the need for the measurement and analysis of prepayment behavior. Prepayments occur for the following reasons:

- The sale of the property
- The destruction of the property by fire or other disaster
- A default on the part of the borrower (net of losses)
- Curtailments (i.e., partial prepayments)
- Refinancing

A useful nomenclature is to divide prepayments into "rate-sensitive" and "rate-insensitive" categories. Rate-insensitive prepayments traditionally have been comprised of housing turnover, which normally consists of home sales, along with equity extraction through the vehicle of *cash-out refinancings*. The spike in delinquencies and credit problems after 2007, however, meant that credit-related prepayments also needed to be taken into account in assessing prepayment speeds. (Since mid-2010, for example, the GSEs have bought seriously delinquent loans out of pools. Such *buyouts* are treated as prepayments in agency pools. As we will discuss, credit-related prepayments are treated differently in private-label securities.)

Rate-sensitive prepayments primarily consist of refinancings for which borrowers do not monetize their homes' equity, called *rate-and-term* refinancings. This activity is dependent on borrowers' ability to obtain a new loan at a lower rate, making this activity highly sensitive to the level of interest and mortgage rates. In addition, the amount of refinancing activity can change greatly given a seemingly small change in rates. (Cash-out refinancings are impacted by both interest rate changes and rates of home price appreciation.)

The paradigm in mortgages thus is fairly straightforward. Mortgages with low note rates (that are "out-of-the-money," to borrow a term from the option market) normally prepay fairly slowly and predictably, whereas loans carrying higher rates ("in-the-money") can see spikes in prepayments when rates drop, as well as significant volatility in prepayment speeds.

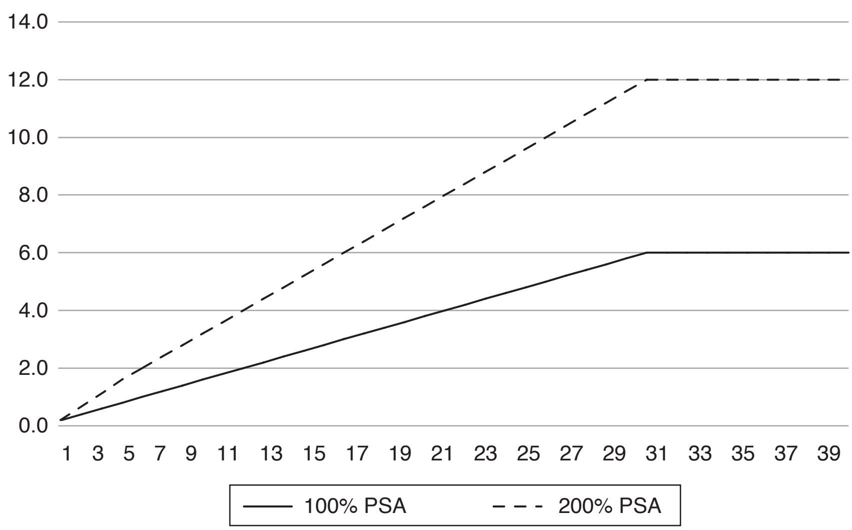
The measurement of prepayment rates is, on its face, fairly straightforward. A metric referred to as *single monthly mortality* (SMM) measures the monthly principal prepayments on a mortgage portfolio as a percentage of the balance at the beginning of the month in question. (Note that SMM does not include regular principal amortization.) The *conditional prepayment rate* (CPR) is simply the SMM annualized using the following formula:

$$\text{CPR} = 1 - (1 - \text{SMM})12$$

While CPR is the most common term used to describe prepayments, other conventions are also used. Logic suggests, for example, that prepayment behavior is not constant over the life of the loan. Immediately after the loan is funded, for example, a borrower is unlikely to prepay his mortgage; however, the propensity to prepay (for any reason) increases over time. This implies that prepayments adhere to some sort of "ramp," where the CPR increases at a predictable rate. The most common ramp is the *PSA model*, created by the Public Securities Association (now called the Securities Industry and Financial Markets Association, or *SIFMA*). The base PSA model (100% of the model or 100% PSA, to use the market convention) assumes that prepayments begin at a rate of 0.2% in the first month and increase at a rate of 0.2% per month until they reach 6.0% CPR in month 30; at that point, prepayments remain at 6% CPR for the remaining term of the loan or security. Based on this convention, 200% PSA implies that speeds double that of the base model (i.e., 0.4% in the first month ramping to a terminal speed of 12% CPR in month 30), Exhibit 21-8 shows a graphic representation of the PSA model.

EXHIBIT 21-8

The PSA Model



The PSA model depends on the age of the loan (or, in a pool, the weighted-average loan age). For example, 4.0% CPR in month 20 equates to 100% PSA, whereas 4.0% CPR in month 6 represents 333% PSA. Conversely, the usefulness of the PSA model (or other ramps that are similar in nature) depends on how quickly prepayments move toward a terminal rate (or, to put it differently, how quickly they "ramp up"). It is generally understood that prepayment ramps have shortened since the model was derived, reflecting the lowering of refinancing barriers and costs. In turn, this arguably has distorted the reported PSA speeds for loans that are 30 months old or less, making the PSA model less useful as a measure of prepayment speeds.

While a full discussion of prepayment behavior and risk is far beyond the scope of this chapter, it is important to understand how changes in prepayment rates affect the performance of mortgages and MBS. Since prepayments increase as bond prices rise and market yields are declining, mortgages shorten in average life and duration when the bond markets rally. As a result, the price performance of the mortgage portfolio or security tends to lag that of bonds without prepayment exposure when interest rates decline. Conversely, prepayments tend to slow when market yields are rising, causing the average life and duration of the mortgages or MBS to increase. This phenomenon, generally described as *extension*, causes the price of the mortgage or MBS to decline more than comparable fixed-maturity instruments (such as Treasury notes) as the prevailing level of yields increases.

Owing to changes in prepayment rates, mortgages and MBS exhibit price performance that is generically referenced as "negative convexity." Since prepayments increase when rates decline, MBS shorten in average life and duration at precisely the time when their performance would benefit from extending. Conversely, when the bond market sells off, mortgage average lives and durations lengthen. This behavior causes the price changes in mortgages and MBS to be decidedly nonlinear in nature and to underperform those of assets that do not exhibit negatively convex behavior. Exhibit 21-9 shows a graphic representation of this behavior. Investors are generally compensated for the lagging price performance of MBS through higher base-case yields. However, the necessity of managing negative convexity and prepayment risk on the part of investors dictates active analysis and management of their MBS portfolios.

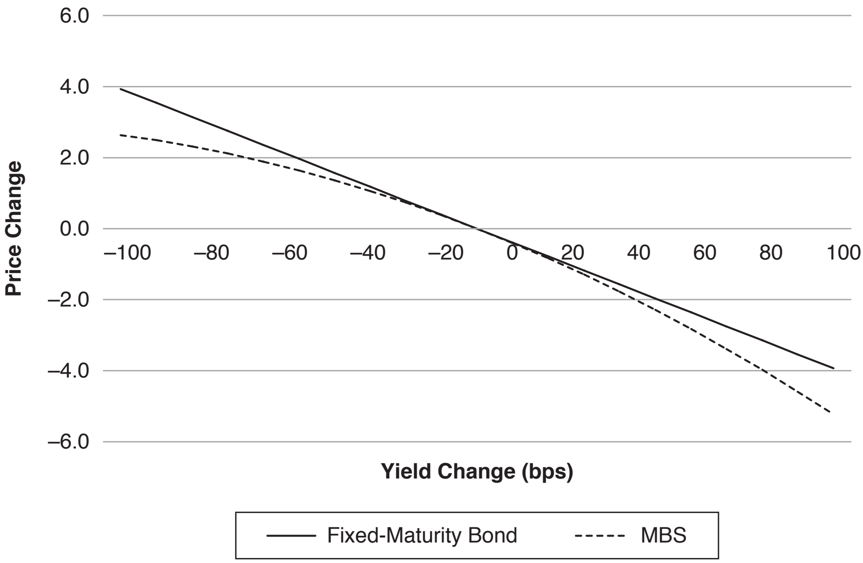
Credit and Default Risk

Analysis of the credit exposure in the mortgage sector is different from the assessment of credit risk in most other fixed income instruments because it requires:

- Quantifying and stratifying the characteristics of the thousands of loans that underlie the mortgage investment
- Estimating how these attributes will translate into performance based on standard metrics and the evaluation of reasonable best-, worst-, and likely-case performance
- Calculating returns based on these scenarios

EXHIBIT 21-9

Changes in Bond Prices Given Yield Changes



In a prior section, some of the factors (credit scores, LTVs, etc.) that are used to gauge the creditworthiness of borrowers and the likelihood of a loan to result in a loss of principal were discussed. Many of the same measures are also used in evaluating the creditworthiness of a mortgage pool. For example, weighted-average credit scores and LTVs are calculated routinely, and stratifications of these characteristics (along with documentation styles and other attributes) are used in the credit evaluation of the pool. In addition to these characteristics of the loans, the following metrics are also relevant for the *a posteriori* evaluation of a mortgage pool.

Delinquencies

Delinquency measures are designed to gauge whether borrowers are current on their loan payments or, if they are late, stratifying them according to the seriousness of the delinquency. The most commonly used convention currently used to classify delinquencies is one promulgated by the Mortgage Bankers Association (MBA); this *MBA method* classifies loans as follows:

- Payment due date to 30 days late: Current
- 30–60 days late: 30 days delinquent
- 60–90 days late: 60 days delinquent
- More than 90 days late: 90+ days delinquent

Defaults

At some point in their existence, some delinquent loans become current (or cure) because the condition leading to the delinquency (e.g., job loss, illness, etc.) resolves itself. However, some portion of the delinquent loan universe ends up in default. By definition, default is the point where the borrower loses title to the property in question. Default generally occurs for loans that are 90+ days delinquent, although loans where the borrower goes into bankruptcy may be classified as defaulted at an earlier point in time.

It is important to note that the treatment of defaults in agency and nonagency securities is different. As noted in the previous section, seriously delinquent loans are bought out of agency pools. Since the agency in question is responsible for the repayment of the full amount of principal to investors, buyouts are prepayments for all practical purposes. No such mechanism exists for private-label securities; principal is only paid to investors once it is recovered through the foreclosure process (or through some alternative mechanism, such as a short sale). Moreover, only the recovered amount of principal is returned to investors, with the transaction absorbing the resulting losses.

Therefore, defaults in private-label transactions must be treated and quoted separately from refinancings, turnover, and other types of voluntary prepayments. Rates for involuntary prepayments are generally measured by the *conditional default rate* (CDR). CDRs are calculated in a fashion similar to CPRs, in which the face value of loans going into default in any given month is divided by that month's initial value. The resulting monthly default rate (MDR) is then annualized in the same fashion as SMMs.

Severity

Since the lender has a lien on the borrower's property, some of the value of the loan can be recovered through the foreclosure process. Loss severity measures the face value of the loss on a loan after foreclosure is completed. Severities are often heavily influenced by the loan's LTV (since a high LTV loan leaves less room for a decline in the value of the property in the event of a loss). However, in the event of a default, even loans with relatively low LTVs can experience significant losses, generally for several reasons:

- The appraised value of the property may be high relative to the property's actual market value.
- The value of a property may have declined since the loan's origination due to changes in the real estate market.
- There are costs and lost income associated with the foreclosure process.

In light of these metrics, the process of evaluating the credit-adjusted performance of a pool involves first understanding the expected delinquencies, defaults, and loss severities of the pool based on its credit characteristics and attributes. Subsequently, loss-adjusted yields and returns can be generated.

KEY POINTS

- Mortgage loans can be categorized using a number of different factors, including lien status, original loan term, interest-rate type, balance classification, amortization type, and borrower credit and documentation standards. Loans can also be categorized by the type of credit support they receive, that is, guarantees directly from the U.S. government, through Freddie Mac or Fannie Mae, or some form of private credit enhancement. Mortgages are also classified as Qualified Mortgages based on their lack of "risky" features and full documentation of income and assets; such mortgages are presumed to comply with the Ability to Repay rule established by the Dodd-Frank Act and policed by the CFPB.
- The payments on a fixed-rate fully amortizing mortgage remain fixed for the term of the loan. Early in a loan's life, the bulk of the payments are classified as interest. However, the portion directed to repay principal grows as the loan ages.
- Mortgage underwriting is a complex process that takes into account borrowers' ability and apparent willingness to service their loans. These are judged using metrics such as credit scores, loan-to-value ratios, and income ratios. The accurate documentation of income, employment, and assets has also proved to be important in assessing borrower creditworthiness.
- Mortgage lenders calculate their pricing in the form of the discount points required or rebated for a series of note rate strata. Consumer mortgage pricing is computed through a complex process that incorporates MBS levels, servicing values, and the cost of credit support.
- Securities backed by residential mortgages have a variety of risks. In addition to interest-rate risk, mortgage-backed securities are exposed to prepayment risk, as well as credit risk if the securities in question do not have explicit or implicit government backing.

CHAPTER
TWENTY-TWO

AGENCY MORTGAGE PASSTHROUGH SECURITIES

Glenn Schultz, CFA
Director
Head of Mortgage Backed Security Prepayment Modeling and Strategy
MUFG Securities

Frank J. Fabozzi, Ph.D., CFA, CPA
Professor of Finance
EDHEC Business School

A mortgage note represents a pledge of real estate to secure a loan. The mortgagee (borrower) pledges the property to the mortgagor (lender) as collateral to secure repayment of the loan. Thus, the loan is said to be secured by the pledged property. Ownership of the property rests with the borrower throughout the term of the loan. However, the lender holds a lien against the property and if the borrower is unable to repay the loan according to its terms, then the ownership of the property is transferred to the lender to settle the outstanding debt.

Most residential mortgages are pooled and used as collateral for the issuance of residential mortgage-backed securities (RMBS) as explained in this chapter. The residential mortgage market can be divided into two subsectors based on the credit quality of the borrower: the prime mortgage market and the subprime mortgage market. Certain prime mortgage loans can be included in RMBS issued by either the Government National Mortgage Association (Ginnie Mae), a federally related institution, or one of the two government-sponsored enterprises, Fannie Mae and Freddie Mac. An RMBS issued by any of these three entities is referred to as an *agency passthrough security*, or simply *agency passthrough*. Whether a prime loan can be included in a pool of loans backing an agency passthrough securities depends upon whether it satisfies the underwriting standards specified by these three issuers. Prime mortgages that do not satisfy the underwriting standards of the three entities are typically pooled in private-label RMBS (also called nonagency RMBS), as are subprime mortgages. Agency passthroughs, their cash flow and risk characteristics, and the market in which they are traded are the subject of this chapter. Private-label RMBS are covered in Chapter 25. Agency passthroughs are used to create agency collateralized mortgage securities (REMICs) and agency mortgage stripped securities, the subjects of Chapters 23 and 24, respectively.

ISSUERS OF AGENCY PASSTHROUGHS

The three issuers of agency passthroughs, all created by Congress to increase the supply of capital to the residential mortgage market, are Ginnie Mae (GNMA), Fannie Mae (FNMA), and Freddie Mac (FHLMC).

Ginnie Mae is part of the Department of Housing and Urban Development and the agency passthroughs that it guarantees carry the full faith and credit of the U.S. government with respect to timely payment of both interest and principal. That is, the interest and principal are paid when due even if the underlying mortgagors fail to make their monthly mortgage payment. The security guaranteed by Ginnie Mae is called a "mortgage-backed security." Although Ginnie Mae provides the guarantee, it is not the issuer. The agency passthroughs that carry its guarantee and bear its name are issued by lenders it approves, such as thrifts, commercial banks, and mortgage bankers. These lenders receive approval only if the underlying loans satisfy the underwriting standards established by Ginnie Mae. When it guarantees securities issued by approved lenders, Ginnie Mae permits these lenders to convert illiquid individual loans into liquid securities backed by the U.S. government. In the process, Ginnie Mae accomplishes its goal of supplying funds to the residential mortgage market and providing an active secondary market. For the guarantee, Ginnie Mae receives a fee, called the guaranty fee.

The mission of the two GSEs, Fannie Mae and Freddie Mac, is to support the liquidity and stability of the mortgage market. They accomplish this by (1) buying and selling mortgages, (2) creating passthroughs and guaranteeing them, and (3) buying RMBS. The agency passthroughs they issue are not guaranteed by the full faith and credit of the U.S. government. Rather, the payments are secured first by the cash flow from the underlying pool of loans and then by a corporate guarantee. That corporate guarantee, however, is the same as the corporate guarantee to the other creditors of the two GSEs. The GSEs have a line of credit with the U.S. Department of the Treasury. As with Ginnie Mae, the two GSEs receive a guaranty fee for taking on the credit risk associated with borrowers failing to satisfy their loan obligations.

The passthroughs issued by Fannie Mae are referred to as "mortgage-backed securities": Freddie Mac uses the term participation certificate (PC) to describe its passthrough security.

During the global financial crisis both Fannie Mae and Freddie Mac became insolvent and placed into conservatorship. The Federal Home Finance Agency's (FHFA's) strategic plan for the conservatorship of both Fannie Mae and FHLMC included the goal of developing a new securitization infrastructure, shared by both Fannie Mae and Freddie Mac. The result, the establishment of Common Securitization Solutions, is a joint venture of both Fannie Mae and Freddie Mac. Common Securitization Solutions acts as both Fannie Mae's and Freddie Mac's agency to facilitate issuance of single-family mortgage securities, the release of related at-issuance and ongoing disclosures, and the post-issuance administration of their securities.

Common Securitization Solutions created the Common Securitization Platform to support Fannie Mae's and Freddie Mac's single-family mortgage securitization business. Importantly, the common securitization platform included the issuance by both Fannie Mae and Freddie Mac of a common single mortgage-backed security, the Uniform Mortgage Backed Security (UMBS). The objective of UMBS is to improve the overall liquidity of Fannie Mae's and Freddie Mac's securities to ensure the ongoing liquidity of the U.S. housing financing markets. The characteristics of the UMBS security is discussed in detail later in the chapter.

CASH-FLOW CHARACTERISTICS

To illustrate the cash-flow characteristics, let's begin with the cash flow of a standard loan. Exhibit 22-1 provides a partial amortization table for a standard loan. The monthly payment is $1,013.67. Working across the table, in the first month the scheduled interest is $750 and the scheduled principal is $263.37. By month 12, the scheduled interest has fallen to $738.93 and the scheduled principal has increased to $274.44.

The cash flow of an agency passthrough depends on the cash flow of the underlying loans. The cash flow of a mortgage-backed security includes the monthly mortgage payments representing interest, the scheduled repayment of principal, and any prepayments. A prepayment occurs when the borrower terminates the note due to refinancing or sale of the property or makes a partial payment of principal against the outstanding balance. The termination of the note prior to its final scheduled payment date is termed a "full prepayment," while the partial payment of principle is termed a "curtailment." Notice that only the first and the second components are shown in Exhibit 22-1. What is not known when the investor is considering the acquisition of an agency passthrough is the amount of the cash flow. Moreover, prepayments will alter the schedule shown in Exhibit 22-1 because the balance of the amount outstanding after a prepayment is made changes the interest that will be paid in subsequent months.

Payments are made to security holders each month. However, the amount and the timing of the cash flow from the pool of mortgages and the cash flow passed through to the security holders are not identical. The monthly cash flow for an agency passthrough is less than the monthly cash flow of the underlying mortgages by an amount equal to the servicing and guarantor fee. The latter fee is charged by the issuer or guarantor of the passthrough security for guaranteeing the payment to security holders should any of the underlying borrowers miss a payment or default (discussed later).

The timing of the cash flow also differs. The monthly mortgage payment is due from each mortgagor on the first day of each month, but a delay affects the passing through of the corresponding monthly cash flow to the security holders. The length of the delay varies by the type of agency passthrough.

360	1,009.58	1,013.37	3.79	1,009.58	0.00

An investor who is considering investing in an agency passthrough does not know what the cash flow will be because the cash flow depends on prepayments. Prepayments are classified as voluntary repayments and involuntary repayments. Voluntary repayment occurs when the borrower exercises the right to prepay the loan at any time. Voluntary repayments occur due to refinancing and turnover. Refinancing occurs when the borrower obtains a lower rate and/or extracts equity from the property. Turnover involves the sale of property, which is typically related to relocation, family formation, or a life event such as death or divorce. Involuntary repayment is the repayment of a loan as a result of the borrower defaulting and the property repossessed and sold. Defaults may occur as a result of a life event (e.g., a job loss, illness, or family break-up, and the like) or the value of the property falls below the amount owed on the loan (referred to as a strategic default).

The risk associated with prepayments is called *prepayment risk*. This risk can be divided into two risks: contraction risk or extension risk. As interest rates drop and prepayments accelerate (or expectations of prepayments) increase, the expected average life or duration of the passthrough contracts. That is, its price sensitivity to declining rates shrinks as it becomes an effectively shorter security. As such, it will underperform noncallable bonds. This is contraction risk. When rates rise, the passthrough extends in terms of its average life or duration and its price declines faster than comparable noncallable bonds. This is extension risk and this property of passthroughs is referred to as negative convexity.

Prepayment Conventions

Because a borrower may terminate a loan at any time, the lender is said to be "short" the prepayment option to the borrower. Residential real estate loans typically do not carry prepayment penalties, and as a result are subject to considerable prepayment risk attributed to voluntary repayments. In this section we explain the conventions used to describe prepayments and in the next section we review the elements of prepayment modeling.

Single Monthly Mortality Rate and Conditional Prepayment Rate

The monthly prepayment rate, or *single monthly mortality rate* (SMM), measures the percentage of a pool's principal balance that has prepaid in the current month. It is based on the change in the pool's factor (survival factor) from one period to the next, and is given by the following formula

$$\text{SMM} = \frac{\text{Scheduled balance} - \text{Ending balance}}{\text{Scheduled balance}} \times 100 \qquad (22\text{-}1)$$

The equation can be rewritten as

$$\text{SMM} = \frac{\text{Beginning balance} - \text{Scheduled principal} - \text{Ending balance}}{\text{Beginning balance} - \text{Scheduled principal}} \times 100 \qquad (22\text{-}2)$$

The market convention is to state the SMM, as an annualized measure, known as the *conditional prepayment rate* (CPR). The formula for CPR is

$$\text{CPR} = 1 - (1 - \text{SMM})^{12} \times 100 \qquad (22\text{-}3)$$

Public Securities Association Model

The *Public Securities Association (PSA) model* was developed to describe how mortgage prepayments evolve as a function of loan age. The PSA model specifies the mortgage prepayment loan age (seasoning) function as follows:

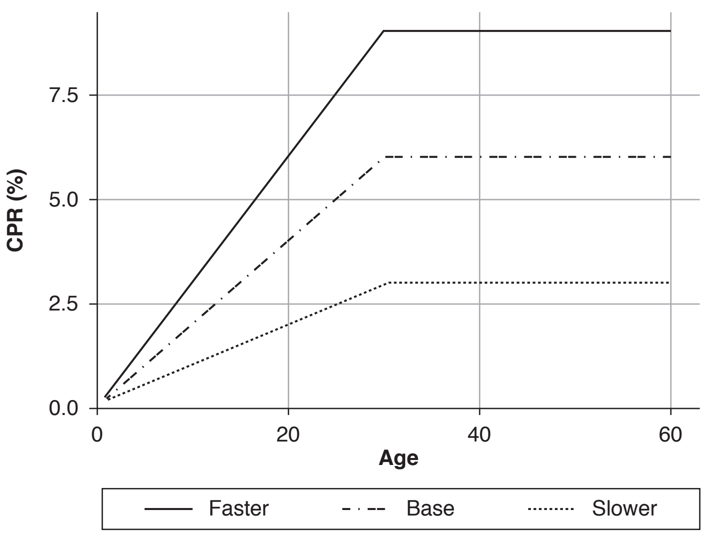
- Begins at 0.2% CPR the first month
- Increases by 0.2% CPR per month
- Reaches a maximum of 6.0% CPR in month 30

Exhibit 22-2 illustrates the application of the PSA model. For example, at 100 PSA the investor is assuming that the pool's prepayment rate will follow the seasoning ramp described above.

- A 150 PSA assumption multiplies the PSA model by 150%. Under this assumption, the pool's prepayment rate will begin at 0.3% in the first month, season 0.3% per month, and reach a peak of 9.0% in month 30.
- A 50 PSA assumption multiplies the PSA model by 50%. Under this assumption, the investor believes that the pool's prepayment rate will begin at 0.1% in the first month, season 0.1% per month, and reach a peak of 3.0% in month 30.

EXHIBIT 22-2

PSA Mortgage Prepayment Assumption



Modeling MBS Cash Flows

Cash-flow modeling drives the valuation of agency passthroughs. It establishes a framework that defines the following: (1) timing of the return of principal, and (2) payment of interest to the investor.

Cash-flow analysis for an agency passthrough is complicated by the presence of any or all of the following: (1) servicing fees, (2) guarantee fees (GFee), and (3) private mortgage insurance (PMI). These three costs are subtracted from the borrower's note rate. The net of the borrower's note rate less servicing, GFee, and PMI is the net note rate, or *net weighted average coupon* (NWac). The servicing fee compensates the servicer on a monthly basis for the mortgage lender's administrative duties.[1] The PMI fee protects the lender from loss in the event that the borrower defaults and there is insufficient equity in the home to cover the outstanding balance of the note. The guarantee fee is a premium paid by the borrower to the guarantor, typically the party that securitized and sold the MBS pool, for its guarantee of timely principal and interest to the investor.

The NWac, scheduled principal, and prepaid principal are "passed through" to the investor, hence, the term *passthrough security*.

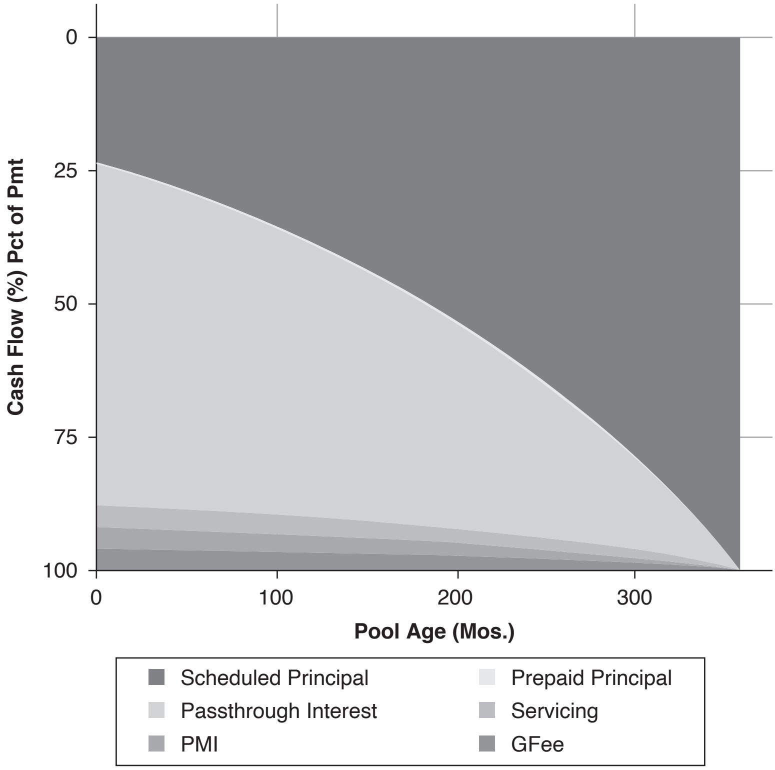
Exhibit 22-3 illustrates the cash-flow profile of a 4.0% MBS pool assuming a 0% PPC—*no prepayments*. In the absence of prepayments, the investor receives a level cash flow over the life of the pool. In this case, the investor receives $609.13 per $100,000 invested. Early in the life of the pool, a greater share of the mortgage payment consists of interest. As the loans underlying the pool amortize, the share of scheduled principal, as a percentage of the borrower's scheduled payment, increases. About halfway through the life of the loan the amount of scheduled principal paid is greater than the amount of interest paid. This accelerates the amortization of the loans underlying the pool as it approaches its final payment *maturity* date.

The borrower's option to prepay the loan at any time alters the timing of the cash flows received by the investor because prepayments are passed through as the *unscheduled* return of principal. The example presented in Exhibit 22-4 uses a 100 PPC assumption and shows that as the borrowers in the pool exercise their option to prepay the principal returned to the investor becomes *front loaded*. This exhibit illustrates how the application of a prepayment assumption changes the share of principal and interest paid to the investor. For example, at month 100 the share of principal paid—both scheduled and prepaid—account for around 75% of the total principal received. In contrast, Exhibit 22-3 shows that in the absence of prepayments, scheduled principal accounts for around 50% of the total principal received by the investor.

1. Loan administration fees are compensation for the following duties: (1) administering escrow accounts for the payment of taxes and insurance, (2) in the absence of escrow, verifying the borrower has paid property taxes and that insurance coverage is maintained on the property, and (3) send the borrower tax information at the end of the year.

EXHIBIT 22-3

Cash-Flow Share Assuming 0% PSA



Applying Prepayment Assumptions

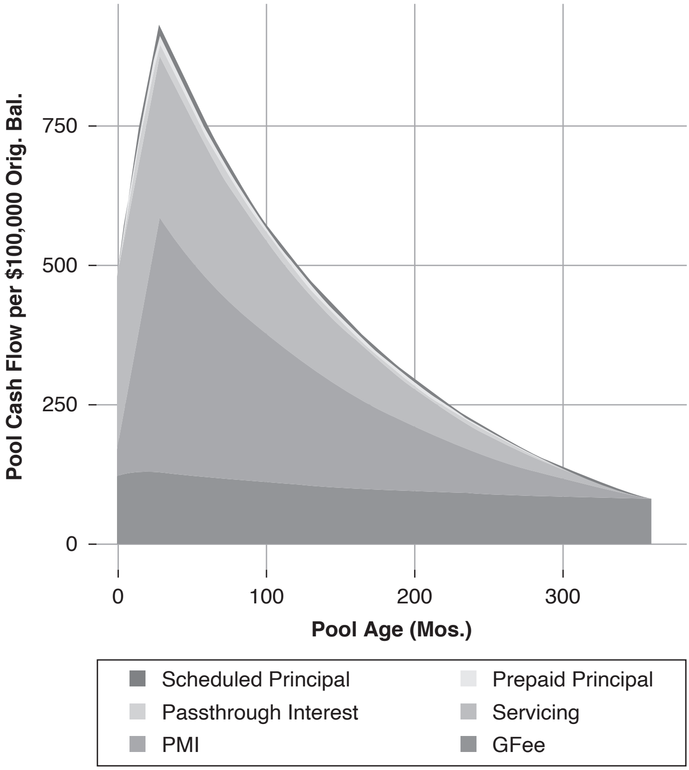
From the cash-flow analysis just presented, it can be seen that the derivation of MBS cash flows is dependent on the investor's underlying prepayment assumption. As a result, it is important to understand both the nomenclature used in the description of structured security cash flows as well their practical application.

The foundation of all prepayment applications is SMM, which is the percentage of the outstanding balance that prepays. However, most investors annualize the measures of prepayment rates. The measure quoted is the CPR, the annualized expression of the SMM. It refers to the amount of prepaid principal an investor would receive over a 12-month period assuming the SMM remains constant.

To calculate a prepaid principal amount, it may be tempting to simply take the CPR or SMM and multiply it by the period's beginning balance. However, that would be an incorrect application of the concept. The amount of prepaid principal is calculated only after giving credit to the scheduled principal paid in the

EXHIBIT 22-4

Pool Cash Flow Assuming 100% PSA



period. Exhibit 22-5 provides the derivation of the cash flows of a passthrough, including the allocation of servicing, the guarantee fee, and PMI.

To calculate an agency passthrough's cash flows assuming 100 PSA, the following steps are taken. First, determine the appropriate CPR. For example, a loan age of 10 along the 100 PSA assumption is equal to 2.2% CPR. Second, de-annualize the CPR to an SMM—this is the monthly principal prepaid and is computed using the following formula:

$$\text{SMM} = 1 - (1 - \text{CPR}^{(1/12)})$$

Assuming a CPR of 2.2%, we get

$$\text{SMM} = (1 - (1 - 0.022)^{(1/12)}) = 0.001852$$

Third, after giving credit to the scheduled principal due, the prepaid principal is calculated as follows:

$$(\text{Beginning balance} - \text{Scheduled principal}) \times \text{SMM}$$

In our illustration,

$$\text{Prepaid principal} = \$96{,}784.04 - \$273.84 = \$162.34$$

Finally, allocate interest in the following priority: investor interest amount, servicing fee, PMI, and G-Fee.

EXHIBIT 22-5

Determinants of Prepayment Rates

Prepayments are the chief determinant of a passthrough's investment performance. The factors described below have been found to impact agency mortgage prepayments and are incorporated into statistical prepayment models.

Over a holding period, the amount of repayment and actual collections of interest are a function of realized prepayments. So too, the price performance of a passthrough is a function of the market's expectations of future prepayments. Earlier we mentioned the causes of prepayments. Here we take a closer look at the determinants of prepayments, which fall into four categories: refinancing, turnover, seasoning, and default.

Refinancing

Homeowners refinance for three reasons: (1) to lower their monthly payment by lowering the mortgage interest rate (often referred to as a "rate refinance"), (2) to alter the term of the mortgage refinancing from a 30- to 15-year term (generally referred to as "rate and term" refinance), and (3) to extract paid-in equity and/or increases in appraised home value due to home price appreciation (often referred to as a "cash-out refinance").

To varying degrees, all the sources of prepayments in pools are interest-rate-sensitive, but the most variable source of prepayments is refinancing. In theory, a rate refinance occurs when the difference in monthly payment between the current note rate and prevailing mortgage rate is sufficient enough to permit the homeowner to recover the loan fees and points, as well as the legal, appraisal, title-related, and other costs of refinancing over some reasonable period of time. In the 1980s, a commonly invoked rule of thumb estimated that the minimum incentive was an interest rate savings of 200 basis points (bps). Aggressive competition among lenders, innovation, and technological advances have shaved closing costs, simplified paperwork, and cut approval times dramatically. The reductions in the cost and "hassle" of obtaining a mortgage began to be evident in the early 1990s, as mortgage bankers stepped into the breach left by the collapse of the thrift industry and accelerated as the decade progressed. Today, market participants estimate that an interest rate savings as little as 35 bps may be sufficient to trigger a refinance. Indeed, declining transaction costs and originator efficiency have multiplied the refinancing response to a given interest rate decline.

Turnover

MBS investors typically refer to prepayments occasioned by the sale of the house as "turnover."

Intuitively, turnover is interest-rate-sensitive in the sense that houses are easier to sell when interest rates are declining or low.[2] However, the level of

2. Note, however, that turnover is not directly indicated by the pace of existing home sales. Those numbers need to be adjusted for existing housing stock, which generally increases as new homes are built.

interest rates is only one of several factors that determine housing affordability and hence the level of turnover. Household income and housing prices are significant as well and tend to offset somewhat the impact of rising interest rates. That is, improving economic conditions, along with rising employment and incomes, tend to accompany upward pressure on interest rates. Somewhat conversely, rapid home sales tend to be accompanied by rising home prices, diminishing affordability to some degree. By the same token, rising mortgage rates may slow home price appreciation, keeping home prices within reach.

Some degree of turnover takes place even in high-interest-rate environments. Seasonality is an important characteristic of turnover, with peak home sales occurring in the summer and troughs typically occurring in the winter. Weather is a factor, at least in northern states, because house hunting and moving are easier in good weather and houses "show" better in good weather. Also, households with children prefer to move between school years. Understandably, the seasonality of prepayments has a more demonstrable impact on passthrough cash flows in high-interest-rate environments, when refinancings are at a low ebb. Likewise, it dominates perception of value in high-rate, low-refi environments.

Seasoning

Seasoning refers to the number of months since the loan origination or first payment date. For example, a loan outstanding 12 months after the origination or first payment date is said to be 12 months seasoned. Investors broadly classify mortgage pools are "new," "moderate," or "seasoned." A new pool is one whose loan age is 30 months or less, a moderate seasoned pool is one whose loan age is between 31 and 60 months, and a seasoned pool is one whose loan age is greater than 60 months. Seasoning can indicate *burnout*. Burnout refers to the fact that the more times the pool of borrowers is exposed to refinancing incentives, the less likely the remaining borrowers are to respond to subsequent refinancing incentives. That is, as borrowers whose circumstances permit them to respond to attractive borrowing rates do so, the fewer the borrowers remaining in the pool that are likely to respond to a given level of rates—a phenomena known as adverse selection.

Consequently, refinance-driven prepayment rates begin to slow. Likewise, passthroughs that have been heavily refinanced in past rallies tend to respond more sluggishly to subsequent refinancing opportunities. A better indication of the refinancing *path* experienced by a passthrough is origination year and coupon.

Defaults

A default can result in a prepayment when the servicer forecloses on the mortgage and sells the property. A borrower default may be of two kinds. The first is a strategic default wherein the borrower holds—especially in the case of a high loan-to-value—a put option to the lender. A precipitous decline in home prices whereby the borrower is underwater—the value of the home is less than the balance of the loan outstanding—may trigger a default. The second is a life event, typically a job loss or serious illness.

In the case of agency passthroughs, because of the passthrough guarantee, investors are protected from any loss that might occur on foreclosure and sale by the passthrough guarantee. In addition to prepayments in full, borrowers may partially prepay their loans at any time.

Prepayment Modeling

To value an agency mortgage passthrough, as well as any derivative RMBS such as a CMO and stripped RMBS, an investor must generate a prepayment estimate. Typically, a model that estimates both voluntary and involuntary repayment is used for this purpose. Before one can "build" a prepayment model, an understanding the fundamental drivers of mortgage prepayments is essential. For this reason, mortgage prepayment analysis is treated as a separate topic from modeling. Prepayment data and the analysis thereof fall under the rubric of *big data* and *statistical learning*.[3] The topic is beyond the scope of this chapter.

SOME MBS ANALYTICS

In addition to prepayments and models there are other analytics that an investor in the MBS as sector of the market should understand: cash-flow yield, average life, and duration. These measures apply to all MBS, not only agency passthrough securities.

Cash-Flow Yield

Once the prepayment rate for an agency passthrough security is predicted, the cash flow can be projected. Given the market price and projected cash flow, a yield can be determined. The yield is nothing more than an interest rate of return. It is the interest rate that makes the present value of the monthly cash flow equal to the market price. In MBS terminology, this yield when annualized is called the *cash-flow yield.* However, the cash-flow yield resulting from the calculation is a monthly yield.

By market convention, to compare the yield for a passthrough that pays monthly to that of a Treasury or corporate bond, the monthly yield should *not* be annualized by simply multiplying the monthly yield by 12. The reason is that a Treasury bond and a corporate bond pay interest semiannually, whereas a passthrough has a monthly cash flow. By reinvesting monthly cash flows, the investor in a passthrough security has the opportunity to generate greater interest than can be earned by a bondholder who has only semiannual coupon payments to reinvest. Therefore, the yield on a passthrough must be calculated so as to make

3. For a comprehensive discussion of the use of big data and machine learning in estimating prepayments, see Chapters 8 and 9 in Glenn Schultz, *Investing in Mortgage and Asset Backed Securities, Financial Modeling with R and Open Source Analytics*, Hoboken, NJ: Wiley 2016.

it comparable to the yield to maturity for a bond. This is accomplished by computing the *bond-equivalent yield*. The bond-equivalent yield for a semiannual-pay bond is found by doubling the semiannual yield. In the case of a monthly-pay MBS such as an agency passthrough, the annualization of the yield to get the cash-flow yield is done in two steps. The first is to calculate a semiannual cash-flow yield:

$$\text{Semiannual yield} = (1 + \text{Monthly yield})^6 - 1$$

The yield corresponding to a price must be qualified by an assumption concerning prepayments. Although yields are frequently quoted, remember that the yield is based on some underlying prepayment assumption. Consequently, a yield of 4.5% based on 120 PSA means that it is assumed that the underlying mortgages will prepay at a rate equal to 120 PSA. A yield number without qualification as to the prepayment assumption is meaningless. In fact, even with specification of the prepayment assumption, the yield number is meaningless in terms of the relative value of an agency passthrough. For an investor to realize the yield based on some PSA assumption, a number of conditions must be met: (1) the investor must reinvest all the cash flows at the calculated yield, (2) the investor must hold the passthrough until all the mortgages have been paid off, and (3) the assumed prepayment rate must actually occur over the life of the passthrough. Now, if all of this is likely, we can trust the yield numbers. Otherwise, investors must be cautious in using yield numbers to evaluate passthroughs.

Weighted Average Life

The average life of an MBS is the average time to receipt of principal payments (scheduled principal payments and projected prepayments), weighted by the amount of principal expected. That is,

$$\text{Weighted average life} = \sum_{t=1}^{T} \frac{t\,(\text{Principal projected for month } t)}{12\,(\text{Total principal})}$$

where T is the number of months. The weighted average life of any MBS depends on the PSA prepayment assumption. Exhibit 22-6 illustrates the calculation of the weighted average life assuming a 120 PSA. The sum of the time weighted principle is the weighted average life of the passthrough; in this case, 8.8 years.

The PSA assumption determined the prepaid principal in any given period and by extension the scheduled principal in the subsequent period. The acceleration of the return of principal shortens the weighted average life of the passthrough. For example, assuming a 0 PSA, no prepayment, the weighted average life of the passthrough is 15.08 years, given a 100 PSA assumption the weighted average life is 9.5 years, and applying a 200 PSA assumption the weighted average life is 6.7 years. Hence, the need to qualify MBS passthrough yield number with a prepayment assumption.

					Weighted Average Life		**8.80**

Duration of an MBS

Duration is a measure of the sensitivity of a bond to a change in the level of interest rates. The duration of a bond is calculated as follows:

$$\text{Duration} = \frac{V_{-} - V_{+}}{2V_0(\Delta y)} \tag{22-4}$$

where

Δy = change in the bond's yield (in decimal form)
$V0$ = initial price of the bond (per \$100 of par value)
$V+$ = the estimated value of the bond per \$100 of par value if the yield is increased by Δy
$V-$ = the estimated value of the bond per \$100 of par value if the yield is decreased by Δy

The two unknowns in Equation (22-4) are the prices when the yield is increased ($V+$) and decreased ($V-$). The method used to determine the new prices if yields change is what distinguishes the different types of duration measures. And, how good the new prices are in estimating the new price determines how good the specific duration measure is in forecasting the future price change.

In implementing Equation (22-4) it is necessary to change the bond's yield by some number of basis points (Δy). The number of basis points to use to compute the new prices is selected by the investor. There is no rule but only guidelines for how large the change should be, which we describe later.

In general, duration measures fall into two categories: model duration and empirical duration.

Model Duration

Model duration means that the two prices used in the numerator of Equation (22-4) are obtained from some analytical model. For agency passthroughs, model duration measures include modified duration, cash-flow duration, and effective duration. The difference between these duration measures is what the model assumes happens to the cash flow if interest rates change.

***Modified duration*:** This duration measure is the simplest one to compute but is likely to be the least reliable in many circumstances. In the calculation of the two values in the numerator of Equation (22-4), it is assumed that the cash flow used to generate the current price is the cash flow when interest rates are shocked up and down. Thus, the agency passthrough is revalued only by using the interest rate associated with the interest rate shock (i.e., discounting the cash flow by the interest rate associated with the interest rate shock). For example, suppose that given today's price for an agency passthrough (V_0), the implied prepayment rate is 120 PSA. This means that a 120 PSA generates the cash flow that leads to V_0. If interest rates are shocked to obtain the two values in Equation (22-4), V_+ and V_-, the cash flow used is based on 120 PSA but the cash flow is discounted at the new interest rate (i.e., the original yield plus the interest rate shock) to obtain these two values. The assumption being made here is that the change in interest rates will have no impact on future cash flows because it will not change prepayments.

The problem with using modified duration to estimate the interest rate sensitivity is that for an agency passthrough that is highly prepayment sensitive to interest rate changes, failing to recognize how the cash flow will change because prepayments change will produce a misleading estimate of duration.[4]

Cash-flow duration: Rather than assume that the cash flow does not change when interest rates change because prepayments do not change as assumed in the computation of modified duration, it can be assumed that prepayments will change based on a new prepayment speed that reflects the interest rate change. That results in a new cash flow based on the projected prepayment speed, which is then discounted at the new interest rate. When the new prices in Equation (22-4) are computed in this manner, the resulting duration means is referred to as *cash-flow duration*.

For example, assume that the current prepayment rate is 120 PSA for an agency passthrough. To get the two values to use in the duration formula given by Equation (22-4), suppose the cash-flow yield is shocked by 50 bps. If the cash-flow yield is increased, then a prepayment model is used to determine the new cash flow at the higher yield level. Suppose that a prepayment model indicates that at the higher yield level the prepayment speed will decline to 105 PSA. Then the cash flow for this security is generated based on 105 PSA and discounted at the current yield plus the change in interest rates. This gives the value of V_+. Suppose that if interest rates decrease by 50 bps the prepayment model projects that the prepayment rate will increase to 135 PSA. Then the new cash flow for this security will be generated based on 135 PSA and at the original yield level reduced by the change in interest rates. The resulting value for the security is V_-. Using these two values in Equation (22-4) gives the cash-flow duration.

Cash-flow duration is superior to modified duration in that it at least recognizes that the cash flow may change when interest rates change. However, it still suffers from the problem that in computing the V_+ and V_- it only recognizes one possible cash flow in contrast to the valuation methodology described next.

Effective duration**:** In contrast to modified duration, *effective duration* is a duration measure that assumes when interest rates change, the original cash flow will change. Unlike cash-flow duration, which allows for the cash flow to change when interest rates change, effective duration uses a valuation model to determine what the two prices for Equation (22-4) are. This is done as follows. When

4. The same problem with using modified duration applies to its close cousin, *Macaulay duration*. Modified duration is simply Macaulay duration divided by 1 plus a periodic interest rate. That is, there is a simple mathematical relationship between modified and Macaulay duration and since modified duration holds little interest to us, so does the Macaulay duration. In a very low interest rate environment, Macaulay duration and modified duration are almost identical.

interest rates are changed, as explained next when we describe the valuation model, a large number of potential future interest rate paths and associated cash-flow patterns are used to obtain the two new prices. Because the valuation model itself takes into consideration the embedded option associated with an agency passthrough, effective duration is also referred to as *option-adjusted duration***.**

The most common model used to value an agency passthrough is the Monte Carlo simulation model (simply Monte Carlo model, hereafter). All mortgage-backed securities are interest rate path-dependent financial instruments. This means that the cash flow received in one month is determined not only by the current interest rate level, but also by the path that interest rates took to get to the current level. In the case of an agency passthrough, prepayments are interest rate path-dependent because this month's prepayment rate depends on whether there have been prior opportunities to refinance since the underlying mortgages were originated. The bottom line is that valuation by Monte Carlo simulation, the subject of Chapter 37, provides the two values for the numerator in Equation (22-4).

There several key underlying assumptions that are made in the Monte Carlo simulation model for valuation of agency passthroughs. This is the reason why there are differences in the effective durations reported by dealers and vendors of analytical services for all types of mortgage-backed securities.

Market-Based Duration

Market-based duration measures for an MBS use observed market prices rather than projected prices. Several approaches based on observed market prices are used to calculate duration. These market-based approaches are empirical duration, hedging duration, and coupon curve duration.

Empirical duration: This duration measure, sometimes referred to as *implied duration*, is the sensitivity of an MBS as estimated empirically from historical prices and yields. Regression analysis is used to estimate the relationship.[5] On a daily basis the following regression is calculated:[6]

$$\text{Change in mortgage price} = a + b\,(\text{Change in 10-year Treasury yield}) \qquad (22\text{-}5)$$

5. This approach was first suggested by Scott M. Pinkus and Marie A. Chandoha, "The Relative Price Volatility of Mortgage Securities," *Journal of Portfolio Management* (Summer 1986), pp. 9–22. The model was then refined in Paul DeRossa, Laurie Goodman, and Mike Zazzarino, "Duration Estimates on Mortgage-Backed Securities," *Journal of Portfolio Management* (Winter 1993), pp. 32–37.

6. The model described here is the one proposed in Laurie S. Goodman and Jeffrey Ho, "Mortgage Hedge Ratios: Which One Works Best?" *Journal of Fixed Income* (December 1997), pp. 23–33, and Laurie S. Goodman and Jeffrey Ho, "An Integrated Approach to Hedging and Relative Value Analysis," chapter 15 in Frank J. Fabozzi (ed.), *Advances in the Valuation and Management of Mortgage-Backed Securities* (New Hope, PA: Frank J. Fabozzi Associates, 1999).

Given the estimate of b from Equation (22-5), the empirical duration is then calculated as follows:

$$\text{Empirical duration} = \frac{b(\text{Change in mortgage price/ Change in 10-year yield})}{\text{Full price of the MBS}} \tag{22-6}$$

There are advantages of the empirical duration approach:

1. The duration estimate does not rely on any theoretical formulas or analytical assumptions.
2. Estimation of the required parameters is easy to compute using regression analysis.
3. The only inputs that are needed are a reliable price series and Treasury yield series.

The empirical duration approach has the following disadvantages:

1. A reliable price series for the mortgage security may not be available. For example, there may be no price series available for a thinly traded mortgage derivative security or the prices may be matrix priced rather than actual transaction prices.
2. An empirical relationship does not impose a structure for the options embedded in an MBS and this can distort the empirical duration.
3. The price history may lag current market conditions. This may occur after a sharp and sustained shock to interest rates has been realized.
4. The volatility of the spread to Treasury yields can distort how the price of an MBS reacts to yield changes.

From an implementation perspective, there is no standardization as to the frequency of the data that should be used (i.e., daily, weekly, monthly), the length of the time period that should be used, and even the appropriate Treasury maturity yield that should be used. Moreover, it is not possible to calculate the empirical duration for illiquid or non-conforming MBS where little trading is performed.

Hedging duration: A more elaborate empirical model for estimating duration of an MBS that takes into account factors that we have noted impact its price (level of rates, shape of the yield curve, and expected interest rate volatility) has been suggested by Goodman and Ho.[7] The price model that they present, a special type of empirical duration model, allows not only an estimate of the sensitivity

7. Goodman and Ho, "An Integrated Approach to Mortgage Hedging and Relative Value Analysis."

of the price to changes in the level of rates, but also to the other factors. In their price model:

- The 10-year Treasury yield is used as a proxy for the level of rates.
- The spread between the 10-year and 2-year Treasury yields is used as a proxy for the shape of the yield curve.
- The implied 3-month yield volatility on the 10-year Treasury note is used as a proxy for expected interest rate volatility.

The price model involves estimating the following regression:

$$\text{Price} = \begin{aligned} &a + b\,(\text{10-year yield}) + c\,(\ln[\text{10-year yield}]) \\ &+ d\,(\text{10-year/2-year spread}) + e\,(\text{volatility}) \end{aligned} \qquad (22\text{-}7)$$

where ln[10-year yield] means the natural logarithm of the 10-year Treasury yield.

Hedging duration, also referred to as price model duration, is then computed as follows given the estimates for the parameters for Equation (22-7):

$$\text{Price model duration} = -[b + c/(\text{10-year Treasury yield})] \qquad (22\text{-}8)$$

***Coupon curve duration*:** This duration measure uses market prices to estimate the duration of an MBS. It is an easier approach to duration estimation than empirical duration but is limited in its application for the reason explained below.

Coupon curve duration, first suggested by Douglas Breeden,[8] starts with the coupon curve of prices for similar MBSs. By rolling up and down the coupon curve of prices, the duration can be obtained. Because of the way it is estimated, this approach to duration estimation was referred to by Breeden as the "roll-up, roll-down approach." The prices obtained from rolling up and rolling down the coupon curve of prices are substituted into the duration formula given by Equation (22-4).

To illustrate this approach, let's assume the following coupon curve of prices for agency passthroughs as of a particular date are:

Coupon (%)	Price ($ per $100 par)
3.0	101.0000
3.5	103.9688
4.0	106.4063
4.5	108.3750
5.0	110.5625

8. Douglas Breeden, "Risk, Return, and Hedging of Fixed-Rate Mortgages," *Journal of Fixed Income* (September 1991), pp. 85–107.

Suppose that the coupon curve duration for the 4s is sought. If the yield declines by 50 bps, the assumption is that the price of the 4s will increase to the price of the 4.5s. Thus, the price will increase from 106.4063 to 108.3750. Similarly, if the yield increases by 50 bps, the assumption is that the price of the 4s will decline to the price of the 3.5s (103.9688). Using the duration formula given by Equation (22-4), the corresponding values are

$$
\begin{aligned}
V_0 &= 106.4063\\
V_- &= 108.3750\\
V_+ &= 103.9688\\
\Delta y &= 0.005
\end{aligned}
$$

The estimated duration based on the coupon curve is then

$$\text{Current coupon duration} = \frac{108.3750 - 103.9688}{2\,(106.4063)\,(0.005)} = 4.14$$

Note that if a 100 bps rate shock is used, the current coupon duration would be

$$\text{Current coupon duration} = \frac{110.5625 - 101.0000}{2\,(106.4063)\,(0.01)} = 4.49$$

While two advantages of the coupon curve duration are the simplicity of its calculation and the fact that current prices embody market expectations, there are disadvantages. The approach is limited to generic MBS and TBAs and difficult to use for mortgage derivatives.

ANATOMY OF THE AGENCY PASSTHROUGH MARKET

In general, the "anatomy" of the agency passthrough market is driven by two concerns: liquidity and expected prepayment behavior. Liquidity is maximized in the trading of generic agency passthroughs, and prepayment behavior is parsed in the trading of specified pools and small pooling programs.

Generic Securities

One of the unique features of the agency passthrough market is the existence of a liquid forward market for trading these securities, out to a horizon of one to three months. The market for forward trading of agency passthroughs is known as the *to be announced (TBA) market*. The TBA market allows for forward trading of agency passthrough based only on the generic attributes of coupon and term. The actual pools delivered to settle the trade are "announced" 48 hours prior to the settlement of the contract. The agency passthrough TBA market is recognized as one of the world's most liquid markets, second only to the U.S. Treasury market. Indeed, throughout the Global Financial Crisis, the TBA market functioned flawlessly as the GSEs were placed into conservatorship and liquidity in the private label MBS market seized. The performance of the TBA market throughout the financial crisis garnered the TBA market the title of the "The Eighth Wonder of the World." As a result of the TBA market's performance throughout the financial crisis, policy regulators were keen to support and enhance the TBA market's liquidity. Hence the creation of the Uniform Mortgage Backed Security (UMBS).

Beginning June 3, 2019, both Fannie Mae and Freddie Mac began offering TBA-eligible Uniform Mortgage Backed Securities (UMBS). It is important to note that UMBS are TBA-eligible securities and both Fannie Mae and Freddie Mac continue to offer passthroughs that are not TBA-eligible and by extension are not UMBS.

UMBS contracts mirror that of the Fannie Mae's legacy mortgage contract in terms of guarantee and payment day delay, specifically the mortgage contracts pay cash flow through to the investor on a 55-day delay. Thus, all outstanding Fannie Mae TBA eligible passthroughs are considered UMBS. However, Freddie Mac's TBA-eligible Gold fixed-rate passthroughs pay cash flow through to the investor on a 45-day delay. Thus, legacy TBA Gold mortgage contracts are not considered UMBS. However, investors may exchange Freddie Mac Gold passthroughs for Freddie MAC UMBS. As part of the exchange a one-time 10-day float compensation is paid to the investor. UMBS are issued as 30-year fixed rate, 20-year fixed rate, 15-year fixed rate, and 10-year fixed rate pools. Both Fannie Mae and Freddie Mac guarantee the timely payment of interest and scheduled principal.

Fannie Mae and Freddie Mac UMBS are considered fungible. That is, the investor or dealer may deliver each to satisfy TBA delivery. The fungibility of the UMBS created the concept of level 1, level 2, and level 3 securities with respect to mortgage securitization. Level 1 securities are passthroughs and include UMBS, Level 2 securities are pools of pools, Supers are pools of pools of UMBS, and Level 3 securities REMICs and Strips. UMBS are eligible for re-securitization in either Supers (Level 2) or REMICs (Level 3) securities. An investor or dealer that owns a UMBS may re-securitize either by itself or comingled with other Fannie Mae or Freddie Mac securities. The re-securitizing Enterprise will also guarantee the re-securitization.[9]

Generic passthrough classes are divided first by agency. GNMA should trade distinctly from GSE passthroughs; the guarantee is backed by the U.S. government, and the underlying loans are assumable, subject to lower loan limits, and possess demonstrably different credit performance.

The market does perceive a difference in credit quality between GNMA and the GSEs and consequently demands a risk premium for the conventional agency passthroughs. All other factors being equal, this would translate into a higher yield for the GSE-guaranteed issues. However, all else is not equal.

9. SIFMA Single Security Fact Sheet 2019. Available at https://www.sifma.org/wp-content/uploads/2016/05/Single-Security-Fact-Sheet.pdf.

Fundamental and technical issues influence the price behavior of the securities and over time have tended to swamp differences in credit quality. At one time, 30-year GNMA also enjoyed a liquidity advantage over the conventional 30-year programs. In the 1970s and 1980s, 30-year GNMA passthroughs were the de facto market benchmarks (Ginnie Mae was virtually a synonym for mortgage-backed security), giving way to Fannie Mae by the mid-1990s. However, declining market share (of both new and outstanding passthrough supply) has not consistently hurt its price relationship to FNMA (and by extension, FHLMC). Rather, much of the demand for GNMA passthroughs is entrenched, coming from foreign investors who look more to the guarantee than to the underlying credit quality of the loans or quality of the GSE's reserves funded by guarantee fees and from Ginnie Mae and "government" mutual funds that have written these securities into their prospectuses. Entrenched demand in the face of sharply shrinking supply now tends to support GNMA prices, so they can be significantly higher than FNMA prices than the difference in payment delay alone would suggest (the 14 days of delay are worth four to eight ticks depending on the interest rate environment and FNMA should trade behind GNMA).

Finally, changes in pooling criteria boosted production of GNMA IIs relative to GNMA Is. This resulted, at times, in new issuance of GNMA Is trailing that of GNMA IIs. Also, differences in pooling criteria have an effect on the prepayment characteristics and hence on the relative value of GNMA IIs to GNMA Is. An exploration of these differences, however, is beyond the scope of this chapter.

Fannie Mae and Freddie Mac guarantees are comparable, and the eligible loans are fungible, but they trade differently for a variety of reasons. The difference in delay is worth about four to eight ticks, depending on the level of yields, making Freddie Mac's shorter delay more expensive, a factor that influences demand, all else equal.

Coupon Stacks

Within programs, such as 30-year Gold PC or GNMA I SF, pools are aggregated by coupon. While it is feasible to create agency passthroughs with coupons that vary by as little as one-eighth of a percent, concentrating issuance in whole and half coupons simplifies relative-value analysis, and trading strategies and maximizes liquidity. Most standard market reports, such as daily price reports or monthly prepayment reports, ignore the small amounts of quarter and eighth coupons outstanding. Market slang refers to the whole and half coupons as the "coupon stack."

Within a generic coupon, pools are grouped by issue year or vintage. The most useful strategy is to define issue year at the loan level rather than by the issue date of the pool. In other words, if a pool is issued January 1, 2019, but the average age of loans at issue indicates the loans were closed in November 2018, the pool is included in the 2018 vintage.

TBA COUPONS

In current practice, in the fixed-rate market, TBA securities, or coupons, are the whole and half coupons of the mainstay 30- and 15-year programs, as well as the 10- and 20-year GSE pools. As noted earlier, the term TBA means that the actual pools delivered to settle the trade are "to be announced."[10] Actual pool numbers are provided within 48 hours of the delivery date; notification or "allocation" dates are set by the Securities Industry and Financial Markets Association (SIFMA).

Unlike other fixed-income securities and other structured products that settle a defined number of days after the trade, TBA passthroughs settle once a month, roughly mid-month. This practice evolved in the early days of agency securitization to accommodate the fact that originators want to sell forward to hedge their pipelines (lock in the prices at which they are originating loans) but cannot predict to a round number the actual principal amount of closed loans going into a pool. (It also follows that pool numbers would not be known.) The practice of trading new pools TBA enlarged quickly to include existing pools, permitting dealers to sell agency passthroughs in response to investor inquiry without owning or having to quickly buy them from another investor or dealer.

Dollar Roll Financing in the TBA Market

The mortgage *dollar roll* is a financing mechanism used in the agency passthrough market. This discussion provides a brief description of the mechanics of the dollar roll. Break-even and financing analyses and the risks associated with implementing a dollar roll program are not addressed.[11]

For investors, the dollar roll is a specialized type of collateralized borrowing unique to the agency passthroughs market that allows for a 100% advance rate against a pool of agency MBS.[12] It evolved due to the dealers' need to borrow these securities to cover short positions and mortgage originators' need to hedge their origination pipeline (long positions) by *selling forward*. The dollar roll is named such because dealers are said to either *roll in* collateral (borrowing) or *roll out* collateral (returning).

The mortgage dollar roll is similar in nature to a mortgage repurchase (repo) agreement in that it represents a loan collateralized by mortgage-backed

10. Those terms are resolved in the pool notification process, which must take place at least 48 hours before delivery. Cutoff times are set by the SIFMA, along with standard requirements for delivery on settlements of agency passthroughs. The chief of these are numbers of pools and variance between trade amount and the current principal balance of pools delivered. The requirements for TBA trading are spelled out in the *Uniform Practices Manual*.

11. For an explanation and illustration of how an investor should evaluate a dollar roll, see Chapter 10 in Glenn Schultz, *Investing in Mortgage Backed and Asset Backed Securities Financial Modeling with R and Open Source Analytics*, Hoboken, NJ: John Wiley & Sons, 2016.

12. The dollar roll also provides mortgage originators and dealers with a flexible means to hedge and finance their respective residential mortgage positions.

securities and calls for the simultaneous sale and purchase of the MBS at execution. However, it is materially different from a *repurchase agreement* in two ways. First, the dealer is not required to return the identical securities rolled out by the investor. Instead, the dealer need only return substantially similar securities.[13] Second, unlike a traditional repurchase agreement, the investor surrenders the right to the bond cash flows. As a result, the forward settlement price is lower than the initial settlement price. The *drop* in price compensates the investor for the forgone interest and principal, which is another feature that differentiates a dollar roll transaction from a traditional repurchase agreement.

SPECIFIED TRADES[14]

Specified pools are those pools whose characteristics have been found to exhibit superior or inferior convexity relative to generic (TBA) pools. Specified pools are identified either by a prefix that is designated by either FNMA or FHLMC or by the pool's characteristics found in either the geographic disclosure files or the quartile files. In some cases, a pool may meet several specified pool criteria. To avoid confusion as to which specified pool sector a particular pool may belong a hierarchical ordering is employed as follows:

1. Assign sector by prefix.
2. Assign sector by geography.
3. Assign sector by loan balance.
4. Assign sector by investor percentage (100%).
5. Assign sector by refinance (100%) and loan-to-value ratio.
6. Assign sector by FICO (≤ 680).

Any pool not assigned to the above sectors is considered TBA or worst to deliver.

Specified pools trade at a premium or concession to TBA pools; the extent to which each trades to a premium or concession is dependent on the convexity profile of the pool. Those pools with superior relative convexity trade to larger a premium while those with inferior convexity trade to a concession. Each of the sectors described above have different convexity profiles.[15]

The earliest established specified pool sector is the loan balance sector. Originally, the specified pool sector was defined by low loan balance (LLB), moderate loan balance (MLB), and high loan balance (HLB). Over time, the

13. Meeting this condition is important from a financial accounting standpoint as set forth in Financial Accounting Standard (FAS) 40. Failure to meet the FAS 140 standard would result in a dollar roll transaction being accounted for as a sale rather than a financing.

14. For a more detailed discussion, see Glenn Schultz, *The Bond Lab Guide to Investing in Agency MBS Specified Pools*, unpublished manuscript.

15. See Schultz, *The Bond Lab Guide to Investing in Agency MBS Specified Pools*.

sector was further stratified to include moderate high loan balance (MHLB), high-high loan balance (HHLB), and super high loan balance (SHLB).

The prefix sectors can be divided into the jumbo loan balance sector, the loan-to-value (LTV) sector, and the relocation sector. The geographic sectors are for geographic pools with a 100% concentration to a given state. The most common geographic pools are Puerto Rico, New York, Florida, and Texas.

Aside from the sectors previously outlined, pools also trade according to New, Moderate, and Seasoned. The definition of each is as follows: (1) New Seasoned pools are defined as those pools whose loan age (WALA) is less than or equal to 30 months, (2) Moderate Seasoned pools are defined as those pools whose loan age (WALA) is greater than 30 months and less than 60 months, and (3) Seasoned pools are defined as those pools whose loan age (WALA) the greater than or equal to 60 months.

KEY POINTS

- Agency mortgage passthrough securities are issued and guaranteed by Ginnie Mae, Fannie Mae, or Freddie Mac and distribute the cash flow pro rata to investors on a monthly basis after deducting servicing and a guarantor fee.
- The monthly cash flow of an agency passthrough includes interest, scheduled principal payments, and prepayments. To project the cash flow for an agency passthrough, a prepayment assumption must be assumed. Prepayment conventions include single monthly mortality rate/conditional prepayment rate and the Public Securities Association model. Because of the uncertainty about the cash flow due to prepayments, investors in agency passthrough are exposed to prepayment risk.
- The chief determinants of prepayments fall into four categories: refinancing, turnover, seasoning, and default.
- The cash-flow yield is the yield calculated based on some prepayment assumptions and is a poor measure of relative value.
- The weighted average life of an MBS passthrough security measures the weighted average time to receipt of principal and is dependent on the prepayment assumption. A slower prepayment assumption extends the weighted average life of a MBS passthrough security. Conversely, a faster prepayment assumption shortens the weighted average life of a passthrough.
- There are various measures of duration for any mortgage-backed security: model duration (modified duration, cash-flow duration, and effective duration) and market-based duration (empirical duration and hedging duration). Of these. the most commonly used by investors and dealers are effective duration and empirical and hedging duration.

- The to-be-announced (TBA) market allows for forward trading, up to three months, of agency MBS passthrough securities. The market is recognized as one of the most liquid markets in the world, second only to the U.S. Treasury market. Trading in the TBA market is based on the generic characteristics of coupon and term. The securities delivered are "announced" 48 hours prior to settlement of the forward agreement.
- Specified pool trading is based on security specific CUSIP or pool number. Specified pools trade at a premium or concession to TBA pools, the extent to which is dependent on the convexity profile of each.
- The dollar roll is a specialized type of financing found in the agency passthrough market that allows 100% collateralized borrowing against a pool of agency mortgage-backed securities. The dollar roll allows dealers to easily cover short positions and originators to sell forward current loan production.
- Specified pool trading is based on security specific CUSIP or pool number.
- Each specified pool sector exhibits a unique convexity profile relative to those pools considered TBA. Due to their unique convexity profiles, specified pools trade at a premium or concession to TBA pools.

CHAPTER
TWENTY-THREE

AGENCY COLLATERALIZED MORTGAGE OBLIGATIONS

Alexander Crawford

This chapter provides an introduction to the U.S. agency collateralized mortgage obligation (CMO) market. It begins with the background of the CMO market and explains the difference between agency and nonagency CMOs. The chapter introduces the issuers Fannie Mae, Freddie Mac, and Ginnie Mae and then covers all of the major CMO tranche types in terms of structure and analysis, providing practical examples. It also covers information about option-adjusted spread (OAS) and prepayment models, and how to use that information to hedge CMOs or determine relative value. Coverage of nonagency CMOs is provided in Chapter 25.

THE CMO MARKET

The CMO market has existed since the mid 1980s. Its original purpose was to allow investors to more closely control when they receive principal from mortgage-backed securities. With mortgage pass-throughs, principal is received each month throughout the life of a security, often for a full 30 years. In a CMO, the principal is divided up into pieces or "tranches" creating some bonds that receive principal right away (and hence have shorter durations) and bonds that do not, typically resulting in longer durations. The creation of so-called PAC, or planned amortization class bonds took the CMO a step further, attempting to create a corporate bond surrogate.

To create a CMO, a dealer must gather agency pass-through collateral, structure a deal, and then pay a fee to Freddie Mac, Fannie Mae, or Ginnie Mae to issue the CMO. Ginnie Mae has the full faith and credit of the U.S. government, whereas the other agencies have the implicit guarantee of the U.S. government.

Now, the CMO market has exploded into a myriad array of tranches using different types of collateral. The cash-flow priority of tranches can even jump around based on prepayments. The same financial technology used to create

---

This chapter was written when the author was an employee of Deutsche Bank.

CMOs has been employed to create other securitized products in the world global market.

When comparing nonagency CMOs to agency CMOs, agency CMO analysis tends to be simpler because of more established prepayment models and minimal credit risk. Collateral information disclosure on nonagency CMOs tends to be slightly better, but in general the information gap is marginal for new deals.

THE REASONS WHY CMOs EXIST

Like any security, CMOs exist because there is a market to buy and sell them. From the demand side, there are investors who still want to more closely control the cash flows they get from an MBS investment. In addition, the CMO market has grown to such an extent that many other things are possible using the CMO market than with the MBS pass-through market, such as bonds with coupons that adjust on a monthly basis (floaters). From the supply side, CMO originators continue to operate as long as they can make a reasonable profit in the business. Often, all the CMO tranches are not sold right away, which forces the dealer to hold inventory, and thus take risk.

Size of the CMO Market

Peak issuance of agency CMOs was over $600 billion in 2003. CMO issuance dropped to only $150 billion during the financial crisis of 2008, but has since rebounded. For example, agency CMO issuance in 2020 reached over $400 billion. Historically, issuance of new CMOs has been similar to or surpassed that in most other markets, including Treasuries and corporate bonds.

Liquidity

The raw size of the CMO market suggests it should have enormous liquidity. However, liquidity is somewhat hampered by lack of homogeneity in the CMO market. Even the most common tranche types, PACs and sequentials, may have subtle differences that need to be examined and valued. (We will discuss this in detail later.) The liquidity of CMOs is typically less than agency pass-throughs, but comparable to corporate bonds.

Practical Details

In this section, we cover practical details such as typical payment and settlement structure for CMOs. Rules are generally different for CMOs than for corporate bonds. In some cases, rules are different for certain types of CMO tranches than for pass-throughs.

Bond Settlement

CMOs usually settle in book entry via DTC (Depository Trust Co.). Primary market CMOs may have delayed settlement, similar to pass-throughs. For example, many new-issue CMOs settle in the month after the trade date. New-issue CMOs usually settle at the end of the month, to allow the dealer time to bring in collateral and finish structuring the deal.

Secondary market CMO transactions are typically for corporate settlement, presently T+2 business days. It is possible to trade CMOs for other settlements, such as cash (T+0), if necessary.

Monthly Interest and Principal Payments

CMOs pay interest monthly, similar to the underlying pass-throughs. Tranches eligible to receive principal payments will receive them at the same time as the interest payments. Most CMOs have the same number of delay days as the underlying collateral, for example, 45 stated delay days for GNMA pass-throughs. However, certain tranches, such as CMO floaters, may have reduced delay days to facilitate comparison to corporate bonds. The number of delay days for each tranche is available in the prospectus or from electronic sources. Of course, the number of delay days impacts yield, as interest and principal are returned later (and hence reinvestment interest on that interest and principal is foregone) the longer the delay is.

Deal Clean-Up Calls

Some deals may contain clean-up calls triggered when only a small portion of the deal remains. The percentage trigger is typically set between 1% and 10%, inclusive. This feature is typically set up to avoid the burden of high fixed costs for the deal's trustee when a small amount of bonds remains outstanding. We discuss analyzing deal clean-up calls later in this chapter.

New Issue vs. Secondary Markets

The new issue CMO market typically settles as much as one or two months in the future, allowing the issuer to gather the requisite collateral for the deal and complete structuring. This structuring period also affords the investor the opportunity to custom design CMO tranches that fit the portfolio. Most secondary tranches trade for corporate settlement. While the investor cannot change existing tranches, more information about the tranche, such as historical prepayment speeds, can be valuable to the investor.

CMO TRANCHE TYPES

The crux of understanding the CMO market is understanding the different tranche types and how they are structured. Today, CMO deals are very complex, with multiple collateral sources, multiple tranche types, etc., in a complex array for each CMO deal. It is important to realize that each of these deals is made primarily from two basic flavors.

- A *planned amortization class* (PAC) deal, in which the non-PAC (support or companion) tranches have highly variable cash flows and average lives, while the PAC enjoys relatively stable, prescheduled cash flows.
- A *sequential deal*, where standard sequential tranches have cash-flow priority (i.e., absorb most or all of the principal from the deal) in turn until they are all retired.

These types of deals can be altered or dressed up slightly (such as in a PACquential deal), but there are still two basic flavors. Once the PACs and sequentials are created, they can be divided even further (e.g., into a PAC floater and PAC inverse floater). It is also possible to add other tranches with special features, such as a tranche where interest accrues back into the principal, called a Z-bond (i.e., zero coupon). Nevertheless, to understand the structure of CMOs, one must always start with that first question on which deal type it is, then walk through how an individual tranche was created in order to correctly analyze it.

For each tranche type in this section, we will provide the following: description, example, yield table, and methods of analysis. Note that while we have tried to be as realistic as possible in showing yield table and OAS analysis for CMO tranches, these numbers do not necessarily correspond to anything available in the market currently. These examples have been constructed mainly for learning purposes, not to illustrate relative value or hedging purposes! We also do not identify deal names or CUSIPs on any of these bonds for those reasons.

Sequential

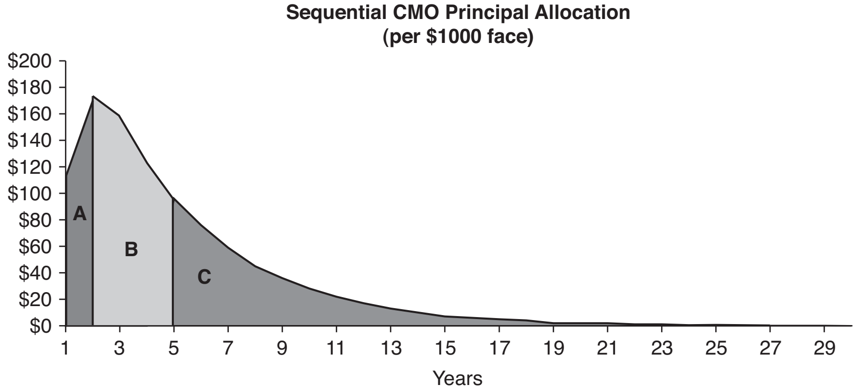
A *sequential CMO*, also historically referred to as a "vanilla bond," deal typically takes the collateral's principal and time tranches it. The first sequential tranche receives all of the prepaid and scheduled principal from the deal until the tranche is retired, then the next sequential in line starts receiving principal. For example, in a simple three-tranche sequential (Exhibit 23-1), the first sequential could be allocated 30% of the deal's principal. All principal cash flows from the underlying collateral would pay down the first sequential tranche to a zero balance. Then, the second sequential would receive its principal, and finally the third. The purpose of this structure is twofold. Investors may want a shorter or longer duration than the underlying collateral. In addition, the period of time before which the second sequential receives any principal is known as *lockout*. This lockout feature may be valuable to some investors who do not want to receive (and possibly need to reinvest) principal for some period of time.

Example

Sequential bonds will have a different duration, average life, and projected cash flow for each prepayment assumption tested. In many respects, they perform like

EXHIBIT 23-1

Cash Flows from a Three-Tranche Sequential Deal



the underlying collateral of the CMO deal. Increase prepayments, and sequentials shorten their average life and duration. A few differences between sequentials and collateral:

- The window of time principal is returned to the investor in a sequential is narrower than that for collateral.
- A sequential can be locked out from prepayments (i.e., the factor remains 1.0) for some period of time. Pass-throughs start to factor down from 1.0 as soon as they are created.
- The coupon on a sequential (or any other CMO bond) can be different from the underlying collateral. Most commonly, the coupon on the sequential is "stripped down" lower than the collateral in order to create bonds that trade at or below par.

When a sequential coupon is stripped down, a portion of the interest from the collateral is diverted elsewhere in the deal.[1] The purpose of this maneuver is to lower the price of the sequential bond, although typically the yield of the bond will also fall. Nomenclature in the CMO world talks of the *tranche coupon* versus the *collateral coupon*. For example, a 5.0/5.5 sequential would be a bond with a 5% coupon in a deal using 5.5% pass-through collateral.

Exhibit 23-2 compares the yield tables of a full coupon, 5.5/5.5 sequential with a stripped down 4.0/5.5 sequential. Note that the principal cash flows are essentially the same—the principal cash flows on these bonds react in the same way to changes in prepayment rates. However, market performance will likely be

1. Note that the coupon income stripped off these tranches could become an IO/IOette tranche, or could be added to a regular tranche with principal to create a premium tranche, for example, a 6% coupon off 5.5% collateral.

EXHIBIT 23-2

Comparing the Yield Tables of Full vs. Stripped Down Coupon Sequentials

Sequential, 4% on 5.5% Scenario	–200	–100	0	100	200

quite different, due to the longer duration of the 4.0/5.5 tranche. The 4.0/5.5 tranche has a 5.26 option-adjusted duration (OAD) versus a 3.11 OAD for the 5.5/5.5 full coupon sequential in our example. When interest (IO) is removed from a tranche, the negative duration associated with the IO is also removed, extending the duration of the remaining bond.

An intuitive way to think about premium and discount CMO durations is callable corporate bonds. As the price of the bond goes over par, it becomes harder for the price to rise given a drop in interest rates because of the call feature (in the case of MBS, faster prepayments). The duration of a high premium callable bond will be close to the call date because it is likely to be called. However, the duration of a deep discount callable bond is longer, close to the maturity date of the bond, because the bond is unlikely to be called.

Analysis

Analysis of sequentials falls into two broad categories:

- Analysis of short duration sequentials that are currently paying, typically as short duration bonds. They may be compared to short agencies, ABS, hybrid ARMs, other CMOs, etc.
- Longer duration sequentials that are often compared with the underlying collateral. Many characteristics of the sequential and collateral are typically similar: prepayment speeds, duration profile, etc.

For short duration bonds, investors are typically looking at yield and comparing it with similar duration bonds. In addition, investors need to evaluate the extension risk of the sequential to make sure it is not beyond their risk tolerance if interest rates rise, prepayment speeds slow, and the sequential extends.

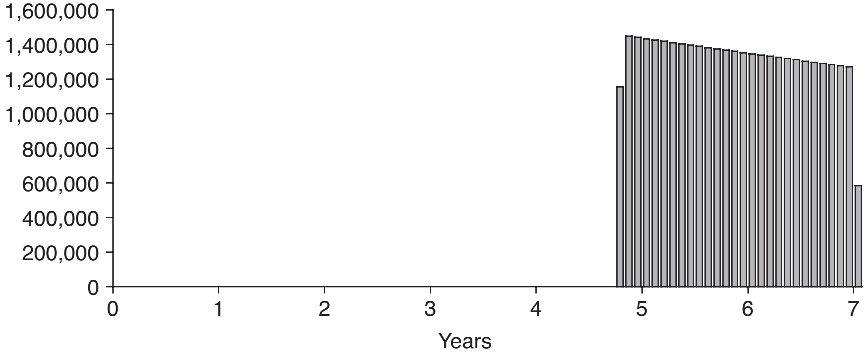
For long duration bonds, comparison to collateral can be made using OAS or yield analysis, plus potentially a total rate of return analysis that compares expected returns of different bonds under different interest rate scenarios.

Planned Amortization Class

The second basic type of CMO deal is a PAC/support structure. PAC stands for *planned amortization class* and is one of the most stable classes of CMO. It is given a pre-set schedule for its principal pay down. If prepayment speeds were to remain at a fixed speed in a specific prepayment band (the *PAC band*) for the life of the security, the PAC would adhere to its original schedule and behave similarly to a corporate bond with a pro rata sinking fund structure. Exhibit 23-3 shows the amortization schedule for a hypothetical PAC.

EXHIBIT 23-3

Amortization Schedule for a Hypothetical PAC



Source: DB Global Markets Research.

PAC Bands, Band Drift, and Broken PACs

As mentioned, each PAC has a band, expressed in PSA terms. If prepayments remained constantly at that level throughout the life of the PAC, it would adhere to its planned amortization schedule and have the expected average life.

Of course, prepayments do not remain constant from month to month, let alone the life of a security. Therefore, over time, especially in a fast prepayment environment, the *PAC bands* on a PAC can drift, generally growing tighter over time (i.e., less advantageous for the investor).

One example of PAC band drift is in a fast prepayment environment. If approximately one-third of a PAC CMO deal is support bonds and prepayments increase over the top end of the PAC band, at some point, all the support bonds will be paid off. When the supports are gone, the PACs behave like sequential bonds, and are termed *broken PACs* in the marketplace. In reality, a broken PAC will behave like a sequential bond. However, due to the stigma of being "broken," the broken PAC may trade more cheaply than a similar sequential.

Exhibit 23-4 shows an example of a new PAC with a band of 100–250 PSA. Note that as interest rates rise, its average life stays around 5.95 years. However, since all MBS are inherently callable in any given month, very fast prepayment speeds engendered by a drop in mortgage interest rates cause the PAC to break out of its PAC band and shorten its duration significantly.

Exhibit 23-5, by contrast, shows a broken PAC originated a few years ago. All the support bonds in this deal have been paid off, so it effectively behaves like a sequential. Note also that its OAS happens to be higher than the sequential bond analyzed earlier in this chapter. This can occur in the market if there is a glut of broken PACs. This bond currently does not have a PAC band left, but originally had a band of 100 to 255 PSA.

EXHIBIT 23-4

Analysis

The decision to buy PACs over sequentials or pass-throughs involves a couple of questions. First, is there a reason to buy cash-flow stability?

- Is cash-flow stability cheap via purchasing PACs?
- Is hedging pass-through or sequential cash flows using options or other derivatives expensive or cumbersome from an accounting perspective?
- Does the investor think the bond market is range-bound or could break out of its range?
- What do implied and actual volatility in the market look like and where are they going?

The answers to these questions can guide an investor toward whether to purchase PAC bonds.

Note that broken PAC analysis will be similar to sequential bond analysis. As mentioned, often broken PACs will trade at wider spreads than similar sequentials, creating relative value opportunities.[2]

Like sequentials, PACs can be compared using OAS analysis, yield, total return analysis, etc., with other MBS or even to corporate bonds because of the PACs' stable nature.

2. Broken PACs tend to trade slightly cheaper than sequentials, whether because of the stigma of the "broken" deal or selling by investors who sell them to buy new PACs with intact bands.

PAC 2

In some structures, the effectiveness of PAC classes is enhanced by creating a structure similar to a PAC, but with tighter PAC bands. In the priority of the cash-flow waterfall, the PAC takes priority, followed by the PAC 2 (also referred to as Level II PACs and supports with schedules), and finally the support bonds. If the support bonds are retired and PACs remain, then the PAC 2s effectively become the new support bonds.

In return for the higher cash-flow variability of the PAC 2, it will yield more than similar PACs in the same deal. At the same time, in extreme prepayment environments, the PAC 2 will suffer extension or call risk before the PAC. The PAC 2 bond selected for Exhibit 23-6 has a relatively tight PAC band—so tight we cannot observe cash-flow stability on this bond in the ± 100 bp scenarios.

Analysis

PAC 2 analysis needs to be very careful, as bonds from this class exhibit much more variability of structure, cash flows, and value than the PAC 1 or sequential tranche types. OAS analysis can help an investor make a determination if a bond is attractive. Investors also need to focus on potential duration extension and shortening in radical interest rate scenarios to make sure that duration change is tolerable. In our example bond, duration extension if rates rise is worse than with our example sequential bond.

Support Bonds

The support or companion bonds take whatever principal is left over each month after the PAC bonds have been paid as closely to schedule as possible. If prepayment

EXHIBIT 23-7

speeds are fast, excess principal will pay down support tranches once planned principal payments to the PACs have been made. On the other hand, if prepayment speeds are very slow, all of the principal may go to the PAC bonds, with the support bonds receiving no principal for that month.

Example

The structuring of the support bond, with approximately 30% of a deal being companions and the balance PACs, makes for highly variable cash flows and a wide variety of performance characteristics. Because of this, companion yields tend to be quite high. Exhibit 23-7 shows how the average life of the bond can vary widely.

Analysis

Structures are very deal specific, and OAS models can help determine relative value among support bonds. Note however, that OAS and hence relative value will be very sensitive to model assumptions. Discount companions are more popular because they can be sold to retail investors more easily. Exhibit 23-7 shows our example companion, with high average life variability, but a big OAS. Note also that the structure and price prevents the yield of the bond from falling much below 6%, even in a rising interest rate environment. The yield can exceed 40% in a dramatic interest-rate rally in our example bond.

Targeted Amortization Class

A *targeted amortization class* (TAC) is similar to a one-sided PAC. The bond has some call protection from adverse prepayment speeds. However, it can have a lot of extension risk if prepayments drop too low.

EXHIBIT 23-8

Example of a TAC

Scenario	–200	–100	0	100	200
Prepayment (PSA)	1,595	800	225	145	120
Price					
92.1875	32.71%	20.16%	8.90%	6.33%	6.22%
93.1875	28.78%	18.09%	8.44%	6.22%	6.13%
94.1875	24.97%	16.08%	7.98%	6.12%	6.04%
Average Life	0.32	0.59	2.74	17.94	21.7
OAS	44				
OAD	10.11				
OAC	–2.46				

Source: DB Global Markets Research.

Example

In Exhibit 23-8, we see that our example TAC has a lot of extension risk. Even at reasonable, although slow, prepayment speeds, the bond extends out to 20-plus year durations.

Analysis

TACs are not all created equal. Some behave more like PAC bonds or PAC 2s. Others look more like companion bonds. The defining characteristic of TACs is they should have some call protection. A first cut of analysis should involve looking at the spread of average lives that can occur. In addition, OAS and perhaps total return analysis may be useful.

While the TAC we have chosen does have a high OAS, it clearly has a large amount of risk if rates rise. The TAC is already at a discount dollar price, and its price could plunge further if prepayments slowed and extended the TAC out to a 20Y average life in a steep yield-curve environment.

PACquential

A PACquential blends characteristics of a PAC and a sequential. While a Type I PAC typically has a lower band of 100 PSA, a PACquential has more extension risk, with a lower band more typically around 150 PSA. Nevertheless, a PACquential does have a PAC band and is supported by its own companion bonds. This feature makes it more stable than a standard sequential tranche.

Example

Our example bond has a PAC band of 150 to 360 PSA, within which it has a 5.1 average life (Exhibit 23-9). In this case, the extension risk of the bond down to

EXHIBIT 23-9

Example of a PACquential

Scenario	–200	–100	0	100	200
Prepayment (PSA)	1,665	800	220	145	120
Price					
96.75	6.14%	5.26%	4.73%	4.72%	4.65%
97.75	5.42%	4.84%	4.49%	4.48%	4.44%
98.75	4.72%	4.43%	4.26%	4.26%	4.23%
Average Life	1.53	2.7	5.1	5.23	5.85
OAS	37				
OAD	4.48				
OAC	–1.38				

Source: DB Global Markets Research.

120 PSA is minimal. Therefore, the difference between this bond and a regular PAC is not that great.

Analysis

Note that since PACquentials are not that well standardized in the market, each bond must be carefully examined on its own merits. One factor to pay special attention to is extension risk of the PACquential below its PAC band down to as low as 100 PSA. Beyond that, all the standard analysis tools apply: OAS, average life variability, and total return analysis.

Z-Bonds

A bond can have different cash-flow characteristics (PAC, sequential, PACquential). Also, it can have different interest payment features. In the case of a Z-bond, interest accrues and is added to principal initially. This initial phase of a Z-bond's life is similar to a zero-coupon bond. At some point, the Z starts to pay down interest and principal. The characteristic of suspension of interest for some period of time extends the duration of the Z-bond. A Z-bond can be created from any of the fundamental cash flows. Note that the accrued interest taken in from a Z-bond can be used to pay down principal on another CMO tranche. This technique can be used to create bonds with a short legal final maturity, very accurately determined maturity (VADM) bonds.

Example

The companion Z-bond we have chosen for our example (Exhibit 23-10) has a deep discount dollar price, giving it PO-like characteristics, including negative convexity that is pretty close to zero. Note the wide variation in average lives in different scenarios.

EXHIBIT 23-10

Example of a Z-Bond

Price					
84	12.58%	8.75%	6.64%	6.45%	6.39%
85	12.09%	8.36%	6.57%	6.39%	6.34%
86	11.61%	8.16%	6.49%	6.33%	6.28%
Average Life	2.57	6.05	17.36	21.03	22.28
OAS	53				
OAD	19.47				
OAC	–0.09				

Source: DB Global Markets Research.

Analysis

There are a few main differences when analyzing a Z-bond versus a regular tranche of the same variety.

- Is the Z-bond currently a payer? If not, the audience of investors may be reduced.
- The OAD of the Z-bond can swing extremely widely in different interest rate scenarios because of its ability to accrete interest payments into principal.
- The OAD can be much longer than that for collateral.

Standard OAS or total rate of return (TRR) analysis should take these factors into account. On our example bond, the OAD is extremely long, almost 19.5. The fundamental question to ask is whether an investor would prefer to own this bond or a zero-coupon Treasury bond. The two can best be compared using TRR analysis.

Note also that these bonds will be extremely sensitive to small changes in model assumptions. Different models will almost certainly give a wide range of OAS valuations.

Very Accurately Determined Maturity

Very accurately determined maturity (VADM) bonds are structured to have short final maturities. They use accrued interest from Z-bonds to pay off principal (see Z-bond discussed previously in the chapter). In general, the average life of a VADM bond is more stable than a comparable duration sequential bond. They are

EXHIBIT 23-11

Example of a VADM

Scenario	–200	–100	0	100	200

OAD	3.56				
OAC	–1.20				

Source: DB Global Markets Research.

especially resistant to extension risk, as the short final maturity of the bonds is guaranteed even if prepayments drop to zero, a highly unlikely event.

Example

Exhibit 23-11 shows our example VADM bond, 5.95-year average life even as prepayments drop to zero. Note however, that the premium price exposes the bond to big issues if interest rates drop and prepayments speed up.

Analysis

Investors should primarily purchase VADMs if they absolutely need the guaranteed final maturity—such as in certain mutual funds or other investor situations. Check that the VADM maturity does fit the requirements of the investor. In addition, check what the call risk of the bond looks like, which can vary widely among CMOs.

Floater

As well as the principal cash flows having different types, interest may also be paid in different ways. Most tranches have fixed-rate cash flows, as most collateral for CMOs has a fixed interest rate. However, it is possible to construct tranches with a floating rate of interest, generally tied to LIBOR historically and SOFR now, but conceptually to any market interest rate. One possibility is to use an interest rate swap to create a floating-rate bond. However, more likely is the division of a fixed-rate tranche into a "floater" and "inverse floater" whose interest rate moves down as the floater's moves up (see Inverse Floater later in the chapter).

Key components for a floater include:

- The index such as SOFR.
- The margin or spread over the index, paid to the investor.
- The cap, or maximum coupon rate, that the floater can pay, inclusive of the margin paid over the index.
- The floor, or minimum coupon rate, often equal to the margin.

Example

Our example bond shown in Exhibit 23-12 is a companion floater. The average life is highly variable. The major issue for a bond buyer would be difficulty in hedging the risk of the embedded cap. Thus, higher cash-flow variability will in general push the OAS of a floater lower.

Analysis

Floating-rate bond analysis is similar to fixed-rate analysis in terms of examining cash flows and the bond's OAS. However, the floater has the additional complexity of having embedded caps and floors to value (even if the floor is 0%). It is especially important to make sure the term structure model employed correctly values caps and floors at market values in this type of analysis. Additionally, an investor can price out an actual cap or floor for the expected average life of the security and see if the package of floater plus hedge makes sense.

Discount margin refers to the effective spread over the index once the bond's price and a prepayment assumption are factored in. An investor would look at discount margin as well as OAS to determine value in a floater.

EXHIBIT 23-12

Example of a Floater

Scenario	–200	–100	0	100	200
Prepayment (PSA)	1,665	800	220	145	120
Price					
98	6.84%	5.12%	2.74%	2.53%	2.52%
99	2.47%	2.47%	2.56%	3.64%	4.42%
100	2.04%	2.19%	2.39%	2.41%	2.41%
Average Life	0.42	0.7	7.05	21.34	23.56
OAS	19				
OAD	2.58				
OAC	–2.82				

Source: DB Global Markets Research.

Note that a floater's OAD (if uncapped) is effectively limited to the combination of index and index reset. Most of the duration of the floater duration would be due to the duration from the cap.

Inverse Floater

An inverse floater is typically created by dividing a fixed-rate tranche into a floating-rate portion and the inverse floater. The key understanding is that the sum of the parts (floater and inverse floater) must equal the whole (the underlying tranche) in terms of both interest and principal payments. (Also see the discussion later in the chapter dealing with "creation value.")

Example

Our example is shown in Exhibit 23-13, a discount companion inverse floater. These bonds have a lot of duration and are often used as substitutes for POs. Our example has a highly variable average life, but high yields across interest rate scenarios.

Analysis

Inverse floater duration is increased by higher leverage in the inverse floater's coupon formula. In our example bond, the underlying tranche has an OAD of 9.57 and the inverse floater's leverage is 2.75. If the floater had a duration of 0, then the inverse floater's OAD is roughly equivalent to 1 + leverage times the underlying tranche's OAD. In this case, the floater has significant duration (over 2) because of the extension risk along with the relatively low coupon cap of the floater.

OAS analysis is important for analyzing inverse floaters, and as with floaters, inverse floaters have embedded caps and floors. Therefore, the term structure

EXHIBIT 23-13

Example of an Inverse Floater

Scenario	–200	–100	0	100	200
Prepayment (PSA)	1,665	800	220	145	120
Price					
84.3125	60.38%	41.89%	19.84%	17.08%	17.04%
85.3125	56.69%	39.75%	19.41%	16.87%	16.83%
86.3125	53.09%	37.66%	18.98%	16.66%	16.63%

OAS	696				
OAD	28.80				
OAC	–12.45				

Source: DB Global Markets Research.

model is important for evaluation. Also, the prepayment model used to evaluate the inverse floater is critical. As market rates fall, the inverse floater's coupon rises, but faster prepayments (and hence principal paydowns) may eat away the value of this to the bondholder. Effectively, the inverse floater buyer is leveraged to prepayments, and thus must be careful to examine the effect of variations in prepayment assumptions on bond valuation.

Inverse Floater vs. Leveraged Collateral

Does OAS analysis work? One way to check is to compare inverse floaters with leveraged collateral positions. While at first glance it may appear that one should simply buy the bond with the highest OAS, in reality, the duration (or OAD) of the two assets being compared also matters significantly. To correctly compare inverse floaters with collateral, the collateral must be implicitly levered (by borrowing money) to the same duration as the inverse floater for the comparison to be fair. (The comparison is still not completely fair because leveraged collateral probably has more liquidity and easier funding than the inverse floater.)

In Exhibit 23-14, we can see that our prepayment model still prefers the inverse floater over a position of leveraged collateral. Levering the collateral involves investing a similar cash amount as for the inverse floater, then borrowing additional cash to buy more collateral until the investor has a similar duration and convexity exposure between the inverse floater and the leveraged collateral. In this example, we have borrowed money equivalent to the 2.75 times leverage of the inverse floater.

Creation value is another method used to analyze inverse floaters. The value of floaters is relatively easy to determine, as they are relatively liquid and easy to price. Likewise, the underlying tranche for the floater/inverse combination is typically easy to price. Given those two prices, the arbitrage-free creation value of the inverse floater can be determined (Exhibit 23-15). Investors prefer to purchase inverse floaters at or below creation value in the secondary market.

EXHIBIT 23-14

Comparing Leveraged Collateral vs. an Inverse Floater

Trade Against Forward Rates

Some investors buy inverse floaters as a trade against forward rates rising as fast as the market would suggest. For example, the yield of our inverse floater at unchanged rates and 220 PSA is 19.41%. The yield assuming this prepayment speed but forward rates is 18.4%. If rates rise more slowly than forward rates suggest, the true yield of the bond will be somewhere in between the two numbers.

Analyzing inverse floaters is complex and can be done in many different ways. They are not as liquid as regular tranches. The reward may be discovering some true value in the bonds, or taking advantage of specific views on the market.

Interest-Only and Principal-Only Tranches

Interest-only tranches (IOs) come in several forms. The primary one we will discuss is "trust IOs," in which collateral is contributed to an IO/PO deal by dealers, a small fee is charged by a GSE or Agency, and IO and PO tranches are returned to the dealers involved in proportion to their collateral contribution. This type of structure gets its own IO/PO trust number, hence the name. An IO can also be created by stripping interest off a CMO tranche or in other ways, which typically result in CMO tranches with IO characteristics. Trust IOs tend to have the most liquidity, as they are large size deals that trade on broker screens, while smaller deals have less price transparency.

IOs typically have negative Option Adjusted Duration (OAD). If interest rates rise, prepayment speeds tend to slow. Slower speeds benefit the IO holder, who wants the collateral factor to stay as high for as long as possible. Once loans prepay, they stop paying interest beyond the month in which prepayment occurs. An IO investor wants prepayments to be as slow as possible. In the most extremely negative case for an IO holder, an investor could buy an IO and discover the entire tranche has paid off in that month, reported in the following month.

The principal only (PO) is the complement of the IO. It returns only the principal portion of the pass-through. Thus, a PO holder would prefer prepayments to be extremely fast. Under a dollar price of approximately $85-00 (which is typical), POs have positive convexity. This makes them useful for hedging purposes, for example hedging mortgage servicing rights.

Example

Exhibit 23-16 shows an example of an IO. Since trust IO and PO pricing is relatively liquid, most of the analysis for IOs and POs will concern an investor's view of prepayments or interest rates versus the market's (as represented by IO/PO pricing). Nevertheless, IO/PO prices can also fluctuate due to technicals, including short squeezes on certain tranches. Note how the IO in Exhibit 23-16 has a high negative OAD.

Exhibit 23-17 shows an example PO from the same Trust deal. Some investors buy POs for prepayment protection or positive convexity, but others buy them simply to add duration to their mortgage portfolio. As interest rates drop, observe that the PO yield rises significantly due to increased prepayments. Often, as in our hypothetical example, the PO will have a negative OAS in return for its positive convexity. Effectively, an investor is paying a premium to buy call options when they buy a PO.

Analysis

IO/PO analysis using OAS models or other techniques is notoriously complex, and even seasoned traders have lost money due to technicals in the IO market.

EXHIBIT 23-16

As IOs and POs are notoriously sensitive to even small changes in prepayment assumptions, one must be very careful to examine the model used to calculate OASs. Variables such as seasoning and burnout are magnified many times in between analyzing the collateral and the IO/PO derivative.

Creation value can also be used to analyze IOs and POs, similar to the analysis of inverse floater/floater combinations. For Trust IOs and POs, at first the combination (combo) typically trades at a small premium above collateral. The combination cannot trade significantly below the price of collateral, because they may be recombined into collateral for a small fee and sold. However, the combination may trade at a price significantly above TBA collateral for a number of reasons:

- The underlying collateral is valuable, for example, it has seasoning worth a pay-up to TBA collateral.
- There is a squeeze or scarcity of the IO or PO, which raises the price of the combination in turn. Sometimes POs get restructured in other deals, potentially leaving them dear.

Historical analysis of IO and PO OAS numbers may be somewhat useful, but ends up being highly prepayment and OAS model dependent.

Premium tranche/IO arbitrage is another way to compare relative value of IOs versus regular classes of CMOs. For example, a PAC IO plus a stripped down PAC should equal the value of the full coupon PAC, or there is an arbitrage. This is similar to the recombination value of an inverse floater. In practice, since many investors are willing to accept tighter spreads for lower dollar price PAC bonds, we can see arbitrage opportunities occur during deal pricings, which make the restructuring of a premium PAC tranche into a stripped-down coupon PAC and a PAC IO attractive.

For POs, some investors may be using them to hedge other assets, such as mortgage servicing rights (MSR). In that case, all the above analysis may be performed, but the investor probably also wants to check how well correlated changes in price of the PO will match changes in price of the hedged asset.

Unusual Features

Note that IOs can be stripped off of any CMO type, for example, PACs, creating PAC IOs. This class of bond will behave like a high-yielding PAC within the band, but if prepayments speed up, will pay off quickly, perhaps leaving a loss for the investor. Other non-Trust IOs must be examined carefully as to the nature of their cash flows.

Exotics

We now describe a number of exotic CMOs for the sake of completeness, but will not spend a lot of time looking at individual bonds.

Inverse IOs

Inverse IOs are created by stripping the premium portion off an inverse floater. In some respects they behave as an interest rate floor. At times, their pricing has been described in relation to floor prices (e.g., 80%). However, they are more like "knockout" floors because if interest rates fall enough, prepayment rates will speed up and pay down the notional principal of the tranche, reducing the remainder of the investment to zero. Because of their illiquidity, these bonds are difficult to hedge and value even more so than trust IOs.

Inverse IOs are highly levered to one's interest rate scenario and prepayment forecast. It is important to analyze how small variations in prepayment or interest rate assumptions change the potential value of the bond.

Jump Zs

A jump Z reacts to fast prepayments by suddenly shifting from accrual to paying interest and principal (becoming a "payer"). This option can be of great value to the investor if the Z-bond is at a discount price. Note also that some Jump Zs are sticky, meaning once the "payer" trigger has been pulled, they continue to pay even if prepayment rates subsequently drop.

Structured POs

POs themselves can be structured into TAC POs, Super POs (companion POs), etc. Analysis is similar to that for PO analysis, except the bonds will probably be even more sensitive to slight changes in prepayment assumptions.

AGENCY VERSUS NONAGENCY CMOs

While most investors who can buy agency pass-throughs are allowed to buy agency CMOs, certain investors cannot participate in the nonagency CMO market. Here, we describe some of the differences between the two markets (see Exhibit 23-18 for a synopsis). Nonagency CMOs are discussed in more detail in Chapter 25.

EXHIBIT 23-18

Agency vs. Nonagency CMO Differences

	Agency CMOs	Nonagency CMOs
Credit support	Agency guarantee of underlying mortgages, primary mortgage insurance	Credit enhancement (e.g., Senior Subordination), underlying mortgages, primary mortgage insurance
Actual delay days	Variable: 0,14, 24	Variable: 0, 24
Collateral types	Agency pass-throughs, conforming Alt-A loans, VA loans	Jumbo or other nonconforming pass-throughs, re-performing loans, Alt-A loans
Prepayment model	Standard agency prepayment model	Specialized model based on collateral
Subject to interest shortfall	No, compensating interest is paid by GSEs	On some deals

AGENCY CMO ANALYSIS

The following section looks at how investors analyze and use agency CMOs. We also cover term structure and prepayment models briefly.

Analysis for Regular CMO Tranches

CMO analysis depends upon investor needs. While relative value may seem to be one answer, one rule does not necessarily hold for all investors. The definition of relative value can be different for different investors. Other investors have portfolio constraints. For example, an insurance company may need assets that closely match liabilities even if interest rates exhibit large moves.

Investor Goals and Constraints

Investors can have many goals and constraints when purchasing CMOs. For example:

- Insurance companies and banks sometimes have yield levels (bogies) below which they do not wish to purchase bonds.
- Relative value investors may require a certain OAS, or OAS advantage versus collateral.
- Hedge funds may require a certain amount of liquidity in purchases they make, both for bonds and potential hedges (such as cancelable swaps). If liquidity in the bond or the hedges is insufficient, they may decline to do an otherwise attractive trade.

- Funded investors may need to issue debt or raise equity before adding MBS. If the environment is not amenable to such issuance, then CMO purchases may be delayed.
- Banks may have internal maturity or duration restrictions or preferences on bonds for their portfolio.
- Individual or institutional investors may have a top dollar price limit above which they will not purchase bonds.

Perhaps the variability of investors explains why there are so many different kinds of CMOs, some unique. Different requirements and views are what makes a market.

Cash-Flow Analysis

For most regular tranche types, cash-flow analysis consists of testing various prepayment models and static prepayments to determine what the sensitivity of a bond is to changes in interest rates. This analysis would include a comparison of the negative convexity of different CMO bonds.

For some investors, cash-flow analysis becomes more detailed, as they may be trying to hedge their own stream of liabilities, or perhaps they are hedging the CMO with an amortizing swap.

Finally, for nonstandard tranches, it pays to examine the cash-flow waterfall and test various interest-rate scenarios, examining the results in terms of cash-flow streams. It is important to check for bonds that have unusual cash flows. For example, anything that could cause a bond to have a longer-than-expected maturity, or a gap when principal was not paid would be suspect.

OAS Analysis

For most regular CMO tranches, OAS analysis is relatively useful. For similar tranches off similar collateral, it is easy to use OAS to determine relative value of bonds. In addition, comparing OAS numbers for CMOs versus underlying collateral also is straightforward. The more difficult issue is how to compare OAS numbers of tranches of different durations. For example, often longer dated tranches are at higher OAS numbers than similar shorter dated tranches. This structural issue makes it difficult to evaluate relative value of longer versus shorter dated CMOs.

More issues in OAS analysis are presented later in this chapter and in Chapter 37.

Hedging

For normal CMO tranches, OADs are an acceptable way to calculate how to hedge. However, wide window sequentials may require hedging on multiple points on the yield-curve to avoid yield-curve risk, similar to hedging yield-curve risk in the underlying collateral. Exhibit 23-19 shows how the bulk of duration risk may be in the 10-year area for a specific bond, but hedging in the 2 year, 5 year, and 30 year would help reduce yield-curve risk.

EXHIBIT 23-19

Partial Durations of a Five-Year-Wide Window Sequential

Yield-Curve Point	2	5	10	30
Partial Duration	0.685	1.56	2.795	0.17
OAD	4.7			

Issues in OAS Analysis

There are a number of issues in OAS analysis to discuss in order to determine if the OAS received on a bond is truly what the investor seeks to find out: the spread of the mortgage-backed security, ex-option cost, versus a benchmark such as swaps. While in the 1980s and early 1990s, the primary variable differentiating OAS numbers was the prepayment model, at this point in the technology, the term structure model has become equally as important. We cover a number of other issues in this section, such as deal call risk and variations among prepayment models.

Term Structure Model

As mortgages have linked more tightly over time with the OTC derivatives markets (swaps and swaptions), modeling the relationship between these two markets has become critical. When swaps and swaptions are used to hedge MBS (or vice versa), the two markets need to be evaluated using the same term-structure model and the same assumptions, or else different, and perhaps erroneous, results can be obtained.

While a one-factor interest-rate model was used in the past and may work reasonably for pass-throughs, it is clearly not enough if an investor is looking at ARMs, floaters, or inverse floaters of any kind. More degrees of freedom for modeling the yield-curve are needed. Therefore, in order to keep analysis consistent among different types of MBS tranches and derivatives, it appears critical to use the least common denominator of term structure models that will accommodate all possible tranche types and analysis, and not succumb to using different models for different types of bonds or situations.

Advances in term structure modeling have placed the following features into the hands of mortgage analysts:

- Multiple knots on the yield-curve
- Correct pricing of OTC derivatives using the model
- Pricing in a volatility “skew” (i.e., options not struck at-the-money may be priced at a different volatility than standard at-the-money options)
- Sophisticated simulation of future mortgage interest rates based on the swaps curve and volatility

The point is that a term structure model that does not do these things opens up arbitrage opportunities against an investor using it. In an extreme case, flaws in the term structure model will misstate value and risk numbers associated with a CMO.

Forward Curve Bias

Despite all the care being put into term structure models, and their freedom from arbitrage, it is important also for investors to recognize the forward curve bias in these models, which creates a paradox.

- In order to remain arbitrage free, the term structure model must use the forward yield-curve as its base case.
- In practice, the forward yield-curve is usually wrong.

How can we reconcile these two facts?

The short answer is that we should use the forward yield-curve because if we do not believe something that it is predicting, we can trade against it and make money if we are correct. At times, the second point becomes plainly obvious. For example, when the yield-curve is extremely steep, forward rates predict massive flattening of the yield-curve over a short period of time. If the Fed appears to be on hold during this time, are we likely to get the full amount of the yield-curve flattening? Perhaps not. However, it may be easier to trade on this view directly in the derivatives or futures market rather than trying to implement it in the mortgage market.

Prepayment Model

The prepayment model is a very important component of mortgage analysis and OAS. Over time, prepayments have become more efficient. While most prepayment models address the standard issues of age, relative coupon, etc., there are now various subtleties for which a model needs to account:

- What future home price inflation does the model assume?
- Does the model account for "credit impaired" mortgages issued at above market rates?
- How does prepayment "burnout" work in the model? Can burnout be erased over time?
- Does the model account for "underwater" mortgages correctly (where the loan is for more than the home is worth)?

A prepayment model that is out of date or incorrect, even if only on a small segment of the market (e.g., high-premium mortgages) can have a large impact on an OAS because OAS models tend to generate some paths with very high and low interest rates—testing the boundaries of prepayment models and their ability to generate reasonable prepayment forecasts at out-of-sample interest rates.

Why A + B Can Be Greater Than C…

One of the last topics we will cover in this section is why A + B > C, even if A and B are made up of the component cash flows of C. Here are some factors:

- *A and B are unique and more cannot be created*. For example, once a Trust IO/PO deal is closed, additional collateral cannot be added later to increase the size of the deal. Thereafter, a squeeze in A or B will increase their price in relation to C, which is simply TBA collateral. A + B can never be less than (C – transaction cost) for long, as this would create a recombination arbitrage.[3]
- *A or B is getting squeezed*. One of the risks in the IO/PO market is that bonds can be re-securitized and hence lost to the possibility of recombination. For example, if virtually all of the POs in a Trust deal are re-securitized, the remaining POs will be in very high demand to hedge the remaining IO tranches. In addition, trust IO/PO sizes can be small enough that one dealer or investor can potentially squeeze the market in one of these bonds, making A + B > C.
- *The underlying collateral is valuable*. Sometimes A + B may be compared with the wrong C. For example, comparing a Trust IO and PO to TBA collateral may be appropriate most of the time. However, after the deal is seasoned for a while, the underlying collateral itself may be worth a pay-up to TBAs (seasoned collateral typically commands a premium price to TBAs).

Examining Deal Call Risk

A feature in many CMO deals, but not discussed often and sometimes not modeled, is the embedded ("clean-up") call. Calls were originally conceived as a way to limit ongoing fixed expenses for deal trustees on CMOs that have shrunk to a very small size, but the implications for investors can be significant. For example, the last cash-flow holder will typically be exposed to the call. A call that sounds small for an entire deal (say, 1%), may actually make up a large portion of the last tranche remaining in a CMO deal. For a tranche that was only 5% of the deal's original principal, a 1% cleanup call is exercised when 20% of the last tranche is remaining. The impact for investors of other tranches is *de minimus,* but obviously can be large for the last cash-flow holder.

The good news is this call is exercised most of the time because the fixed costs of the deal tend to be large enough that the trustee wants to exercise the call whenever possible. This assumption makes analysis easy. However, if the price of the collateral is significantly below par, calling the deal costs the trustee money. Analysis of the probability of call of deals in this situation is difficult. Therefore, the bondholder may want to run the bond with and without the call to assess the possible impact.

3. Typically, an IO and a PO from the same trust can be recombined to form the underlying collateral for a 1/32nd fee and resold as collateral. While this typically never happens in practice, it creates an arbitrage floor for the IO and PO prices, which is important from a liquidity and pricing standpoint. This is much harder to do for floaters and inverse floaters, as both sides of the combination in that case may be harder to find and less liquid, not trading on broker screens as Trust IOs and POs do.

Investor Types and Behavior

In this section, we examine different types of investors, such as commercial banks. We cover the following information for each:

- Types of CMOs typically purchased by these institutions
- Methods potentially used by these institutions for bond selection

Historically, banks have been the largest holders of MBS.

Banks

Banks are large consumers of CMOs. For many banks, the longer duration and possible duration extension of pass-throughs does not match their liabilities adequately. Often, it is easier for many banks to achieve a shorter duration security or less extension risk by buying appropriately structured CMO bonds than pass-throughs. Banks are typically buy and hold investors in CMOs, although some bonds may be placed in the trading account.

In general, banks focus on shorter duration CMOs. A 10-year bond typically does not fit the liability structure of a bank. A two-year sequential CMO is a typical purchase for a bank. In general, banks will accept some prepayment and convexity risk in order to get a better spread. Therefore, banks tend to prefer sequentials over PAC bonds. Banks do very little hedging of their negative convexity using the options market, although they may delta hedge their mortgage position as its duration changes.

CMO selection at banks generally comes down to a few things: yield bogey, duration, extension risk, and OAS. In general, a bank will have a target net interest margin over their cost of funds in order to purchase a security. This target may be translated into a yield or spread bogey over a market rate. Also, a bank may not want to take too much duration risk, so the duration of the security must fit the asset-liability framework of the bank, or it must be prepared to hedge the duration of the CMO. Some banks use OAS to determine relative value among tranches, but in general asset-liability and liquidity concerns tend to dominate their CMO purchase decisions.

Note also that banks are the largest consumer of mortgage "whole loans," or mortgages that are not securitized. These whole loans are mostly ineligible for agency securitization, or are ARMs or hybrid ARMs.

Insurance Companies

Insurance companies buy CMOs across the spectrum of "regular" tranches—PACs, sequentials, and PACquentials. Property and casualty companies tend to buy shorter maturity tranches, such as two-year sequentials. Life insurance companies are looking for more structure to match against their liabilities and are more likely to purchase longer duration bonds, such as 10-year PACs. While MBS are a break from the credit risk that insurance companies typically take on the corporate bonds in their investment portfolio, they are well aware of the convexity risk that they are taking in MBS.

In general, insurance companies may have restrictions on selling CMOs because of gain or loss constraints. Property and casualty companies may sell bonds against claims (e.g., after a hurricane).

Money Managers

Money managers vary in sophistication. They generally are not subject to gain/loss constraints because they mark-to-market constantly, unless they are managing a separate account for a financial institution. Some money managers are active in the CMO derivatives market, but many are not. Most money managers are benchmarked against an index that contains pass-throughs. Therefore, any CMO is effectively an "out of index" investment for them. They will typically be comparing that CMO either to collateral or perhaps to Treasuries/agencies for certain types of CMOs. OAS analysis tends to be an important tool for them.

Liquidity tends to be a bigger issuer for money managers than for insurance companies. The money manager may need to be able to shift assets around quickly, and thus is prepared to give up something in order to have better liquidity. Most money managers own many more pass-throughs than CMOs because of this fact. In addition, pass-throughs have the opportunity to finance special (via the dollar roll market). Income from special financing can be a windfall for money managers, as this income is typically not included in mortgage index returns the money managers are benchmarked against.

Money managers frequently take long-term strategic views about the market in mortgages. One type of view is to have a portfolio that has better (or worse) convexity than their benchmark index. A money manager can typically get better convexity by buying PAC bonds, or give up convexity to gain yield by buying companion bonds or certain types of sequentials or broken PACs.

Pension Funds

Pension funds in some ways operate similarly to money managers. However, ERISA (pension fund law) or investor considerations sometimes keep them from investing in mortgage derivatives. Similar to life insurance companies, they can be interested in longer duration tranches at times.

Hedge Funds

Hedge funds can operate in a manner similar to money managers, but at times they enter into more complex trades involving OTC derivatives. For example, they might buy a CMO and try to hedge its cash flows over time using swaps and options, netting a positive spread that they hope to earn over time.

Certain hedge funds specialize in mortgage derivatives: inverse floaters, IOs, inverse IOs, etc. They use sophisticated models to value these tranches, purchase them, and hedge them. One of the main issues for these funds will be pricing of their inventory (as individual bonds may not trade for months) and liquidity. Financing for CMOs can also dry up in a crisis.

Retail Investors/Regional Dealers

Many CMOs, including CMO derivatives such as inverse floaters, end up in the hands of regional dealers. In turn, these regional dealers may sell those bonds to retail clients. In general, yield tends to be the focus of these buyers, and thus companion bonds are often sold via this channel.

Note that any broker who sells CMOs to retail investors must include a series of special disclaimers that is mandated by securities regulation.

Lessons from the Past

Investors in MBS, and especially in derivative MBS, have gone out of business in the past. In a crisis, while the mortgage market may continue to trade via pass-throughs, the CMO market can lose liquidity, and the derivatives market can practically stop trading for some period of time. Investors should be prepared for all risks, including the risk of illiquidity and radical changes in pricing due to such illiquidity. Dealers must make sure they "know their customer" and that the customer is buying bonds appropriate for their goals.

KEY POINTS

- Agency CMOs are structured by broker-dealers into multiple tranches using agency pass-throughs as collateral. The deals are wrapped and issued by Fannie Mae, Freddie Mac, or Ginnie Mae. Ginnie Mae has the full faith and credit backing of the U.S. government, while the other two have an implied guarantee.
- Agency CMOs can be a safe, attractive investment for banks, mutual funds, insurance companies, and other institutional investors. Standard types of CMO tranches include PACs (created to mimic corporate bonds), sequentials (that time tranche principal cash flows), and companions (that return a high yield in return for highly variable principal cash flows).
- Unlike most other bonds, all MBS (including CMOs) have unpredictable return of principal, creating the opportunity of higher yield and the risk of callability. The homeowner in the United States typically has the option to refinance at any time, effectively exercising a call to the investor. Using OAS and prepayment models helps investors understand the nature of the MBS they own or are buying.
- Analysis of CMOs depends to some degree on the type of investor: yield tables, possible bond maturity profile and OAS analysis are all important. Banks typically look at average life profiles and yield tables,

and may consider OAS. Money managers tend to be more focused on OAS and compare CMOs to pass-thoughs and agency bonds.

- CMO derivatives can provide hedging benefits or unusual return profiles. For example, Interest-only strips have a negative OAD—they generally increase in price as interest rates rise. Inverse floaters have bond coupons that rise as interest rates fall, sometimes creating bonds with very long OADs.

CHAPTER

TWENTY-FOUR

STRIPPED MORTGAGE-BACKED SECURITIES

In 1983 Freddie Mac (FHLMC) launched the collateralized mortgage obligation (CMO) structure that enabled issuers to tailor-make mortgage securities according to investor coupon, maturity, and prepayment risk specifications. In July 1986, Fannie Mae (FNMA) introduced a new addition to the mortgage security product line—*stripped mortgage-backed securities* (SMBS). By redistributing all or portions of the interest and/or principal cash flows from a pool of mortgage loans to two or more SMBS classes, FNMA developed a new class of mortgage securities that enabled investors to take strong market positions on expected movements in prepayment and interest rates. As the mortgage pass-through market has matured, the number of derivative products available has increased to give investors a broad range of choices to help them achieve their investment goals. In addition to straight *interest-only* (IO) securities and *principal-only* (PO) securities, investors may now choose from a wide array of synthetic coupons from each strip issue. Investors are able to fine-tune their derivatives to match their desired sensitivity to interest rate, prepayment, and market risk.

SMBS are highly sensitive to changes in interest rate and prepayment speeds and tend to display asymmetric returns. SMBS certificates that are allocated all or large proportions of underlying principal cash flows tend to display very attractive *bullish* return profiles. As market rates drop and prepayments on the underlying collateral increase, the return of these SMBS will be greatly enhanced since principal cash flows will be returned earlier than expected.

Conversely, SMBS that are entitled to all or a large percentage of the interest cash flows have very appealing *bearish* return characteristics since greater amounts of interest cash flows are generated when prepayments of principal decrease (typically when market rates increase).

OVERVIEW OF THE SMBS MARKET

The SMBS market has grown substantially since the introduction of the first SMBS in July 1986. In total, over $500 billion agency SMBS in over 700 issues have come to market as of December 2019, as shown in Exhibit 24-1. In addition to Trust IOs and POs—the most common form of SMBS—there are billions of structured IOs and POs within collateralized mortgage obligation (CMO) deals (described below). In 2010, Markit introduced the SMBS Indices, i.e., MBX, IOS and PO Index as another source for IO and PO exposure.

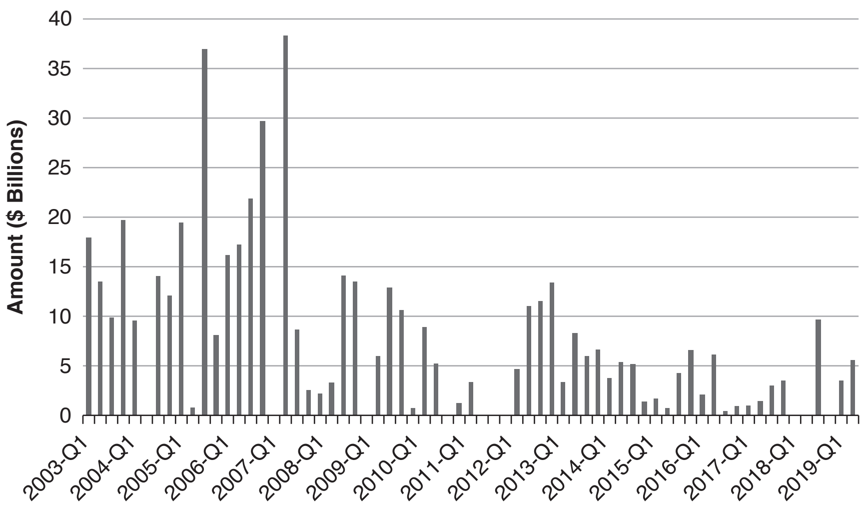
Types of SMBS

Strip securities exist in various forms. The first and earliest type of mortgage strip securities were called *synthetic-coupon pass-through securities*. Synthetic-coupon pass-throughs receive fixed proportions of the principal and interest cash flow from a pool of underlying mortgage loans. Synthetic-coupon pass-throughs were introduced by FNMA in mid-1986 through its "alphabet" strip program.

Trust IOs and Trust POs, the second type of strip securities, were introduced by FNMA in January 1987. IOs and POs receive, respectively, only the

EXHIBIT 24-1

Growth of SMBS Market



interest or only the principal cash flow from the underlying mortgage collateral. FNMA and FHLMC Trust IO/PO SMBS represent the major issuance and trading activities in the SMBS market. A liquid and dynamic secondary market in conjunction with the agency to-be-announced (TBA) market has been established to allow quick and frequent transactions. Benchmark bonds in the sector (large in size and most liquid issues) enhanced liquidity and investor pricing transparency.

A third type of strip security, the *CMO strips* (also called structured IOs and POs) are also popular among issuers and investors. As implied by their name, structured IOs and POs are tranches within a CMO issue that receive only principal or interest cash flows or have synthetically high coupon rates.

Development of the SMBS Market

In this section we provide the historical development of the SMBS market.

The First Mortgage Strip—FNMA SMBS "Alphabet" Strip Securities

FNMA pioneered the first stripped mortgage security in July 1986 through its newly created SMBS Program. For each issue of SMBS Series A through L, FNMA pooled existing FHA/VA and GPM mortgage loans that had been held in its portfolio and issued two SMBS pass-through certificates representing ownership interest in proportions of the interest and principal cash flows from the underlying mortgage loan pools. Alphabet strips were subsequently called synthetic discount- and premium-coupon securities, since the coupon rate of the alphabet strip was quoted as the percentage of the total principal balance of the issue.[1] In total, 12 alphabet strip deals were issued by FNMA in 1986, totaling $2.9 billion.

The FNMA SMBS Trust Program and IOs and POs

The successive and current FNMA strip program, the SMBS Trust Program begun in 1987, provided a vehicle through which deal managers (e.g., investment banks) can swap FNMA pass-throughs for FNMA SMBS Trust certificates. In the swapping process, eligible FNMA pass-through securities submitted by the deal managers are consolidated by FNMA into one FNMA Megapool Trust. In return, FNMA distributes to the deal manager two similarly denominated SMBS certificates evidencing ownership in the requested proportions of that FNMA Megapool Trust's principal and interest cash flows.[2]

---

1. For example, a strip that receives 75% interest and 50% principal of the cash flow from a FNMA 10% would be a synthetic 15% coupon security, since the 7.50% coupon is expressed as a 100% principal (i.e., 7.50% coupon/50% principal = 15.00% coupon/100% principal). By the same logic, a strip security from a FNMA 10% that receives 50% interest and 1% principal would be a 5,000% coupon security.
2. FNMA tightly restricts the type of collateral that can be placed in Trust. For example, all mortgage securities must have the same prefix (be of the same loan type) and be within a certain WAC and WAM range to correspond with preliminary pricing. Moreover, the minimum initial principal balance of each SMBS Trust must be $200 million.

To date, the majority of FNMA SMBS Trusts have contained IO and PO securities. IOs and POs represent the most leveraged means of capturing the asymmetric performance characteristics of the two cash-flow components of mortgage securities. Although IOs and POs can be combined in different ratios to create synthetic-coupon securities, some investors have shown a preference for one-certificate synthetic securities due to their bookkeeping ease. In late 1993, FNMA added another feature to their SMBS structure. In addition to IO and PO classes, FNMA SMBS Trusts contained a provision for exchanging IOs and POs for another class with a synthetic coupon. The synthetic-coupon classes that are available are determined in the prospectus supplement for each Trust and generally range from 0.5% to double the coupon on the underlying collateral in increments of 50 basis points (bps). Exchanges are executed for a small fee and may be reversed back into IO and PO components as well as into any other available combination, provided the proportions of IO and PO are correct. To promote liquidity in the SMBS market, all FNMA SMBS certificates (except FNMA SMBS Series L) have a unique conversion feature that enables like denominations of both classes of a FNMA SMBS issue or Trust to be exchanged on the book entry system of the Federal Reserve Banks for like denominations of FNMA MBS certificates or Megapool certificates. Because of the potential for profitable arbitrages, the aggregate price of the two classes of any same FNMA issue or Trust tends to be slightly higher (the "recombo premium") than the price of comparable-coupon and remaining-term FNMA pass-through certificates.

FHLMC Stripped Giant Program

FHLMC is also a participant in the SMBS market. In October 1989, FHLMC announced the Stripped Giant Mortgage Participation Certificate Program.

FHLMC's Stripped Giant Program is similar to FNMA's swap SMBS Trust Program. Deal managers submit FHLMC PCs to FHLMC; FHLMC, in turn, aggregates these PCs into Giant pools and issues Strip Giant PCs representing desired proportions of principal and interest to the deal manager. All FHLMC strip PCs have the same payment structure, payment delays, and payment guarantee as regular FHLMC PCs. Like FNMA SMBS, FHLMC Giant Strip IOs and POs have a conversion feature that allows them to be exchanged for similarly denominated FHLMC PCs. Under the FHLMC Gold MACS (Modifiable and Combinable Securities) program, IO and PO securities may be exchanged for synthetic-coupon classes that have been predetermined in the prospectus supplement for a fee.

GNMA Collateral for SMBS

In 1990 FNMA began to issue SMBS collateralized by GNMA pass-through certificates. Since the beginning of 1990, FNMA has issued 76 trusts that have had underlying GNMA collateral. FHLMC began to issue GNMA-backed SMBS in 1993 and has issued seven GNMA strips to date. The increased availability of GNMA SMBS has further broadened the investor base of SMBS, enhanced the liquidity of the SMBS market, and increased the number of hedging alternatives available to GNMA investors.

In July 2004, GNMA issued its first Trust security GNS 1 of $2.2 billion. Although very few GNMA SMBS have been issued subsequently, structured IO and PO within GNMA-backed CMOs are very popular.

Private Issuance

Investment firms began to issue private-label SMBS in late 1986. Many of these private-labels SMBS were issued through REMIC structures. Since one class of REMIC issue must be designated the residual interest, the super-premium coupon class of many of these private-label SMBS is often the residual interest of the REMIC deal. Unlike investing in FNMA SMBS, investors who purchase these residual securities are responsible for the tax consequences of the entire REMIC issue.

PO-Collaterized CMOs

Profitable arbitrage opportunities led to the introduction of CMO securities collateralized by POs. PO-collateralized CMOs allocate the cash flow from underlying PO securities between several CMO tranches with different maturities and prepayment patterns. The potential for profitable arbitrages with PO securities has enhanced the efficiency of the SMBS market by effectively placing a floor on the price potential of POs and a price ceiling on corresponding IOs in a given market environment.

CMO Strip Securities

Strip securities are included in CMO issues as regular-interest (nonresidual) CMO tranches. CMO strip securities that pay only principal, large proportions of interest cash flows (relative to principal cash flows), or only interest over the underlying mortgage collateral's life are termed PO securities, "higher-interest" securities, and IO securities respectively; they tend to have performance characteristics similar to FNMA SMBS. Other types of CMO strip securities receive initial and ongoing collateral principal or interest in cash flows after other classes in the CMO issue are retired or have been paid. These types of strip CMO securities are structured as PO or PAC IOs, TAC IOs, or Super-POs and can have similar characteristics to FNMA SMBS or can be structured to have higher or lower performance leverage.

IOS, PO Index, and MBX

In February 2010, Markit introduced the IOS, PO Index, and MBX. They are Synthetic Total Return Swaps. The IOS Index was the most actively traded among the three as it served as an additional source for IO exposure. The Markit IOS Indices are composed of the interest component of reference pools of loans. The most common reference pools of loans are 30-year fixed-rate Fannie pools with coupons from an entire issue year. For example, the first pools were issued with coupons of 4.0, 4.5, and 5.0 in 2009. Today there are various reference pools from 3.0 fixed-rate coupon to 6.5 fixed-rate coupon with vintage years from 2003 to 2014.

The economics of the IOS Index is similar to that of owning a cash IO. If an investor buys the IOS index of 2009 4.5 coupon, they will receive the net cash flow based on the reference pool and will pay one-month LIBOR in return.

Buyers of SMBS

The asymmetric returns of SMBS appeal to a broad variety of investors. SMBS can be used effectively to hedge interest rate and prepayment exposure of other types of mortgage securities. Combined with interest rate derivatives, SMBS is a typical instrument for mortgage servicers to hedge the interest rate and prepayment exposure of the mortgage servicing rights. SMBS can also be combined with other fixed-income securities such as U.S. Treasuries and mortgage securities to enhance the total return of the portfolio in varying interest rate scenarios. Insurance companies and pension funds frequently use SMBS as a method of tailoring their investment portfolio to meet the duration of liabilities and thus minimize interest rate risk.

SMBS are used by various types of investors to accomplish their investment objectives. Insurance companies, pension funds, money managers, hedge funds, and other total rate of return accounts use SMBS to improve the return of their fixed-income portfolios.

INVESTMENT CHARACTERISTICS

SMBS enable investors to capture the performance characteristics of the principal or interest components of the cash flows of mortgage pass-through securities. These individual components display contrasting responses to changes in interest rates and prepayment rates. PO SMBS are bullish instruments, outperforming mortgage pass-through in declining interest rate environments. IO SMBS are bearish investments that can be used as a hedge against rising interest rates.

Variation of Interest and Principal Components with Prepayments

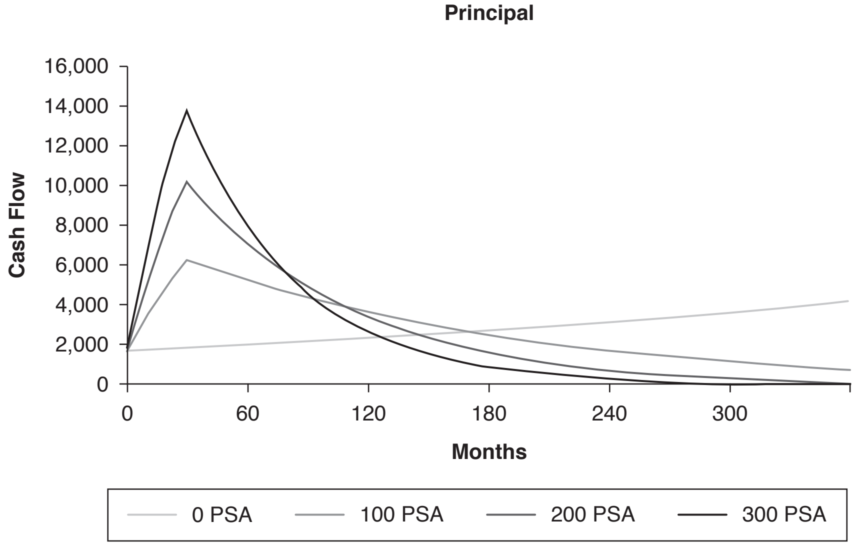
The cash flows that an MBS investor receives each month consist of principal and interest payments from a large group of homeowners. The proportion of principal and interest in the total payment varies depending on the prepayment level of the mortgage pool. Exhibit 24-2 illustrates these cash flows for $1 million 30-year FNMA current-coupon pass-through securities at various PSA prepayment speeds.

Panel a of Exhibit 24-2 shows the principal component of the monthly cash flows. Since the interest is proportional to the outstanding balance, the exhibit can also be viewed as showing the decline in the mortgage balance at the various prepayment speeds.

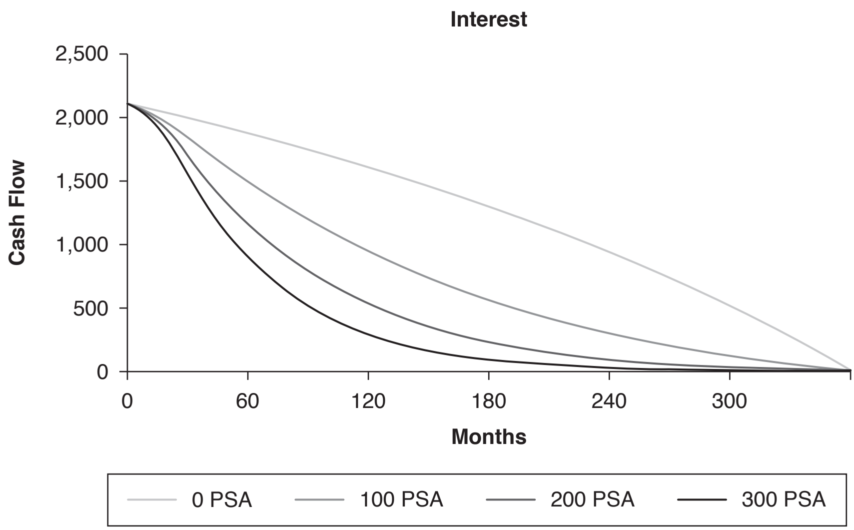
EXHIBIT 24-2

Monthly Cash-Flow Components

Panel a: Principal Component of Monthly Cash Flows



Panel b: Interest Component of Monthly Cash Flows



At a zero prepayment level, the interest and principal cash flows in Exhibit 24-2 compose a normal amortization schedule. In the earlier months of the security's life, the cash flows primarily contain interest payments. This occurs because interest payments are calculated based on the outstanding principal balance remaining on the mortgage loans at the beginning of each month. As the mortgage loans amortize, the cash flows increasingly reflect the payment of principal. Toward the end of the security's life, principal payments make up the bulk of the cash flows.

Prepayments of principal significantly alter the principal and interest cash flows received by the mortgage pass-through investor. Homeowners who prepay all or part of their mortgage loans return more principal to the investor in the earlier years of the mortgage security. All else being equal, an increase in prepayments has two effects:

1. The time remaining until return of principal is reduced as shown in panel a of Exhibit 24-2. At 100% PSA, the average life of the principal cash flows is 10.49 years, whereas at faster speeds of 200 and 300% PSA, principal is returned in average time periods of 7.25 years and 5.50 years, respectively.
2. The total amount of interest cash flows is reduced, which is shown in panel b of Exhibit 24-2. This occurs because interest payments are calculated based on the higher amount of principal outstanding at the beginning of each month and higher prepayment levels reduce the amount of principal outstanding.

Effect of Prepayment Changes on Value

A mortgage pass-through security represents the combined value of the interest and principal cash flows. The effects of prepayments on the present value of each of these components tend to offset each other. Increases in prepayments reduce the time remaining until repayment of principal. The sooner the prepayment of principal is repaid, the higher the present value of the principal. Conversely, since increasing levels of prepayments reduce interest cash flows, the value of the interest decreases.

Thus, the interest and principal cash flows individually are much more sensitive to prepayment changes than the combined mortgage pass-through. This is illustrated in Exhibit 24-3 which shows the present values of the principal and interest components of a FNMA pass-through at various prepayment levels.

The greater sensitivity of IOs and POs to prepayment changes is further illustrated in Exhibit 24-4, which shows the realized yields to maturity (or internal rates of return) for a typical IO and PO and for the underlining collateral for given purchase prices.

The IO and PO reflect sharply contrasting responses to prepayment changes; the IO's yield falls sharply as prepayments increase, whereas the PO's yield falls as prepayments decrease. The yield of the underlining collateral is, on the other hand, relatively stable compared to PO and IO.

Price Performance of SMBS

The discussion in the previous section indicates that prepayment speeds are by far the most important determinant of the value of an SMBS. Since the price response of an SMBS to interest rate changes is determined, to a large extent, by how the collateral's prepayment speed is affected by interest rate changes, we begin with a discussion of mortgage prepayment behavior.

The Prepayment S Curve

The prepayment speed of an MBS is a function of the security's characteristics (such as coupon and age), interest rates, and other economic and demographic variables. Although detailed prepayment projections generally require an econometric model, the investor can obtain some insight into the likely behavior of an SMBS by examining the spread between the collateral's gross coupon and current mortgage rates

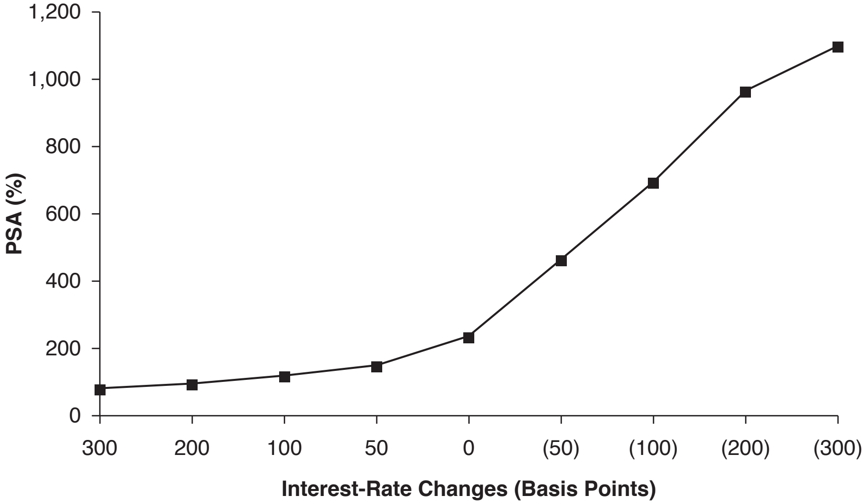
This spread is generally the most important variable in determining prepayment speeds. A decrease of current mortgage rate translates to a higher spread and hence more rate incentive to prepay. A decrease of current mortgage rate has the opposite effect on prepayment. With respect to this spread, prepayment speeds have an S shape; speeds are fairly flat with increasing mortgage rate (when the spread is negative and prepayments are caused mainly by housing turnover), they start increasing when the mortgage rate starts to decrease (when the spread becomes positive), they surge rapidly until the spread is several hundred bps, and then they level off when the security is a high premium. At this point, there is already substantial economic incentive for mortgage holders to refinance, and further increases in the spread lead to only marginal increases in refinancing activity. This S curve is illustrated in Exhibit 24-5, which shows projected long-term prepayments for specified changes in mortgage rates.

In the remainder of this section, we make repeated reference to Exhibit 24-5, since the performance of an SMBS can be explained to a large extent by the position of its collateral on the prepayment S curve.[3]

3. However, the investor should note that not all aspects of prepayment behavior are explained by the spread between the coupon and the mortgage rate. The projected prepayments shown in Exhibit 24-5 are long-term averages. Month-to-month prepayment rates vary (e.g., due to seasonality) even if mortgage rates do not change. If a substantial and sustained decline in mortgage rates occurs, then mortgage holders exposed to mortgage refinancing incentives for the first time initially exhibit a sharp increase in prepayments. This gradually decreases as the homeowners most anxious and able to refinance do so. This non-interest-rate-related decline in the prepayment speeds of premium coupons usually is referred to as "burnout." The projected speeds shown in the declining-rate scenarios are the average of the high early speeds and lower later speeds. For seasoned coupons that have experienced a heavy refinancing period, burnout implies that prepayments may be less responsive to decline in interest rates. This applies to the majority of premium coupons currently outstanding. The age effect on prepayments is well known. Prepayment speeds are low for new mortgages and increase gradually until the mortgages are two to three years old, after which the age is less important. This means that, other things being equal, an IO is worth more if it is collateralized by new FNMA 5.5s, for example, than by seasoned FNMA 5.5s.

EXHIBIT 24-5

Payment S Curve



Projected Price Behavior

Exhibit 24-6 gives projected price paths for a pair of IO and PO for parallel interest rate shifts.[4]

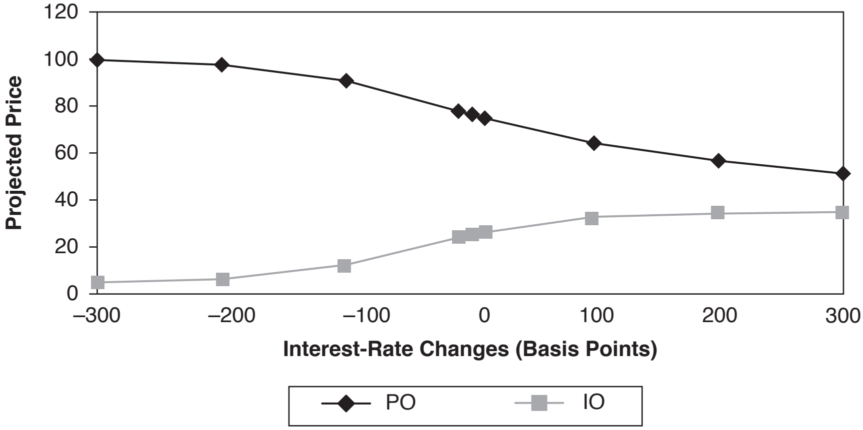
The projected price behavior of the SMBS as interest rates change can be explained largely by the prepayment S curve in Exhibit 24-5.

- As rates drop from current levels, the collateral begins to experience sharp increases in prepayment. Compounded by lower discounted rates, this causes substantial price appreciation for the PO. For the IO, however, the higher prepayments outweigh the lower discount rates and the net result is a price decline.
- If the rates drop by several hundred basis points, the collateral becomes a high-premium coupon and prepayments plateau. The rates of price appreciation of the PO and price deprecation of the IO both decrease. Eventually the IO's price starts to increase, as the effect of lower discount rates starts to outweigh the effect of marginal increases in prepayments.
- If rates rise, the slower prepayments and higher discount rates combine to cause a steep drop in the price of the PO. The IO is aided initially by the slower prepayments, giving the IO negative duration, but eventually prepayments plateau on the slower side of the prepayment S curve and the IO's price begins to decrease.

4. The prices are calculated with constant yield assumption in all cases. The collateral price is the sum of the IO and PO prices.

EXHIBIT 24-6

Projected Price Paths for an IO and a PO for Parallel Interest Rate Shifts



Effective Duration and Convexity

Exhibit 24-7 indicates that POs tend to have large positive effective durations, whereas IOs have large negative effective durations.[5]

The effective durations in Exhibit 24-7 reflect the price paths in Exhibit 24-6:

- For the PO, as rates decline, the effective duration initially increases, reflecting its rapid price appreciation as prepayments surge. Note that this is in complete contrast to traditional measures such as Macaulay or modified duration, which, reflecting the shortening of the PO, would actually decrease. As rates continue to drop, the PO's effective duration levels off and then decreases, reflecting both a leveling off of

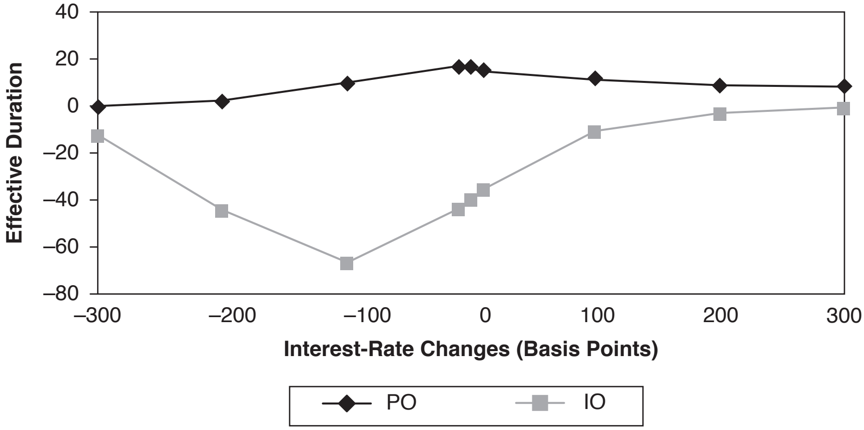
5. Effective duration is a measure of the proportional price change if interest rates change by a small amount. Let Price(0) be the current price of a security. Let Price(Δ) be the price if interest rates increase by a small amount Δy and Price(−Δ) be the price if interest rates decrease by a small amount Δ. Then

$$\text{Effective duration} = \frac{\text{Price}(-\Delta) - \text{Price}(\Delta)}{\text{Price}(0) \times 2\Delta y} \times 100$$

This formula is straightforward: we take the total price change (the difference in the new prices) and divide by the initial price (the 100 is a scaling factor). To obtain the projected price and durations, we have, for simplicity, assumed parallel shifts in interest rates. In practice, of course, rates do not move in parallel (typically, short-term rates tend to be more volatile than long rates). However, using nonparallel yield curve shifts raises questions that, although interesting, are best left for another book. For example, suppose the yield curve shifts such that short rates move twice as much as long rates, and we compute the corresponding price change. The effective duration will be twice as large if we compare the price change against the change in short rates (i.e., Δy change in short rates) as opposed to comparing the price change against the change in long rates (i.e., Δy change in long rates).

EXHIBIT 24-7

IO and PO Effective Durations



prepayments and the fact that, to calculate the effective duration, we are dividing by an increasing price. If rates increase, the PO's duration decreases but remains positive.

- For the IO, the effective duration is initially negative and decreases rapidly as rates drop, before eventually increasing and becoming positive after prepayments plateau. If rates increase, the duration increases and eventually becomes positive.

Convexity measures the rate of change of duration and is useful in indicating whether the trend in price change is likely to accelerate or decelerate. It is calculated by comparing the price change if interest rates decrease with the price change if rates increase.[6] Exhibit 24-8 shows the convexities obtained using the projected prices in Exhibit 24-6.

6. Convexity is calculated by comparing the price change if rates move up or down by small amounts. Let

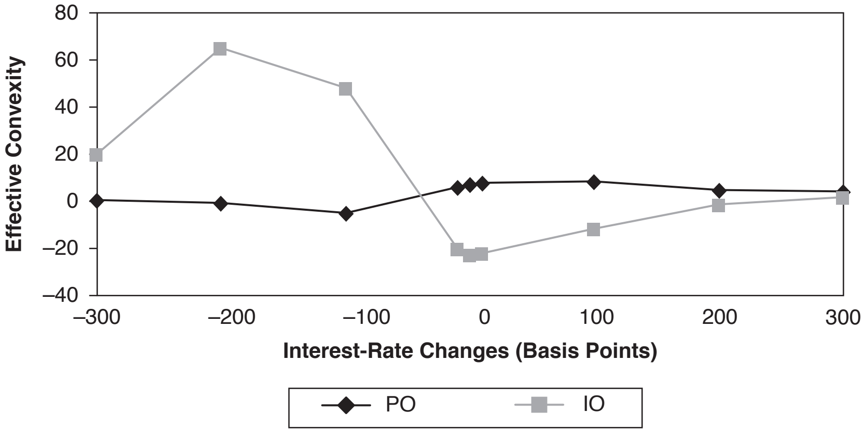
$$\Delta P^{+} = \text{Price}(0) - \text{Price}(\Delta)$$
$$\Delta P^{-} = \text{Price}(-\Delta) - \text{Price}(0)$$

where ΔP^{+} and ΔP^{-} are the price changes if rate increases or decreases by Δy, respectively. Then

$$\text{Convexity} = \frac{\Delta P^{-} - \Delta P^{+}}{\text{Price}(0) \times (\Delta y)^2} \times 100$$

EXHIBIT 24-8

IO and PO Convexities



Comparing Exhibits 24-7 and 24-8 shows that the convexity indicates how the duration is changing. When the duration is increasing (as in the case of the PO when rates begin to decline from the initial value), the convexity is positive, and when the duration is decreasing, the convexity is negative. For example, the IO's convexity is initially negative but begins to increase after rates fall by more than 100 bps; although the duration is still negative at 200 bps, the positive convexity indicates that the duration is increasing. The peak in the convexity of the IO at a change of 200 bps indicates that the rate of increase in its duration is greatest at this point, as shown in Exhibit 24-7.

In summary, the prepayment S curve implies that:

- For SMBS collateralized by current or discount pass-throughs, the PO has substantial upside potential and little downside risk, whereas the converse is true for IOs.
- For SMBS backed by low premiums, there is a somewhat comparable upside potential and downside risk.
- For SMBS backed by high premiums collateral (including the majority of SMBS issued to date), the PO has little upside potential and significant downside risk whereas the reverse is true for IOs.

Pricing of SMBS and Option-Adjusted Spreads

The strong dependence of SMBS cash flows on future prepayment rates, combined with the typically asymmetric response of prepayments to interest rate changes, make traditional measures of return such as yield to maturity of limited usefulness in analyzing or pricing SMBS. The most common method of pricing SMBS is with option-adjusted spreads (OAS). OAS analysis uses probabilistic methods to evaluate the security over the full-term range of interest rate paths that may occur over its term. The impact of prepayment variations on the security's cash flows is factored into the analysis. The OAS is the option-free spread over the benchmark curve (Treasury or swap curve) provided by the security. It gives a long-term average value of the security, assuming a market-neutral viewpoint on interest rates.

Exhibit 24-9 shows the OAS analysis for IOS, PO Index, and MBX of 2013 3% coupon that are illustrations for IO strip, PO strip, and the underlying collateral. Also shown are the yields to maturity, WAL, spread to WAL equivalent treasury rate.

The OAS at a 0% volatility (the ZV-Spread) when mortgage rates stay at current levels, is typically close to the standard benchmark curve spread in a flat yield curve environment. The difference between the ZV-Spread and OAS, which we label the *option cost*, is a measure of the impact of prepayment variations on a security for the given level of interest rate volatility. The option cost, to a large extent, does not depend on the pricing level or the absolute level of prepayment projections (although it does depend on the slope, or response, of prepayment projections to interest rate changes). Hence, the option cost is a measure of the intrinsic effect of likely interest rate changes on a mortgage.

Before discussing the option cost in Exhibit 24-9, note that, in general, interest rate and prepayment variations have two effects on an MBS:

1. For any callable security, being called in a low interest rate environment typically has an adverse effect, since a dollar of principal of the security in general would be worth more than the price at which it is being returned. (An exception is a mortgage prepayment resulting from housing turnover, when the call could be uneconomic from the call-holder's point of view.) To put it another way, the principal that is being returned typically has to be reinvested at yields lower than that provided by the existing security.
2. For MBS priced at a discount or a premium, changes in prepayments result in the discount or premium being received sooner or later than anticipated. This may mitigate or reinforce the call effect discussed in (1).

In general, the first effect is much more important than the second; however, for certain deep-discount securities, such as POs, the second effect may at times outweigh the first. The net result of the two effects depends on the position of the collateral on the prepayment curve shown in Exhibit 24-5.

- For discount or current-coupon collateral, prepayments are unlikely to fall significantly but could increase dramatically if there is a substantial decrease in interest rates. This asymmetry means that the PO is, on average, likely to gain significantly from variations in prepayment speeds. The option cost for the PO is usually negative; that is, the PO *gains* from interest rate volatility, indicating that the benefits of faster

EXHIBIT 24-9

OAS Analysis for IOS, PO Index and MBX of 2013

	Price	YTM	WAL	I-Spread	OAS	ZV-Spread	Option Cost
IOS FN-3013 PO	94-12	1.177	5.07	82	55	100	45
IOS FN-3013 IO	12-08	4.781	5.07	442	16	456	440
IOS FN-3013 PT	106-20	1.595	5.07	124	50	142	92

return of principal outweigh the generic negative effects of being called in low interest rate environments. On the other hand, the underlying collateral tends to have a positive (but usually small in the case of discount collateral) option cost; the negative effects of being called when rates are low outweigh the benefits of faster return of principal. Finally, the IO typically has a large positive option cost; the asymmetric nature of likely prepayment changes, discussed above, means that the IO gains little if interest rates increase (since prepayments will not decrease significantly), whereas a substantial decline in rates is likely to lead to a surge in prepayments and a drop in interest cash flows.

- Given continued rates rally for many years, all outstanding SMBS are backed by premium collateral. FNMA IOS, PO index, and MBX of 2013 3 coupon, shown in Exhibit 24-9, illustrate the characteristics typical of SMBS with premium collateral. For *premium* collateral, there is, generally speaking, potential for both increases and decreases in prepayments, and the net effect of prepayment variations will depend on the particular coupon and prevailing mortgage rates. Seasoned premiums, for example, will not have potential for substantial increases in speeds, and hence IOS FN-3013 PO has a small but positive option cost. The collateral IOS FN-2013 PT has a more positive option cost for the same reasons.

The importance of likely variations in prepayments makes the standard yield to maturity of very little relevance in pricing SMBS, and therefore they tend to be priced (as in Exhibit 24-8) on an OAS basis.

KEY POINTS

- There are many forms of stripped mortgage-backed securities, including pass-throughs, Trust IOs and POs, and CMO strips.
- SMBS are used both as hedges of prepayment and interest rate risk and as yield-enhancement mechanisms.
- POs and IOs exhibit contrasting responses to changes in interest rates: POs outperform mortgage pass-throughs in a declining rate environment, while IOs underperform them.
- Prepayment speeds are by far the most important determinant of the value of an SMBS. As such, the price performance of SMBS is largely determined by the prepayment S curve.
- Current- or low-premium collateral POs tend to have large positive effective durations, while IOs have large negative effective durations.
- Traditional performance measures such as yield to maturity have limited usefulness in the analysis of SMBS; the most common method of pricing them is using option-adjusted spread.

CHAPTER
TWENTY-FIVE

NONAGENCY RESIDENTIAL MORTGAGE-BACKED SECURITIES: LEGACY, RMBS 2.0, AND NON-QM

Dapeng Hu, Ph.D., CFA,
Managing Director
BlackRock Financial Management, Inc.

Mario Triantafillou, Ph.D.
Director
BlackRock Financial Management, Inc.

Nonagency residential mortgage-backed securities (nonagency RMBS) are securities that are backed by mortgage loans lacking guarantees from either government-sponsored enterprises (GSEs; e.g,. Fannie Mae and Freddie Mac) or government agencies (e.g., Ginnie Mae). This makes them fundamentally different from agency RMBS in that they are exposed to the *credit risk* of the underlying loans in addition to their prepayment risk. Nonagency loans fail to receive agency guarantees for two primary reasons: they are originated with loan balances exceeding the agency conforming limit and/or they do not meet agency underwriting standards.

Each nonagency RMBS deal contains hundreds to thousands of mortgage loans. The cash flows of a deal are structured into various pools or tranches that each bear different risks to suit different investors. Each tranche is an RMBS bond. Nonagency RMBS deals are primarily categorized by the dominant mortgage type in each deal. Deals issued before or during the subprime mortgage crisis are termed *legacy* RMBS deals, including prime jumbo, alternative-A

The views here are the authors' only and do not represent the views of BlackRock. This chapter was rewritten based on the chapter "Nonagency Residential Mortgage-Backed Securities," coauthored by Dapeng Hu and Robert Goldstein, in the 8th edition of *Handbook of Fixed Income Securities*. The authors thank Robert Goldstein for his contribution to the previous version and his encouragement in this new version. The authors thank Neeraj Kumar for his great assistance in updating many charts and tables. The authors also thank Ying Shen, James Watkin, Caroline Liu, Scott Anderson, Manish Sinha, Kelly Schneiter, Sophia Su, Ibrahim Incoglu, Adam Levi, and other colleagues for their helpful comments and discussions on these materials.

(Alt-A), option adjustable-rate mortgage (OARM), subprime, second (2nd) lien, and manufactured housing (MH) mortgages. After the crisis, new issuances are dominated by three major products: NPL and RPL deals, which repackage legacy nonperforming loans (NPL) and re-performing loans (RPL); RMBS 2.0 deals, which are primarily backed by newly originated high-quality prime jumbo loans with simpler deal structures; and non-QM deals backed by nonqualified mortgages, a new mortgage category following the Consumer Finance Protection Bureau's rule on Qualified Mortgages in 2014.

During the housing boom, nonagency RMBS provided slightly higher yields than agency RMBS with seemingly little additional risk. Perennially yield-hungry investors poured money into this sector. This led to rapid increases in loan origination, to innovations in mortgage products, and to a flood of so-called affordability mortgages. Furthermore, the development of ABS credit default swaps and collateralized debt obligations (CDOs) led to a surge of nonagency RMBS issuance beginning in 2005. Nonagency RMBS issuance reached its peak in 2006 with more than $1 trillion in new issuance and spreads at their tightest levels. The subprime mortgage crisis and its concomitant housing market meltdown substantially slowed new issuance in 2007. Issuance ground to a halt in 2008 and 2009. These legacy securities, still have, as of this writing, a large outstanding balance.

Starting in 2011, nonagency mortgage lenders found that the market was once again willing to finance ultra-prime loans through the issuance of private-label securitizations, termed prime jumbo new origination, or RMBS 2.0. Large banks that have strong mortgage origination operations joined in with their own securitizations in 2013. Collateral characteristics of these deals typically have a large loan size, very high FICO credit score, and low loan-to-value (LTV) ratio. While issuance has currently peaked at $10 billion per year, total outstanding is nearly $50 billion today. These RMBS 2.0 deals typically have simpler capital structures compared to legacy deals.

Another innovation was the introduction of non-Qualified (non-QM) loans starting in 2014. Non-QM refers to loans that do not meet all Qualified Mortgage standards set by the Consumer Finance Protection Bureau (CFPB). Examples of this include loans to borrowers who are self-employed, loans to borrowers who are asset rich but cash constrained, and loans to borrowers who are investing in properties and will use rental proceeds for loan repayment. Precluding these loans from mainstream lending means originators of non-QM loans can charge higher rates and thus reward non-QM deal investors with higher yields. Consequently, the non-QM market has gained increasing interest from investors and the issuance of non-QM products has grown continuously since 2014.

This chapter first provides an overview of the nonagency RMBS market, with a review of the rise, fall, and likely reincarnation of securitization. It then examines three core aspects of nonagency RMBS—collateral, servicing, and capital structure—for legacy RMBS deals, prime jumbo 2.0 deals, as well as non-QM deals. The housing market, the most important macro factor for nonagency RMBS performance, is also discussed. Finally, it concludes with an introduction of relative value and risk analysis.

MARKET OVERVIEW

Industry Structure

The process of nonagency securitization involves several types of institutions including originators, warehouse lenders, issuers, rating agencies, servicers, trustees, and so on. Originators underwrite and originate mortgage loans to borrowers. Major originators include banks, mortgage companies, correspondents, and brokers. Warehouse lenders provide short-term financing to originators allowing a critical mass of loans to be accumulated for a deal. Issuers package the loans and structure them into various tranches, work with rating agencies to obtain credit ratings, and sell the tranches in the capital markets as RMBS. Major issuers include banks, mortgage companies, real estate investment trusts (REITs), and investment banks. Rating agencies analyze the potential collateral loss and deal structure and assign credit ratings to each tranche. They also conduct surveillance of existing bonds to determine if they are eligible for rating upgrades or downgrades. The major rating agencies are Moody's, S&P, and Fitch. Trustees administer the deals including releasing remittance reports that detail the performance of the collateral and the bonds and distributing the cash flows to investors.

Mortgage servicers play a critical role in the nonagency RMBS life cycle. They collect payments from borrowers and pass them on to trustees. Depending on the type of deal and the terms of the prospectus, the servicer is generally responsible for advancing principal and interest payments for delinquent borrowers, provided the servicer believes that the advanced amounts are recoverable. Servicers are also responsible for collection, foreclosure, real-estate owned (REO), and liquidation efforts. Servicers have also become responsible for conducting loan modifications.

During the nonagency securitization boom, several industry participants built vertically integrated securitization businesses named conduits. These businesses acquire loans, either funding them directly through brokers or through a flow program with various correspondents for ultimate securitization exit. They also typically retained the servicing rights to the purchased loans, either performing the servicing themselves or subcontracting to third-party servicers.

Deal type is often identifiable from a deal's prospectus. A prospectus is an offering document that describes collateral characteristics and deal structure and discloses the associated transaction parties (e.g., underwriters, trustees, servicers) and investment risks. Because issuers typically use different entity or "shelf" names for different product types, the shelf is often used to classify the deal type.

Rise and Fall of Legacy Nonagency RMBS Market

Nonagency securitization started in the 1980s. During the early stages of the RMBS market's development, there was an essentially binary division in the secondary mortgage market between agency pools/deals and nonagency deals. Loans that were not agency-eligible were either retained as whole loans or put into a "nonagency deal." The gradations in credit quality and underwriting that later characterized the nonagency sector were, at that point, mostly absent. Consequently, nonagency deals issued in the 1980s and early 1990s frequently contained a wide variety of collateral types.

In the early 1990s, nonagency RMBS began to employ more systematic underwriting standards, standards that were closer to those used by the GSEs. This resulted in more homogenous credit quality among prime jumbo deals. Credit (FICO) scores began to be used in mortgage lending, providing a consistent industry-wide measurement of credit risk levels. This allowed the market to shift from generic "nonagency deals" to "prime jumbo," "Alt-A," and "subprime" deals. Prime jumbo was the dominant sector, while Alt-A was the smallest.

As the housing market started booming in the early 2000s, U.S. mortgage lending began to move away from its traditional roots in the 30-year fixed-rate product. Various alternative affordability products emerged and expanded rapidly. Hybrid adjustable-rate mortgages (ARMs) captured an increasingly large slice of the origination market, as did hybrid nonamortizing (i.e., interest-only) and negatively amortizing (NegAm or Option ARM) products. Before 2003, nonagency RMBS accounted for about 20% of the total U.S. RMBS new issuance market. Beginning in 2004, the nonagency market captured an increasing portion of market share from the agency sector, still dominated by prime jumbo. By 2005, securitized nonagency RMBS origination surpassed that of agency origination reaching $1.2 trillion with subprime as the largest nonagency sector followed by Alt-A.

Nonagency securitization was further fueled by the adoption of the pay-as-you-go (PAUG) structure in ABS credit default swaps (CDS) and the rapid expansion of the ABS collateralized debt obligation (CDO) market. Unlike traditional CDS that requires a hard or clear singular credit event to determine payoff, under PAUG structure if an ABS security encounters a principal loss or an interest shortfall, the protection seller pays the protection buyer the amount of the loss or shortfall. If the security later catches up on the payment, the protection buyer returns the payment to the protection seller. This essentially made ABS CDS work just like a cash bond, which greatly increased the liquidity of ABS CDS.

The PAUG template facilitated two key developments that ultimately became critical ingredients for the subprime mortgage crisis: the launch of ABX, an index for or a basket of subprime ABS CDS, and the creation of synthetic ABS CDOs. The ABX index became the barometer of nonagency RMBS market and the dominant instrument for shorting the market. The creation of synthetic ABS allowed the ABS CDO machine to roar. Synthetic ABS, as opposed to cash bonds, refers to using ABS CDS contracts to create cash flows that are similar to owning the reference bond. Synthetic ABS liberated CDO managers from the relative scarcity of cash bonds by allowing them to create tens of billions of synthetic instruments without actual mortgage origination. This greatly magnified the impact of nonagency mortgage defaults on the overall financial system.

The surge in nonagency mortgage demand directly led to the relaxation of mortgage underwriting criteria. Total combined LTV ratios were increasing as borrowers were not always required to put down the typical 20% of equity in order to buy a house. Debt-to-income ratio, credit score, and documentation requirements were all loosened. Appraisal values were often inflated in order to qualify for a loan, underwriting due diligence was often compromised, and the share of affordability products (interest-only, negative amortization, etc.) increased sharply.

The consequence of loose underwriting soon became apparent as early delinquency (defined as within the first few payment periods) ramped up sharply in newly issued 2006 subprime deals. At the same time, the housing market started to weaken and home sales slowed, which accelerated the 2006 vintage delinquency rates as many borrowers little or no equity buffer. As delinquency levels continued to rise rapidly beyond these early payment defaults (EPDs) in late 2006, it became clear that the 2006 vintage was seriously challenged from a credit perspective and market prices for associated bonds started to fall.

By early 2007, as the housing market showed no signs of a soft landing and both subprime and Alt-A delinquency rates accelerated monthly, the capital markets started to penalize all RMBS prices, and many leveraged investors had to deleverage in order to meet margin calls. This triggered a vicious cycle of decreased valuations and deleveraging in bonds that were originally issued as AAA. As a consequence, the demand for new issuance vanished and many originators either went out of business or ceased production. By the end of 2007, almost all nonagency originations had stopped. Nonagency securitization ground to a halt and RMBS spreads widened dramatically.

Through this vicious cycle and thanks to the large exposures to ABS CDS and CDO, the credit problem in the nonagency RMBS market quickly spread to turmoil in the entire credit market. A downward spiral unfolded as banks started to mark-to-market their balance sheet assets. The mounting nonagency mortgage related credit losses not only led to huge unanticipated write downs to bank balance sheets, but also dramatically increased the capital reserve requirements for these large institutions, which further worsened market liquidity. Because many banks and large financial institutions were the major issuers and holders of RMBS, ABS CDS, and CDO assets, the mortgage credit meltdown eventually led to the downfall of large institutions like Countrywide, Wachovia, Washington Mutual, Bear Stearns, Lehman Brothers, Merrill Lynch, AIG, Fannie Mae, Freddie Mac, and so on.

Since late 2008, the legacy nonagency sector has been in runoff mode with little new issuance. Asset valuations hit a rock bottom in March 2009 and has since been in recovery. Subprime CDO liquidation and bank sales provided a supply of existing bonds to the market. During the crisis, the vast majority of bonds originally rated as AAA experienced rating downgrades, including 99% of

Option ARM, 97% of Alt-A, 94% of subprime, and 85% of prime bonds. Many were downgraded from AAA to below investment grade, including most 2005, 2006, and 2007 vintage bonds.

In early 2010, re-securitization has emerged as a meaningful mechanism to help absorb and repackage the universe of legacy nonagency RMBS. Re-securitizations, also known as re-REMICs, place nonagency RMBS bonds into a trust that then issues a senior and a junior bond to investors. These re-REMICs were primarily created using bonds that were AAA at issuance. They have utilized a simple structure where the senior bonds receive all the principal cash flows until they are paid off while all the losses are first absorbed by the junior bonds. The presence of junior bonds provides the senior bonds a greater credit enhancement; hence the senior bonds can obtain AAA ratings to meet investor needs. These transactions provided capital relief by allowing new AAA bonds to be created and retained while selling a smaller quantity of lower-rated bonds.

Another attempt to revive the nonagency market was the introduction of PrimeX indices in April 2010. PrimeX allowed investors to synthetically gain exposure to a basket of prime jumbo RMBS deals via credit CDS. At inception, they were traded actively and had facilitated the trading of existing prime bonds.[1] However, as the legacy bonds ran off, PrimeX became illiquid.

Today, there are still about $350 billion legacy RMBS loans remaining in running-off mode, including $203 billion subprime, $90 billion Alt-A, $38 billion OARM, and $27 billion prime jumbo. In addition, there are RPL/NPL deals that repackaged legacy loans. Since the remaining bonds are mostly below investment grades, the market liquidity is low with large price volatility. However, given the high coupons and burnout in prepayment and credit, many bonds provide relatively high yields.

RMBS 2.0 and Non-QM

Following the financial crisis, the financial market has been subjected to heightened regulation. Among others, two requirements from The Dodd-Frank Wall Street Reform and Consumer Protection Act of 2010 (the Dodd-Frank Act) have had significant impact on mortgage securitization market. First, Dodd-Frank requires lenders to consider certain underwriting criteria and make a good-faith determination that borrowers will have the ability to repay their home loans. Second, the law requires securitization sponsors to retain not less than a 5% share of the aggregate credit risk of the assets they securitize.

Based on the Dodd-Frank Act, CFPB released the Ability to Repay (ATR) rules in 2014. The ATR rules require lenders to consider and verify several different underwriting factors, including debt-to-income ratio and credit history. Lenders must make a reasonable determination that a borrower will be able to pay back the loan. At the same time, it compensates for this added regulation by

1. See Dapeng Hu and Kishore Yalamanchili, "PrimeX—A Roadmap for Investors," *American Securitization* 4(3), August 2010, pp. 19–21.

creating a rule that defines a qualified mortgage (QM). If a loan meets the QM standard, it is presumed to meet the Ability-to-Repay rule and thus provides lenders with a "safe harbor" from buy-back and litigation.

In 2015, the Office of the Comptroller of the Currency (OCC), Federal Reserve Board, Federal Deposit Insurance Corporation (FDIC), Securities and Exchange Commission (SEC), Federal Housing Finance Agency (FHFA), and Department of Housing and Urban Development (HUD) finalized risk retention rules. The rules established several exemptions from risk retention requirements, including for RMBS collateralized exclusively by "qualified residential mortgages," as defined in the rule. Later, the interagency decided to define a QRM in full alignment with the definition of a QM.

Ever since the end of the financial crisis, the nonagency mortgage sector has struggled to revive in the securitization market. For several years, the only securitization activity was issuances of RPL and NPL deals, which were repackaging reperforming or nonperforming loans. Nonagency RMBS securitization began to see nascent activity in 2011. The new deals, dubbed RBMS 2.0 by the industry, were (and continue to be) composed of super-jumbo mortgages made with low LTVs to borrowers with the highest credit scores. As all these mortgages are qualified for QRM, the prime jumbo new origination deals are therefore exempted from risk retention. The deal structures are also mostly simple and straight forward. As shown in Exhibit 25-1, new issuance of prime jumbo deals has since increased over time to more than $10 billion a year in recent years, but it remains a much lower level compared to the dominant agency market.

Given the heightened regulation environment after the financial crisis, banks have steered clear of the nonagency mortgages aside from jumbo prime. The vacuum has created an opportunity for private lenders that are willing to offer credit to borrowers outside agency or super prime. These borrowers may not meet all the QM requirements, hence the term "non-QM." As securitization of these loans would require risk retention, which was a hurdle for many private lenders, the issuance of non-QM deals has been slow until recently. As of May 2020, there have been 124 non-QM deals issued with $42 billion in total balance.

COLLATERAL

Collateral analysis is a key component of relative value analysis for nonagency RMBS. Here we provide an overall review of the major characteristics of nonagency mortgages, their performance, and major issues in analyzing the collateral for legacy nonagency RMBS deals, and RMBS 2.0 prime jumbo deals, as well as non-QM deals.

Key Collateral Drivers for Loan Performance

Different products, vintages, and deals each have different characteristics. These characteristics, together with the macroeconomic environment, drive different prepayment and credit performance.

Coupon rate and fixed vs. hybrid: Coupon rate and weighted average coupon (WAC) refer to the interest rate of a mortgage or the average rate for a pool of mortgages. Higher coupon usually indicates a higher prepayment incentive. On the other hand, a higher than prevailing interest rate at origination often associates with certain credit impairments. Hybrid borrowers are typically more leveraged than fixed-rate borrowers. In addition, the rate reset can cause substantial payment shocks under an increasing rate environment. Therefore, hybrid loans tend to have worse credit performance. In terms of prepayments, hybrids are also very different from fixed rate mortgages.

In the prime jumbo and Alt-A sectors, deals contain either 100% fixed-rate mortgages or 100% hybrid (fixed for several years then floating) mortgages. In the non-QM or subprime sectors, however, deals typically have a mixture of fixed and hybrid mortgages.

Loan-to-value ratio: LTV is the most important factor for mortgage credit performance. There are several LTV measurements. Original LTV is the loan amount to house value ratio at origination. Original combined LTV includes second liens at origination in the loan amount. Current LTV refers to the current loan amount to current house (home price appreciation adjusted) value ratio, and current combined LTV measures the current total loan amount including second liens to the current house value. Current combined LTV measures how little equity the borrower currently has in the house. When the LTV is higher than 100%, the borrower has "negative equity." Their mortgages are higher than the value of the underlying home.

If the original LTV is greater than 80%, lenders typically require borrowers to buy mortgage insurance. Borrowers often avoided buying insurance by taking out an 80% LTV first lien loan while simultaneously getting a second lien loan. This is referred to as a "piggyback."

High combined LTVs lead to high rates of delinquency and default. When a borrower has negative equity, the default option is in-the-money and the so-called rational default rate increases substantially. High LTVs cause high loss severities when a loan defaults. In addition, high LTV loans prepay more slowly because it is difficult for the borrower to obtain a new loan.

Credit score: The mortgage industry started using credit scores in the 1990s. The most commonly used credit score is the FICO score, which is generated by independent credit bureaus for each borrower using empirical models created by the Fair Isaac Corporation (FICO). Scores range from 350 to 900, with a higher score indicating better credit quality. In mortgage origination, FICO is the most important variable to determine if a borrower is prime, subprime, or Alt-A. The average FICO is around 735 for prime borrowers but only 620 for subprime borrowers.

FICO scores help predict credit and prepayment performance, even though the FICO reported in nonagency RMBS data is the FICO at origination. Borrowers with lower FICO scores tend to have worse credit performance. After the financial crises, with the absence of subprime and Alt-A originations, minimum FICO score thresholds for which a borrower could refinance became nearly universal, making it extremely challenging to obtain a new loan with a FICO score below 660.

Debt-to-income ratio and documentation: The debt-to-income ratio (DTI) is a measure of a borrower's ability to pay the loan. There are commonly two DTI ratios in mortgage underwriting, front-end and back-end. Front-end DTI is the ratio of the housing payment (including mortgage payment and escrow) to gross income, also known as housing ratio. Back-end DTI adds all other financial debt and child support to the numerator. As an ability to pay measurement, a high DTI indicates a high payment risk. The level of DTI is a key criterion in defining non-QM.

Lenders often require various documents as proof of a borrower's income and assets. In general, full documentation involves verification of income (W-2, pay stubs, etc.) and assets (bank statements, brokerage statements, etc.). The definition of limited documentation, also known as "low doc." includes stated income, stated assets, no income, and verified assets. A small number of legacy loans were even originated with no documentation. Low documentation used to be prevalent for special borrowers such as small business owners who may have difficulty obtaining regular income documentation. However, in the run up to the financial crisis, these low-documentation loans were used frequently to qualify borrowers who overstated their income ("liar loans").

In addition to the these risk factors, there are several other factors that impact mortgage performance. They include loan size, loan purpose (purchase, refinancing, or cash-out), occupancy (owner-occupied, second home, or investment property), amortization versus interest-only, property type (single house, planned urban development, condo, co-op, town house, and so on), and prepayment penalty (commonly found in subprime and option ARM products and mainly impacting prepayments).

Measurements of Collateral Performance

Key measurements of collateral performance include delinquency, default, voluntary prepayment, and loss severity. Voluntary prepayment and default speeds are quoted as annualized conditional prepayment rates (CPR) and annualized conditional default rates (CDR), respectively. Additionally, the roll rate metrics provide important indicators for near-term future performance. A roll rate is the rate at which previously current or delinquent loans are "rolling" into another status. A transition matrix is a combination of roll rates for each status.

There were two standards of measuring a borrower's contractual delinquency status; the Mortgage Bankers Association (MBA) standard and the Office of Thrift Supervision (OTS, now part of Office of the Comptroller of the Currency), standard. The difference between the two has to do with whether there is a grace period on the receipt of payment. In the MBA method, which is used in the prime and Alt-A market, there is no grace period. In the OTS method, which was used in the subprime market, there was a one-day grace period on the receipt of the payment that effectively lowers the reported delinquency by one full month, as compared to the MBA method. The OTS standard was thus more relaxed than that of MBA.

There is no standard definition for default, but a commonly used one is liquidation, that is, when a previous delinquent loan is liquidated through short sale, foreclosure sale, or REO sale, the remaining balance of the loan is counted as default balance. In the case of principal forgiveness, the forgiven part of principal is counted as default balance as well. Forbearance is sometimes treated as default as well for the balance forborne with a future recovery assumption at the expiry. A short sale is a sale of the underlying property in which the sale proceeds fall short of the remaining balance of the loan. It occurs when a servicer decides that selling the property short is better than going through a costly foreclosure process. Foreclosure is a process in which a mortgagee (or other lien holder) obtains a legal termination of the mortgagor's (borrower) equitable right to redeem the property. There are two types of foreclosure sales. Judicial foreclosure, which is available in every state and required in many judicial states, involves the sale of the mortgaged property under the supervision of a court. Non-judicial foreclosure is authorized by many states if a power of sale clause is included in the mortgage agreement or if a deed of trust with such a clause was used instead of an actual mortgage. After a mortgage is foreclosed, the property becomes REO. The different types of default can have a large impact on the liquidation timeline and recovery rate and thus greatly impact cash flow and timing for a bond.

When a mortgage is liquidated, the net proceeds from selling the home are remitted to the investors. The proceeds from the home sale are net of maintenance fees, tax and interest, homeowner dues, service fees, and servicing advances, while insurance recoveries (if applicable) are added back. Loss severity refers to the loss after recovery as a percentage of unpaid principal balance. Following the financial crisis, because of the surge in defaulted loans, liquidation timelines extended significantly, very often to five years or longer, which contributed greatly to loss severity.

Legacy RMBS Collateral Characteristics

Exhibit 25-2 provides the average characteristics of legacy prime, Alt-A, option ARM, subprime, and second lien collateral.

As shown in the exhibit, legacy RMBS contained a large amount of hybrid-rate loans. Unlike prime or Alt-A hybrids, subprime hybrids were dominated by short-reset products such as 2/28 and 3/27. While most prime or Alt-A hybrids reset every 12 months where the rate can increase or decrease (subject to caps and floors), most subprime hybrids reset every 6 months where the rate can only increase on reset. There were a large number of piggybacks in Alt-A, option ARM, and subprime loans. Legacy prime originations typically required low DTIs, while subprime originations tolerated higher DTIs.

A key feature of Alt-A and option ARM products is the large percentage of loans with limited or no documentation. Without having to fully document one's income, many Alt-A borrowers grossly overstated their income levels in order to qualify for their loan. From 2005 to 2007, the documentation standards were substantially relaxed, and some full-documentation loans could have considerably inflated incomes. As a consequence of the various documentation standards, the historical relationship between credit performance and DTI became obscured.

Another problem for legacy RMBS was the "silent seconds," or second or third liens that were originated after the first lien. During the housing boom from 2004 to 2007, many borrowers took equity out of their houses by borrowing through a home equity loan (HEL) or home equity line of credit (HELOC) outside of the existing first or second lien. This substantially increases leverage and default risk, but neither the first lien holders nor the servicers would necessarily be aware of these loans (hence the name "silent"). Only recently has data on "silent seconds" been made available through credit bureau reports. Exhibit 25-3 shows how severe the problem was—36% of option ARMs, 30% of prime, 30% of Alt-A loans, and 26% of subprime loans have at least one silent second in addition to the first lien and the simultaneous piggyback.

When these problems were layered together, legacy RMBS credit risks increased exponentially. During the 2005–2006 peak of loose underwriting standards, many subprime and Alt-A lenders provided interest-only (IO) mortgages with no down payment. Other common layered risks include high LTV with low documentation and high LTV with high DTI. These loans were extremely sensitive to small declines in home prices because they could easily result in both negative equity and higher future payments.

Legacy RMBS Collateral Performance

The four panels in Exhibit 25-4 show the historical performance across major products. Voluntary prepayment speeds had declined substantially for all products after the crisis. This was a consequence of increasing delinquency rates, higher current LTVs, tightened underwriting standards, and vanished subprime and Option ARM origination. While prime jumbo speeds have demonstrated some sensitivity to interest rate movements, prepayments for subprime, Alt-A, and Option ARM have been mainly driven by housing prices rather than by interest rates. Delinquency rates rose sharply from 2006 and peaked in 2009. They stayed at an elevated level until 2012 and then started to fall as credit burnout kicked in and the housing market recovered. Subprime default rates peaked in 2008 and have been slowing since 2009 as loan modification requirements and foreclosure documentation issues substantially extended foreclosure timeframes. Default liquidations peaked in 2012 for AltA, Option ARM, and prime jumbo. Loss severity increased greatly from the lows of 2006 and reached a plateau in 2009. Given the massive amount of defaulted loans and loan modification requirements, the mortgage liquidation timeline has become extremely long, hovering around five-plus years on average recently. With the increased liquidation timeline, severities continued to remain at elevated levels despite the housing recovery.

EXHIBIT 25-4

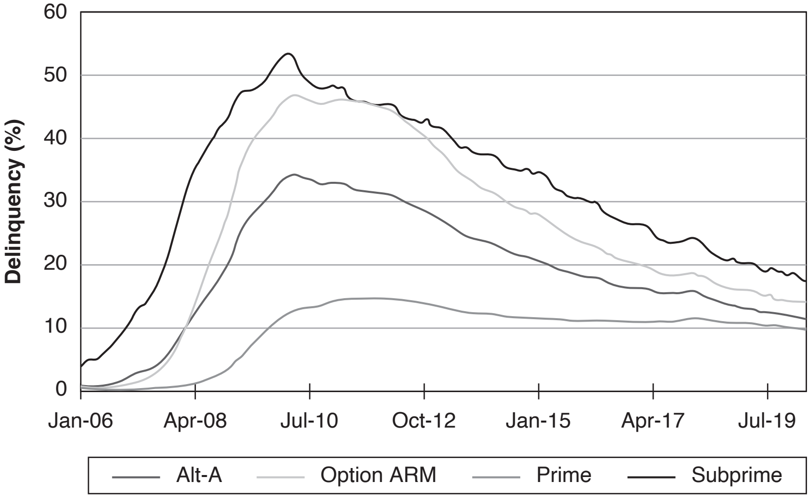
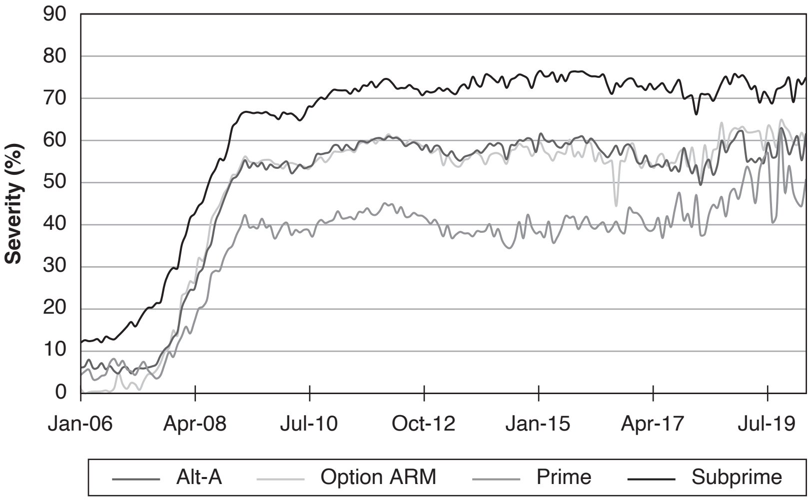
Historical Performance Across Major Products (*Continued*)



c. Delinquencies



d. Loss Severity

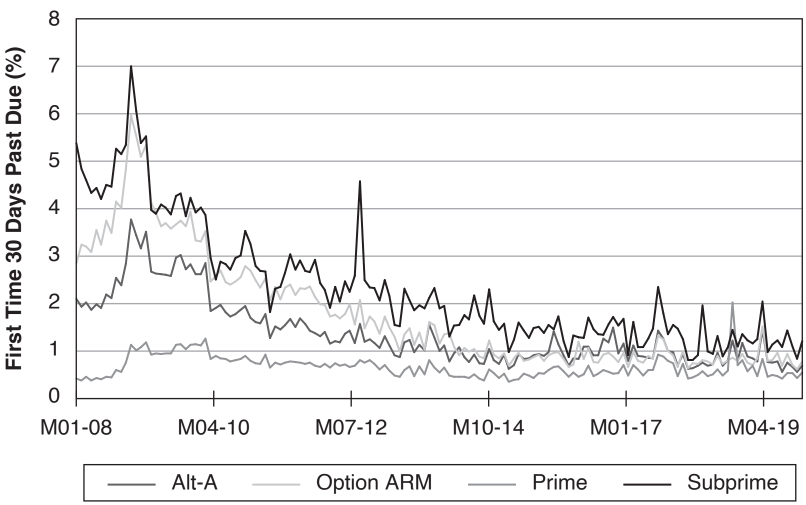
Credit Burnout

After delinquency reached its peak in 2009, subprime mortgage performance started to show signs of improvement. The stabilization can be partially attributed to credit burnout. There are two mechanisms for credit burnout. In a pool of loans, the loans with the worst credit quality will become delinquent and exit the pool, leaving loans with better credit quality remaining in the pool. After flushing out the weakest borrowers from the pool through defaults, the performance of a pool of loans improves because the remaining loans are of better credit quality. Another mechanism is at the loan level. If a high LTV loan is underwater for a long period but the borrower continues to pay, the chance of the borrower becoming delinquent tends to decrease.

Credit burnout can be observed through declines in the first-time delinquency rate. As shown in Exhibit 25-5, the new delinquency rate reached its peak at the end of 2008 and started to decline in 2009. The trend is quite clear for subprime, Alt-A, and option ARM collateral. Credit burnout was less pronounced in prime jumbo collateral. As a consequence, the default and credit performances of various legacy RMBS types tend to converge overtime. See defaults and delinquency trends in Exhibit 25-4.

EXHIBIT 25-5

First-Time Delinquency Rates Since 2008



Servicing Concerns

Collateral performance varies greatly among servicers. While this is partly due to the collateral type and characteristics, differences in servicer behavior have attracted much attention in the industry. Servicer variations are observed in many aspects of deal performance, including liquidation timelines, stop-advance rates, utilization of short sales, and loan modifications.

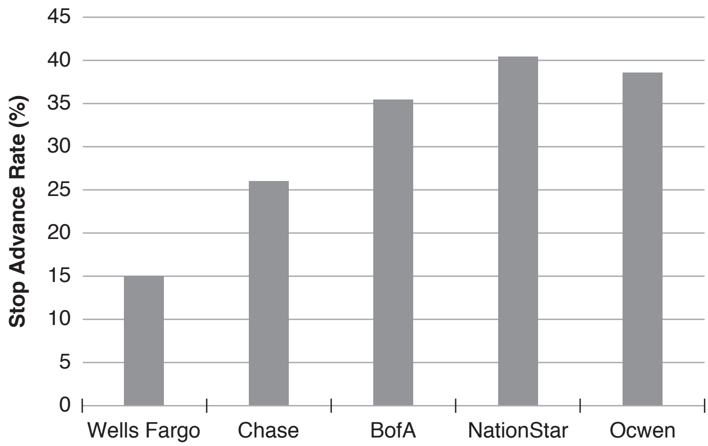
Some servicers are more aggressive and are more efficient in liquidating distressed properties and, as a consequence, the liquidation timeline (time from a loan becoming delinquent to default to liquidation) is much shorter for these servicers. Investors prefer shorter timelines as the recovery can happen earlier, fees are lower, and loss severity tends to be lower.

Service Advance and Stop Advance

In most nonagency deals, the servicer is required to advance delinquent principal and interest (P&I) to the trustee to the extent that it is deemed recoverable. Most RMBS transactions permit the servicer to be reimbursed for advances at the top of the trust payment waterfall.

EXHIBIT 25-6

Stop-Advance Rates by Servicer (as of March 2020)



The high delinquency rates and increased foreclosure and REO timelines after the financial crises had caused liquidity challenges for many servicers that were advancing into RMBS. Additionally, the cost of servicing a delinquent loan had increased and in some cases a servicer may not be able to recover all of its costs from the liquidation proceeds. Consequently, there had been an increasing trend for servicers to stop advances.

There are also large servicer variations, as can be seen in Exhibit 25-6. Servicers with difficult financing are more likely to stop advances. On the other hand, servicers within large banks tend to have a lower stop-advance rate. Servicers that push for more short sales also have lower stop-advance rates.

The impact of stop advance on loss severity comes from savings on advanced principal and interest payments. The more months that the servicer stops advancing, the fewer payments that will be deducted from the liquidation proceeds and therefore the severity will be lower.

Loan Modification

Although loan modifications were always available to servicers as a loss mitigation tool, they had never been widely applied before the crisis. As mortgage delinquencies worsened in 2007, the government started asking mortgage servicers to increase their loan modification efforts to try to keep people in their homes. Several guidelines or programs were created by various government agencies. Many failed due to lack of practical clarity, lack of servicer incentive, and lack of mechanisms to prevent corresponding moral hazards. In 2009, the government introduced the Home Affordable Modification Program (HAMP). HAMP set forth a standard model to determine the net present value of modifications and provided monetary incentives for servicers to participate. HAMP was implemented by most servicers.

There are several types of modifications. The most common approach is recapitalization, in which the accrued interest on a past due loan is rolled into the principal. Sometimes this is accompanied by a term increase, but more often a recapitalization results in an increased monthly payment. A more effective type of modification involves reducing the interest rate of the mortgage, which can reduce the borrower's monthly payment without an immediate principal loss to investors. Principal forgiveness and forbearance are more aggressive approaches, but also the most direct to address the negative-equity issue that borrowers face. Under principal forgiveness, the borrower is forgiven for a certain amount of remaining balance of the loan, which lowers the LTV. Under principal forbearance plan, the remaining balance is due as a balloon payment at maturity.

Subprime mortgages had experienced the highest ratio of modifications or re-modifications, with more than 80% of subprime loans having been modified at least once. There have been fewer modifications in Alt-A loans, but generally the pattern is similar to what is observed in subprime modifications. The number of modifications in Option ARM has been relatively smaller, but the most common type is principal forgiveness or forbearance. Prime jumbo modifications are not as common.

The success rate of modification has varied over time and between servicers. Recidivism, or re-default after a modification, was a challenge to modification policy. In the years just after the crisis, the recidivism rate was very high. When recapitalizations were the most common type of modification, re-delinquency rates within the first year of modification surpassed 60% for subprime. After HAMP was implemented, in the second half of 2009, delinquency rates fell due to the greater use of interest rate and principal modifications. Principal modifications are particularly effective for borrowers with negative equity.

The impact of modification for bond investors depends on the type of bond, where it is in the capital structure, type of modification, and recidivism rate. When recidivism is high, modifications typically do not materially change the cumulative loss to the bonds but delay defaults, thereby extending the WAL of the bonds and lowering their implied yields. Under most pool servicing agreements, servicers can modify a borrower's mortgage if they feel that it will benefit the trust by increasing expected recoveries or making timely payments more likely. If expected default and loss severity levels are high without modification, then modifying loans can actually lead to more cash flowing to the trust. However, for high-risk loans, the re-default risk also tends to be high if modified. So, it is largely up to servicers' discretion on which loans to modify and how many loans to modify.

Prime Jumbo New Origination Collateral Characteristics

New issuance for the nonagency market made a comeback starting in 2011, and since 2013 annual issuance levels have ranged between $15 billion and mid-$20 billion. Exhibit 25-7 shows the history of issuance. While there has been some adjustable-rate loan origination, Pct. FRM shows that fixed-rate loans comprise the vast majority of collateral in this asset class. Average loan sizes have drifted lower over the years, yet as Pct. of Non-conforming shows, almost all the loans continue to be jumbo loans.

The peak in origination in 2013 was due to historically low mortgage rates at that time, and most of these originations were for refinance activities. The peak seen in 2018 occurred where rates were elevated and the high level of purchase loans indicates that the platform had grown to include new business. Credit has been slowly loosening as can be seen in the drift toward lower OALS, higher OLTV, and lower FICO.

Exhibit 25-8 investigates the credit loosening in more detail by plotting the 20%, 50%, and 80% quantiles of OALS, OLTV, and FICO by deal vintage. The shift over the years to lower OALS happened for both the 80% and the 20% quantiles, yet the 80% quantile fell more, and thus produced a compression in the variability of loan sizes. For OLTV and FICO, the greatest move was in the 20% quantile, with FICO falling 20 points from 2011 to 2019.

Prime Jumbo New Origination Collateral Performance

Prime jumbo new origination prepayment performance has been varied over the past few years, as is shown in Exhibit 25-9. Prepayments remained at levels typical for turnover activity prior to 2019. Yet from the beginning of 2019 until mid-2020, as mortgage rates rallied from their highs in November 2018, prepayment speeds have hastened reaching levels nearing 50%.

EXHIBIT 25-7

EXHIBIT 25-8

Prime Jumbo New Origination OALS, OLTV, and FICO Issuance Quantiles by Deal Vintage

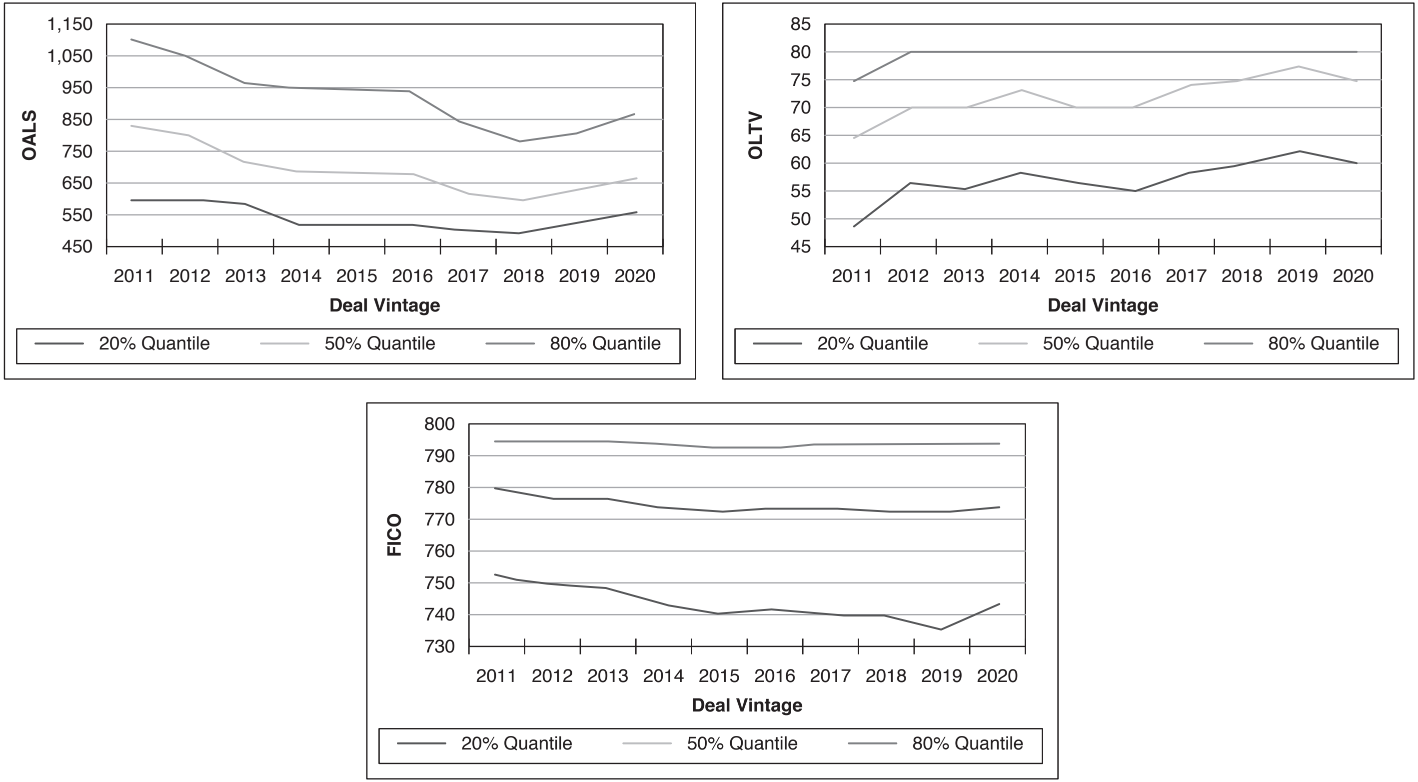

EXHIBIT 25-9

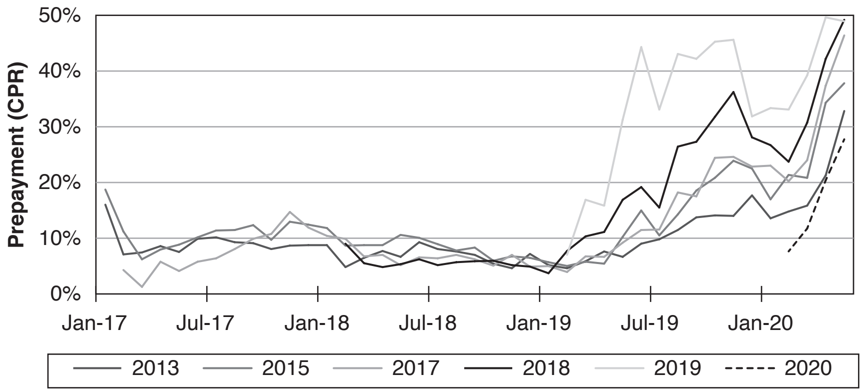
30-Year FRM Prime Jumbo New Origination Prepayment by Date Stratified by Deal Vintage



The prepayment behaviors known as the S-curve and the seasoning ramp are major differentiators of prepayment speeds for this asset class and are highlighted as follows.

S-curve: Strong sensitivity to interest rates is observed for new origination mortgages (Exhibit 25-9). Exhibit 25-10 plots s-curves, using WAC spread defined as the contemporaneous difference between loan rates and jumbo rates. The strength of prepayment response can clearly be seen in the s-curve chart stratified by WALA; for loans with between 7 and 12 months seasoning, prepayment rises from 20.1% at a WAC spread of 0.0% to 44.2% at a WAC spread of 0.5%.

Seasoning: Prime Jumbo New Origination loans have a steep seasoning ramp (Exhibit 25-11), peaking at eight months of age. It is interesting to observe that seasoning occurs even for loans that have WAC spreads from –0.5% to 0.0%.

Sensitivity to other key attributes is shown in Exhibit 25-12. Actual response to average loan size (ALS) indicates that larger loan size loans tend to prepay less in this asset class. While Current LTV is typically a strong driver, especially when it reaches levels near 100 and higher, prime jumbo new origination collateral were originated with low LTVs and experienced only positive HPA trends during their history. Thus, this collateral has exclusively lower than 80 current LTVs, levels at which this variable plays a limited role in determining prepayment speeds. Strong curtailment behavior is seen from both ALS and Current LTV curves. Higher FICO borrowers are observed to prepay slightly faster than lower FICO borrowers, as expected.

EXHIBIT 25-10

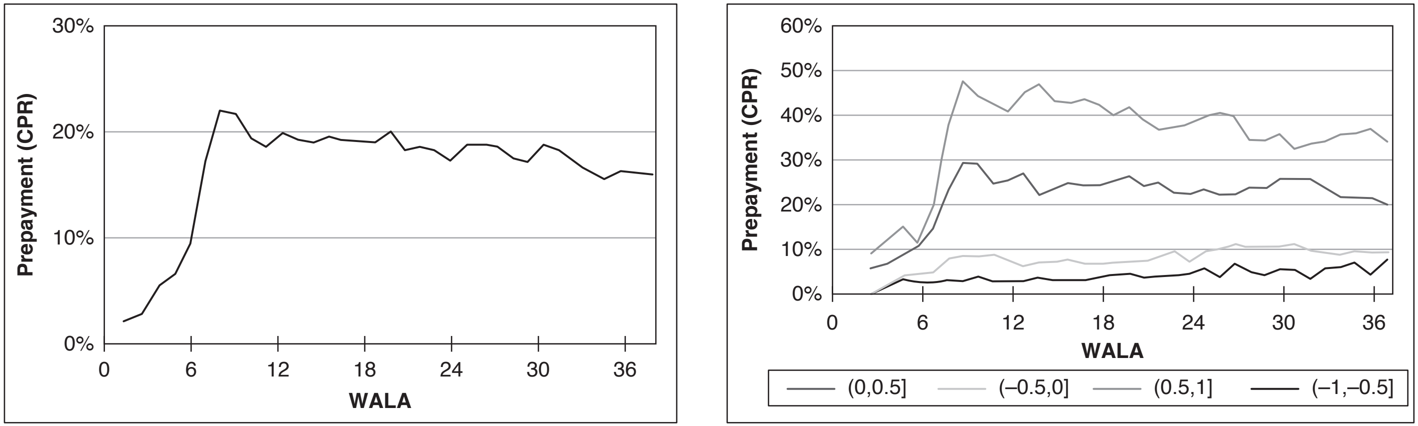

EXHIBIT 25-12

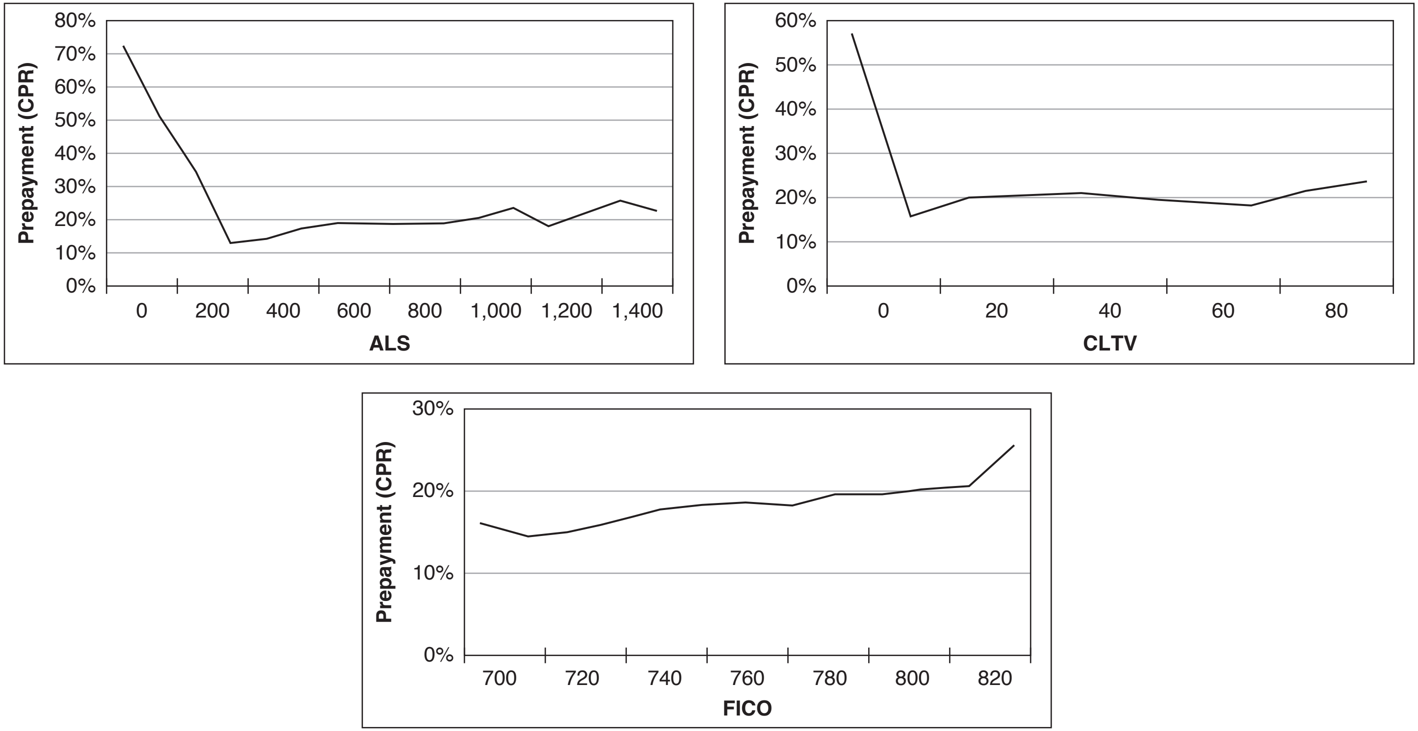
30-Year FRM Prime Jumbo New Origination Prepayment Loans Response to ALS, Current LTV, and FICO



Note: Records are restricted to WAC Spread between –1% and 1% and WALA between 7 and 12 months.

Non-QM Collateral Characteristics

Recall that Exhibit 25-1 details the historical levels of non-QM issuance since 2014. The overall issuance has increased substantially from $384 million in 2015 to over $21 billion in 2019; the origination balance nearly tripled in 2016, 2017, and 2018. Issuance in 2020 has been $6 billion at this writing (May 2020), but is likely to be constrained by the ongoing Coronavirus pandemic.

As of May 2020, the total origination balance for nonagency non-QM deals is $41.9 billion, with over half coming from the top five originators, as listed in Exhibit 25-13. Angel Oak, Verus, COLT, and Deephaven are among the leading pioneers in this newly established market.

EXHIBIT 25-13

Non-QM Issuance by Top 5 Originators

Data Source: Intex and BlackRock Solutions

Key non-QM deal loan characteristics are detailed in Exhibit 25-14. Note that the data here do not include the entire universe of new issuance loans, yet does include the vast majority which was verified by comparing loan data across vendors. For non-QM deals issued between 2015 and 2020, the average LTV is 72, FICO is 716, DTI is 36, and loan size is $452,000. In terms of loan type, only 38% are FRM and 31% have conforming balance. Finally, OWAC is relatively high at 6.3%.

Important to note is the drift of loan characteristics over time. Most significantly, the percentage of low- or no-documentation loans increased from 11% in 2015 to 63% in 2019 (these were percentages of records where documentation is known), showing a large shift to looser credit standards. Although this statement must be tempered as the percentage of loans (by balance) that have documentation type disclosed has plummeted from 100% to 74% for these two vintages. Average loan size increased from $339,000 in 2015 to $458,000 in 2019. Mitigating these trends are slight drops in LTVs (from 75 in 2015 to 72 in 2019) and increases

EXHIBIT 25-14

Data Source: CoreLogic and BlackRock Solutions

Note: The Pct. Low Doc column is the weighted averaged of low and no documentation loans when documentation is known.

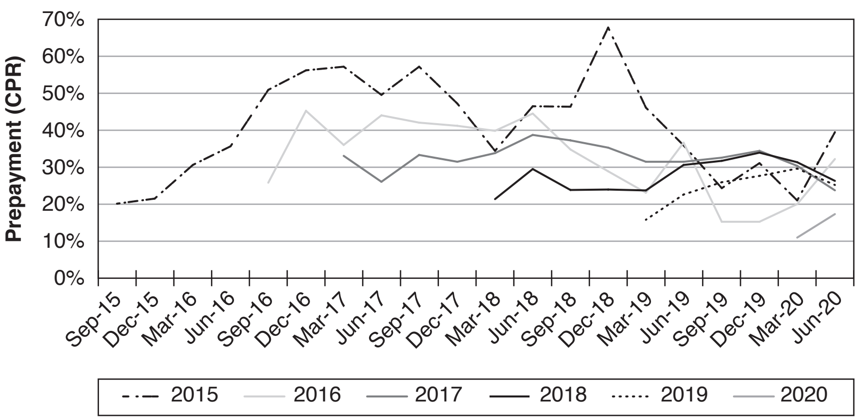
in FICOs (from 694 in 2015 to 717 in 2019). Note that for non-QM loans, the average FICO for full-documentation and for low-documentation borrowers is 705 and 723, respectively, showing that there is a tradeoff between FICO and documentation. Although the non-QM market is expanding to include more low-documentation borrowers, the overall credit profile remains sound given that the credit scores of low-documentation borrowers are scrutinized to ensure the credit quality of the loans.

Non-QM Collateral Performance

One important feature of non-QM collateral performance is elevated prepayment speeds, which can be seen in Exhibit 25-15. Prepayment speeds overall have been 30% CPR or higher and in some cases have been near 60% CPR. Compared this to legacy Alt-A, which in aggregate did not reach 20% CPR, and to prime jumbo new origination, which in aggregate ranged from 5% to 50% CPR. Speeds for seasoned non-QM collateral have abated somewhat since the start of 2019, yet remain generally above 20% CPR.

EXHIBIT 25-15

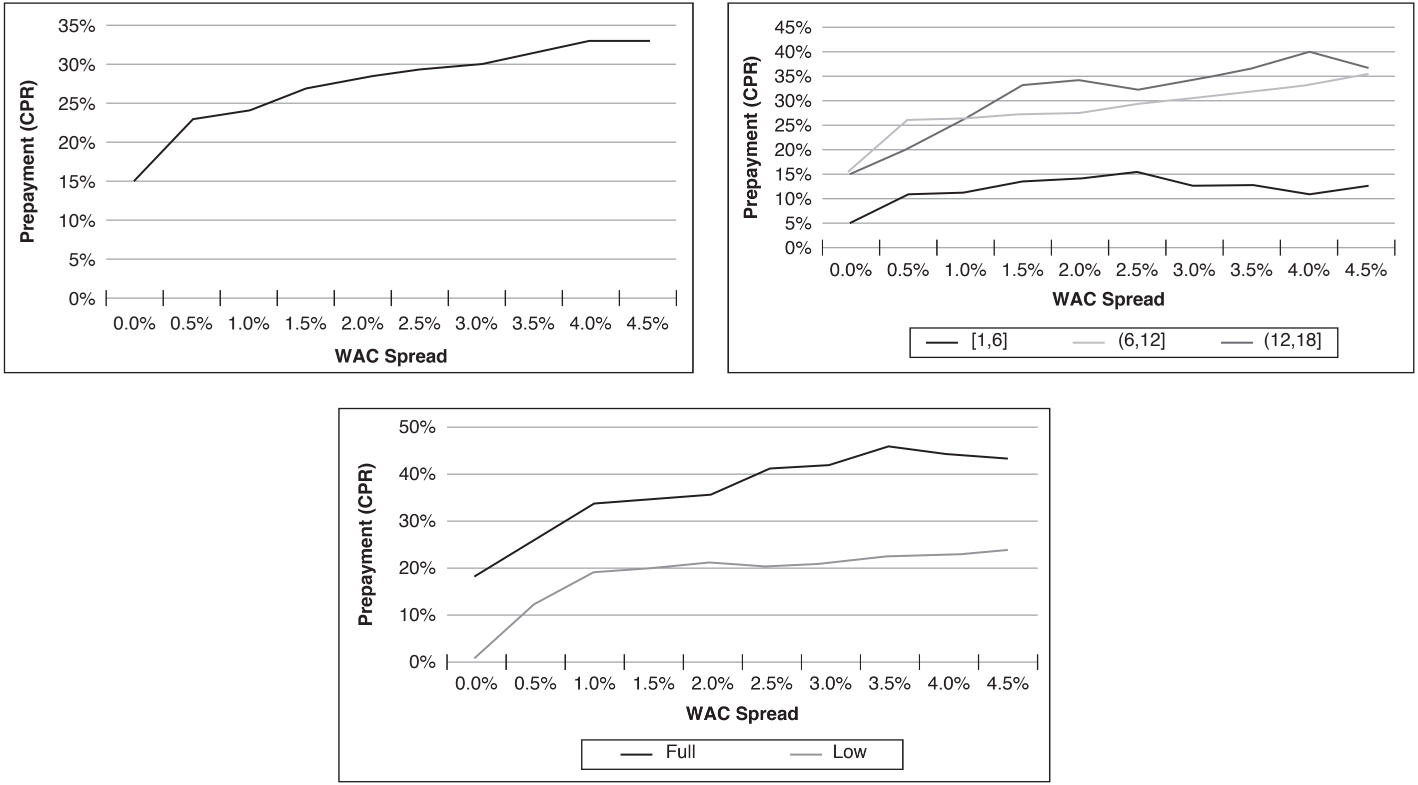
Non-QM CPR by Date, Aggregated Quarterly, Stratified by Deal Vintage



Non-QM loans are typically issued with relatively high interest rates (on average 6.3%). These loans are thus susceptible to having strong prepayment incentives if their credit circumstances change (credit curing, lowering of DTI, etc.). To measure the strength of prepayment incentive, Exhibit 25-16 shows a strong response between monthly prepayment speed and WAC spread. The WAC spread is defined against the corresponding product market reference rate, for example, Jumbo FRM 30Y for nonconforming balance 30-year amortizing

EXHIBIT 25-16

Non-QM Prepayment Loans S-Curves Stratified by WALA and Documentation Type



Note: The Documentation Type plot uses loans with WALA between 7 and 12 months.

loans and Conforming 5/1 ARM for conforming balance 5/1 ARM loans. CPRs increase from 25% to 30% as WAC spread goes from 1.0% to 2.0%. Note that this is significantly less steep than for prime jumbo new origination. As the majority of non-QM borrowers are deep in-the-money, moderate amounts of credit curing have the potential to elevate prepayment speeds.

Non-QM deals also have a strong seasoning ramp, as can be seen in Exhibit 25-17. Prepayment activity ramps up quickly, reaching near 35% CPR in the loan's first year. The seasoning ramp is stratified by WAC spread in the right-hand chart and shows that all but the lowest WAC spread show a quick ramp. When stratifying by documentation type, bottom chart, loans with low documentation have significantly lower speeds than those with full documentation.

Non-QM deals show better credit behavior compared to legacy Alt-A. Deterioration rates are slower and curing rates are much faster for non-QM deals than legacy Alt-A deals. Exhibit 25-18 shows that the current clean-to-30-day delinquent roll rate by loan age for non-QM deals is generally below 1% while for Alt-A deals it reaches almost 2%. The right-hand chart indicates that the 90-day delinquent-to-current roll rates for non-QM deals are generally around 10%, much higher than for Alt-A deals, where this rate drops to around 3% after seasoning. This suggests that the non-QM deals are backed by better credit loans and that once loans go delinquent active actions may be taken to help the loans cure.

CAPITAL STRUCTURE

Nonagency RMBS deals are structured to manage the two principal risks inherent in residential mortgages: prepayment and credit. The structure separates aggregated cash flows from the underlying loans into principal and interest and redistributes the cash flows and associated losses to individual tranches (bonds) according to rules specified in the deal prospectus (this is known as the waterfall).

From a prepayment point of view, many nonagency RMBS work similarly to agency CMOs. They manage prepayment exposure and average life variability through time-tranching the cash flows, that is, each senior tranche has a different expected maturity and expected time window for principal repayment. Actualized maturities will vary based upon realized prepayments, but the bonds are marketed based upon assumed prepayment speeds. One complication is that in nonagency RMBS the recovery from a credit default is treated as prepayment.

Many senior classes of RMBS deals also include specialty tranches which provide additional exposure or protection to mitigate prepayment risk. Some of these include planned amortization classes (PAC) and companion (support) bonds, nonaccelerating senior bonds (NAS), interest only (IO), inverse IO (IIO), and principal only (PO). These are often created to cater to specific investors' preferences. In general, they make up a small percentage of total RMBS issuance, but it is important to carefully examine each tranche for cash-flow timing. Because these classes are analogous to those in an agency CMO, we are not going to cover them in this chapter.

EXHIBIT 25-17

Non-QM Prepayment Seasoning Ramps Stratified by WAC Spread and Documentation Type

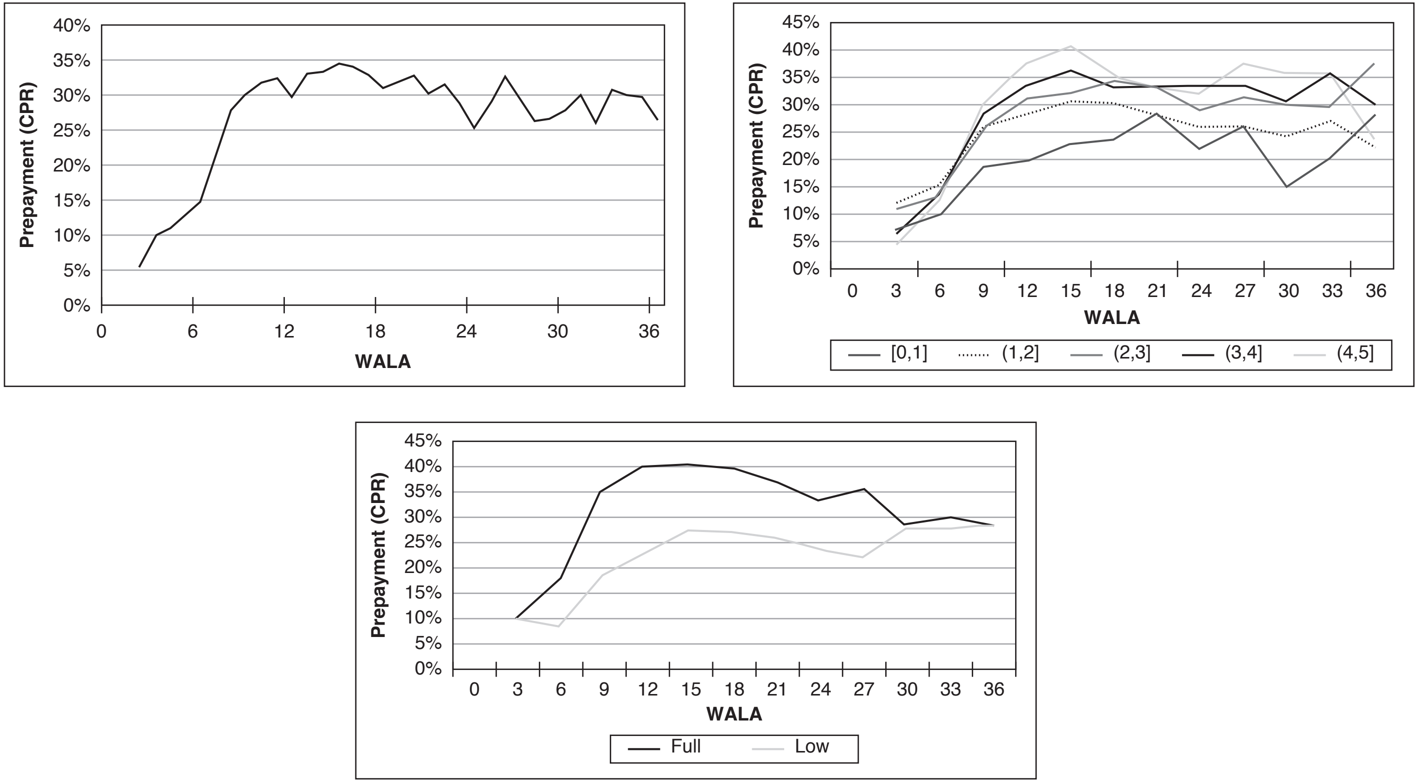


EXHIBIT 25-18

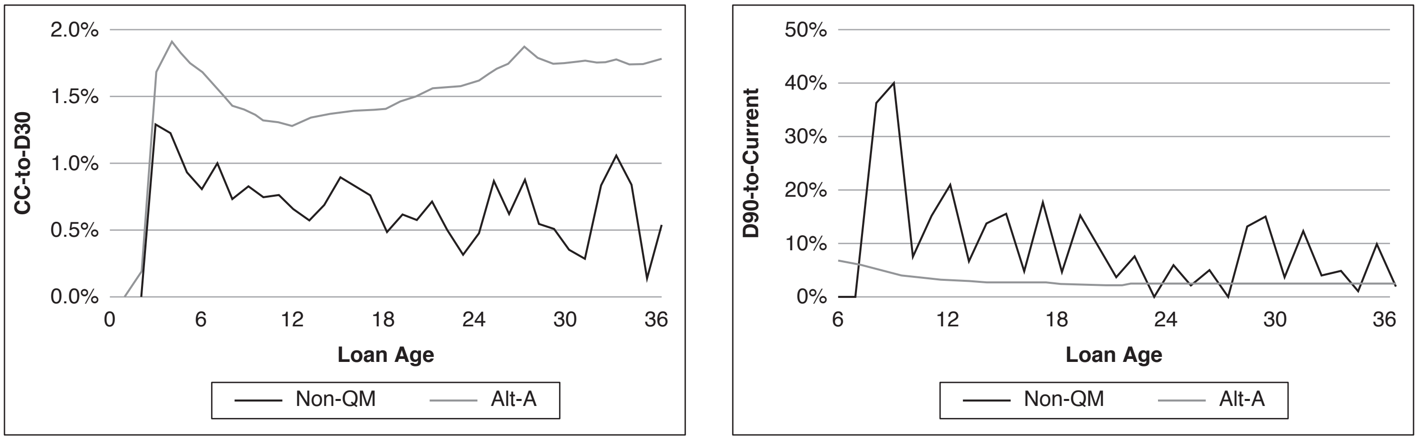
Non-QM and Alt-A CC-to-D3 and D9-to-CD Transitions by Loan Age



Credit risks in nonagency RMBS deals were addressed through credit enhancements: external, internal through deal structure, or both. Credit enhancement levels are established to reasonably insulate senior bond investors from the risk of losses. In practice, issuers structure deals to maximize the issuance of AAA bonds since this maximizes the total deal proceeds. Deals that are backed by loans of high credit quality require less subordination than deals that are backed by loans of low credit quality.

External credit enhancements, primarily bond insurance, were commonly used in the early stages of the nonagency securitization business. Since the early 2000s, internal credit enhancements through deal structuring became the dominant method.

There are two major internal credit enhancement structures, senior/subordination (senior sub) and overcollateralization/excess spread (OC/XS). For deals with moderate credit concerns, such as most prime jumbo deals, credit support relies entirely on redirecting losses to lower tranches. A deal typically has AAA-rated senior classes (groups of bonds that are pari pasu with respect to collateral losses) and subordinate tranches rated from AA to B. The prepaid principal is allocated to the senior tranches first and is then allocated down the deal structure while the losses are absorbed from the bottom up. This is known as the senior/subordination shifting interest structure. For collateral with greater credit loss concerns, as is the case with subprime loans, additional layers of support were often added to the senior/sub structure through extra collateral principal and/or interest. This is the OC/XS structure. Alt-A deals and early vintage deals are more likely to have the senior/sub structure, while deals originated after 2004 increasingly utilized the OC/XS structure.

Fixed versus floating coupon: While deals backed by ARM collateral (hybrid and option ARM) mostly issue floating coupon bonds, deals backed by fixed-rate mortgages can issue both fixed and floating coupon bonds. While the underlying collateral is fixed, floating-rate bonds can be created by simultaneously creating an inverse IO tranche where the coupon is inversely correlated to the underlying index. Almost all residential ABS (subprime, HEL, and MH) and option ARM bonds have floating coupons. Prime, Non-QM and Alt-A deals can issue both fixed rate and floating rate bonds.

Sequential versus pro rata payment: Sequential and pro rata refer to the method of distributing payments across the classes in the deal. For sequential structures, the senior class tranches are paid principal sequentially with all principal going to one tranche until it is paid-in-full, before the next senior tranche starts to receive all principal payments, and so on. Pro rata refers to making payments proportional to each tranche's unpaid principal balance. For senior tranches with the same seniority, principal payments can be sequential or pro rata, but losses are mostly pro rata. Sometimes there are further hierarchies in AAA classes, with senior support bonds receiving losses before super senior bonds.

Lockout period: Subordinate bonds are locked out of receiving prepayments for a period of time after deal settlement. The lockout periods for prime and Alt-A deals are typically 5 to 10 years, while lockout periods for subprime deals are almost always 36 months. At the end of the lockout period, if the collateral performance meets or exceeds minimum credit conditions, determined by what are known as trigger tests, prepayments can flow into junior classes.

Triggers: To ensure that the credit support is still intact during the period when deals are most likely to experience losses, many deals contain a series of trigger tests to place limits on the amount and timing of any release of credit support (i.e., repayment of principal to the owners of the OC and/or subordinate bonds). The most common trigger is a delinquency test, which allows credit support to be reduced only if the 60+-day delinquency ratio is low in relation to the current senior credit enhancement level, expressed as a percentage of the current outstanding balances. Other trigger tests include the factor test, requiring that the pool be paid down by at least half (i.e., the pool factor must be at or below 50%), the credit support level test, which requires that the senior credit support level (in percentage terms) has at least doubled, and the cumulative loss trigger test, which limits principal payments to the OC and/or subordinate bonds if cumulative losses exceed some target level.

Linear or Y-structure vs. H-structure: A deal can have one or several collateral groups. The linear structure is the most straightforward as it only has one collateral group and the cash flows from the single collateral group are distributed to all bonds. The Y-structure is a slight variation of the linear structure. In this structure, all of the subs and mezzanines receive cash flows and are assigned losses from all collateral groups. Yet at the AAA level, the collateral is divided into two groups by loan size (conforming vs. jumbo balance) or by coupon type (fixed rate vs. adjustable rate). Each AAA bond receives payments (including principal prepayments) from only one of these two groups. The separation was intended to provide convenience for the GSEs to buy bonds backed by conforming-size loans or large insurers to buy bonds backed by fixed rate loans. In the H-structure, there are two (or more) sets of mezzanine tranches and collateral groups and each mezzanine tranche is supported by each collateral group, respectively. Each set of mezzanine tranches supports its own senior tranches. There is often cross-collateralization between groups in H-structure deals: after interest payments are made to bonds in one group, available funds from that group can be used to pay interest to bonds from another group. Among other things, this feature can also affect the value of residuals.

Clean-up call provision: Before turning to the details of each type of structure, there is a final provision that is very common to nonagency RMBS deals, similar to agency CMOs—the clean-up call. The clean-up call gives the owner of that call, who is generally the residual holder, the option to purchase the remaining bonds at a pre-specified price, usually at par plus accrued interest, when the factor is at or below certain threshold, typically 10%. The main purpose of the clean-up call provision is to minimize administration costs but it also adds additional risk to senior bond or IO holders. A deal is more likely to get called if the collateral is clean with premium coupons and less likely to get called if it is distressed. When exercised, the call shortens the payment window and the average life of the back-end tranches. If the clean-up call is not exercised when the factor is below the threshold, there is typically a *step-up in coupon* provision, which requires a moderate increase in coupon for the bonds that are still outstanding.

Senior Subordination Shifting Interest Structure

Senior/sub is the most direct approach to generate credit enhancement for senior tranches. In this structure, the senior classes (AAA-rated) typically have six supporting classes (AA, A, BBB, BB, B, and unrated), hence these structures are referred to as "six-packs." The AA, A, and BBB classes are called the mezzanines as they are still investment grade, and the BB, B, and unrated residual classes are often referred to as subs. There is a lockout period at the early age of the deal when all of the unscheduled principal payments are allocated to the senior tranches and the subordinate bonds are locked out from receiving prepayments. The losses are absorbed from the bottom up, starting from the unrated piece, which is often called the "first loss" piece. At the end of the lockout period, if triggers are passed, the subordination will start to receive prepayments pro rata.

Exhibit 25-19A illustrates the capital structure of a prime jumbo fixed-rate RMBS deal. In this deal, 96.1% of the total collateral was designed as senior AAA tranches (excluding the IO, which is nominal based). Those tranches were supported by 3.1% of mezzanine tranches and 0.8% of subs.

There is one IO tranche that receives interest based on all the deal collateral balance. IO tranches are present in most six-pack structure deals. Although it is not the case in this deal, sometimes IO tranches are used to manage the differences between collateral interest payments and bond interest liabilities (essentially the excess spread).

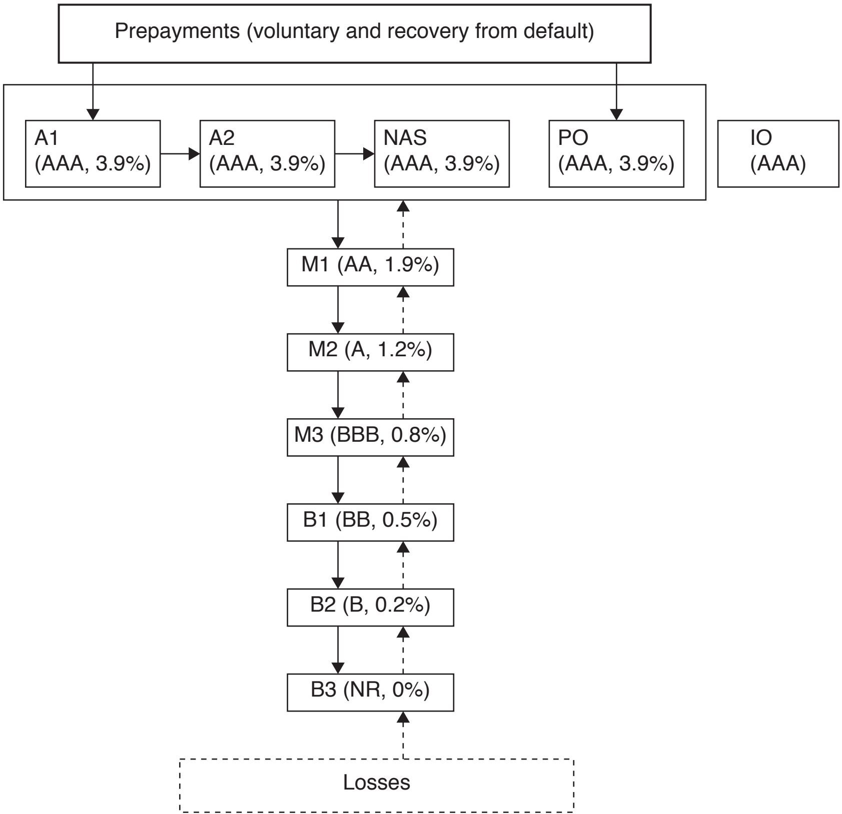
When prepayments are received before the lockout period (in this case, five years), they first go to senior tranches. Prepaid principal only flows down to mezzanines and subs after the lockout expires and trigger tests are passed. Within the senior tranches, A1 and A2 are sequential so that A2 will not get any principal until A1 is paid off. A3 is a nonaccelerating fixed pay bond that receives only a fixed interest strip in the first five years and then amortizes down on a fixed schedule (hence the name). PO and A1 are pro rata for all principal payments.

After the lockout period, if the shift-interest trigger test, measured by delinquency rate, is passed, prepayments will start also flowing to the mezzanines and then to the subs. If at any point the trigger test fails, all of the unscheduled principal will be re-directed back to the senior bonds.

It is important to note that in shifting interest structures, mezzanines and subs are receiving scheduled principal payments (and scheduled interest) during the lockout period. This is different from typical OC/XS structures. In the case of very slow prepayment speeds, as seen in many fixed-rate Alt-A deals, this

EXHIBIT 25-19A

Illustration of the Shift Interest Structure for a Legacy Prime Jumbo Deal RFMSI—2005 S8



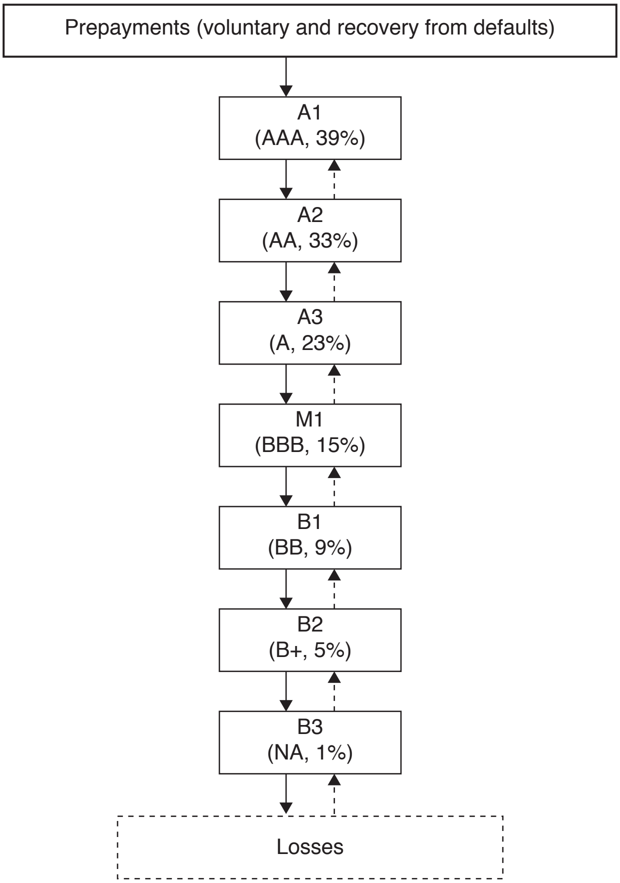
amortization can help shorten the WAL of mezzanine tranches substantially in senior/sub deals compared to that in OC/XS deals.

Losses will be absorbed first by the B3 class and then from the bottom up to other subs and the mezzanines subsequently. If losses penetrate all the way through M1, they will be distributed to all the senior tranches (A1, A2, A3, and PO) pro rata. Note how thin (i.e., small size) these credit cushion classes are. It is not surprising to see the entire sub or mezzanine classes get wiped out (in fact, in this particular deal all sub and mezz tranches were wiped out).

The shift-interest structure was designed mainly to deal with prepayment risk for senior bondholders. Obviously if losses come in much higher than the support level, senior bonds will suffer significant principal write down because of the thin enhancement. In recent non-QM deals, credit support levels for AAA

EXHIBIT 25-19B

Illustration of the Shift Interest Structure of a Non-QM Deal HOFI Trust—2018 2



bonds have been much higher. See Exhibit 25-19B. In addition, the overall structure of non-QM deals are also much simpler than Alt-A deals.

Overcollateralization and Excess Spread

When collateral credit loss becomes a large concern, issuers typically use the OC/XS structure to add extra layers of protection. Most subprime deals and a large number of option ARM and Alt-A deals use this structure. Given credit pressures, some 2007 prime jumbo deals also adopted this structure.

OC/XS also uses the senior, mezzanine, and subordinate framework, but it adds extra collateral so that the collateral balance backing the deal is larger than the total balance of its bonds. In addition, the note rates of subprime or Alt-A mortgages are typically high, allowing collateral WAC (weighted average coupon) to be higher than the WAC of the underlying bonds. As a consequence, there can be extra interest payments (excess spread) each month. In terms of the order of absorbing losses, XS spread is the first line of defense, OC is the second, and the traditional subordinate tranches provide the final protection before losses reach senior tranches.

OC target: There is a predetermined OC target, for example, 2% of deal collateral, before the step-down date. At the inception of a deal, OC can be anywhere from 0 to the target (OC fully funded). If OC is not fully funded at inception, excess spread (after covering losses) will be used to build up OC. When OC is at its target, excess spread will go to the residual holder. For deals with fully funded OC at inception, there is typically a NIM (net interest margin) class to receive excess spread. NIM tranches are often owned by residual holders. After the lock-out period ends (step-down date) and trigger tests are passed, OC is allowed to be released or step-down gradually into either the NIM or residual holder, on the condition that senior bonds have pre-determined levels of support. If triggers fail, the OC step-down can be stopped, or it can step-up.

Step-down: The step-down date refers to the time when junior bonds can start to receive principal and the OC can start to be released. It is typically the later of 36 months and the date at which the senior credit enhancement doubles the original CE or reaches a pre-determined level.

In addition to the credit enhancement requirement for step-down, there are also many collateral performance trigger tests to control the direction of cash flows starting at the step-down date. Delinquency and cumulative loss triggers are quite common. These triggers are designed mainly according to accommodate rating agencies' requirements.

Different from a six-pack deal, junior bonds in OC deals do not receive any principal until the step-down date and performance triggers are passed. The junior and mezzanine bonds can only start to receive principal after the deal step-down and once senior classes have been paid off. Because of the large losses, the vast majority of the junior and mezzanine tranches in such deals had never received any principal since inception. In fact, most of them had been wiped out by losses.

Compared to six-pack deals, the OC/XS structure is much more complicated. There are also more trigger events, which can make a bond's cash flows extremely volatile because small changes in performance can trigger large swings in the cash-flow waterfall and have a major impact on a bond's valuation. Even though most triggers were set according to the rating agencies' requirements at the time to protect senior tranches, all senior bonds in such structure were downgraded and many by several notches. Further, because most OC/XS deals pay floating rates to their bonds, there are additional complications in the structure to manage the mismatch of collateral cash flow versus bond payment and to hedge interest risk. This substantially increased the uncertainty of future cash flows and made it very difficult to properly analyze these deals. This structure has not been used in new issuances post-crisis.

External Credit Enhancements

External credit enhancements are third-party guarantees that provide for loss protection against losses up to a specified amount. Typically, external credit enhancements include pool insurance, letters of credit, bond insurance, and reserve funds.

Pool insurance is lender-paid mortgage insurance at the pool level covering bankruptcy cramdown–related losses, losses due to fraud in origination, or losses due to special hazards not covered by homeowner insurance. A letter of credit (LOC) is a financial guarantee by the issuing bank. LOC is one of the oldest forms of credit enhancement yet has rarely been used in recent years. Reserve funds are straight deposits of cash generated from issuance proceeds. The fund typically invests in money market instruments. While reserve funds are common in auto and other consumer ABS deals, they are less frequently used in nonagency RMBS deals.

Bond insurance is a financial guarantee for the timely payments of principal and interest if these payments cannot be obtained from the cash flows of the underlying collateral. Bond insurance (aka monoline wrappers) was provided mainly by monoline insurance companies. The major primary insurers included Municipal Bond Insurance Corporation (MBIA), Ambac Assurance Corporation, Financial Guaranty Insurance Corporation (FGIC), and Financial Security Assurances (FSA). The main reinsurers are ACE Guaranty Re, AXA Re Finance, Enhance Re, and RAM Re.

Bond insurance covers implied write downs as well. An implied write down occurs when a trustee is prohibited from writing down a bond by the deal documentation and there is a discrepancy between the remaining collateral balance and the bond principal balance. In order to correct this discrepancy and realize the losses more quickly, wrappers typically recognize an implied write down as a credit event, which will decrease the reference obligation notional amount even though the bond principal balance remains unaffected. This works the same way as CDS.

Unlike internal credit enhancements, external enhancements are simple and reduce overall credit risk. However, they introduce counterparty risk. During the subprime mortgage crisis, the monoline insurers suffered a large amount of losses. Some of them are currently in bankruptcy or under serious financial stress and as a result, many bond protections were rescinded. The values of monoline wrappers have dropped substantially and some are even valued at or near zero.

HOUSING MARKET

The housing market is the single most important macro economic driver in the nonagency market. Price appreciation and home sales volume are two critical measures of the housing condition. Exhibit 25-20 shows home price appreciation (HPA) and existing home sales (EHS) in the United States since the late 1980s.

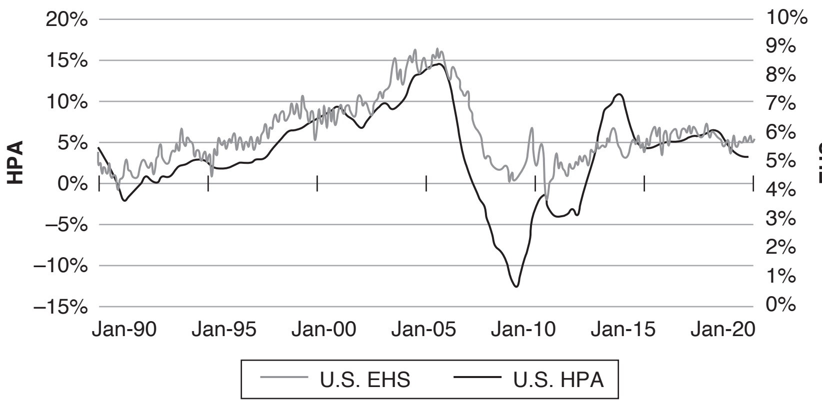
The housing market had experienced rapid growth in the early 2000s, with 10%+ annualized HPA, accompanied by sharp increases in home sales. As a result of the housing market boom, many lenders and investors neglected mortgage credit risks, which in turn greatly stimulated the nonagency RMBS market.

However, this growth was followed by the greatest housing bust in American post-war history as home sales slowed down in mid-2006 and prices started to decline. The decline in 2006 was relatively mild and many people were expecting a soft landing. By early 2007, it was clear that this was wishful thinking and a downward spiral began. Demographic factors played a key role here as baby boomers were entering retirement age and had started to reduce their housing demand. However, the housing market bust also consisted of several vicious cycles. Due to declining home prices, many potential buyers, particularly speculative buyers, held off on purchases, and this substantially slowed down home sales. Additionally, declining prices triggered increases in delinquency, which further increased the distressed housing supply and dragged down overall prices even further. The liquidity crunch then put huge pressure on the housing market as many borrowers could not get a new mortgage. Therefore, the weakened housing market further deepened the subprime mortgage crisis.

The housing market reached its worst point in early 2009 with a –18% year-over-year HPA nationwide. Case-Shiller HPI declined by 32% from the peak of Q2 2006 to Q1 2009, while existing home sales declined from its peak value of 9% in Q1 2005 to 5.2% in Q2 2009 (see Exhibit 25-20).

EXHIBIT 25-20

Annualized House Price Appreciation and % Exiting Home Sales in the U.S. Since Jan. 1990



In mid-2009, driven largely by pent-up demand, the Federal housing tax credit, a low interest rate environment, and credit becoming re-accessible, the housing market started to rebound. Home sales activities increased substantially, and prices started to stabilize with the rate of depreciation slowing. However, after the tax credit expired, excess demand was quickly exhausted. Momentum disappeared and the rate of home sales slowed substantially yet again. At the same time, a significant problem became obvious: the existence of millions of distressed properties, including those in REO, in foreclosure, and with loans in serious delinquency. With this large shadow inventory, it took a few years for home prices to recover. Loan modifications and foreclosure moratoriums slowed the pace of distressed properties flooding the market, which mitigated near-term housing supply pressure. However, these mechanisms also prolonged the liquidation timeline and resulted in a longer housing overhang and a slower recovery.

Five years after the housing crisis, the market started to see a steady increase in home prices and regular home sales activities, which were driven by pent-up demand, low interest rates, a low level of new home construction, a strong job market, and rising consumer confidence. HPA once again reached double-digit growth in 2014 and has since stabilized around 5%. Meanwhile, home sales activities also stabilized around a healthy 6% level.

Geographic Segmentation

The home price and existing home sales indices reveal a clear geographic segmentation within the overall housing market. Exhibit 25-21 shows Case-Shiller HPI for U.S. Census Geographic Divisions along with U.S. aggregate HPI. Geographic segmentation is observed on each level—for states within each census division, metropolitan statistical areas (MSAs) within each state, and zip codes within each MSA.

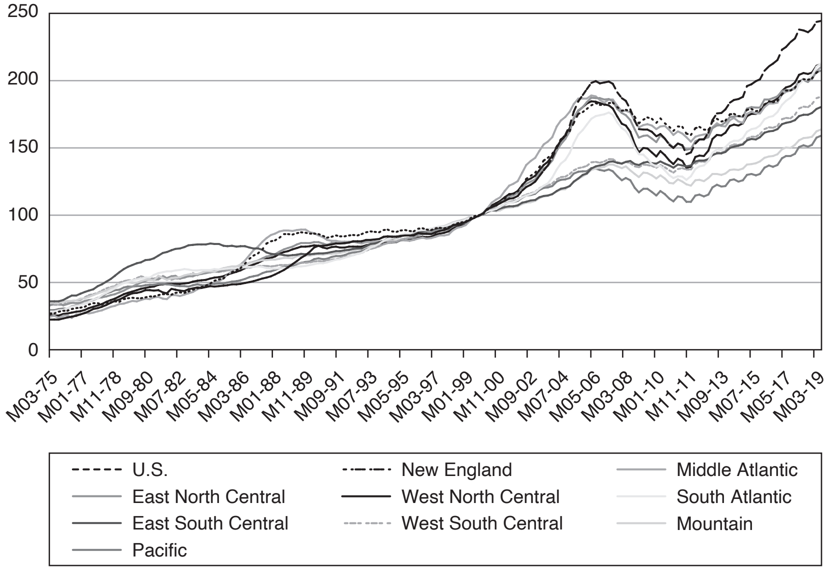
Geographic segmentation within the housing market makes it extremely important to understand the geographic distribution of nonagency collateral. Loans with the same original LTV but collateralized by homes in different geographic regions will have very different mark-to-market LTVs. Future home price appreciation will also be different. It is worth noting that historically the correlation among geographic regions is relatively small, which gives MBS the benefit of diversification. However, the correlation during the crisis was much higher, leading to substantial fat-tail risk.

Variation Among Property Tiers

There is also observed segmentation of the housing market based on home values, that is, price tiers. Fiserv/Case-Shiller provides HPI on different price tiers. All sales are divided into three groups based on property value, high-price, medium-price, and low-price tiers, so that proportions of each tier in total sales are equal. A home price index is then constructed for homes in each pricing tier. Depending on the state, different tiers experienced very different home price appreciation and consequent depreciation paths. For example, in California, low-price homes

EXHIBIT 25-21

Housing Price Index in Different Regions



appreciated the fastest, growing by 230% from Q1 2000 to the peak of Q2 2006, while high-price homes during the same period appreciated only by 115%. Consequently, on the way down, the drop from peak values was –58% for low price homes and only –31% for high price homes.

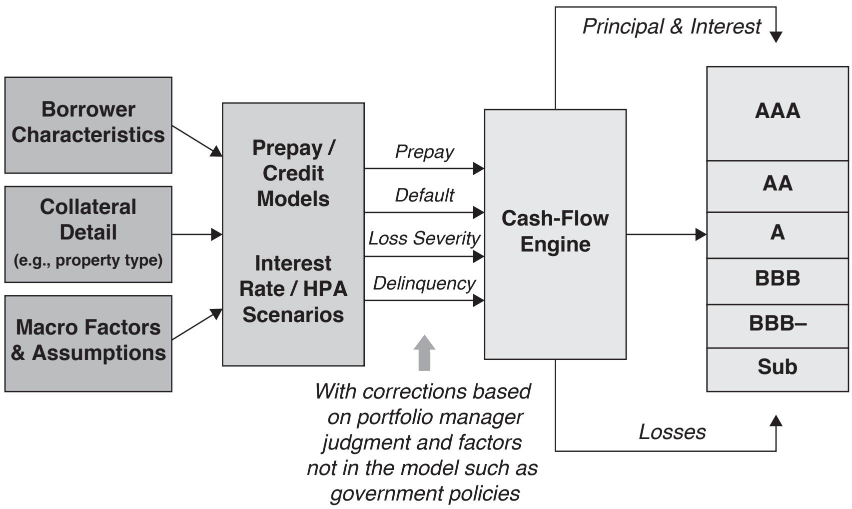
The difference between the high-end and the low-end of the market has a large implication on nonagency RMBS relative values. The prime jumbo sector, for example, is mainly backed by high-end properties. Home price depreciation is less pronounced for high-end properties, which partially contributed to the relatively low delinquency rate in this sector—the prime jumbo delinquency rate is even lower than that of agency mortgages. However, after the crisis, lack of financing in the jumbo mortgage market has been much more serious than in the conforming market.

RELATIVE VALUE AND RISK ANALYSIS

Here we introduce the analytical framework for relative value and risk analysis. Prepayment and credit models and roll-rate analysis are commonly used in this framework**.** As describe above, collateral, servicer behavior, capital structure, and the housing market are all important aspects to analyzing nonagency RMBS bonds. To combine all these factors, investors need an analytical framework similar to the one described in Exhibit 25-22. The primary components of this framework include collateral data, macro assumptions, performance projection models, and cash-flow engines.

EXHIBIT 25-22

Nonagency Analytical Framework



Key Risk Metrics

In addition to the standard mortgage valuation and risk measurements such as yield, spread, weighted average life (WAL), discount margin, option-adjusted spread (OAS), option-adjusted duration (OAD), option-adjusted convexity (OAC), and so on, the following metrics are widely used in the nonagency industry:

1. *Cumulative loss*: realized principal loss plus future expected loss divided by original balance of the deal
2. *Remaining loss*: future expected loss divided by current balance of the deal
3. *Principal write down*: principal loss for the bond
4. *Interest shortfall*: interest distributed is less than the amount of interest accrued
5. *Coverage ratio*: measured by the ratio of remaining loss of a deal collateral to credit enhancement of a bond within the deal
6. *Breakeven multiplier*: an intensity multiplier that when it is applied to a model, the projected remaining loss will be equal to the credit enhancement to a bond

Prepayment and Credit Models

Prepayment and credit models help project collateral future performance, including CPR, CDR, delinquency, and loss severity for each collateral group within a deal. The models typically use historical data to establish relationships of prepayment and credit performance to loan characteristics, current loan status, and macroeconomic environments. For example, a delinquency model can be a function of seasoning, FICO, LTV, DTI, documentation, state, and so on. The delinquency to foreclosure roll rate can be a function of current LTV, state judicial law, the housing market condition, and so on.

The purpose of prepayment and credit models is to project future cash flows under various rate, home price, or other scenarios. Given the empirical natural of these models and the ever-changing market dynamics, it is critical to keep the model updated. As we learned from the mortgage crisis, history does not simply repeat itself. Therefore, a model should never be about purely fitting history. A good model uses historical data to learn about borrower behavior under various environments and puts less emphasis on historical fit and more on forward-looking capabilities; it is really a mix of science and art.

All models require some assumptions. Some are explicit (e.g., the future HPA assumption), while others are more implicit (e.g., the prepayment model may assume that a prepayment channel is always available). It is very important for investors to understand each assumption within the model.

Roll Rate Analysis

Roll rate analysis is a simple but intuitive way to analyze a bond's performance and can be quite accurate in forecasting near term performance. This approach only requires the deal's transition matrix, which can be obtained using recent historical data. Exhibit 25-23 is a sample transition matrix. Given the transition matrix, one can compute the prepayment and default rates for each delinquency status bucket.

The disadvantage of roll rate analysis is that it ignores the underlying economic drivers. For example, it must assume the roll rates stay the same going forward, which is inconsistent with the natural selection phenomena many loan pools exhibit over time. If the macro economic environment changes the roll rates are unlikely to stay constant.

KEY POINTS

- Nonagency RMBS are not guaranteed by GSEs or government agencies and include securities backed by new prime jumbo, non-QM, RPL/NPL loans, and legacy deals of prime, Alt-A, option ARMs, subprime, second lien, and manufactured housing mortgages.

EXHIBIT 25-23

Sample Transition Matrix of Alt-A FRM as of March 2020

	Weight	CC	CD	DQ30	DQ60	DQ90	Fcl	REO	Prepay	Default

Note: CC is currently clean with no delinquency history in the past 12 months; CD refers to a loan that is current but with some delinquency history in the past 12 months.

Data Source: CoreLogic and BlackRock Solutions

- Ten years after the financial crisis, which was trigged by nonagency RMBS issue, the market is gradually recovering with cleaner collateral and simpler capital structure. Non-prime loan securitization is on the rise, although still at nascent stage and small scale.
- The two principal risks inherent in a pool of mortgages that nonagency RMBS deals are structured to manage are prepayment risk and credit risk. The structure separates aggregated cash flows from the underlying loans into principal and interest and redistributes the cash flows and associated losses to individual tranches according to rules specified in the deal waterfall.
- Collateral characteristics, capital structure, and servicing concern are the key aspects of nonagency RMBS relative value and risk analysis.
- Key measurements of collateral performance include delinquency, default, voluntary prepayment, and loss severity. Major characteristics of collateral include product type, fixed versus hybrids, coupon, LTV, FICO, and loan size. Servicers can play a large role in servicing advances, loan modification, liquidation timeline, and so on, which can significantly alter bond cash flow and timing.
- Credit risks in nonagency RMBS deals were addressed through credit enhancements: external, internal through deal structure, or a combination of the two.
- The housing market is the key fundamental determinant of nonagency mortgage performance.
- Roll rate analysis, prepayment, and credit models help project collateral future cash flow and timing.

CHAPTER
TWENTY-SIX

COVERED BONDS

Vinod Kothari
Financial Consultant

As financial intermediaries create and hold financial assets, they search for variety of ways to refinance them. Corporate bonds are the most traditional form of capital market-based refinancing. However, corporate bonds are a direct exposure on the issuer and are directly affected by the financial strength of the issuer. The issuer's rating determines the rating of corporate bonds. Obviously, over the period of time till maturity, these bonds are affected by the changes in the rating of the issuer, as also its probability of default.

A country's financial system may, for variety of reasons, want financial instruments that are either unaffected, or less severely affected by the credit and rating of the issuer. Assume an issuer creating or holding standard financial assets, such as prime mortgage loans. If a system of refinancing these mortgages allows investors legal access to the portfolio of assets, investors will prefer a claim over a pool of healthy assets over a claim over the issuer. From a policy perspective, if an issuer is allowed to issue bonds that are either solely based on the strength of the asset pool or at least derive from the same, the issuer may hopefully issue better-rated bonds and therefore raise relatively cheaper financing to be able to create and hold the pool of assets in question. If an issuer had to depend on corporate bonds, a low-rated issuer would not be able to raise cheaper financing and therefore hold healthy assets. This leads to a self-sustaining cyclicality whereby a weaker bank must hold inferior quality assets and therefore remain weak or become weaker.

In the world of fixed income securities, markets have been searching for instruments that are asset backed, rather than entity backed. Mortgage-backed and asset-backed securities are instruments that seek to detach completely from the rating of the issuer and depend entirely on the quality of the pool of assets and the structural credit enhancements, mostly to reach highest ratings. Covered bonds, the subject of this chapter, are alternative instruments that may be perceived as midway between corporate bonds and mortgage-backed securities, in the sense that they depend both on the quality of the issuer and the quality of the assets underlying the funding.

COVERED BONDS: FROM EUROPE TO THE REST OF THE WORLD

In an environment of institutional investing that is so heavily reliant on ratings of investment options, both mortgage-backed securities and covered bonds are devices to uplift the rating of the instrument above the rating of the issuer. In case of mortgage-backed securities, under an assumption of complete independence of the funding from the risks of the issuer, the securities often get highest ratings. These ratings, and the strength of the security that they evidenced, came under acute challenge during the subprime crisis of 2007–2008, making mortgage-backed securities at least periodically unpopular. The search for an alternative ended at covered bonds, which have been used in Europe for 250 years. Depending on the jurisdiction, covered bonds may not have the fascination of mortgage-backed securities; however, whereas mortgage-backed securities have suffered the loss of investors' confidence, even if temporarily, during and after the subprime crisis, covered bonds have maintained healthy investor appetite.

Covered bonds, as an instrument of mortgage funding, have a long history. They are first said to have been issued in Germany, then Prussia, in 1769. The first issuance in Denmark occured in 1797, after the fire of Copenhagen in 1795. They are known by variety of names over Europe—*pfandbriefe* in Germany, *realkreditobligationer* in Denmark, *obligations fonciers* in France, and *pantbrev* in Spain, for example. Covered bonds have been essentially a European instrument, mostly backed by specific laws, until recently when countries outside Europe either started enacting legislations to promote covered bonds, or structurers used a combination of securitization-type structuring devices using common law to create covered bonds.

In the United States, Washington Mutual became among the first to come up with U.S. covered bonds in September 2006, followed by Bank of America the next year. Post the subprime crisis, then-U.S. Treasury Secretary Paulson came out with the Treasury's plan to promote covered bonds, including a statement of best practices. However, Washington Mutual went into receivership by the Federal Deposit Insurance Corporation, and its debt was acquired by JP Morgan. Both of the U.S. issuances of covered bonds have been paid off, and there were no issues thereafter.

Other countries too have taken legislative measures to promote covered bonds including, for example, Australia, New Zealand, and Canada. As explained later in this chapter, in some countries covered bonds have been tried without the strength of legislation, on the basis of flexibility of their legal structures.

UNDERSTANDING COVERED BONDS

There is no uniformity in the structure of covered bonds—there are reasons why these differences exist. Before we come to the nuances of their structure, let us understand the philosophy behind covered bonds. Corporate bonds, whether secured or unsecured, have the probability of default dictated by that of the issuer. If the issuer defaults, even secured bonds will default, though one may expect a significantly higher recovery rate based on the value of the collateral. Mortgage-backed securities, on the other hand, are presumably structured to insulate the pool of assets from the risk of bankruptcy of the issuer. Mortgage-backed securities typically attain highest ratings on the basis of credit enhancements sized up to absorb the losses of such insulated pool, to an extent that justifies the highest rating.

Covered bonds borrow from securitization framework, as also from the age-old secured bonds. Secured corporate bonds are the obligation of the issuer and are backed by security interest in the collateral. To what extent this collateral is available in the event of bankruptcy of the issuer, and what are the prioritized or parallel claims on this collateral, is a function of bankruptcy law, which differs from country to country. In the case of securitization, the presumption is that the collateral pool will remain completely aloof from the issuer and would be unaffected by the bankruptcy of the issuer, thus allowing investors undeterred access to its full value. Covered bonds strike an "approximate" midway, by creating a structure that combines at least the following:

- A recourse both against the issuer and the collateral pool, in that order, such that, like corporate bonds, the bond is still the obligation of the issuer yet backed by a claim over a collateral pool that is expected to withstand competing or overriding claims in the event of bankruptcy of the issuer; therefore, there is no complete isolation of the collateral from the issuer as in the case of securitization, yet a structure is in place that will protect the collateral and preserve it for payment to covered bonds investors on a first-priority basis.
- Presence of credit enhancements that are expected to absorb losses, at a stress level to attain the best ratings, is common in covered bonds too. However, the credit enhancement structures used in covered bonds have traditionally been simpler than they are in securitization.
- Thus, covered bonds lean both on the credit of the issuer as also on the strength of the asset pool.

STRUCTURE OF COVERED BONDS

Covered bonds are on-balance sheet securitizations. If by "securitization" is meant the transfer of a pool and its transformation into securities, then covered bonds are not securitization: they are closer to a secured bonds issuance. In a mainstream covered bonds transaction, there is no transfer of the assets to a *special purpose entity* (SPE). On the other hand, the assets are identified, and collateral rights are created on the assets as per local secured lending law and are placed as a security for the bonds. In the event of bankruptcy of the mortgage originator, a general secured lending law or a special law relating to the assets grants the bondholders recourse against the pool of mortgages over which security interest had been created. More often than not, there are overriding and parallel claims, arising out of bankruptcy laws or other laws, that erode a part of the value of the assets attributable to payment to the secured bondholders. In other words, the secured assets are prone to the bankruptcy risk of the issuer.

Securitization structures intend to eliminate this risk by relying on "true sale"—the asset pool itself is sold using a legally defensible sale, generally to an SPE. The SPE itself is, in legal presumption, bankruptcy remote; that is, it is so structured as to be free from the risk of being called into bankruptcy. Thus, securitization transactions may be taken to have insulated the asset pool from the bankruptcy risk of the issuer. That having been done, the only risk to be concerned about is the risk of credit losses in the asset pool. If there are credit enhancements present to absorb that risk to a sufficient degree, the resulting securities may attain the highest rating.

The need for securitization structures to depend on isolation or true sale resulted into some consequential features. One of the most significant consequences is the correlation between the cash inflows from the asset pool and the cash outflows to repay investors. This is commonly known as the *pass-through* nature of the transaction, implying that what is received, and whenever it is received, is the paid out to investors. The pass-through feature leads to several implications:

- The maturity of the mortgage- (or asset-) backed securities is the same as that of the asset pool. For example, if the mortgage pool pays off in 20 years, the last dollar to flow to the securities will also take 20 years. There are, of course, several modifiers that come into play; for example, there may be tranches of securities, with some tranches paying before others. There may also be a *clean-up call option* that allows the seller to complete the redemption once outstanding pool value becomes insignificant. However, on a holistic basis, there are no asset/liability mismatches in the transaction—the repayment of the liability, namely, the bonds, is driven by the repayments on the assets.
- As the mortgage loans prepay, the investors get prepaid too. Therefore, the much-discussed prepayment risk gets completely shifted to investors. Once again, reallocation devices that differentially reallocate the prepayment risk to different classes of investors may be used.
- The repayment of the liabilities flows from a static pool. *Static pool* refers to the mortgages that were there in the pool when it was sold to the SPE. Hence, the mortgage-backed securities will be affected by the expected behavior of a static pool—behavior of key variables, such as prepayment rate, default rate, and average rates of return, as a function of time to maturity.

- Since securitization is based on a true sale of the asset, questions arise as to whether what is a sale in law is also a sale in accounting parlance—leading to questions of off-balance-sheet treatment of the assets and whether the sale treatment is attainable—there is obviously a related question of acceleration of the profit/loss and upfront recognition thereof.

Let us now take the case of covered bonds. Given the fact that covered bonds are the obligations of the issuer, they do not have to exactly derive the cash flows from those of the asset pool. In other words, covered bonds are not based on a pass-through of cash flows of the asset pool. There may be mismatches (however, within limits as discussed further below) in the cash-flow structure. Therefore, all the consequential features of securitization depending on the pass-through nature of the transaction can be avoided, or at least, mitigated, in the case of covered bonds.

But here comes the key question: If covered bonds are nothing but obligations of the issuer, then what is the difference between secured corporate bonds and covered bonds? As discussed before, the genesis of covered bonds lies in giving to the bondholders bankruptcy-proof access to the assets. Hence, covered bonds have to create a legal structure that may allow investors to use the collateral assets, even if the issuer goes into bankruptcy. The basis of this bankruptcy-protected right lies in either a legislation granting them a special privilege, or in the design/structure of the transaction. Accordingly, covered bond structures, based on nature of jurisdictions, may be classified into legislative covered bonds and structured covered bonds.

Legislative Covered Bonds

A legislative covered bonds structure is one where a special legislation gives bankruptcy protection to the investors. This goes with the very genesis of covered bonds—they were created to allow investors in the bonds to have the strength of the assets, not just the strength of the issuer. In most European jurisdictions, covered bonds legislation grants a special immunity to the assets backing the covered bonds—that the bankruptcy trustee shall not take over these assets.

Take, for instance, the German pfandbriefe. Under German law, pfandbriefe could traditionally have been issued only by specialized banks, but the requirement was relaxed in 2005. These pfandbrief issues are expected on a regular and consistent basis, rather than on an opportunistic or sporadic one. There are several different types of pfandbriefe permitted by the German Pfandbrief Act: mortgage pfandbriefe, public pfandbriefe, ship pfandbriefe, and, more recently, aircraft pfandbriefe, each backed by the type of assets that the name implies. Public pfandbriefe are those backed by claims against public sector authorities.

The key feature of pfandbriefs is "covered assets," the collateral backing up the pfandbriefe. Depending on the type of pfandbriefe, the covered assets should be qualifying mortgages, public sector financial claims, or mortgages on ships. In addition, within specific limits, claims against central banks, credit institutions, and derivatives transactions are also recognized as covered assets.

The key to the bankruptcy remoteness of pfandbriefe lies in Section 30 of the Pfandbrief Act. This section provides that if insolvency proceedings are opened in respect of the Pfandbrief bank's assets, the assets recorded in the cover registers shall not be included in the insolvent estate. The claims of the Pfandbrief creditors must be fully satisfied from the assets recorded in the relevant cover register; they shall not be affected by the opening of insolvency proceedings in respect of the Pfandbrief bank's assets. Pfandbrief creditors shall only participate in the insolvency proceedings to the extent their claims remain unsatisfied from the covered assets.

There are independent administration provisions for the covered assets. Section 30.2 provides that the court of jurisdiction shall appoint one or two natural persons to act as administrators, whereupon the right to manage and dispose of the covered assets shall be transferred to the administrator. Thus, the administrator either continues to collect cash flows from the assets or dispose of it and pay down investors at once.

Similar provisions exist in other laws dedicated to covered bonds. In fact, a lot of harmonization has been attained by a pan-EU common regulatory framework. The definition of covered bonds is set forth in article 52(4) of the UCITS Directive. Exemption from any bail-in in the case of a bank restructuring is provided by article 44(2) of the BRR Directive, and preferential capital treatment is provided by article 129 of the CRR Directive.

Structured Covered Bonds

There are several covered bonds jurisdictions that do not have any specific laws to supply the bankruptcy protection. In these countries, issuers have been using a combination of SPEs and a transfer of the assets, presumably to attain bankruptcy-proofing. These may be called structured covered bonds jurisdictions.

There are several parties involved in a structured covered bond:

- Originator—the bank/entity that wanted to raise funding.
- SPE—the special-purpose entity that is interposed in the picture to hold legal title over the pool of assets and to provide bankruptcy protection. The SPE should be so structured as to be free from the risk of consolidation with the originator.
- Cover pool monitor—an entity to ensure that the cover pool satisfies the minimum credit enhancement required by the transaction.
- Administrator—an entity that will take over the assets in the event of bankruptcy of the originator.
- Bond investors.

The typical structure of a structured covered bond is shown in Exhibit 26-1. Although structured covered bonds rely on the common law of the country, and therefore may differ from case to case, the mechanics of a typical structured bond can be described in the following steps:

Step 1: A structured covered bond will typically have an independent SPE that will hold title to the assets or the cover pool. Note the significant difference: In normal securitization structures, the bonds are issued by the SPE. But in the case of structured covered bonds, while the collateral or cover pool is legally sold to the SPE, the issue of bonds is done by the originator or the bank that wanted to raise funding. Hence, the bonds are the direct and unconditional obligation of the originator. The role of the SPE is to provide a secondary recourse. Hence, in structured covered bonds, the SPE is typically a guarantor.

Step 2: The proceeds raised through the issue of covered bonds will be on-lent to the SPE. In turn, the SPE uses these proceeds to purchase from the originator the cover pool on a true sale basis.[1] Thus, the SPE becomes the legal owner of the pool. In other words, from a legal perspective, the sale from the originator to the SPE must satisfy the legal features of a true sale. The sale, however, is not a sale from accounting viewpoint—see discussion below. Also, note that the loan given by the originator to the SPE is subordinated to the obligations of the SPE to the bondholders.

Step 3: Backed by the cover pool, the SPE provides a guarantee to covered bondholders for the payment of interest and principal on the covered bonds, which becomes enforceable if the issuer defaults. The guarantee represents an irrevocable, direct, and unconditional obligation of the SPE and is secured by the cover pool.

Step 4: The originator continues to collect and service the cash flows from the mortgage loans. As there is a mismatch between the payments from the mortgage pool and the payments on the bonds, the originator is allowed to (a) retain the collections from the pool and (b) make payments toward the bonds in excess of collections from the pool. As the originator repays the mortgage bonds, the inter-company loan and the purchase of assets by the SPE are squared off; that is, the SPE's obligation to repay the inter-company loan is taken to have been satisfied.

Step 5: Though the originator holds the collateral pool and may use the collateral pool's cash flows—and may replace assets in the collateral pool or add new assets in place of those amortized or prepaid—the originator needs to ensure that the credit enhancement levels are maintained at all times. Usually, an independent cover pool monitors the compliance with this requirement.

1. As an alternative, the SPE buys the assets but the price for the same is kept unpaid—by way of a deferred purchase price.

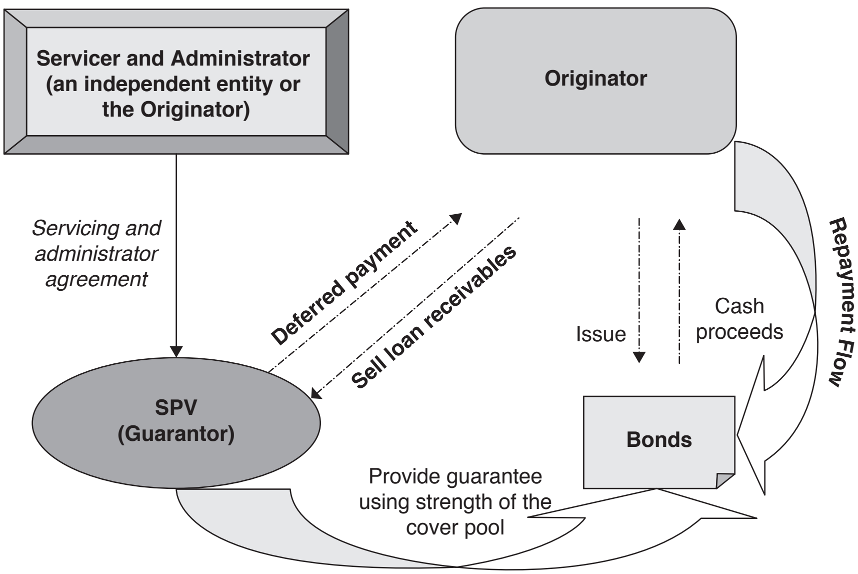
Step 6: While the originator may add further loans to the collateral pool, or withdraw loans from the pool, the aggregate amount of collateral "sold" to the SPE must have a minimum amount of credit enhancement.

Step 7: If an originator bankruptcy event takes place, the SPE's guarantee to the bondholders kicks in. At this stage, the SPE attaches the collateral lying with the originator and passes it to the administrator.

Step 8: The claims of the bondholders are paid from the cover assets. In case of a deficiency, the bondholders will have an unsecured receivable from the issuer.

EXHIBIT 26-1

Structure of Structured Covered Bonds



MATURITY STRUCTURE OF COVERED BONDS

We mentioned above that covered bonds' repayment may not be entirely matched with the repayment profile of the cover pool. In fact, the cover pool itself is dynamic. Thus, there are many covered bond issuances that have a "hard bullet" repayment structure, and many others that have a "soft bullet" structure. A hard bullet has a pre-fixed maturity; a soft bullet allows that maturity to be extended on the occurrence of trigger events, such as issuer default.

There is also an increasingly common structure, called conditional pass-through (CPT). In a CPT structure, on the occurrence of certain trigger events with respect to the issuer, mainly insolvency, the repayment structure of the bond shifts from its original one to a "pass-through." A pass-through, as in the case of mortgage-backed securities, implies that the collateral pool then becomes static and the cash flows from that underlying pool start paying the bondholders on an as-received basis. This enables the cover pool trustee from having to force-liquidate the cover assets and suffer value destruction.

COVER ASSETS AND CREDIT ENHANCEMENTS

Since covered bonds rely both on the asset pool and on originator credit, it is important to ensure that the credit risk of the asset pool is absorbed by credit enhancements. While securitisation transactions have used a variety of forms of credit enhancements, covered bonds have traditionally used *overcollateralization*. That is to say, the originator needs to ensure that the "cover" assets overcollateralize the outstanding bonds by the required minimum degree of overcollateralization. For example, if the required overcollateralization is 10%, for outstanding bonds of \$100, there need to be covered assets of at least \$110. As the bonds are amortized over time, this overcollateralization ratio must be maintained at all times.

In addition to this, the cover assets, that is, assets forming part of the cover pool, must also satisfy certain features laid down by either legislation or regulation, for example, the loan-to-value ratio in case of each loan. In other words, the quality of the underlying loans in the cover pool is carefully guarded by regulators.

ASSET/LIABILITY MISMATCHES AND LIQUIDITY RISK

Covered bonds are repaid independent of the cash flows of the cover pool. So, they are paid from the regular cash flows of the originator. Likewise, the cash flows received from the asset pool go and become part of the regular cash flows of the cover pool. This clearly implies an asset/liability mismatch underlying a covered bond.

If this asset/liability mismatch was completely uncontrolled, then the obligation to repay covered bonds would have been no different from an obligation to repay any secured or unsecured bond issued by the originator. Hence, the strength of a covered bond depends on how wide the asset/liability mismatch is. The asset/liability mismatch reflects the liquidity risk of the transaction. If the asset/liability mismatch is too wide, a covered bond leans too heavily on the liquidity strengths of the issuer and therefore is no different from corporate bonds. If the asset/liability mismatch is negligible, a covered bond leans toward being a mortgage-backed security. Hence, usually, covered bonds issuers keep the asset/liability mismatch under control. The extent of asset/liability mismatch also affects the likely rating upliftment that a covered bond may receive as discussed below.

Exhibit 26-2 shows a computation of the asset/liability mismatch done by rating agency Standard and Poor's. In this exhibit, column A shows the likely balances in the asset pool, and column B shows the likely balances outstanding of the covered bonds. As one may notice, at the inception the cover pool value is \$120, while the bonds outstanding add to \$100, implying an overcollateralization of 20%. There is a mismatch between column A and column B—as is apparent. The outstanding balances of the assets are based on the amortization of the mortgage loans, incorporating assumptions of prepayment and default. The outstanding balances of the bonds in column B are based on the contracted repayment of the bonds—this may be seen in column D. It may also be noted that while the asset pool will take several years to fully pay down, the bonds are scheduled to be fully paid down at the end of 10 years.

The gap between the cash inflows and cash outflows is given in column E. Column F applies a scaling factor, giving more weight to a mismatch in earlier years, and lesser to those in later years. The scaling factor is array of scales used by the rating agency in question.

Finally, in column G the asset/liability mismatches are accumulated and find the highest level of mismatch. This is defined as the asset/liability mismatch of the transaction. The greater the mismatch, the greater the transaction's dependence on the issuer's rating.

We discussed soft bullet maturity above. In the example, column D shows payments to the bonds in five different years. This would most likely not be five payment dates on a single bond, but five different tranches of bonds with single bullet maturity dates each.

RATINGS OF COVERED BONDS

As we have discussed, the desire of a covered bond issuer is to raise funding by an instrument that pierces the rating of the issuer. That is, rating upliftment is a significant objective of every issuer.

All the major rating agencies have come up with criteria to give ratings, in fact, rating enhancements to covered bonds transactions. These criteria have been evolving over time, and as volatility spikes occur within the financial system, rating agencies become more conservative.

We do not intend to discuss the rating criteria of each of the agencies here, but we need to observe that, unlike in case of securitization, ratings of covered bonds are not completely detached from the rating of the issuer. In fact, the issuer's rating significantly controls the ratings of covered bonds. Hence, rating agencies typically lay down a matrix of factors, on consideration of which they will notch-up the rating of the covered bonds by specified level of notches.

COVERED BONDS AND SECURITIZATION

As we have stated before, though covered bonds are historically grounded into secured bonds, in the recent past, transactions have been enriched by

EXHIBIT 26-2

Computation of Asset/Liability Mismatch in Covered Bonds (S&P)

Year	Performing asset balance (€ Mil.)	Liability balance (€ Mil.)	Stressed periodic asset cash inflows (€ Mil.)	Stressed periodic liability cash outflows (€ Mil.) ALMM percentage = maximum ALMM / outstanding liability balance (%)								–52.34%

securitization methodology, particularly in countries that do not have specific covered bonds legislation. Hence, they are a hybrid between securitization and secured bonds. The few points of similarity between the two are (a) both result in the creation of securities, (b) both are methods of funding from the capital markets, (c) both involve creation of a pool of assets, and (d) both have trustees overseeing the implementation of the transaction covenants. The structure of covered bonds would look very similar to the master trust structure of securitization, particularly if the structure is used in case of residential mortgages. However, there are significant points of dissimilarity, as shown in Exhibit 26-3.

EXHIBIT 26-3

Covered Bonds and Securitization Compared

	Covered Bonds	Securitization
Purpose	Essentially, to raise liquidity	Liquidity, off balance sheet, risk management, monetization of excess profits, etc.
Risk transfer	The issuer continues to absorb default risk as well as prepayment risk of the pool. To achieve a partial transfer of prepayment risk, there may be a call option embedded in the bonds.	The originator does not absorb default risk above the credit support agreed; prepayment risk is usually transferred entirely to investors
Legal structure	A direct and unconditional obligation of the issuer, backed by creation of security interest. Assets may or may not be parked with a distinct entity; bankruptcy remoteness is achieved either due to specific law or by using ring-fencing structures of common law.	True sale of assets to a distinct entity; bankruptcy remoteness is achieved by isolation of assets
Type of pool of assets	Mostly dynamic. Borrower is allowed to manage the pool as long as the required “covers” are ensured. From a common pool of cover assets, there may be multiple issuances.	Mostly static. Except in case of master trusts, the investors make investment in an identifiable pool of assets. Generally, from a single pool of assets, there is only issuance.

(Continued)

EXHIBIT 26-3

Covered Bonds and Securitization Compared (*Continued*)

	Covered Bonds	Securitization
Maturity matching	From out of a dynamic pool, securities may be issued over a period of time. Usually, covered bonds are “programs”, that is, series of issuance from out of a dynamic and replenishing mortgage loan pool.	Typically, securities are matched with the cash flows from the pool. When the static pool is paid off, the securities are redeemed.
Payment of interest and principal to investors	Interest and principal are paid from the general cash flows of the issuer	Interest and principal are paid from the asset pool
Prepayment risk	In view of the managed nature of the pool, prepayment of loans does not affect investors, except to the extent of call option embedded in the bonds.	Prepayment of underlying loans is passed on to investors; hence investors take prepayment risk
Nature of credit enhancement	The overcollateralization in the cover pool, that is, excess of the cover assets over the outstanding funding.	Different forms of credit enhancement are used, such as excess spread, subordination, over-collateralization, etc.
Classes of securities	Usually a single class of bonds are issued. There may be multiple time tranches, each having hard or soft bullet maturity.	Most transactions come up with different classes of securities, with different risk and returns
Independence of the ratings from the rating of the issuer	Theoretically, the securities are those of the issuer, but in view of bankruptcy-proofing and the value of “cover assets”, usually ratings may achieve notching up by several notches.	AAA ratings are given usually to senior-most classes, based on adequacy of credit enhancement from the lower classes.
Off-balance-sheet treatment	Not off the balance sheet	May or may not be off the balance sheet, as per applicable accounting standards
Capital relief	Cover pool assets will be treated as on-balance sheet retail portfolio, appropriately risk weighted. No specific capital relief to the issuer. Regulations provide investors with lower risk weights.	If significant risk transfer is achieved, permits capital relief and calls for regulatory capital only up to the retained risks of the seller

ACCOUNTING FOR COVERED BONDS

Looking at the structure of covered bonds, particularly in the case of structured covered bonds, one may notice the presence of a legal transfer of the cover assets from the issuer to the SPE. Would this have the impact of removing the cover assets from the books of the seller-issuer? Under IFRS 9, true sale is not a precondition for off-balance-sheet treatment. Transactions that qualify as pass-through arrangements, even if not backed by true sale, may lead to assets being off the balance sheet. Neither does true sale guarantee an off-balance-sheet treatment. On the other hand, off-balance-sheet treatment is based on the substance of the transaction, that is, risks and rewards from the asset pool. For instance, if the reporting entity creates a pass-through obligation in favor of the investor, that is, retains the right to receive the cash flows, but assumes a contractual obligation to pay the cash flows on pass-through basis to one or more recipients, it can still be treated as transfer of significant risks and rewards and qualify for de-recognition. If the seller retains significant risks and rewards, the asset continues to be on the books of the seller, and the funding raised is treated akin to a borrowing.

As we have discussed above, covered bonds transactions, particularly those not backed by legislation, rely on true sale to achieve bankruptcy protection. Hence, a question may arise: As the originator sells the pool to an SPE that guarantees the repayment of the bonds, should the assets go off the balance sheet of the issuer? The answer would be clearly no, since the bonds are unconditional obligation of the issuer. Hence, the making of the true sale does not put the assets off the balance sheet of the issuer.

KEY POINTS

- As a capital market device for refinancing mortgages, covered bonds have existed in continental Europe for more than 250 years. However, their recent popularity seems to be emanating from their proven robustness in the midst of the several crises, both economic and common life.
- Covered bonds may be viewed as a hybrid between corporate bonds and mortgage-backed securities, in the sense that they are an obligation of the issuer, they are close to secured bonds, but since investors also rely on the assets as a backup, they have features of asset-backed securities.
- The asset-backing in the form of cover assets provides dual recourse to investors. How clear is the ability of investors to rely on the assets, immune from the post-bankruptcy claims of other creditors, depends either on the legislation or on the legal structure of the transaction.
- Where the bankruptcy protection comes from legislation, it is called legislative covered bonds; where it comes from the legal structure, it is called structured covered bonds.

- Structured covered bonds use a special purpose entity that agrees to buy the cover assets, albeit with funding provided by the issuer. The SPE then guarantees the repayment of the bonds.
- The key idea of covered bonds is to provide a rating upliftment, so that the bonds are able to achieve a better rating than that of the issuer. The notches by which rating of covered bonds may go up above the rating of the issuer are based on the quality of the cover asset, extent of credit enhancement, inherent asset/liability mismatch, strength of the legislative support, liquidity risk, and related factors.
- Credit enhancements in case of cover bonds are mostly in form of overcollateralization.
- While structured covered bond transactions make use of the device of sale of the cover pool by the issuer to an SPE, the sale is done such that it qualifies as a legal sale but not a sale in terms of accounting standards. Hence, from accounting viewpoint, covered bonds are not different from secured bonds.

Commercial mortgage-backed securities (CMBS) are structured products that provide debt financing to the commercial mortgage market. CMBS are a component of commercial real estate finance (commercial banks, insurance companies, and pension funds also make direct loans to owners of commercial real estate).

As with residential mortgage-backed securities (RMBS) products, CMBS represent economic interests in pools of mortgage loans. The structure used to create CMBS transfers the credit risk of the underlying commercial real estate loans to the owners of CMBS. Certificate subordination increasingly mitigates the commercial mortgage loan credit risk for certificate holders. CMBS certificate structures apply losses to the most junior outstanding certificates and, depending on the levels of subordination, offer substantial credit risk protection to the holders of the most senior certificates.

CMBS investors should understand the fundamentals of commercial real estate valuations and commercial real estate lending standards to properly analyze the credit risk embedded in CMBS investments. The loans underlying CMBS transactions are typically much larger than loans found in other securitized products. The largest 10 loans in a CMBS transaction can comprise 35% to 70% of a collateral pool. This loan concentration makes asset-level reviews much more important than other securitized products in which the law of large numbers allows effective statistical sampling. Key differences between CMBS and nonagency RMBS are enumerated in Exhibit 27-1.

The authors would like to acknowledge the contributions of Nishith Ajitsaria and Kunal Khara, CFA in writing this chapter.

EXHIBIT 27-1

Comparison of Key Attributes of CMBS Transactions and Nonagency RMBS Transactions

Attributes	CMBS	Nonagency RMBS
Collateral Composition	Larger-sized loans with fewer loans in the trust—underlying collateral is more heterogeneous. Higher concentration risk with top 10 loans comprising 35%–70% of the transaction.	Large number of loans in a transaction. Loans are small in size and individual loans represent a small portion of the transaction. Given large number of loans, collateral is fairly well-diversified.
Loan Types	Shorter-term loans, with 5-, 7-, or 10-year balloon maturities. Most loans are fixed-rate.	15- to 30-year fixed-rate and floating-rate loans.
Prepayment	Mortgage loans typically prohibit prepayment until a few months prior to the maturity date.	Many mortgage loans are freely prepayable.
Transaction Structure	Transactions typically pay principal sequentially, credit enhancement is in the form of subordination, and losses are allocated in reverse-sequential order.	Wide range of principal, interest, and loss cash-flow distribution rules, in addition to triggers and multiple forms of credit enhancements such as over-collateralization, subordination, excess spread, reserve accounts, and external credit guarantees.
Modeling	Modeling typically involves detailed loan- and asset-level review given loan concentrations.	Probabilistic modeling of prepayments, defaults, and severities is fairly common with models built on large historical loan-level performance data sets.
Government Guarantee	Agency CMBS securitizations offer senior certificates that typically include a guarantee from the issuing GSE. Private-label CMBS structures do not benefit from a government guarantee.	No government guarantee.

CMBS issuers have developed several types of transactions. CMBS transactions are broadly classified as private-label CMBS and agency CMBS. Private-label CMBS constituted the vast majority of CMBS transactions until 2008. As markets restarted after the 2008 financial crisis, *agency CMBS* that combine many features of private-label CMBS with a payment guarantee for senior certificates from a government-sponsored enterprise (GSE) became much more prevalent as a source of funding for multifamily properties. Fannie Mae and Ginnie Mae are active in the agency CMBS market with various offerings that finance multifamily and healthcare properties and provide investors government-guaranteed investment options. Freddie Mac has created several programs that incorporate many features of private CMBS securitizations and offer government-guaranteed senior certificates. Agency CMBS junior certificates typically do not benefit from a guarantee. Within private-label CMBS, *conduit transactions* are securitizations of fixed-rate commercial mortgage loans in which no loan comprises more than 20% of a transaction. Issuers created *single asset single sponsor* (SASB) *transactions* for sizeable debt offerings for large owners and sponsors of commercial real estate that justify a separate CMBS transaction. CMBS issuers have created *floating-rate transactions* typically comprised of large loans on transitional properties (i.e., under construction/renovation, undergoing a repositioning) and properties with more volatile cash flows (i.e., hospitality). These loans were usually for one or two years with several one-year extensions. Finally, since 2017 commercial real estate *collateralized loan obligation transactions* (CRE CLOs) reemerged to provide a source of financing for mortgage loans that do not meet the requirements of a conduit transaction. These transactions generally consist of two- or three-year loans that accrue interest on a floating-rate basis. CRE CLOs can have a static pool of collateral or a managed pool in which the CRE CLO issuer can replace loans that prepay or payoff with new collateral.

The majority of CMBS transactions were conduit transactions prior to 2008. After 2009, agency CMBS substantially increased in volume to eventually comprise more than half of the CMBS market. CMBS investors (regardless of credit support) typically perform due diligence on the largest loans to understand whether the mortgage loan originator used a prudent valuation and sized the loan appropriately.

THE COLLATERAL POOL

Because most CMBS transactions have large loans that comprise significant portions of the overall trust, investors typically perform a review of the underlying mortgage loans and mortgaged properties to understand the idiosyncratic credit risks of the investment.

Summary of Valuation Techniques for Underlying Mortgage Properties

Typically, office, retail, industrial, hospitality, and multifamily properties serve as collateral for the underlying mortgage loans. Office, retail, industrial, and hospitality properties constitute "commercial" properties, whereas multifamily properties typically have more than four residential units available for lease. Commercial real estate values are typically computed by using the direct capitalization method, a discounted cash-flow analysis, the comparables method, or the replacement cost method. The direct capitalization method utilizes a *capitalization rate* (cap rate), which is the unleveraged yield associated with the current income from a commercial property. The direct capitalization method determines property value by dividing the net operating income (NOI) by the cap rate. That is,

$$\text{Property Value} = \text{Net Operating Income/Cap Rate}$$

Cap rates are based on many factors and include an interest rate component. Multifamily properties have typically garnered the lowest average cap rates due to availability of debt financing from GSEs, diversified income stream from a range of tenants, and historically strong demand for housing throughout market cycles (people need a place to live). Hospitality properties generally average the highest cap rates due to the volatility of NOI associated with the hospitality and travel/leisure industries. Investors value office, retail, and industrial properties with average cap rates between the multifamily and hospitality benchmarks. The direct capitalization method is useful to CMBS investors because the data inputs are typically available from dealers, such that the analysis is based on a standardized data set.

The *discounted cash-flow analysis* (DCF analysis) is a more precise method of commercial real estate valuation that discounts the property's NOI through time using the weighted average cost of capital as a discount rate. Commercial real estate equity investors utilize a DCF analysis when purchasing commercial real estate properties; however, CMBS investors typically do not have the required inputs (i.e., cash-flow forecast) to use this valuation technique.

The comparables method attempts to determine commercial real estate values by determining a property's value based on the actual sales of similar properties in the same area. This approach is effective at finding a market value if similar properties traded in the recent past. When marketing CMBS investments, dealers often verbally disclose comparables for the properties securing the largest mortgage loans within a transaction. Property values are distilled to a value/square foot (SF) or unit. As an example, Midtown Manhattan Class A (high-quality) office buildings can trade in an average range of \$1,000–\$1,400/SF, whereas suburban office buildings in secondary markets can trade at \$150 to \$250/SF. Although dealers make comparable information available during the offering of a CMBS transaction, updated information is not made available through transaction reporting.

The replacement cost approach values real estate by computing the value of the underlying land and the cost associated with constructing the property's improvements less depreciation. This method is not used extensively in commercial real estate valuation as it does not take into account the property's income stream. The appraiser is also required to determine the value of land using the comparables method—given that land sales in highly developed areas are rare, valuations based on this approach would require significant assumptions.

The classic guideline for commercial real estate valuation has not changed in the modern era: Location is essential to determining real estate values. A CMBS investor should appreciate and consider the bespoke nature of commercial real estate properties and their values to properly model the commercial real estate debt exposures in a CMBS transaction.

Commercial Mortgage Lending Standards

As with most hard assets of reasonable credit quality, owners of commercial real estate can improve their overall yields by utilizing leverage. Mortgage loans are sized based on the ratio of the debt to the value of the property (the loan-to-value ratio, or LTV). Prior to the 2008 financial crisis, most owners of commercial real estate borrowed 50% to 80% of the value (or acquisition cost) of the property, and most CMBS originators made loans up to 75% to 80% LTV. In 2006 and 2007, CMBS originators aggressively offered loan products that provided borrowers up to >95% LTV as underwriting standards deteriorated. During the 2008 financial crisis, most commercial real estate debt offerings (including CMBS) disappeared along with market liquidity. If debt was available, the terms were generally economically punitive (i.e., high coupons and maximum loan sizes up to 50% LTV based on depressed property values). As the CMBS market restarted, most CMBS originators reverted to more conservative underwriting standards with loans generally in the 55% to 75% LTV range.

Mortgage loans are also sized based on the ratio of the NOI of the underlying collateral to the debt service of the mortgage loan. This ratio is the *debt service coverage ratio* (DSCR). CMBS originators usually require a minimum DSCR of 1.2×; however, certain property-level characteristics could enable a CMBS originator to make a loan at lower DSCR thresholds (e.g., collateral is a long-term ground lease or tenants with lease terms greater than 15 years).

Finally, CMBS originators also focus on the *debt yield* to gauge the size of the proposed mortgage loan. Debt yield is calculated by dividing the annual NOI of a mortgaged property by the first mortgage balance. This percentage is the yield a lender would receive if the lender foreclosed on the asset (assuming the NOI remains constant) and provides an additional metric to size mortgage loans in environments where low cap rates, low interest rates, and long amortization periods can skew DSCR and LTV ratios. CMBS originators typically originate loans that provide a debt yield of 9% to 10% or higher.

Loan Structures and Features

CMBS dealers will disclose many loan features in the offering documents of a CMBS transaction. Commercial mortgage loans are generally originated with structural features to isolate the underlying collateral for the benefit of the trust. Most borrowers are single-purpose entities (corporations or limited liability companies) that are created for the sole purpose of owning the commercial real estate that is collateral for the mortgage loan. For larger loans, the single purpose entity includes organizational features that make it difficult for the borrower to declare bankruptcy. These legal protections are necessary for loans underlying CMBS transactions since most loans are nonrecourse, meaning the lender's only recourse in the event of a loan default is seizing the underlying collateral.

CMBS originators require additional loan features to protect the trust in the event the borrower fails to prudently operate the mortgaged property. CMBS originators typically require borrowers to establish reserve accounts with the loan servicer for various property expenses. For example, CMBS originators may require the borrower to remit the prorated portion of the annual property tax and property insurance payments as part of its monthly payment. CMBS originators could also require borrowers to make monthly payments for replacement reserves, tenant improvement, and leasing commissions. Depending on the mortgaged property and its condition, CMBS originators could also require debt service reserves, ground lease reserves, and other reserves to mitigate specific property conditions.

Some lenders may structure "holdbacks," which are additional loan proceeds that are held in reserve by the servicer. Holdbacks can be released to the borrower upon the achievement of certain property benchmarks (leasing goals, NOI goals, occupancy goals, and the like). In the event the holdback release criteria are not met, many holdbacks serve as additional loan collateral. In some cases, unreleased holdbacks could be used to pay down the loan principal balance and would cause a prepayment to the certificate holders.

CMBS originators typically require lockbox structures. Lockboxes are deposit accounts held by the servicer. If the CMBS originator required a hard lockbox, immediately following the closing of the loan, the borrower would be required to notify all tenants to forward their rental payments and reimbursements to the servicer for deposit in the lockbox and the borrower would have access to the funds pursuant to the terms of the loan documents. Originators impose various conditions on the release of funds from lockboxes. In many instances, the servicer will fund escrows and debt service on a monthly basis and release the remaining funds to the borrower. As the CMBS market matured, originators would permit soft lockboxes that allowed the servicer to sweep all amounts in the lockbox to a borrower-controlled account on a daily basis. Upon an event of default, the stringent cash management provisions would be imposed and the borrower would no longer have access to funds from the lockbox.

CMBS loans typically restrict prepayment during the loan term. CMBS originators would typically "lock out" all loans from prepayment during the first two to four years of the loan term. After this initial lockout period, borrowers could defease the underlying mortgaged property by substituting U.S. government securities as collateral for the loan. The substituted securities would generate cash flows to make the interest and principal payments of the underlying loan on schedule. The defeasance feature is acceptable to CMBS investors because it preserves the contracted loan cash flows while significantly reducing default risk. In some cases, in lieu of defeasance, CMBS originators would allow borrowers to prepay their mortgage loans with the payment of a prepayment penalty or yield maintenance charge. These prepayment penalties would partially compensate certificate holders for an early prepayment of a mortgage loan since their overall yield could be negatively affected by the prepayment.

CMBS originators will sometimes cross-collateralize several mortgage loans. This feature is utilized when a borrower finances several properties using separate mortgage loans (rather than collateralizing a single mortgage loan with multiple properties). Cross default occurs when the originator requires the borrower to agree that any default under the identified set of mortgage loans will cause a default under all the mortgage loans. Cross-collateralization is the corollary feature that allows the CMBS originator to use the collateral securing all mortgage loans to offset the loss on any single mortgage loan.

Diversification of CMBS Loan Pools

In order to understand credit risk, CMBS investors focus on large mortgage loan exposures and collateral concentration. The Benchmark 2019-B15 Mortgage Trust offering (Benchmark 2019-B15) illustrates many of the loan features, pool concentrations, and certificate features described in this chapter. Exhibit 27-2 describes the top 10 loans in the Benchmark 2019-B15 transaction.

CMBS transactions usually contain mortgage loans from all U.S. regions. Exhibit 27-3 illustrates the geographic concentration of Benchmark 2019-B15.

CMBS transactions should also contain adequate property type diversification. Concentration in a particular property type may make a CMBS transaction susceptible to specific downturns in a particular industry or segment of the economy. Exhibit 27-4 illustrates the property type concentrations in Benchmark 2019-B15.

The mortgage loans sold into a CMBS transaction can also provide default protection by including amortization. CMBS originators required amortization in the early or post-crisis vintages of CMBS but shifted to a preference of interest-only or partial interest only loans as credit markets mature and spreads tighten. Exhibit 27-5 illustrates the amortization terms and interest-only concentrations in Benchmark 2019-B15.

CMBS transactions may also include multiple loans to the same ownership group (Loan Sponsor) that are not cross collateralized. CMBS dealers typically make this information available during the offering process. CMBS investors should monitor the borrower concentrations in conduit transactions to ensure adequate diversity of borrower risk.

To mitigate concentration risk from the largest loans and keep the exposure below certain size thresholds that would require additional disclosures, CMBS issuers may split mortgage loans into multiple pieces. Structures include A/B notes, in which the B note provides subordination to the senior A note. Originators also split loans into "pari passu" structures in which the individual notes receive a pro rata portion of principal and interest (and losses in the event of a note loss).

If an originator creates a pari passu loan structure, the servicing of the loan would be assigned to the master servicer of the first securitization that owns the first securitized note from the pari passu loan. This servicer is responsible for collecting the loan payments and administering the loan for all the various notes created by the originator. Exhibit 27-6 describes the pari passu loans in Benchmark 2019-B15.

(1) Loans marked as “Serviced” are serviced pursuant to the terms of the Benchmark 2019-B15 transaction. Loans marked as “Outside Serviced” are serviced pursuant to the terms of another CMBS transaction which is usually the transaction where the first note of a loan combination is securitized.

(2) Pari passu means the other notes are in equal priority to the loan in this transaction. Pari Passu-AB means there is junior debt in the loan combination as well.

(3) Should control rights transfer from the B note to the A note, this transaction will control the loan servicing.

The Century Towers Mortgage Loan is a complex loan that the loan originator securitized among several CMBS transactions. A substantial portion of the $1.2 billion loan was securitized in CPTS 2019-CPT (a SASB deal). This $825 million transaction included a $525 million senior note and the $300 million B note. The other six senior notes are pari passu with the senior loan securitized in CPTS 2019-CPT and the B note provides credit support to all the senior loans as show in Exhibit 27-7. Exhibit 27-7 illustrates the loan structure.

By performing due diligence on the largest 10 loans in a CMBS transaction, CMBS investors can understand the credit risk profiles of approximately 35% to 70% of the collateral.

CMBS TRUST STRUCTURE

CMBS transactions begin with the origination of commercial mortgage loans by loan originators. Various insurance companies, specialty finance companies, conduits, GSEs, and banks have served as mortgage loan originators for CMBS transactions. Mortgage loans are sold by the originators to a depositor entity to facilitate the legal isolation of the mortgage loans. The depositor typically forms a common law trust via a Pooling and Servicing Agreement and transfers the mortgage loans to the trust. The trust issues certificates to investors in an aggregate amount that equals the cut-off balance of the mortgage loans. There is typically no over- or under-collateralization of CMBS trusts.

The rating agencies are engaged early in the transaction structuring process to review the proposed loan pool and provide preliminary certificate subordination levels for a CMBS transaction. Mortgage loan originators provide each rating agency with data and loan files to assist the rating agencies with performing their loan due diligence and site visits for properties securing mortgage loans. Rating agencies perform due diligence on the underlying loans and properties, including site visits, to determine the subordination levels required to achieve specific ratings. The issuer and transaction underwriters prepare various documentation for the transaction including the prospectus, pooling and servicing agreement (PSA), and Annex A, which contains detailed information about the underlying loans in the collateral pool. The transaction underwriters market the CMBS certificates to potential investors. The transaction underwriters acquire the certificates from the trust on the transaction settlement date and transfer the certificates to the investors. Exhibit 27-8 illustrates the relationships between the standard transaction participants.

Prior to the 2008 financial crisis, CMBS transactions consisted of tranches at every rating notch resulting in thin classes susceptible to being completely written down in the event a large loan experienced significant loss. Subsequent to the 2008 financial crisis, CMBS issuers have simplified capital structures by creating thicker classes that are better able to withstand the default of a single

loan. Exhibit 27-9 illustrates typical CMBS certificate structures before and after the 2008 financial crisis.

TRANSACTION PARTICIPANTS

Post-securitization, several parties are involved in the administration and management of a CMBS trust. The trustee is the administrator of the assets and liabilities of the CMBS trust and fulfills a variety of responsibilities. The trustee calculates and distributes principal and interest payments to CMBS certificate holders, prepares and discloses periodic remittance data, and maintains the trust's books and records. In certain cases, the trustee also provides support to the master servicer if the latter is unable to fulfill its responsibilities. The trustee receives a fee from the monthly interest income generated by the collateral for performing its duties. The trustee fee is senior to certificate holder interest payments. The trustee can also earn additional income by reinvesting cash flows received from the servicer that will be transferred to certificate holders at a later date (i.e., float).

The master servicer collects loan payments for distribution to the trustee in addition to performing basic servicing duties such as management of escrows, reserves, and lockboxes. The master servicer collects and provides periodic loan performance data and property financials to the trustee and rating agencies. When a loan becomes delinquent or distressed, the master servicer transfers its servicing duties to a special servicer that focuses on workout and loss mitigation activities. The master servicer continues to advance principal and interest on the delinquent loan to the trust as long as the advances are deemed to be recoverable upon loan workout. The master servicer also receives a fee that is generally a few basis

points of the outstanding mortgage balance. The master servicer's fee, similar to the trustee's fee, is also senior to certificate holder interest payments. The master servicer can also earn additional income by reinvesting underlying mortgage cash flows for a period of time prior to transferring to the trustee (i.e., float).

The special servicer manages distressed loans, which may be in delinquency, bankruptcy, foreclosure, etc. The determination of a distressed loan is typcially made by the master servicer, who then transfers the loan to the special servicer

*Although the approximate initial credit support percentages shown in the table above with respect to the non-vertically retained principal balance certificates do not take into account the VRR Interest, losses incurred on the mortgage loans will be allocated between the VRR Interest, on the one hand, and the non-vertically retained principal balance certificates, on the other hand, pro rata in accordance with their respective outstanding certificate balances.

for timely resolution and implementation of workout procedures. The special servicer's responsibility to the CMBS trust is to maximize recovery value of the distressed loan. The special servicer receives a monthly fee during the loan workout period based on the outstanding loan balance. The special servicer also receives compensation for a loan resolution, depending on whether a loan is liquidated or modified. Similar to the trustee and master servicer fees, the payments due to the special servicer are paid prior to allocating cash flows to the certificate holders.

The operating advisor was added after the 2008 financial crisis to help provide oversight of the special servicer and to represent the interests of all shareholders. After transaction losses reach a certain threshold, the special servicer is generally required to consult with the operating advisor regarding loan workout strategies. The operating advisor may recommend the replacement of the special servicer to certificate holders. The asset representation reviewer is a transaction participant added pursuant to SEC Regulation AB. Upon breaching a specified delinquency threshold and/or upon a certificate holder vote, the asset representation reviewer reviews delinquent or defaulted mortgage loans to confirm whether any loan seller representations were breached. If a loan seller breaches a representation and cannot cure the breach, the trust can request the loan seller repurchase the loan at par plus accrued interest and expenses.

CMBS transactions typically designate the most subordinate tranche as the controlling certificate holder, also referred to as the B-Piece Buyer. Since the controlling certificate holder is in the first loss position if the CMBS transaction sustains losses from a defaulted loan, the controlling certificate holder (via the controlling class representative) is empowered to make certain decisions. The controlling class representative is typically granted the power to (1) replace the special servicer and (2) approve the disposition plan for loans in special servicing. These control rights migrate to the class immediately senior to the current controlling certificate holder if the controlling certificate holder sustains losses in excess of 75% of its original certificate balance. Prior to 2000 and after 2008, CMBS transactions typically require the control rights to pass to the next most senior certificate holder when principal losses and ARAs (defined below) exceed 75% of the controlling certificate holder's original certificate balance. In contrast, CMBS transactions issued from 2000 through 2008 allowed the controlling certificate holder to remain in place even when principal write downs in excess of 75% of the controlling certificate holders original certificate balance were imminent.

TRANSACTION FEATURES

CMBS issuers generally incorporate a standard set of transaction features regardless of vintage. CMBS transaction features have evolved since the 1990s with issuers incorporating changes to meet investor demands and new risk retention requirements.

Subordination and Risk Retention

CMBS certificates are modeled along time and credit dimensions to create a "capital structure" with varying cash-flow and risk profiles that cater to different investors. For example, senior certificates typically have priority to principal payments, and therefore, are the shortest certificates in a transaction. Junior certificates are subordinate to senior tranches with respect to principal cash flows and are also first in line to absorb collateral losses. The subordination rate, which is a measure of credit support for a certificate, is defined as the percentage of the collateral balance that must experience a complete principal write-down before the certificate in question is exposed to principal loss. Subordination rates are highest for the senior most certificates in the transaction and decrease down the capital structure.

Conduit transactions have three distinct categories of principal-pay certificates—AAA classes, mezzanine classes, and junior credit classes—with one or more interest-only (IO) certificates. Prior to 2008, the AAA classes were generally further divided into three different subordination levels starting with super-dupers (senior-most tranches in the transaction—classes A1 through A4 in Exhibit 27-9) at the top of the capital structure having attained the highest subordination rates (usually 30%), followed by mezzanine AAA (the AM class), and junior AAA (the AJ class) certificates. After 2009, dealers simplified AAA certificate structures. The AAA classes are divided into two subordination levels starting with Senior AAA at the top followed by mezzanine or junior AAA (the AS class).

The senior AAA certificates constitute approximately 70% of the transaction principal balance and are the senior most certificates in the transaction. A typical conduit transaction has six senior classes—A1, A2, A3, A4, A5, and A-AB—each with a different cash-flow profile. The A1 certificate, which is the first-pay AAA, is the shortest certificate in the transaction with a WAL of approximately two years. The A1 also amortizes gradually over time, unlike the A2 and A3 certificates, which have bullet-like principal cash-flow profiles because these certificates are usually tied to five- or seven-year balloon loans. In order to maintain the bullet cash-flow profile of the medium-term AAAs, the A-AB tranche absorbs amortizing principal cash flow between the maturities of the A2 and A3 classes. Similar to the A2 and A3 classes, the A4 and A5 certificates also have a bullet-like principal cash-flow profile tied to 10-year balloon mortgages. The A4 certificates are paid down first in the event of unscheduled principal prepayments from the 10-year loans. The A5 certificate is typically the largest of the AAA classes and also has the longest WAL. The A5 class is often referred to as the benchmark certificate, or "last cash flow" of the transaction.

The mezzanine AAA class (the AS certificates) are usually structured with 18.0% to 22.5% subordination and are also modelled to receive principal from balloon loans with a bullet-like principal cash-flow profile. Most certificates subordinate to the AAA-rated classes are typically rated between AA and BBB– and constitute a smaller portion of the original transaction balance. These certificates are also generally modelled to 10-year balloon payments. CMBS transactions can also include tranches rated below BBB– or unrated first-loss classes known as B-pieces. These tranches are modelled to receive principal from the longest maturity loans in the collateral pool. The B-piece is generally the controlling class and retains certain voting rights that allow them to replace the special servicer.

Government regulation under the Dodd-Frank Wall Street Reform and Consumer Protection Act (Dodd-Frank) significantly impacted CMBS subordination structures. Starting December 24, 2016, CMBS transactions had to comply with the Dodd-Frank Risk Retention rule, which requires securitization sponsors retain 5% of the market value of a transaction to better align the interests of sponsors with those of investors. The risk retention requirements can be satisfied using three methods. First, the issuer can retain a vertical option that equates to a piece of every security in the capital structure such that the total retained amount is equal to 5% of market value. Second, the issuer can retain a horizontal option equating to the most junior 5% first loss tranche. Finally, in the L-shape hybrid option, the issuer can retain a combination of vertical and horizontal interests such that the total interest achieves the 5% level. Transactions sponsors have utilized each of these options with horizontal and hybrid structures being most prevalent.

Dodd-Frank granted an exception to the risk retention rule that allows a B-piece buyer to fulfill the risk retention requirement if certain conditions are met. Regulators recognized that B-piece buyers are sophisticated institutional investors who perform extensive loan-level due diligence and have an alignment of interest with senior investors. B-piece buyers must hold the risk retention certificates for at least five years and they cannot finance the certificates to reduce their credit exposure (interest rate and currency hedges are allowed).

Pass-Through Rates

Traditional conduit transactions are structured such that the net weighted average coupon of the collateral (the assets) exceeds the weighted average coupon of the certificates (the liabilities). The net weighted average coupon of the collateral equals the weighted average coupon of the collateral less the fees payable to the trustee and master servicer. This structure results in excess interest cash flow which is directed to the IO tranches. IOs by definition do not receive any principal.

Conduit CMBS certificates can have three types of coupon structures: fixed-rate, WAC (weighted average coupon), and WAC-capped. Most CMBS tranches pay a fixed-rate coupon. WAC certificates pay the weighted average net coupon of the collateral, which can vary over time as the composition of the collateral pool changes. WAC-capped certificates pay the minimum of a fixed-rate and the WAC rate and are generally lower in the capital structure.

Priority of Payments

In general, given the relative simplicity of CMBS capital structures, the allocation of cash flows and losses across the capital stack—known as the "waterfall structure"—is fairly straightforward. The A-AB tranche adds a layer of complexity, which is described in detail below.

Principal payments are allocated sequentially from the top of the capital structure to the bottom. Principal cash flows are generated from loan maturities, scheduled amortizations, prepayments, and default recoveries. The sequential payment structure implies that in general a certificate will receive principal payments only if the tranches senior to it in the capital structure have completely paid off.

The A-AB tranche first receives principal in accordance with its amortization schedule and any excess is diverted to the A1, A2, A3, A4, and A5 classes in sequential order. The A1 tranche (which is the first-pay certificate) receives principal payments only if the A-AB tranche has received its allocated principal to date. Following the sequential structure, the A2 class does not receive any principal until the A1 class has been fully paid off, the A3 class does not receive any principal until the A2 class has been paid off, the A4 class does not receive any principal until the A3 class has been paid off, and the A5 class does not receive any principal until the A4 class has been paid off.

While principal is allocated in "top-down" fashion, losses are allocated "bottom-up" in reverse-sequential order. Given that the credit enhancement in a CMBS transaction is in the form of subordination, a particular tranche will not experience losses until the certificates underneath it in the capital structure are completely written down. It is important to note that all the senior AAA certificates in a transaction share the same level of subordination. As a result, although principal cash flows are allocated sequentially to the senior AAA certificates, losses are allocated pro-rata across the senior AAA certificates after the more junior tranches experience complete principal write downs. Interest payments are allocated pro rata to the senior AAA certificates and to the IO tranche and then sequentially to the rest of the certificates. Interest cash flows are a function of current debt service payments plus any late interest payments from prior periods, received in the current period.

Exhibit 27-10 illustrates the certificate subordination and priority of payments for the Benchmark 2019-B15 transaction.

Interest-Only Certificates

Most CMBS transactions also have an IO tranche. As mentioned, the weighted average coupon that is paid to all the non-IO tranches is generally less than the total interest from the collateral pool. This excess interest is allocated to the IO tranche, once all the non-IO tranches in the trust have received their allocation of the interest payments. The notional balance of the IO tranche may be based on the aggregate balance of the AAA tranches alone or on the entire transaction, depending on the level of the coupon being stripped off of various tranches.

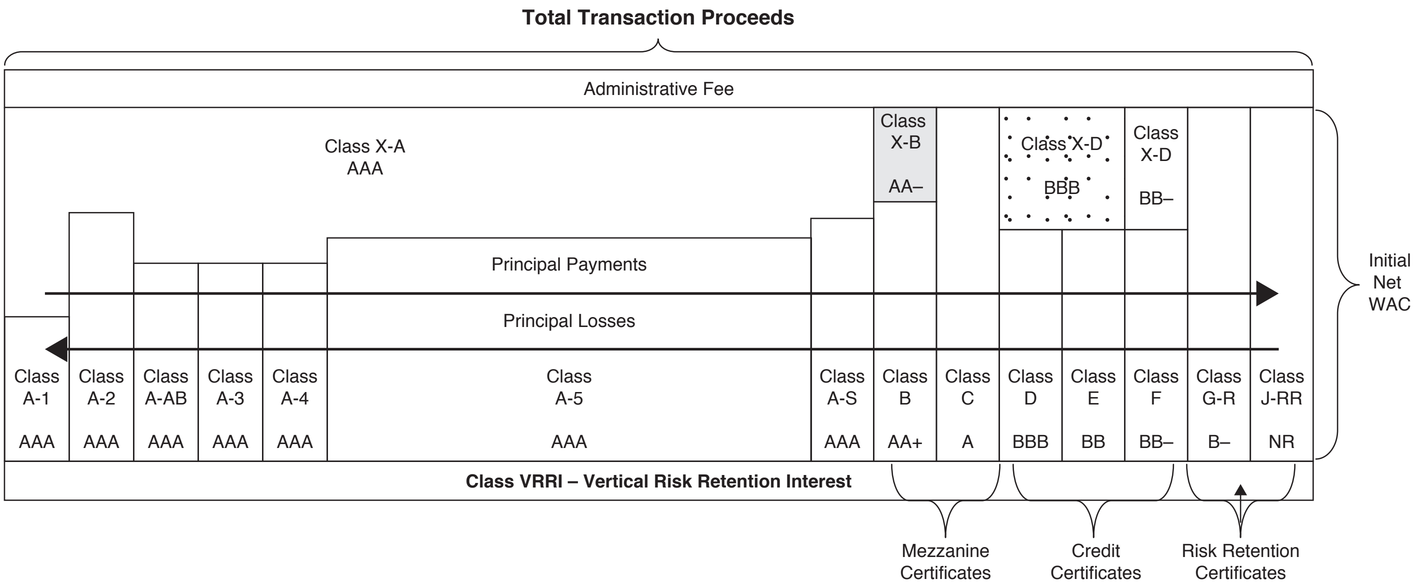
If the difference between the collateral and certificate coupons is substantial, transactions may contain a planned amortization class (PAC) IO structure, where multiple classes of IOs exist, with one class of IO certificates treated as support bonds to absorb the impact of prepayments so that the PAC IO investor receives stable cash flow and low yield variability.

Payment Advancing and Appraisal Reductions

When a loan becomes delinquent, the master servicer is generally obligated to advance principal and interest to the trust to minimize the variability in monthly cash flows to the certificate holders. However, the amount the servicer advances is based on whether it deems the advanced amounts to be

EXHIBIT 27-10

Benchmark 2019-B15 Certificate Structure



recoverable upon liquidation. In order to determine the advanced amount, the servicer hires an appraiser who appraises the property. A haircut (typically 10%) is applied to the appraisal amount and compared to the outstanding loan balance at the time of delinquency. The servicer then advances payments based on the lower of the outstanding loan balance and the adjusted appraised value. This difference is called an *Appraisal Reduction Amount* (ARA). If the delinquency level in a trust is fairly high or if appraised values are substantially lower than the outstanding loan balances, there could be a situation in which interest shortfalls could result to the trust since the servicer's advances are not enough to cover interest payable to all certificate holders. Once the loan is liquidated, proceeds from the liquidation will go first to the servicer to reimburse servicing advances.

Clean-Up Call Provisions

Each CMBS transaction includes a clean-up call provision that enables the outstanding certificate holders to purchase the remaining mortgage loans in a trust. The clean-up call is usually limited to when the remaining balance of mortgage loans represents approximately 1% and 3% of the original balance of the trust. The purchase price is typically the outstanding balance of the mortgage loans plus accrued interest. The clean-up call is utilized to wind down CMBS transactions when the balance remaining in the transaction is too small to justify the ongoing administration costs.

MARKET DEVELOPMENT

The CMBS market developed in the early 1990s with the need to dispose of commercial real estate loans owned by the Resolution Trust Corporation (RTC) as a consequence of the savings and loan crisis. The RTC packaged loans from failed institutions into CMBS transactions using a Real Estate Mortgage Investment Conduit (REMIC) structure under the tax code. This provision was passed as part of the Tax Reform Act of 1986 and allows tranches of securities that would otherwise be treated as equity interests to be treated as debt instruments. The CMBS market grew quickly in the 1990s, culminating in issuance of $74 billion in 1998. The Russian debt crisis and related contagions created substantial turmoil in the debt markets in August 1998, causing a temporary slowdown in CMBS issuance. Transaction volume surpassed 1998 levels in 2003 and CMBS issuance underwent explosive growth through 2007 with $228 billion of issuance as demand for spread products remained elevated.

Beginning in late 2007 with spreads widening and contagion from the subprime crisis spreading, issuers curtailed loan originations, in part due to their inability to hedge credit-spread risk in a spread-widening environment. Issuers delivered nine transactions in 1H-2008 with the CMBS market seizing up in July 2008. No private-label transactions were brought to market until Q4-2009, when the only TARP-eligible securitization was sold to the market. In 2010, the market slowly experienced increased transaction volume with total annual private issuance of approximately $13 billion. Since the 2008 financial crisis, the agency CMBS market has significantly increased in volume compared to pre-crisis offerings. The private-label CMBS market returned to volumes ranging from $70 to $100 billion but never regained the momentum of CMBS 1.0 originations. The CMBS 1.0 deal performance worsened in later vintages, with dozens of junior AAA certificates and at least two mezzanine AAA certificates experiencing losses from the 2005–2008 vintages. This experience validates the modern conduit CMBS structure with mezzanine AAA certificates generally being the lowest offered AAA security with subordination of 18.0–22.5%.

Exhibit 27-11 sets forth historical CMBS origination volumes.

1. Private label U.S. CMBS data in this document does not include CRE-CLOs. It is limited to Conduit, Large Loans, and Single Asset/Single Borrower.

2. Agency CMBS data does not include Fannie Mae DUS. It is limited to Freddie Mac, Fannie Mae Remics, and Ginnie Mae Project loans.

From 2001 through 2007, CMBS credit-spreads experienced a general tightening trend.[1] At the height of the market in early 2007, CMBS spreads relative to Treasuries (T) had tightened to approximately T+0.60% for 10-year senior AAA certificates and T+1.20% for BBB-rated certificates. The 2007 subprime mortgage crisis impacted CMBS pricing and in August 2007, spreads on 10-year senior AAA certificates had widened considerably (T+1.50%). Spreads on BBB-rated certificates in early 2007 were T+1.25% and subsequently widened to T+4.75% by the fall of 2007. During the 2008 financial crisis, dealers and investors began trading all certificates on dollar prices (vs. spread-based pricing) with senior AAA certificates trading at steep discounts to par value. Since the restart of the CMBS market in 2010–2011, spreads on senior AAA certificates have generally traded in a range of T+0.60% to T+1.50% and BBB-rated certificates in a range of T+2.00% to T+6.00% (other than spikes related to the 2020 COVID-19 pandemic). Spreads on lower-rated certificates have not returned to the low levels observed prior to the 2008 financial crisis. See Exhibit 27-12 for a history of CMBS spreads for AAA and BBB–certificates.

MODELING

Market participants consider two primary types of risks when analyzing CMBS—interest rate risk and credit risk. Interest rate risk is important given most certificates are fixed-rate and relatively long duration because the underlying loan maturities are in the 5- to 10-year range. Credit risk is relevant since any losses resulting from loan defaults are borne by the certificate holders.

The 0/0 Scenario

Prior to the 2008 financial crisis and subsequent downturn, commercial mortgage defaults had been low and had not impacted senior certificates. As a result, investors traditionally relied on what is referred to as a *0/0 framework,* which means zero prepayments (as measured by the conditional prepayment rate, CPR) and zero default rates (as measured by the conditional default rate, CDR), to quote CMBS prices and yields. This implies that there are no prepayments, defaults, or losses on the collateral pool. This simplistic modeling framework is often augmented with additional loan default and extension scenarios as liquidations and extensions have become more common. Prepayment risk is generally not significant for commercial mortgages due to typical prepayment restrictions at the loan level.

The 0/0 Scenario is important to determine when a certificate holder receives principal payments. CMBS certificates have a *Rated Final Distribution Date* that is usually three years after the amortization term of the mortgage loan with the longest amortization period. For example, the securities in the Benchmark

2019-B15 transaction have a Rated Final Distribution Date of December 2072, which would indicate the investments have a 52-year term. This date was set due to one loan with a long amortization period (see Exhibit 27-5) and it would be inaccurate to model cash flows for all certificates assuming this date. CMBS transactions also disclose an *Assumed Final Distribution Date* for each tranche of offered certificates. The Assumed Final Distribute date is the date a certificate's balance would be reduced to zero assuming the 0/0 Scenario. Exhibit 27-13 sets forth the Assumed Final Distribution Dates for the publicly offered certificates in the Benchmark 2019-B15 transaction.

EXHIBIT 27-13

Assumed Final Distribution Dates for the publicly offered certificates in the Benchmark 2019-B15 transaction

Class of Certificates	Assumed Final Distribution Date

Class A-2	November 2024
Class A-3	November 2026
Class A-4	October 2029
Class A-5	November 2029
Class A-AB	May 2029
Class B	November 2029
Class C	December 2029

Probabilistic Modeling

Probabilistic models attempt to draw statistical relationships between commercial loan performance and identified drivers of performance. For example, loan default and severity are generally built as a function of DSCR and LTV. All else equal, perceived credit risk is higher with higher LTV and lower DSCR. Investors attempt to project future loan performance by studying the empirical relationship between historical defaults/severities and the pool's DSCR/LTV.

Deterministic Modeling

Market participants also rely on a deterministic modeling approach. Deterministic models employ a rules-based framework in which loan outcomes are determined by projected property performance and valuation after subjecting the underlying collateral to a series of tests and triggers. Loan performance and valuation are estimated using projected DSCR and LTV (similar to probabilistic models), which in turn are calculated from NOI and cap rate. The NOI and cap rate inputs into deterministic models can vary by property type and/or geography and are typically generated using macroeconomic models that incorporate real estate fundamentals. Each mortgage loan's projected DSCR and LTV is compared through time to a set of trigger levels to discretely determine one of three possible loan outcomes: term default, timely pay-off, or maturity default/loan extension. The three loan outcomes are described in more detail below:

- *Term Default*: During the term of the mortgage loan, periodic tests are run to determine if the loan's DSCR drops below a pre-defined *DSCR default trigger and LTV default trigger.* The loan is immediately defaulted and enters a workout period if both triggers fail. At the end of the workout period, the property's terminal value is determined using NOI and cap rate, less a workout or disposition fee. If the final property value is less than the outstanding loan amount, the deficit is recorded as a loss. If the property's NOI never drops below the DSCR trigger, no default is assumed during the loan's term.
- *Timely Pay-Off*: At the loan's maturity date, property value is once again determined by applying a cap rate to projected NOI. The loan is assumed to pay off on time if the property value is sufficiently above the outstanding loan amount (e.g., LTV < 80%).
- *Maturity Defaults/Loan Extensions*: If the loan does not pay off as scheduled at maturity, it either enters into a one-time term extension or defaults. Deterministic models generally assume that the loan is extended as long as it is not underwater (LTV < 100%), whereas under-collateralized loans (LTV >100%) are assumed to default at maturity. In the case of maturity default, the property value is calculated at the end of the workout period to determine the loss amount. If the loan is extended, the pay-off versus default calculation is repeated at the end of the extension period.

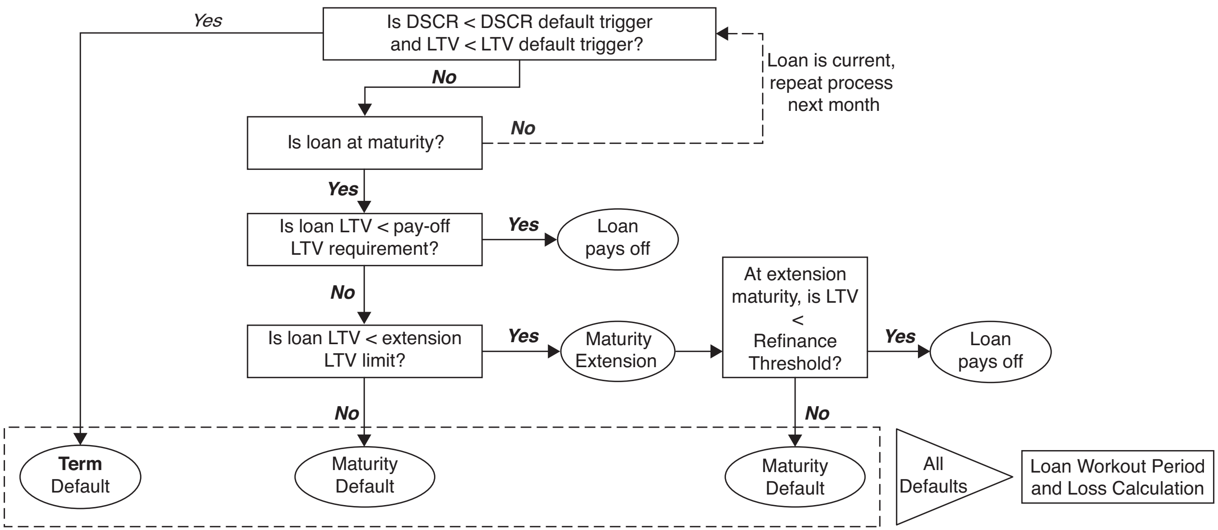
The DSCR and LTV thresholds are typically set based on a combination of observed historical performance, real estate market trends, and the participant's experience and judgment. Exhibit 27-14 is a graphical representation of a sample deterministic framework.

KEY POINTS

- There are major structural and modeling differences between CMBS and other mortgage products.
- Agency CMBS transactions have increased market share in recent years alongside private-label transactions. Agency CMBS transactions are generally backed by multifamily and healthcare facilities, while private-label transactions have office, retail, industrial, hotel, and multifamily as the primary real estate property types.
- CMBS typically have many structural features that protect senior investors from credit losses while allowing flexibility for the senior portion of the capital structure to target narrow maturity windows.

EXHIBIT 27-14

Deterministic Model Logic Tree



- Impacts of prepayments can be somewhat muted given the prepayment restrictions of most mortgage loans.
- Given the idiosyncratic nature of commercial real estate within CMBS transactions, bottom-up loan and property level analysis is necessary to understand the underlying credit and extension risks.

CHAPTER

TWENTY-EIGHT

CREDIT CARD ASSET-BACKED SECURITIES

John McElravey, CFA
Managing Partner
First XV Partners

The securitization of credit card receivables began in 1987, but truly exploded onto the fixed income scene during the mid- to late 1990s. Credit card asset-backed securities (ABS) grew rapidly over the ensuing 20 years to become the largest nonmortgage ABS sector. Primary market volume increased rapidly as large commercial banks tapped a growing pool of capital. New specialty credit card lenders used ABS to fund expansion. Credit card ABS averaged $62.5 billion per year from 2000 to 2009, and credit cards became a consumer ABS staple (Exhibit 28-1).

Because of its liquidity, transparency, and relatively high-credit-quality sponsors, credit card ABS became the benchmark for most other kinds of securitizations, and something of a safe haven for ABS investors during periods of market volatility. Indeed, many investors making their initial foray into ABS would likely dip their toes into credit cards before wading into the many other asset classes available. This chapter summarizes the key structural features of credit card securitization and provides an overview of the credit card ABS market.

As a result of the growing use of securitization, credit card ABS outstanding grew from just $131 billion in 1995 and peaked at $325 billion in 2007 (Exhibit 28-2). The size of the credit card ABS market corresponded with the growth in the credit card lending market overall. Consumers came to rely on credit cards as a convenient method of payment for an expanding universe of goods and services, as well as an easy means of accessing credit. At the same time, credit card lenders viewed direct access to funding in the capital markets as a cost-effective alternative to gathering core deposits.

However, since 2009 the amount of credit card ABS outstanding has fallen precipitously. Commercial banks have come to rely less on ABS as a source of funding for credit card loans because of an abundance of lower-cost deposits. Furthermore, regulatory incentives have been put in place that encourage other kinds of corporate debt that count for capital purposes. ABS is not included for regulatory capital purposes. Issuance of credit card ABS seems likely to lag

EXHIBIT 28-1

Credit Card ABS Issuance: 1987–2018

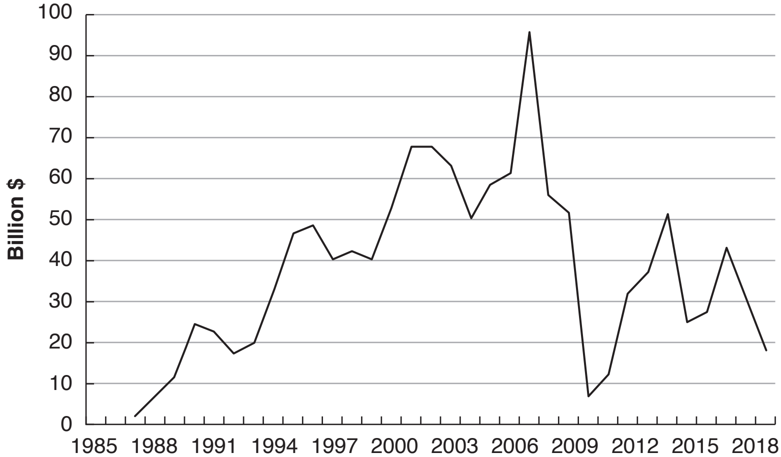


EXHIBIT 28-2

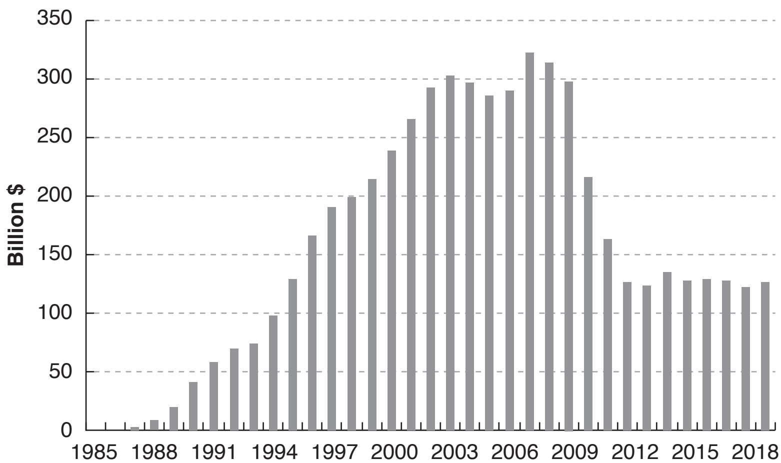
Credit Card ABS Outstanding



other sectors, such as auto loans and leases, unless receivables growth increases or other incentives for banks change. Nevertheless, credit spreads on credit card ABS remain low, and credit card spreads offer benchmark comparisons to other ABS sectors.

SECURITIZATION OF CREDIT CARD RECEIVABLES

Credit card securitizations began in the late 1980s and early 1990s by banks looking to diversify funding sources for their credit card businesses and as a way to remove assets from balance sheets. At that time, the banking industry faced the imposition of stricter capital standards by regulators. Securitization provided a vehicle to help meet these standards by reducing balance sheet assets and thereby improving regulatory capital ratios.

Beyond the beneficial capital treatment, securitization also allowed specialized credit card banks to enter the market and grow rapidly without having to rely heavily on attracting consumer deposits as a cheap funding source. These specialty banks, which included MBNA, First USA, and Capital One, were able to access the credit markets directly and achieve funding costs that were competitive with those of the established bankcard issuers. Much of the increased innovation and competition in the credit card market during the 1990s can be traced to these banks, which could not have grown as rapidly as they did without the benefits afforded by securitization.

Certain changes in accounting rules over time, namely FAS 166/167, forced most credit card securitizations back on the balance sheets of commercial banks. This move reduced or eliminated the advantageous capital treatment of securitization relative to other forms of on-balance-sheet funding. As a result, credit card ABS compete with equity, debt, and deposits to fund the credit card lending businesses of commercial banks. While it may be smaller than it was in the past, it seems likely that the credit card ABS market will remain a core segment of the consumer ABS market, and an important source of funding for some credit card lenders.

Basic Master Trust Structure

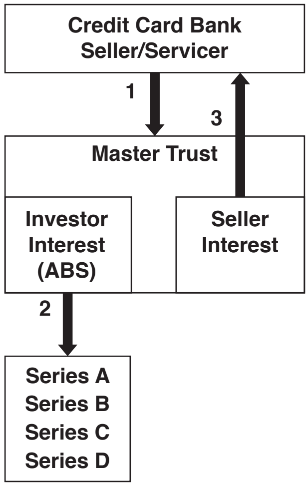
The structure used for credit card securitization until 1991 was a stand-alone trust with a dedicated pool of credit card accounts and the receivables generated by those accounts. Each securitization required a new trust and a new pool of collateral, and the securities were backed only by that collateral pool. Since 1991, the master trust has become the predominant structure in the market (Exhibit 28-3).

As the name implies, the issuer establishes a single trust that can accept periodic additions of accounts and issue multiple series of securities. All of the securities issued by the master trust are supported by the interest and principal collections from all of the receivables contributed to it. The collateral pool is not segmented to support any individual securities.

The credit card issuer, and seller/servicer of the accounts and receivables, pledges the accounts to the master trust (step 1). The master trust sells securities to investors (step 2) in various series. The investors are entitled to their share of interest and principal collections and are allocated their share of defaults and losses. At the same time, the seller/servicer maintains an interest in the master

EXHIBIT 28-3

Basic Master Trust Structure



trust called the seller interest. This seller interest is not credit enhancement for investors but is *pari passu* with investors. The seller interest receives its share of interest and principal collections and is allocated its share of defaults and losses. This is returned to the issuing bank (step 3).

For the issuer, the master trust structure reduces the cost of issuing ABS and provides greater flexibility. From the investor's point of view, assessing the credit quality of a new issue may require less analysis because there is only one pool of collateral to review. As the collateral pool in the trust grows, it generally becomes more diversified. While the characteristics of the collateral pool may change somewhat over time owing to changes in interest rates, underwriting criteria, industry competition, and so on, any change in the master trust would likely be more gradual than would the differences in stand-alone pools.

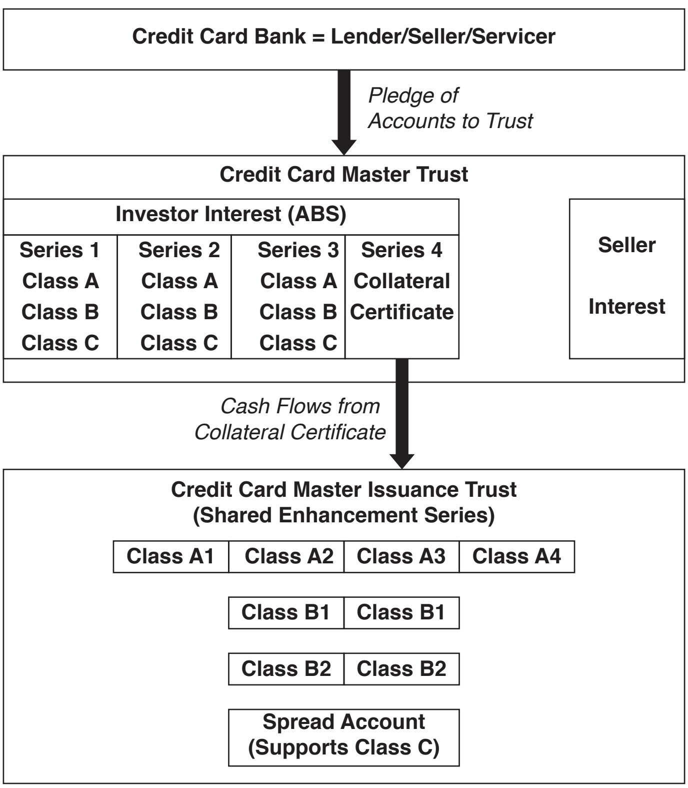
Master Note/Owner/Issuance Trust Structures

Credit card master trust structures evolved over time, and now most issuers utilize structures called master note or owner or issuance trusts. This chapter will refer to them as issuance trusts (IT). The bonds issued by an IT are still backed by a pool of revolving credit card accounts and receivables, and the credit analysis for investors is not affected in a meaningful way. However, there are important structural differences from older credit card master trusts using earlier technology. Perhaps most importantly, the IT structure provides the issuer with additional flexibility to meet investor demand for different maturities or types of bonds.

Because of consolidation in the credit card industry over time, many surviving credit card ABS issuers may have had more than one legacy credit card trust with its particular collateral pool. Exhibit 28-4 presents an example of an IT structured by an issuer active in the market with a legacy credit card master trust. Like our simple example above, the credit card bank pledges the accounts and receivables to its credit card master trust. This legacy trust has several series outstanding in the investor interest and each series has its own dedicated credit enhancement (Series 1–3). Then, the credit card bank decides to establish an MOT to take advantage of the state of the art in the securitization market. To accomplish this, the existing master trust issues a *collateral certificate* (Series 4). The collateral certificate represents an undivided interest in the assets of the legacy master trust and is allocated its proportionate share of principal collections, finance charges, defaults and losses, and servicing fees. For credit card banks with more than one legacy master trust, it is conceivable that each one could issue a collateral certificate that could be used to pass through to the IT.

EXHIBIT 28-4

Master Issuance Trust Structure



Credit card ABS issuers gravitated to the IT structure primarily for the increased flexibility that it allows when issuing new securities. Under the early master trust programs, issuers were required to issue subordinated bonds at the same time as the senior bonds. The senior and subordinated bonds were linked. However, the current credit card issuance trusts can be likened to a corporate medium-term note program. Different classes of securities can be issued at different times, in varying sizes, and with distinct maturities. This flexibility allows the issuer to be opportunistic with regard to the timing of new ABS securities, and to tailor those securities to the demands of its investor base.

This characteristic of the IT is sometimes referred to as a "delinked" issuance trust because the AAA-rated senior securities can be issued separately from the subordinated bonds that provide credit enhancement for the senior notes. The subordinated bonds are no longer directly linked to a specific series of senior bonds having the same maturity. In the IT structure, all of the outstanding subordinated classes act as credit enhancement for all the senior classes. These may be known as the *shared enhancement series*, and it can be seen in the lower section of Exhibit 28-4.

New senior bonds can only be issued to the extent that there is a sufficient amount of subordinated bonds already outstanding. For example, Class B bonds can only be issued if there is a sufficient amount of Class C bonds already outstanding to support them, and Class A bonds can only be issued to the extent there is an appropriate amount of Class B and Class C bonds. A "sufficient amount" is the amount of credit enhancement required by the rating agencies to maintain the desired credit ratings on the bonds.

Subordinated bonds may have different maturity dates than the Class A bonds. If a subordinated class matures prior to a senior class, then a replacement subordinated bond must be issued prior to the maturity to take its place. If a replacement bond cannot be issued in time to maintain the required credit enhancement, then principal collections would be deposited into an account that would support the senior bonds. Therefore, the senior bonds would always have an appropriate amount of credit enhancement outstanding. The senior bonds benefit from the subordination up to and including the required amount. They would not have the benefit of subordinated bonds issued in excess of the required amount.

The IT structure also became popular with issuers and investors because it allowed for an expansion of the potential investor base for credit card ABS, especially for the subordinated bonds. Securities could be issued as notes rather than as pass-through certificates. In doing so, all classes, including the subordinated classes, can achieve Employee Retirement Income Security Act (ERISA) eligibility. This feature is important because pension funds, a significant source of fixed income investor funds, can only buy securities that meet ERISA guidelines. In this way, the total investor base for credit card ABS was expanded, especially for subordinated bonds which very often could not achieve ERISA eligibility. Liquidity improved for subordinated bonds which had lagged the senior classes. In addition, the IT structure allows for easier and more timely execution of reverse inquiry issuance when an investor has a particular coupon or maturity need.

In practice, the issuance of subordinated bonds has stopped among the largest bank card issuers of credit card ABS. Those bank issuers have retained the subordinated bonds. Only a few issuers are continuing to make them available to outside investors, usually those without deposit taking networks. Relatively wide credit spreads on subordinated bonds in the credit card ABS sector means it is more economical for issuers to retain those securities.

Investor Interest and Seller Interest

Credit card master trusts allocate credit and cash flows between the ABS investors and the master trust sponsor. The sponsor is typically the seller/servicer of the accounts pledged to the trust. The *investor interest* is simply the aggregate principal amount owed to the ABS investors. The *seller interest* is a residual interest in the trust that the credit card issuer is required to maintain. The seller interest aligns the incentives of the credit card bank with those of the outside investors because the seller has a pari passu claim on the cash flows of the trust. As noted earlier, the seller interest receives its share of finance charge collections and principal repayments, as well as its allocation of defaults and net losses.

The minimum required seller interest for most master trusts tends to be in the 4% to 7% range of outstanding receivables balances. In practice, the seller interest is likely to be higher than the minimum required by the rating agencies depending on the sponsor's strategy toward using securitization for its funding needs relative to other forms of financing. In addition to aligning the interests of the issuer and the investors, the seller interest is in place to absorb the fluctuations in the amount of outstanding receivables.

For example, seasonal patterns of credit card usage mean that the receivables outstanding can change substantially from month to month. In addition, the seller interest would be allocated dilutions from purchases that have been reversed and any ineligible receivables to back the ABS. The seller interest does *not* provide credit enhancement for the ABS, at least not directly. Credit enhancement for the ABS, discussed more fully later, is provided by subordinated securities in the investor interest, or by other structural features of the master trust.

As an issuer's credit card business grows, new accounts that meet the eligibility criteria may be added to a master trust. An account addition normally requires rating agency approval, unless it would amount to a relatively low percentage of the current receivables balance (usually 10% to 15%). Sponsors may also withdraw accounts from the master trust, again with rating agency approval. Sellers are obligated to add accounts if the seller interest falls below the minimum level. If the seller is unable to add receivables, then an early amortization event is triggered, and investors begin to receive principal repayments immediately. The risk of an early amortization gives the seller a powerful incentive to support its credit card securitization because it is often a substantial portion of the funding for the credit card business. Early amortization and sponsor support will be addressed more fully later in the chapter.

THE CREDIT CARD ABS LIFE CYCLE

Under normal circumstances, the life cycle of credit card ABS can be divided into two main periods after it has been issued: the revolving period and the amortization period.

Revolving Period

During the revolving period, investors receive interest payments only. Principal collections on the receivables are used to purchase new receivables created from customer card usage, or to purchase a portion of the seller interest if there are not enough new receivables being generated by the designated accounts. The revolving period can be used by an issuer to finance short-term credit card loans over an extended period of time. Furthermore, the revolving period is a structural device used to maintain a stable average life on the credit card ABS, and to create more certainty for investors for the expected maturity of the bonds.

Amortization Period

After the end of the revolving period, the amortization period begins and principal collections are used to repay the ABS investors. The length of the amortization period may vary depending on the monthly payment rate (MPR) of outstanding principal of the accounts in the master trust. The MPR is the unannualized percentage of the principal receivables balance repaid each month. Trusts with slower MPRs would likely require longer amortization periods than those with faster MPRs. For example, credit card ABS with a five-year expected maturity might have a 48-month revolving period and then enter amortization for the final 12 months of its life. The amortization period of credit card ABS usually may be accomplished through either controlled amortization or controlled accumulation. Most trusts today favor a controlled accumulation of principal to pay off its maturing ABS.

In a *controlled amortization*, principal payments are made to ABS investors in equal payments during the amortization period (Exhibit 28-5). This simplified example assumes that one investor series has been issued out of the master trust. During the four-year revolving period, investors receive only interest payments and principal collections are used to purchase newly created credit card receivables. The total amount of receivables varies over time between \$1.5 billion and \$1.6 billion during the revolving period, and these fluctuations are absorbed by the seller interest. The seller interest percentage averages 23% through the first 48 months, well above the typical minimum levels. At the beginning of year 5, the revolving period ends, and the controlled amortization begins. In our example, investors receive principal payments in 12 equal installments, and principal collections not needed to repay ABS investors are used to purchase newly created receivables from the cardholders. Interest payments continue based on the declining principal balance of the ABS.

EXHIBIT 28-5

Controlled Amortization

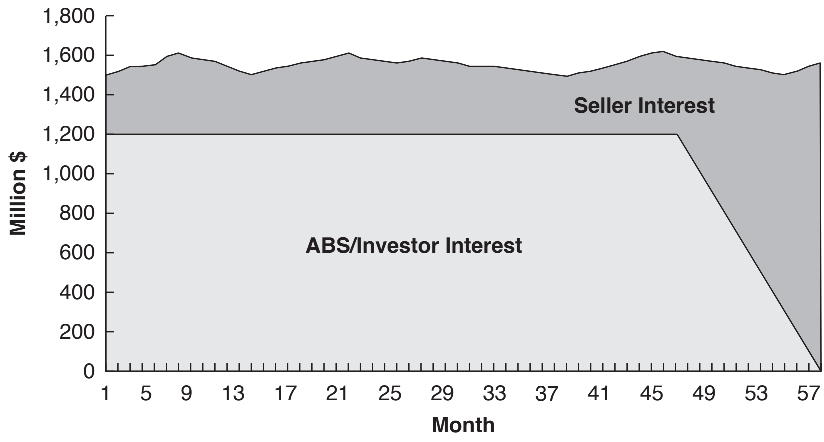


EXHIBIT 28-6

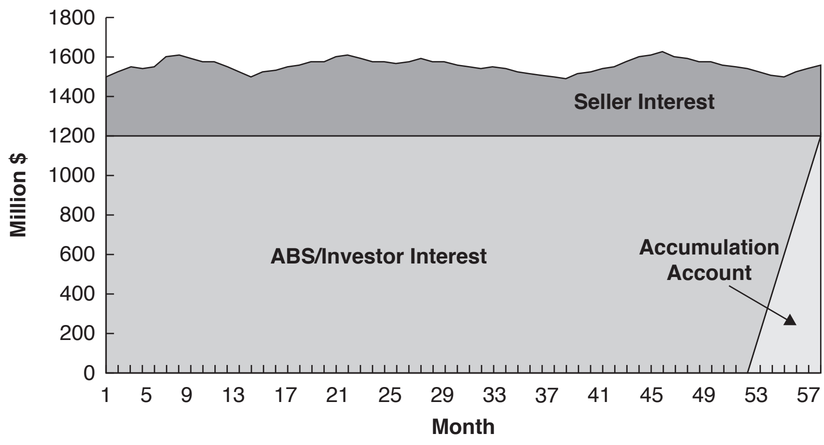
Controlled Accumulation



In a *controlled accumulation*, principal collections needed to repay ABS investors are deposited each month into a trust account and held until the expected maturity date (Exhibit 28-6). This example again assumes a five-year revolving period. As the end of the revolving period approaches, principal collections are collected in installments and excess principal collections are used to purchase new receivables. Interest payments to investors during the accumulation period are made based on the original outstanding invested amount. A single "bullet" payment of principal is made at maturity to the ABS investors.

In this example, principal is accumulated over six collection periods, which funds the repayment of ABS investors. This structural device developed as a way to emulate the cash-flow characteristics of a corporate bond. It is generally referred to as a "soft bullet" because, like most securitizations of consumer assets, the legal final maturity of the ABS bond is beyond the expected maturity date of the bond to account for potential variations in principal collections.

Early Amortization

Under certain circumstances, such as poor credit performance or a financially troubled servicer, an early amortization of the master trust could occur as a mechanism to pay off ABS investors early and minimize their potential credit losses. In most trusts, trigger events are put in place to reduce the length of time that investors would be exposed to a troubled collateral pool.

Exhibit 28-7 lists some common early amortization triggers found in credit card master trusts. If an early amortization trigger is hit, then a master trust with bonds still in their revolving periods would stop revolving and immediately begin to pass through principal collections to the ABS investors in order of priority. One structural enhancement available in most trusts to protect investors allows for principal to be passed through on an uncontrolled or rapid amortization basis. This mechanism diverts principal due to the seller interest toward payment of the ABS in order to get investors repaid more quickly.

EXHIBIT 28-7

Common Early Amortization Triggers

Collateral Pool Credit
Three-month average excess spread falls below zero
Seller interest less than the minimum required level
Collateral outstanding balance below the invested amount
Seller/Servicer Events
Failure to make required deposits or payments
Failure to transfer receivables to the trust when required
Events of default, bankruptcy, or insolvency of the seller/servicer
Breach of representations and warranties
Legal Events
Trust is reclassified as an "investment company under the Investment Company Act of 1940

CASH-FLOW ALLOCATIONS

The collection of principal and interest on the credit card accounts and passing it through to the ABS trust is relatively straightforward. The allocation of cash flows to investors and the sponsor can take on more complexity.

Groups

A credit card master trust may use the concept of a *group* to help allocate cash flow to different ABS issued by the trust. One or more groups may be established, and each series of securities issued to investors would be assigned to a group. At its highest level, the master trust allocates cash flows pro rata between the investor and seller interests. The investor interest would be divided further at the group level. While many trusts have only one group, others could have two or more. In trusts with more than one group, series of securities with similar characteristics would likely be grouped together. For example, all the fixed-rate coupon bonds could be in one group and all the floating-rate coupon bonds could be in another group. Any sharing of excess principal or finance charge collections, if called for in the cash flow waterfall of the master trust, would be determined at the group level.

Principal Collections

Principal collections are allocated on a pro rata basis to each series of ABS bonds in the same group based on the size of its outstanding principal balance. The allocation of principal to each series is determined by where that series is in its ABS life cycle. Series in their revolving period are allocated no principal collections. Their principal is reallocated and may be shared with other series that are amortizing to the extent it may be needed. The sharing of principal collections is a structural enhancement to ensure timely payment of principal to ABS investors. Principal collections that are not needed to repay investors are reinvested in new receivables.

For a series in its accumulation period, principal collections would be allocated to that series. The pro rata amount of principal allocated to that series would be determined and fixed by its original principal balance at the beginning of its accumulation period. An additional advantage of the sharing of principal collections between series means that the issuer would have less idle cash sitting in a collection account. The repayment of a maturing ABS series could be accomplished more quickly than the monthly payment rate might imply. For example, an MPR of 10% would imply a 10-month accumulation period. However, if there is only one maturity occurring, then excess principal collections could be used to shorten the accumulation period and reduce the negative carry of cash in a collection account for an issuer.

Finance Charge Collections and Allocations

The primary components of the finance charge collections by a credit card master trust include the monthly interest collected on the outstanding account balance (the APR), any annual or late fees, recoveries on charged-off accounts, interchange, and discounted principal receivables. When expressed as a percentage of the trust's receivables balance, finance charge collections are called the *portfolio yield*. The portfolio yield can be thought of as the top-line revenue number of the master trust.

Most master trusts in use today (master owner or issuance trusts) allocate finance charge collections on a *socialized* basis. In such a structure, finance charges are allocated to each series within a group based on need. Need is determined by the costs incurred by each series—the bond coupon, servicing fees, and allocated charge-offs based on the size of the series in the group. The expenses for the group are the weighted average of the expenses for each series. Since servicing and charge-offs are allocated on a pro rata basis, the series with higher coupon costs would receive a larger allocation of finance charge collections. The advantage of this method is that collections are combined to help support higher-cost series. However, the fates of all series are linked—all bonds will receive payments as expected, or the entire trust will enter early amortization together.

A few legacy master trusts with bonds still outstanding use older securitization technology that allocates finance charges based first on the size of the series outstanding rather than sharing according to need at the top of the cash-flow waterfall. These are known as *nonsocialized* master trusts. In these trusts, each series receives a "floating" allocation of finance charges based on the outstanding invested amount of each series. Excess finance charge collections may or may not be shared based on the cash-flow rules for the trust. A potential advantage of a nonsocialized trust is that the risk of early amortization can be more isolated at the series level rather than risking the unwinding of the entire trust. The disadvantage is that higher coupon series could be at relatively greater risk of early amortization if there is a shortfall in finance charge collections or charge-off rates increase sharply. The sharing of excess finance charges helps mitigate, but does not eliminate, this risk.

Principal Discounting, Interchange, and Recoveries

One of the key sources of support for credit card master trusts during the financial crisis of 2007–2009 was the discounting of principal receivables by the trust sponsors. This support mechanism had long been available to credit card ABS issuers, but it had rarely been used. Most master trust documents allow for the discounting of principal receivables, which are counted as finance charge collections. Discounting is a way to temporarily boost portfolio yield and excess spread. An issuer would most likely use this approach when a trust is under stress from lower finance charge collections and higher charge-off rates, and thus avoid an early amortization.

During the recession that began in December 2007, charge-off rates rose sharply and peaked in the 10% to 11% range by the middle of 2009. This weak credit performance reduced the excess spread substantially for most credit card master trusts. Since the level of excess spread is a major early amortization trigger, many issuers supported their trusts by discounting principal receivables. Many of the major credit card ABS issuers supported their master trusts in this way.

Two other parts of the finance charge collection calculation deserve some additional attention: recoveries on defaulted accounts and interchange. *Recoveries* are generally reported as part of finance charge collections, and so they are accounted for in the calculation of the portfolio yield. As a result, when reviewing charge-off rates, it would be more consistent to analyze the gross default rate rather than the net charge off rate. That way any double counting of recovery collections would be avoided in the calculation of excess spread. This calculation of excess spread is discussed in more detail in the next section. *Interchange* is a fee paid to the bank that issues the credit card. It compensates the bank for taking on credit risk and allowing a grace period before making a payment. Interchange is created when a bank discounts the amount paid to a merchant for a credit card transaction. It is shared by the merchant's bank, the bank issuing the credit card, and the clearing network (e.g., Visa or MasterCard) of the transaction.

CREDIT AND INVESTMENT CONSIDERATIONS

We analyzed above the key structural features and cash-flow allocations of a credit card master trust. In this section, we review some of the most important considerations for investors purchasing credit card ABS. Most investors in securitized products require an investment grade rating in order to add a security to a portfolio. Furthermore, many ABS investors focus more exclusively on bonds rated AAA by one or more credit rating agencies. Despite the moves by regulators to reduce the fixed income market's reliance on credit ratings, it seems likely that credit ratings will remain an important consideration for ABS investors for the foreseeable future because of a lack of a workable alternative.

In order to establish an investment grade rating on credit card ABS, credit enhancement is necessary to absorb potential losses on the collateral pool. The amount of credit enhancement needed will vary from one master trust to another based on the desired rating level and the credit performance of an issuer's credit card portfolio. In addition, the rating agencies will take into consideration the financial strength of the bank sponsoring the securitization. The credit rating of the bank sponsor has taken on even greater prominence in the rating agency review since the financial crisis of 2008–2009.

Credit Enhancement

Early credit card transactions carried letters of credit (LOCs) from commercial banks to guarantee the payment of the credit card ABS. However, the downgrades of the corporate ratings of a number of credit enhancers exposed ABS investors to downgrades on their investments. Over time, internal forms of credit enhancement that do not rely explicitly on the corporate credit rating of an outside entity have become the norm in the credit card ABS market.

Excess Spread

Excess spread is perhaps the most important measure of the health of a credit card master trust, and it is the first line of defense against losses to bondholders. It is also a key early amortization trigger if the credit performance of the collateral pool begins to deteriorate. Excess spread is the finance charge cash flow left over each month after the investor coupon, servicing fees, and charge-offs have been allocated to the investor interest and the seller interest. The calculation of excess spread is straightforward, as shown in Exhibit 28-8, with the values expressed as annualized percentages of the outstanding receivables balance.

In most credit card master trusts, an early amortization trigger is based on the three-month moving average of excess spread. If the three-month average falls below zero, then the revolving period stops, and all principal collections are used to pay off the outstanding ABS bonds. In a nonsocialized master trust, the excess spread trigger is applied at the series level, so an individual series could experience an early amortization without causing the entire master trust to wind down.

Cash Collateral Account

A *cash collateral account* (CCA) is a cash reserve funded at closing and held by the trust for the benefit of the ABS investors. In most trusts, the CCA is

EXHIBIT 28-8

Excess Spread Calculation

Gross Portfolio Yield	20%
Less:	
Charge-Off Rate	4%
Net Portfolio Yield	16%
Less:	
Investor Coupon	2%
Servicing Fee	1%
Excess Spread	13%

typically available as credit enhancement only to the lowest rated class of securities issued. For example, the Class C bonds in most master trusts (generally rated BBB) are supported by the excess spread and the CCA. The Class A and Class B bonds would have the Class C bonds and the excess spread as credit enhancement, but not the CCA. Investors should carefully note these types of structural features when reviewing credit card ABS. The cash to fund the CCA is usually lent by a third party and invested in high-grade short-term securities until needed to be drawn on against shortfalls in cash flow due to rising charge-offs. Any draws on the CCA would be reimbursed at a later date from future excess spread.

Collateral Invested Amount

An alternative to a cash reserve is a *collateral invested amount* (CIA), which is a privately placed subordinated tranche available as credit enhancement to the bondholders. The CIA is placed with a third-party investor that may or may not require its investment to be rated by one or more credit rating agencies. The CIA can generally be considered an improvement over the CCA from the viewpoint of the issuer because this tranche is backed by collateral from the master trust rather than cash. The CIA tranche normally has the benefit of any spread account. Draws on the CIA may also be reimbursed through future excess finance charge collections.

Subordination

As the credit card ABS market has evolved, structures have become more complex to provide greater flexibility to issuers and to meet the demand of investors. In the alphabet soup of credit card ABS, LOCs have given way to CCAs or CIAs, which in turn have been replaced in most cases by rated subordinated securities as the market for subordinated bonds became larger, deeper, and more liquid. The subordinated bonds are placed with outside investors and tend to be rated in the single-A and triple-B categories. The generalized capital structure of a credit card master trust may look like the example in Exhibit 28-9.

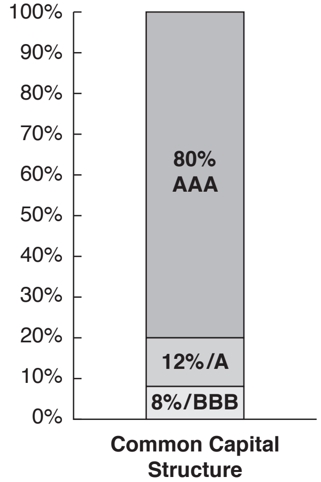
In our example, the rating agencies have determined that the AAA-rated securities are 80% of the capital structure and require 20% subordination in addition to the expected excess spread and the implied support provided by the bank sponsor. Likewise, the Class B and Class C bonds are 12% and 8% of the capital structure, respectively. Issuing subordinated tranches to investors allows the issuer to reach a wider investor audience. As indicated earlier, the issuance trust structure allows an issuer to offer senior bonds separately from the subordinated bonds with varying maturities and coupon types.

Master Trust Credit Analysis

While some of the structures may have changed over time, the credit analysis of credit card master trusts has not changed substantially. For example, most credit

EXHIBIT 28-9

Credit Card ABS Capital Structure



analysts stress the historical performance of critical variables related to the cash flows to test the structural integrity of credit card ABS. A long period of credit performance over several credit cycles would be ideal when analyzing credit card ABS. Credit data that spans the 2007–2010 period would pick up a severe economic downturn that caused charge-off rates and delinquencies to increase sharply and put substantial stress on the credit card ABS sector. In addition, static pool vintage data would be helpful to see how performance or underwriting standards may have changed over time.

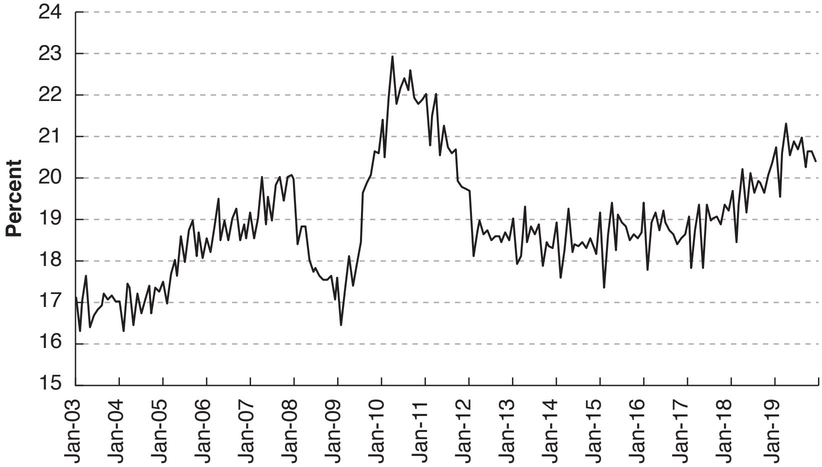
There are several key quantitative variables needed for analyzing credit card securitizations. They include portfolio yield, charge-off rate, delinquency rate, excess spread, monthly payment rate, monthly purchase rate, and the coupon paid to investors. Each of these variables is important for analyzing the ongoing health of a credit card master trust, and they play a role in analysis of a potential early amortization.

Portfolio Yield

As noted earlier, portfolio yield is a measure of the income generated by the credit card receivables. While portfolio yield is driven largely by the annual percentage rate (APR) paid by the cardholders, annual fees and late fees can also boost yield. Furthermore, usage by accountholders is also important. All else equal, a portfolio with proportionately more revolving accounts relative to convenience users will translate into a higher portfolio yield (Exhibit 28-10).

EXHIBIT 28-10

Portfolio Yield



Source: Wells Fargo Securities

Charge-Offs and Excess Spread

Excess spread has been discussed at length earlier in the chapter and is perhaps the most important measure of the health of a credit card master trust. Charge-offs are the credit losses experienced by the portfolio and normally are taken when an account becomes 180 days past due (Exhibit 28-11). Peak losses on static pools of credit card accounts have been observed at about 24 months of seasoning. The juxtaposition of excess spread and charge-offs can be a powerful analytical tool for determining tiering among various credit card issuers.

Serious Delinquency Rate

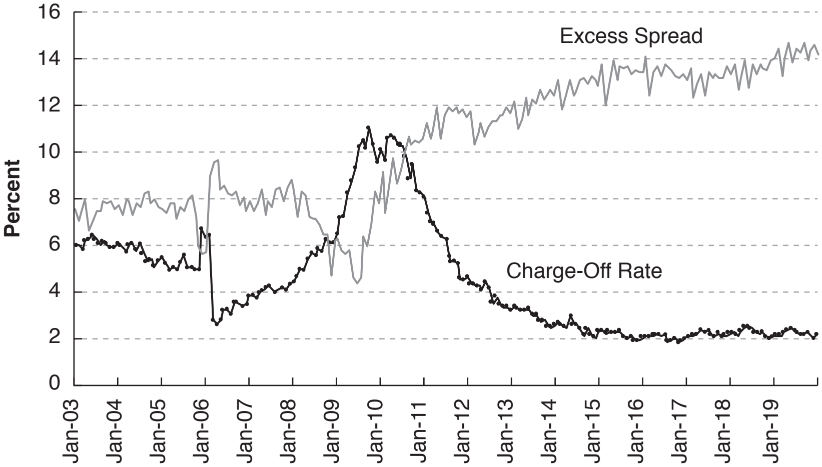
A good leading indicator of future charge-offs is the delinquency rate for accounts 60 days or more past due (60+ dpd). The direction of serious delinquencies can point to important credit trends in credit card master trusts. For example, during the recession of 2007–2009, changes in the direction of 60+ dpd provided an early warning signal for the rapid increase in the charge-off rate of most credit card ABS deals.

Monthly Payment Rate

The *monthly payment rate* (MPR) is an important, but often overlooked, variable in the analysis of credit card ABS because high MPRs can be a source of strength and implied credit enhancement when a portfolio comes under stress. For example, a large proportion of convenience users, while depressing portfolio

EXHIBIT 28-11

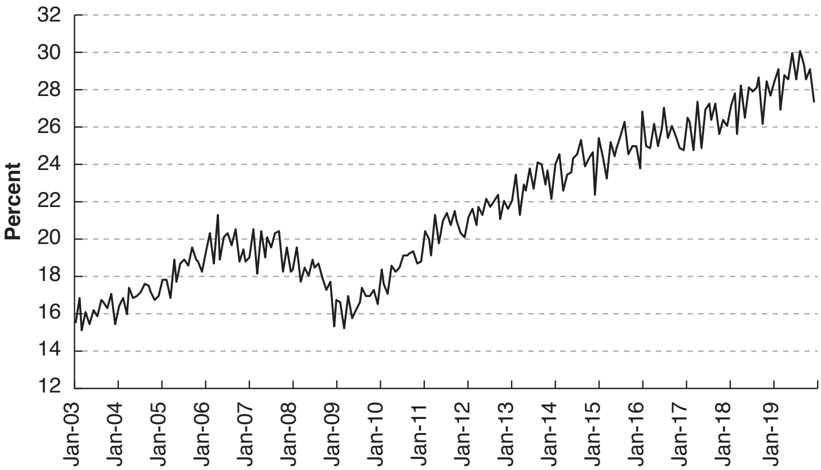
Credit Card ABS Charge-Off Rate and Excess Spread



Source: Wells Fargo Securities

EXHIBIT 28-12

Wells Fargo Securities Payment Rate Index



Source: Wells Fargo Securities

yield, can increase payment rates sharply (Exhibit 28-12). The faster turnover of the receivables means that investors can be repaid more quickly in the event of an early amortization. Since the recession of 2007–2009, the payment rate in credit card ABS trusts has increased significantly based on a strong account base of seasoned account holders using credit cards as a convenient method of payment rather than as a source of revolving credit.

Purchase Rate

Related to the payment rate is the purchase rate, which is generation of new receivables by the designated accounts. A higher purchase rate means that more receivables are being created to support the outstanding ABS. A bankruptcy or insolvency of the seller/servicer is the main risk with regard to the purchase rate because cardholders may stop using their cards as the utility declines. This risk can be particularly acute in private-label or department store cards, however, this event can happen with bank cards as well. As the amount of receivables declines, the credit quality of the portfolio is likely to deteriorate.

Investor Coupon

Floating-rate ABS may require more credit enhancement than fixed-rate bonds because the rating agencies assume in their stress scenarios that market interest rates increase dramatically. Higher funding costs for the ABS reduce the available excess spread to protect ABS investors.

Testing Master Trust Structures

In general, stress testing a credit card master trust structure would involve forcing portfolio yields, payment rates, and purchase rates down sharply at the same time that charge-off rates rise. This combination of factors compresses excess spread and causes an early amortization of the master trust. There have been only a few instances of early amortization, but in general charge-off rates do increase significantly while purchase rates fall and the payment rate drops to a minimal level of about 3%. Interestingly, portfolio yield has held up relatively well in these instances. In addition, early amortization tends to have hit weaker, less diversified issuers of credit card ABS.

There are also some important qualitative elements that should go into any analysis. For example, geographic concentration, the strategic objectives of the firm, seasoning of the accounts, and the type of card (general-purpose card or private-label card). The underwriting standards for new accounts can also play a role in the analysis. These types of qualitative factors can help to determine the degree of stress to apply to various quantitative factors.

As the credit card lending market has consolidated over the past decade, geographic concentration has probably become less of a concern. Most major credit card issuers of general-purpose cards, such as those banks that offer Visa, MasterCard, Discover, or American Express, try to source accounts from the general population. However, market pricing of credit card ABS often considers the corporate credit quality of the bank sponsor. Stronger banks can offer deeper pockets and more support to its credit card master trust in times of stress than a weaker bank. This tiering became more significant during the financial crisis of 2008–2009.

Credit card lenders have long used certain marketing programs to gain market share and to build brand loyalty among cardholders. These programs can play a role in the credit profile of the accounts backing the master trust.

Teaser Rates

For example, lenders may use offers with a low initial APR and no annual fee to lure customers away from competitors. This use of "teaser rates" may also allow borrowers to transfer existing balances from higher-rate cards to the new teaser rate. These teaser rate programs may be available for only a limited time, such as 6 to 12 months. One of the potential problems with this approach is that it can create adverse selection in the account base. Borrowers with a poor credit history may be more likely to respond to the cheaper terms of credit. Most banks tend to use these programs on a targeted base of potential applicants in order to mitigate the likelihood of lending to weaker borrowers.

Affinity and Co-Branded Programs

One of the major uses of the technological investment made by credit card issuers has been in the customer retention effort. A package of interest rates, credit limits, and other services can be offered to entice customers to stay once the teaser period ends. These packages can come in myriad combinations and can be offered based on the credit profile and usage patterns of the cardholder. This strategy of mass customization is made possible by sophisticated computer systems that search huge databases and track the credit history and profitability of existing customers.

Two products created by card issuers to differentiate themselves in the minds of cardholders are affinity and co-branded programs. Affinity cards are issued by a bank in association with a special interest group such as a college alumni association, professional group, or sports team. The group receives a fee from the bank, and the bank gets to market its card to a demographic that it wants to attract. Co-branded cards are programs that associate a bank's credit card with a commercial firm. Customers can earn certain rewards from the firm for making purchases with the card. Mileage awards with airlines, for example, are some of the most popular co-brand programs. However, gasoline companies and hotel chains also make use of these programs to build customer loyalty.

Private-Label Credit Cards

The objectives of private-label credit card issuers may be somewhat different from those of the general-purpose card programs. Private-label credit card programs are sponsored by retailers for use in their own stores as a means of boosting sales, though over the past several years the administration of these programs has moved from the retailers themselves to banks that specialize in private-label credit cards. Underwriting may be less stringent than that of a general-purpose card program, and losses would normally be expected to be higher for credit card ABS backed by private-label accounts. On the other hand, APRs and portfolio yields tend to be much higher to compensate for the greater risk. The market pricing of the ABS issued by private-label programs tends to be at a concession to that of benchmark, general purpose card programs. Good relative value can be found among private-label credit card ABS issuers by investors willing to investigate them.

KEY POINTS

- The securitization of credit card receivables began in 1987, and the credit card ABS market grew rapidly over the years to become one of the largest securitization sectors. many investors making their initial foray into ABS would likely dip their toes into credit cards before wading into the many other asset classes available.
- Credit card ABS are structured using a master trust structure. The credit card bank pledges certain accounts, and all of the receivables generated by the accounts, to the trust. The issuer establishes a single trust that can accept periodic additions of accounts and issue multiple series of securities. All of the securities issued by the master trust are supported by the interest and principal collections from all of the receivables contributed to it. The collateral pool is not segmented to support any individual securities.
- The revolving nature of credit card receivables created unique challenges for securitization. As a result, the master trust structure was developed to allow for a revolving period when only interest is paid to investors, and an amortization period when principal is allocated to pay bondholders.
- The master trust is segmented between the investor interest and the seller interest. The investor interest is the ABS sold to third-party investors. The seller interest is the bank's retained interest in the collateral pool. The seller interest aligns the incentives of the issuer with outside investors because they share in the collections and losses of the collateral pool.
- Bonds carrying credit ratings require credit enhancement to achieve investment grade ratings. Most credit card ABS utilize internal credit enhancement in the form of subordination and excess spread.

- The key variables needed to do credit analysis on a credit card master trust are charge-offs, delinquencies, monthly payment rate, purchase rate, portfolio yield, and excess spread. In the event of distress, an early amortization of the trust could occur. Stressing these variables in a cash-flow model can help determine the structural soundness of the master trust.
- The bank sponsor of the credit card master trust is an important element in the review of credit card ABS. During the financial crisis of 2008–2009, most sponsors of credit card securitizations came to the aid of their ABS trusts. The ability of the sponsor to support its trust should be one of the factors to consider when buying credit card ABS.

CHAPTER
TWENTY-NINE

SECURITIES BACKED BY AUTO LOANS AND LEASES, EQUIPMENT LOANS AND LEASES, AND STUDENT LOANS

John McElravey, CFA
Managing Partner
First XV Partners

The securitization of nonmortgage financial assets has been providing firms with direct access to the capital markets since 1985. The asset-backed securities (ABS) market first began with a computer lease transaction sponsored by Sperry Lease Finance Corporation. Shortly thereafter, auto loans and credit cards were being financed through securitization. Many other types of consumer and commercial assets followed, and the nonmortgage ABS market grew from these humble beginnings to a peak of $871 billion outstanding by 2007.

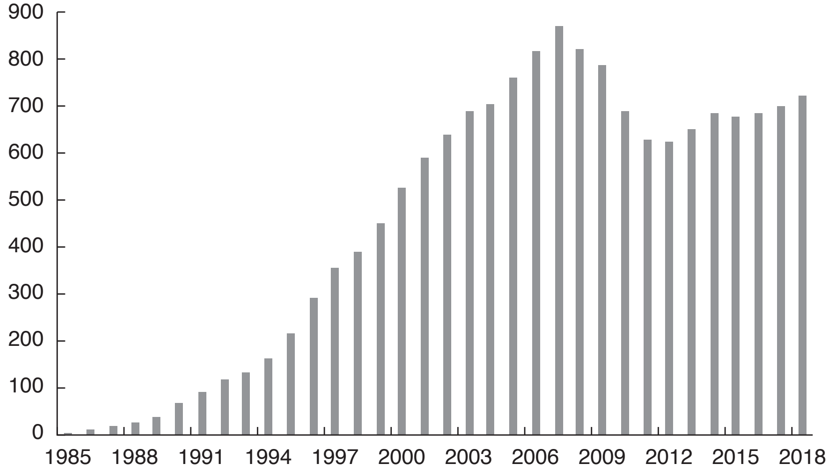
The financial crisis of 2008–2009 was unkind to consumer lending, and the ABS market shrunk from its peak to a recent low of $624 billion in 2012 (Exhibit 29-1). ABS recovered gradually since then and stood at about $720 billion in 2018. The composition of the ABS market has changed since the financial crisis, as well. Credit cards and government-guaranteed student loans, which had been the largest segments outstanding, have decreased and been replaced with credit-oriented sectors such as subprime auto loans, equipment loans and leases, unsecured personal loans, and private student loans. Nevertheless, ABS remain an important source of capital for the financial system. This chapter describes the securitization process and summarizes some of the key features of three of the larger ABS asset classes: auto loans and leases, equipment loans and leases, and student loans.

SECURITIZATION IN BRIEF

Securitization is a process where financial assets are sold to a special purpose vehicle (SPV) from the originator of the assets. Assets securitized are primarily loans and leases, but many other types of receivables and financial obligations, such as accounts receivable or utility charges, have found their way into the

EXHIBIT 29-1

Nonmortgage ABS Outstanding



Source: SIFMA, First XV Partners

asset-backed securities (ABS) market. The use of an SPV in securitization is a critical step because the assets need to be isolated from a potential bankruptcy of the originator.

This bankruptcy remoteness allows the debt of the SPV (the ABS bonds) to carry credit ratings that are likely to be higher than those of the originator of the loans or leases backing the securities that are sold to investors. The vast majority of ABS, roughly 80%, carries a AAA rating from one or more credit rating agencies. In the event of the insolvency or bankruptcy of the lender, the cash flows from the assets are designed to stand on their own to service the ABS debt. The assets backing the bonds would not be consolidated into the bankruptcy estate.

The SPV issues securities to investors that are backed by the cash flows generated by the assets. The assets are typically a diversified pool with hundreds or thousands of obligors. However, in some cases, there may be certain concentrations, either geographic, obligor, or industry, that may need to be mitigated in the structure or with additional credit enhancement. Interest collections on the assets are used to pay interest to the bondholders, and principal collections are used to repay principal to bondholders. As noted above, investors rely on the underlying pool of collateral for repayment and not on the creditworthiness of the originator, or seller of the assets.

This is not to say that the originator or servicer of the collateral pool does not matter. On the contrary, the lender's ability to originate high-quality collateral and service the loans effectively are critical to the success of a securitization. Indeed, the rating agencies explicitly take account of those abilities when determining the amount of the credit enhancement (i.e., referred to as sizing) required to achieve the desired credit rating on the ABS. In most cases, the originator of the loans will also be the servicer.

Exhibit 29-2 displays a generalized schematic of the securitization process. After the assets (loans, leases, receivables, or the like) are sold to the SPV, the transaction is structured and the securities sold to investors. Most ABS transactions offer a senior class of securities (Class A) that are usually rated AAA by one or more credit rating agencies. Subordinated securities, usually rated in the investment-grade categories (AA to BBB), may also be offered to investors, or they may be retained by the issuer

The key to receiving credit ratings on ABS backed by a pool of unrated assets is the credit enhancement required. The level of credit enhancement required will be related to the amount of expected credit losses on the collateral pool. For example, a pool of auto loans to prime quality borrowers might be expected to generate credit losses of just 1% of the original balance of the loan pool. Alternatively, a pool of auto loans to subprime borrowers might be expected to generate losses of 15%. The ABS deal backed by the subprime loans would require substantially more credit enhancement to achieve the same rating than would the ABS deal backed by prime auto loans.

Credit Enhancement

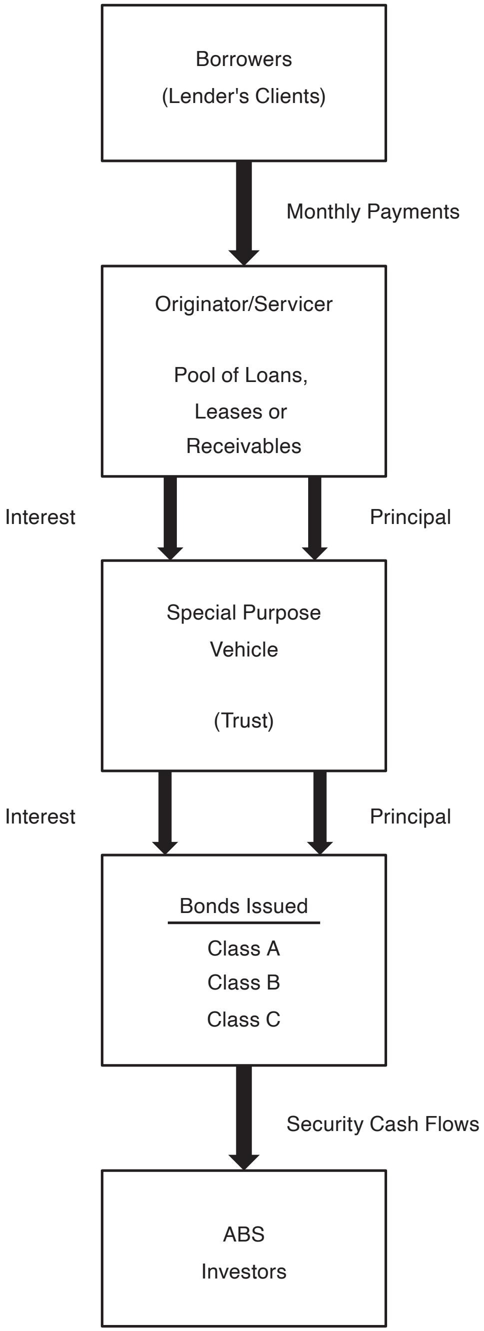
The major types of credit enhancement for ABS transactions include internal sources and external sources. External sources are mainly bond insurance and corporate guarantees, which link the rating of the ABS directly to the corporate credit rating of the guarantor. This method of credit enhancement came under severe stress during the 2008–2009 financial crisis and has fallen out of favor since then with issuers and investors. Internal sources of credit enhancement include excess spread, cash reserve account, overcollateralization, and subordination. Some combination of them is found in every ABS deal.

Excess spread is the amount of interest collected above and beyond that needed to pay interest to bondholders and pay the ongoing expenses of the transaction. This is the first line of defense against losses in most ABS because it can absorb credit losses in each period. The excess interest usually goes back to the servicer if it is not used in a particular payment period, or in some cases it is trapped in an account for the benefit of the bondholders.

A *cash reserve* account may be fully funded at the closing of the ABS transaction, or it may be added to or funded over time by retaining (i.e., trapping) the excess spread. The reserve account is available to provide the deal with additional liquidity in the event that interest or principal collections are less than expected. Cash reserve accounts may also come with a floor on them that allow funds to be distributed to the originator if credit performance meets certain objectives in terms of quantitative tests. Individual ABS transactions should be reviewed for the details of any reserve release conditions.

EXHIBIT 29-2

Securitization Flowchart



Overcollateralization (OC) is the amount of collateral in the pool that is in excess of the ABS bonds issued. For example, if the total collateral pool is $500 million and the ABS issued is $450 million, then the initial OC would be $50 million, or 10% of the collateral pool. This form of credit enhancement may be preferred by an originator that does not want to tie up cash in a reserve fund. OC may also be preferred by investors because it represents the first loss piece in the transaction. The lender holds this equity position, and it helps align the interests of the lender and ABS investors to mitigate risk.

Subordination is the issuance of other classes of securities that would be junior in priority for receiving principal repayment. Many ABS transactions have rated subordinated classes that are sold to third-party investors. Most structures have ratings on these securities from AA to BBB, but it is not unusual to see a BB-rated class at the bottom of the capital structure. This allows an issuer to receive a higher advance rate against its pool of receivables, and it can satisfy investors with differing risk profiles.

Credit Analysis of ABS

The credit analysis of ABS is mainly focused on the performance of the collateral pool. Due diligence of the originator of the loans and its servicing capabilities are still an important component of any credit analysis, but for purposes of this chapter the focus remains on the collateral. Here we simply mention the key data needed to track performance.

Delinquency rates provide a signal of future losses, and in particular serious delinquencies of more than 60 days past due. Defaults, net losses, and loss severity/recovery rates are used by the rating agencies to help determine credit enhancement levels. This data is tracked over time to see if credit performance is in line with expectations. Prepayment rates should be followed because most financial obligations can be repaid early, and almost every ABS deal is priced based on some expected level of loan prepayments. The extent to which prepayments vary from expectations can have significant effects on the valuation of ABS.

Finally, most ABS transactions give the issuer the right, though not the obligation, to exercise a clean-up call of the collateral when the pool balance reaches some predetermined level. The call is usually set at 10% of the original collateral balance, though it is not unusual to see clean-up calls in the 5% to 15% range. It is important to note that the call is on the collateral pool, and not on the outstanding ABS bonds directly. The call is in place because the fixed costs of loan servicing increase as the pool balance declines and the call allows the servicer to manage its securitization costs. The history of an issuer's clean-up call efficiency should be followed because the ability and willingness to exercise the call can have an impact on the valuation of ABS securities.

AUTO LOANS AND LEASES

Auto ABS is one of the earliest and most active securitization sectors beginning in 1986. It has proven to be an attractive and efficient source of funding for auto finance companies. Auto loans and leases offer a steady stream of issuance that has been running roughly $80 billion per year since 2012, and it has become the largest new issue segment. Auto ABS is predominantly based on loans to prime quality borrowers originated by captive finance companies of large automakers. Meanwhile, as investors have increased exposure to ABS, the economics of it has brought new issuers, including commercial banks, specialty finance companies, and lenders to subprime borrowers. Furthermore, consumers opted to lease new cars in increasing numbers over time, and this led to more auto lease ABS transactions. Auto ABS issuers can be divided into five broad groups: the Detroit Three, foreign automakers from Asia and Europe, U.S. bank lenders, independent finance companies, and subprime lenders.

Auto ABS outstanding nearly doubled to $162 billion in 2018 from the near-term low point of $82 billion in 2011 (Exhibit 29-3). The amount of prime auto loan ABS outstanding reached $84.6 billion in 2018, which was still well below the 2003 peak of $102.6 billion. A robust corporate bond market has kept funding costs more competitive in unsecured corporate credit relative to ABS. The increase in auto ABS has been a result of the rise of subprime auto lenders funding in the ABS market, and an increase in auto lease deals as leasing has become a more affordable option for many consumers. Subprime auto loan ABS outstanding reached $52.3 billion in 2018 from $16.3 billion in 2011. Auto lease ABS outstanding rose to $25.0 billion in 2018 from $12.7 billion in 2011.

One of the major elements of credit analysis in auto ABS is based on consumer credit scores. The primary method is to use FICO scores of the obligor pool as a way of gauging credit risk. Subprime borrowers are generally viewed as those with FICO scores of 620 or lower. Prime borrowers have FICO scores of 680 or higher. Scores between 620 and 680 are a narrow group often described as nonprime. These break points should be thought of as general guidelines rather than as hard rules. For example, bank regulators use 660 as the demarcation between prime and subprime borrowers. Market participants may have varying levels of risk tolerance for collateral pools with exposures to subprime borrowers. Subprime auto ABS deals have substantially higher levels of credit enhancement because of the higher risk of default and net loss.

Auto ABS Structure

Auto loan ABS are typically issued using an owner trust structure, which is a legal form that allows for a time tranching of the senior class, as well as credit tranching of subordinated debt. The sequential senior bonds allow lenders to tailor issuance to meet the different maturity preferences of fixed-income investors. For example, an auto owner trust usually has a senior class that may be divided into three or four sequential classes as shown in Exhibit 29-4. The Class

EXHIBIT 29-3

Auto ABS Outstanding

Overcollateralization below the rated bonds (first loss equity)

Cash Reserve Account

Excess Spread

Classes C & D subject to the clean-up call.

EDSF used to price fixed-rate bonds with WAL < 2.0 years.

WAL and payment windows are for illustrative purposes.

A1 tranche is structured with a short average life that would typically meet the requirements for Rule 2a-7 eligibility for money market investors to buy it.

There are also classes with one-year and two-year average lives, as well as a last cash flow (LCF) senior bond, with an average life of three years or more. The LCF senior bond tends to have a more limited investor base than the other senior bonds because this class may have greater variability in its expected maturity from prepayments or the clean-up call. It is usually the smallest of the senior class, as well. One or more subordinated classes also may be offered, usually with ratings from AA to BBB. Many issuers offer just the AAA classes. The average lives of auto loan ABS have been lengthening as loan terms to borrowers have been extended to keep monthly payments affordable. The days of the 48-month loan have been replaced by the 60-month or 72-month loan because the cost of vehicles has increased over time.

The pricing benchmarks for fixed-rate auto ABS depend on the weighted-average life (WAL) of the bond. For example, the money market tranche would be priced against an interpolated LIBOR rate. If the WAL is 0.30 years, then the yield would be based on an interpolated LIBOR rate between three months and four months. For bonds with average lives of 2.0 years or longer, the swap curve normally would be used as the pricing benchmark for the auto ABS. Bonds with average lives less than 2.0 years use the Eurodollar synthetic forward rate (EDSF), which is the rate implied by the prices of Eurodollar futures. This curve may deviate from the interpolated LIBOR rate implied by the cash market.

Since the underlying loans make payments of principal on a monthly basis, the principal is returned to investors also on a monthly basis. This structural artifact creates a "payment window" for each of the bonds. For example, Class A2 has a principal payment window from month 8 to month 16—a nine-month payment window. This feature is unlike credit card ABS, where the bonds are structured with a bullet payment of principal at the expected maturity date.

Investors generally prefer tighter principal payment windows that allow for less uncertainty as to WAL and bond valuation. The return of principal to investors can be affected by prepayments and defaults by borrowers, as well as the exercise of the clean-up call option by the issuer. The Class A2 bonds tend to be the largest class in an auto loan ABS deal, and the majority of the total amount of the bonds issued tends to be in the top of the capital structure to minimize the cost of issuance.

Subprime Auto ABS

As mentioned earlier, loans to subprime credit borrowers have become more common and a larger portion of the ABS market overall. The risk profile of the underlying borrowers means much higher credit enhancement levels to achieve a desired credit rating compared to that of prime auto loans. For example, better-quality pools with somewhat higher-weighted average FICO scores may need original credit enhancement of 35% to be graded AAA. However, it can take as much as 65% to achieve a AAA rating for certain issuers depending on the credit profile of the pool. In general, subprime auto loan ABS deals have three senior sequential classes with the longest being a two-year average life security. The sizes of the subordinated classes can be quite large, and the market prices the credit and liquidity risk at wider spreads compared to prime auto loans. Prepayment rates tend to be secondary in consideration to credit risk and default timing in subprime auto loan ABS pools.

In addition to the usual collateral credit risks in auto loan ABS, servicer risk plays a more important role in subprime auto loan deals because the lenders that service the loans tend to be smaller specialty finance companies that rely more heavily on the ABS market for funding. They may not have ready access to other liquidity or the capital markets. A higher degree of servicer risk should translate into wider credit spreads and more tiering among issuers as the market prices that risk.

Auto Lease ABS

Auto leasing has become more important as new vehicle prices and financing costs have increased. Leasing can be a more affordable option for many consumers needing auto credit because the lease payment can be as much as $100/month lower compared to loan payments for the same vehicle. Lease penetration rates, the proportion of leases to all financings, increased to roughly 30% in 2018 and 2019 from less than 20% before the recession in 2008.

Unlike loans, where the main credit risk is default by the borrower, the primary credit risk in auto lease ABS is the residual value realizations of the vehicles at the end of the lease term. Lease residual collections are generally more than 50% of the cash flows being securitized, with the remainder being the periodic lease payments from the consumer. The maturity distribution of the leases during the securitization and the composition of the vehicles are main drivers of the cash flows.

The risk is that the market price of the vehicle at the term of the lease will be significantly less than the expected value at the time that the lease was written, usually three years earlier. This risk can be captured in the variability of used car prices over time. The largest short-term downside moves in used car prices have been 11% to 12%. The rating agencies will build into their stress scenarios a serious decline in residual values to size credit enhancement. Auto lease ABS will normally price at a concession to auto loan ABS because of the risk of exposure to future moves in auto residual values.

EQUIPMENT LOANS AND LEASES

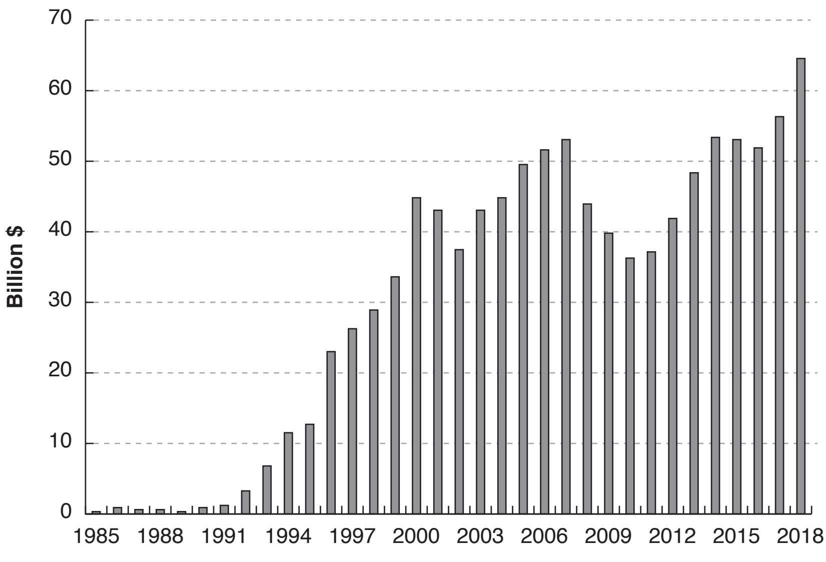
Equipment loans and leases were some of the earliest nonmortgage assets to be securitized. Equipment ABS outstanding has accelerated along with issuance since 2011, rising to $64.3 billion from $37.1 billion (Exhibit 29-5). These deals tend to be structured in a similar way to those in the auto ABS sector, displayed in the example in Exhibit 29-4. Furthermore, trading in equipment ABS securities generally use the auto ABS market as a benchmark for pricing, with equipment deals normally offering a concession to benchmark auto ABS securities.

Equipment loan transactions tend to look much like other types of securitizations where interest from the loans is used to pay interest to bondholders and principal is used to repay principal. The securitization of lease receivables presents a different problem for structuring because leases do not carry an explicit interest rate. As a result, the lease collateral pool is discounted at the weighted average coupon of the securities plus any servicing fees and other expenses to create an interest component on the collateral.

Equipment securitizations may be backed by loans or leases of different types of equipment that fall into three broad categories based on the original cost of the equipment. Small ticket equipment pools, such as telephone systems, computers, or copying machines, are reasonably diverse across geographies and industries, and have an original cost of less than $100,000; mid-ticket equipment pools, such medical or larger printing equipment, heavy duty trucks, trailers, and busses (that may have some obligor concentrations) have an original cost between $100,000 and $500,000; and large ticket equipment pools, such as agricultural or construction equipment with relatively low net loss rates, have an original cost of greater than $500,000.

EXHIBIT 29-5

Equipment ABS Outstanding



Source: SIFMA, First XV Partners

From a credit perspective, analysis of equipment ABS may be relatively labor intensive because of the specialized nature of many types of equipment. In addition, residual values of the equipment are important in lease deals because some items, especially certain types of small ticket equipment, may depreciate more quickly than others. The degree to which any residual value realizations have been securitized and included in the cash flows of the transaction can have a critical impact, particularly for tranches that pay later in the priority of the capital structure.

Equipment ABS issuers and sponsors in some cases may also be smaller, specialty finance firms without a corporate credit rating that use securitization for the bulk of their term funding. Like subprime auto deals, servicer risk can be an important risk in equipment ABS deals when the sponsor is a smaller company. In other cases, the issuers are large manufacturers with their own corporate credit ratings that use securitization as one method of funding to diversify their sources of credit in the capital markets.

STUDENT LOANS

Student loan ABS became the largest individual sector of the ABS market in 2010 at $242 billion. This amount compared to $217 billion for credit cards and $115 billion for autos. The largest source of collateral was government-guaranteed student loans financed by third-party lenders, which accounted for roughly 90% of all student loans. However, the Department of Education ended that program in favor of making loans directly to students. The character of the student loan market has shifted over time as funding for student loans migrated from the private market to direct government lending, which is unlikely to be securitized. Student loan ABS outstanding declined to $171 billion in 2018 and is likely to fall further as older deals amortize.

The student loan ABS market became so large in the first place because education costs have increased faster than the ability of students and parents to pay tuition. Some of this funding gap has been filled by student loans made by private lenders and guaranteed by the government, and also by private student loans with no guarantee. The student loan ABS market follows these two broad categories.

Government-Guaranteed Student Loans

The Federal Family Education Loan Program (FFELP) provided loans to students and parents for postsecondary education. FFELP loans were originated by a lender such as a bank, insurance company, state agency, or not-for-profit student loan company. The loans carry a guarantee from the federal government that covers interest on the loan and repayment of principal up to 97% of the original loan balance. There are four different types of loans available under the FFELP plan: subsidized Stafford, unsubsidized Stafford, PLUS, and consolidation loans. Subsidized Stafford loans are made to students who meet a financial needs test. Unsubsidized Stafford loans are available to students who do not qualify for the subsidized loans or have needs beyond the subsidized loan limits. PLUS loans are made to parents of students. Student borrowers can combine Stafford and PLUS loans into one consolidation loan and make one monthly payment.

A student's status in the school/repayment life cycle is a key factor determining the cash flows in student loan ABS. When a Stafford loan is made and the student is enrolled in school, the borrower's status is "in school." The *in-school period* does not have a time limit, but it would typically be one to four years depending on when the loan was made, the type of school, and the degree pursued. The in-school period is followed by a six-month *grace period* before the loan enters its *repayment period*. During the repayment period, the borrower is responsible for full payments of interest and principal on the student loans.

Borrowers with subsidized Stafford loans do not pay interest or principal during the in-school or grace periods, and the Department of Education makes the interest payments on behalf of the student during these periods. For unsubsidized Stafford loans, accrued interest is capitalized into the unpaid loan balance at the end of the status period. PLUS and consolidation loans enter into repayment of interest and principal 60 days after the funds are distributed to the student.

Once a borrower is in repayment, a loan can go into deferment or forbearance, which allows a borrower to delay payments of interest and principal. *Deferment* allows a borrower to postpone payments due to unemployment, economic hardship, or entering public service or the military. In these circumstances, deferment can be one to three years in length. For a borrower that goes on to further educational programs, there is usually no time limit on their deferment status. *Forbearance* may be used for borrowers that have lost a job or are having some other type of economic hardship. Forbearance may be granted in 6-month or 12-month periods, but the total time in forbearance cannot exceed three years. Different types of schools may carry different credit or prepayment risks. School types include two-year, four-year, graduate, and proprietary or for-profit schools.

Private Student Loans

The federal government has replaced FFELP loans with direct lending from the government. Over time, the student loan ABS market has migrated toward more private loan deals. Private student loan ABS has generally been a very small sector; however, as the cost of college rises, students and parents may need to tap other sources of funds to close the gap between cost and savings. Private student loans carry no federal government guarantee to compensate investors against defaults. In this regard, private student loans are more similar to other kinds of consumer credit, and pools of student loans are likely to be originated and serviced like other types of consumer ABS. One important difference, however, is that, unlike other kinds of consumer credit, student loan debt cannot be discharged in bankruptcy. This factor provides some additional level of protection in terms of potential recovery on defaulted loans.

Private student loans may be disbursed directly to the student rather than through the financial aid office of the school. Direct-to-consumer (DTC) loans may show higher loss rates because the money never makes it to pay tuition, or because of the potential for fraud. Nevertheless, like government-guaranteed student loans, the collateral performance of private student loans depend on a number of characteristics. Investors should look for issuers that provide collateral pool information on the key risk factors in order to make an informed investment decision.

Like FFELP loans, the most significant collateral characteristics include the type of loan made for undergraduate, graduate school, proprietary/for profit, or a consolidation loan. The credit quality of the borrower very often using the FICO score is taken under consideration, as is whether the loan is co-signed by a parent or another party that may take responsibility for repaying the loan. As noted above, if the borrower receives the loan directly from the lender, then it may have a higher risk profile than a loan that is channeled through the school. The type of school plays a role in the credit profile if it is a two-year, four-year, or for-profit school. Like other kinds of consumer credit, the loan seasoning can be an indicator of risk. Generally, a pool of loans with more seasoning tends to be less risky than a pool of loans with little or no seasoning. The loan status—in-school, grace, repayment, deferment, or forbearance—with their differing cash flows may create different risk profiles for a transaction.

Student Loan ABS Structure and Risks

Student loan ABS structures, like all securitizations, are designed to mitigate risks and create a situation where investors can be repaid and the rating agencies can achieve investment-grade ratings on the securities. In student loan ABS, the major risks are credit losses, liquidity, servicing, and interest rate and basis risk. Credit risk can be mitigated through credit enhancement that protects investors against principal writedowns. Excess spread is the first line of defense against credit losses, and it is generated when the yield on the loans is greater than the cost of the liabilities in the securitization. Credit enhancement may be in the form of overcollateralization or subordination that is in a position to absorb losses ahead of rated securities.

Liquidity risk can be particularly acute in student loan ABS because pools of student loans may have a substantial number of loans that are not yet in repayment status. Loans that are in-school, grace, deferment, or forbearance may not pay principal or interest and therefore can decrease the cash flow available for ABS investors. Liquidity support may be provided by a capitalized interest account that can be used to interest to bondholders before loans enter their repayment status. In addition, a reserve account may be part of the deal structure to provide liquidity as well as credit enhancement, much as it would in any other sort of ABS deal. Such a reserve account would be funded at closing and have a minimum level to protect investors against losses.

Interest rate risk and basis risk may be higher in student loan ABS than in most other segments of the ABS market. The reason is that the borrower's interest rate may be either fixed or floating, and if floating it may be linked to a number of benchmarks, including the prime rate, Treasury bill, one-month LIBOR, or three-month LIBOR. In most cases, the interest rate on the ABS is based on one-month or three-month LIBOR. When both sides of the equation are floating, the interest rate risk can be mitigated. However, there may be a mismatch in the timing when the interest rates on the loans reset compared with the reset on the ABS. This situation leads to the potential for the collateral pool to provide sufficient excess spread.

Servicer risk is an important component of a securitization because the lender originates the collateral, is responsible for adequate underwriting, and then must have the capabilities to collect the interest and principal from borrowers and minimize the losses from defaults. On a student loan ABS deal backed by FFELP loans, the collateral pool has the benefit of the government guarantee, so losses would be mitigated through the guarantee. However, the servicer must comply with the rules and regulations set down by the Department of Education in order to get the full benefit of the guarantee for the ABS investors. Private student loans do not have the benefit of a government guarantee, so the underwriting and servicing of the loans must stand on the lender/servicer ability to collect on the loans. The ability of borrowers to delay repayment through various stages of the student loan life cycle suggests that the capability of the servicer can play an important role in the long-run quality of student loan ABS.

Prepayment risks, rather than credit risks, in legacy FFELP student loans have become particularly acute. An uneven economic recovery since 2009 and slow growth in household incomes has made it difficult for many borrowers to make full payments of interest and principal. The Department of Education put in place a number of programs to help borrowers manage their debt loads. This has included income-based repayment (IBR) plans that reduce the monthly payments based on the current income of the borrower.

In the extreme, the payment can be zero, but the loan may still be considered current because of the IBR plan it is in. Payment rates of principal have slowed considerably, and the average lives of the ABS bonds have extended. This extension risk has translated into wider spreads on FFELP student loan ABS to compensate for the longer payment window on legacy bonds. Trading in FFELP student loan ABS has become concentrated in the hands of a few investors and dealers willing to take the extension and prepayment risks.

KEY POINTS

- Securitization is a process where the cash flows from financial assets—interest and principal—are used to back payments on securities sold to investors.

- Assets securitized are primarily loans and leases, but many other types of receivables and financial obligations, such as accounts receivable or utility charges, have found their way into the ABS market.
- Securitizations are usually structured as bankruptcy-remote vehicles to isolate the assets from any potential bankruptcy of the originator. This bankruptcy remoteness allows the ABS debt to carry credit ratings that may be higher than those of the originator of the assets backing the securities sold to investors. The vast majority of ABS sold to investors, in fact, carries a AAA rating from one or more credit rating agencies.
- Credit enhancement in the form of overcollateralization, excess spread, subordination, and/or cash reserve accounts may be used in combination to protect investors against credit writedowns on their bonds.
- The structures of different ABS asset classes will depend upon the cash-flow profile of different kinds of loans or leases. Structures will be put together to mitigate risks that may be unique to each different type of asset class.
- Outside of the credit card ABS sector, the largest segments of the market are auto loans and leases, equipment loans and leases, and student loans.
- Auto ABS has become the largest nonmortgage sector, with rapid expansion in subprime loans and prime leases. Used car prices and lease residual values have become a major focus for those analyzing the sector.
- Equipment ABS consists of several subsectors with their own unique risks. Smaller issuers mean servicer risk is an important component of credit analysis.
- Student loan ABS outstanding has been shrinking after the end of the FFELP government program. Income-based repayment plans have slowed principal collections and extended maturities on many bonds. Private student loans are growing as tuition costs continue to rise.

CHAPTER
THIRTY

COLLATERALIZED LOAN OBLIGATIONS

Frank J. Fabozzi, Ph.D., CFA, CPA
Professor of Finance
EDHEC Business School

Fred Hoffman
Assistant Professor of Practice
Rutgers University Business School

A collateralized debt obligation (CDO) is a structured financial product backed by a diversified pool of one or more types of debt obligations. The pool is usually managed by an asset manager. A CDO issues debt and equity and utilizes the proceeds received to acquire a portfolio of debt obligations. The cash flows from the pool of debt obligations are distributed to the holders of the CDO's various liabilities in prescribed ways that consider the relative seniority of those liabilities.

Issuance of CDOs backed by pools of corporate bonds, residential mortgage-backed securities, commercial mortgage-backed securities, and asset-backed securities has ceased, and few market observers believe these types of CDOs will be issued in the future. A CDO backed by a pool of bank loans is called a *collateralized loan obligation* (CLO). This type of CDO continues to be issued and is the subject of this chapter.

The terminology regarding what is a CLO can be confusing. A CLO is a distinct legal entity that, as explained later, is established as a bankruptcy-remote entity and is the issuer of the securities that investors can purchase. The confusion is that the CLO is the issuer of securities and the securities issued are also referred to as CLOs. That is, a CLO can mean both the issuer and the securities issued by the CLO. The context in which CLO is used in the chapter will make it clear how the term is used.

There are four key attributes of a CLO: assets, capital structure, purpose for creation, and credit structure. We briefly describe each in this chapter.[1]

1. For a more detailed discussion of CLOs, see Stephen J. Antczak, Douglas J. Lucas, and Frank J. Fabozzi, *Leveraged Finance: Concepts, Methods, and Trading of High-Yield Bonds, Loans, and Derivatives* (Hoboken, NJ: John Wiley & Sons, 2009).

ASSETS

The assets of a CLO are corporate loans, most always performing leveraged loans that sit senior in a firm's capital structure and that historically have had recovery values much higher than unsecured debt of the same bankrupt firm. As explained in Chapter 11, leveraged bank loans are loans to corporations with a speculative-grade rating. There are two types of loans currently being used in the CLO market, broadly syndicated loans and middle markets loans. Broadly syndicated loans (BLS) are the most common type of loans, making up a majority of CLO collateral. BLS are larger loans that exceed $500 million or more and trade more actively than middle market loans, which represent smaller loan amounts for smaller, less well-known companies.

The dynamic between the CLO market and the loan market is well understood. As credit spreads tighten and loan prices increase, the amount of the spread they offer to investors decreases, thereby reducing the CLO profit via arbitrage. This condition will cause the new issue market for CLOs to slow or cease.

Only when credit markets fall or liability investors accept a tighter spread will the creation of new issue CLO continue.

CAPITAL STRUCTURE

A CLO's capital structure includes senior debt, mezzanine debt, subordinated debt, and equity. The securities issued by a CLO are commonly referred to as *tranches* and labeled in an offering as Class A, Class B, Class C, and so forth, going from top (in terms of payment seniority) to the bottom of the capital structure. They range from the most secured triple-A rated tranche with the greatest amount of subordination beneath it, to the most levered, unrated equity tranche. This structure is commonly referred to as "the stack." A simplified tranche structure for a CLO backed by a pool of leveraged loans is shown in Exhibit 30-1.

A CLO is created so as to be a "bankrupt remote entity," and this is accomplished by establishing a special purpose entity (SPE) that affords that protection. A very important aspect of a CLO's bankruptcy remoteness is the absolute seniority and subordination of the CLO's debt tranches to one another. Even if it is a certainty that some holders of the CLO's debt will not receive their full principal and interest, cash flows from the CLO's assets are still distributed according to the distribution rules dictated by seniority. The CLO cannot go into bankruptcy, either voluntarily or through the action of an aggrieved creditor. In fact, the need for bankruptcy is obviated because the distribution of the CLO's cash flows, even if the CLO is insolvent, has already been determined in detail at the origination of the CLO. But within the stipulation of strict seniority, there is great variety in the features of CLO debt tranches. The driving force in creating a CLO structure is to raise funds at the lowest possible liability cost. This is done so that the CLO's equity holder, who is at the bottom of the chain of seniority, can get the most residual cash flow.

EXHIBIT 30-1

Simple, Typical CLO Tranche Structure

Tranche	Percent of Capital Structure	Rating	Coupon
Class A	67.50	AAA	LIBOR + 30
Class B	10.00	AA	LIBOR + 40
Class C	9.00	A	LIBOR + 80
Class D	2.75	BBB	LIBOR + 190
Class E	2.75	BB	LIBOR + 480
Equity	8.00	NR	Residual Cash Flow

CREATION PURPOSE

Prior to the passage of Dodd-Frank and the Volcker Rule, CLOs were created for one of two purposes: balance sheet or arbitrage. With banks no longer able to warehouse large amounts of bank loans, balance sheet trades are no longer viable.

The motivation for an arbitrage CLO is that an asset manager specializing in loans seeks to augment assets under management and management fees. It is the asset manager who assembles the initial portfolio into a warehouse facility months before the actual CLO is created. The hope is the weighted average coupon of the asset pool will exceed the weighted average cost of the liabilities. This creates a positive arbitrage CLO that is then managed according to prescribed guidelines set forth in the CLO's indenture. Investors wish to have the expertise of an asset manager specializing in leveraged loan portfolio management. Loans are purchased in the marketplace by the asset manager from many different sellers and put into the CLO.

The difference is that instead of all the investors sharing the fund's return in proportion to their investment, investor returns are also determined by the seniority of the CLO tranches they purchase.

From the perspective of CLO investors, all CLOs have a number of common purposes. One such purpose is the partitioning and allocation of the credit risk of the pool of loans among investor groups that have different risk appetites. Thus, both a triple-A investor and a double-B investor can invest in leveraged loans. Often, CLO debt provides a higher spread than comparable investments.

For the equity investor, a CLO provides a leveraged return on a diversified portfolio of leveraged loans without the need to obtain borrowing via repurchase agreements (repos) from a bank. It allows the investor to obtain nonrecourse long-term financing at a fixed spread to LIBOR (the weighted average of the liabilities above them in the capital structure).

CREDIT STRUCTURES

CLOs have additional structural credit protections beyond the protection afforded by seniority and subordination of the CLO's capital structure. These credit structures fall into the category of either *cash-flow* or *market-value* protections. We will only discuss the cash-flow credit structure here because it is the dominant credit enhancement mechanism in CLOs, being roughly 95% of all CLOs. The specifics of a CLO's cash-flow structure determine the risks taken on by various classes of CLO debt and equity and therefore the return profiles of those classes.

It is necessary to understand a CLO's *cash-flow waterfalls* in order to understand the cash-flow credit structure. There are two waterfalls in a cash flow CLO: one for collateral interest and another for collateral principal. It is the cash-flow waterfalls that dictate the payment priority to the holders of the CLO tranches and thus enforce the seniority of one creditor in the structure over another. The cash-flow waterfalls specify *coverage tests*, and the failure of such tests can result in the diversion of collateral cash flow from subordinated CLO creditors to senior CLO creditors. The most important of these are the *par coverage tests*:

Class A par coverage test = Asset par/Class A par
Class B par coverage test = Asset par/(Class A par + Class B par)

and so on, for all of the CLO debt tranches.

The par of defaulted loans is reduced or excluded from Asset Par in the numerator of par coverage tests.

Here is a simple, typical *interest waterfall* in which collateral interest is applied to CLO creditors in the following order:

1. To the trustee for base fees and expenses
2. To the asset manager for base fees
3. To Class A for interest expense
4. If Class A coverage tests are failed, to Class A for principal repayment until Class A coverage tests are met
5. To Class B for interest expense
6. If Class B coverage tests are failed, to the senior-most outstanding tranche (which could be Class A or, if Class A has been paid in full, Class B) for principal repayment until Class B coverage tests are met
7. To Class C for interest expense
8. If Class C coverage tests are failed, to the senior-most outstanding tranche for principal repayment until Class C coverage tests are met

(Steps 7 and 8 are repeated for remaining debt tranches.)

9. An additional coverage test that determines whether an amount of collateral interest must be reinvested in additional collateral

10. Additional fees to the trustee
11. Additional fees to the asset manager
12. To the equity tranche, in accordance with any profit-sharing agreement with the asset manager

Note that coverage tests force a decision to be made about whether to pay interest to a class or pay down principal on the senior-most outstanding class.

Here is a simple, typical *principal waterfall* in which collateral principal is applied to CLO creditors in the following order:

1. Amounts due in 1 through 8 of the interest waterfall that were not met with collateral interest
2. During the CLO's reinvestment period, to purchase new collateral assets
3. After the reinvestment period, for principal repayment of tranches in order of their priority
4. Amounts due in 9 through 12 of the interest waterfall

The purpose of the diversion of collateral interest is to provide greater protection to senior CLO tranches. The CLO's debt tranches can receive all their principal and interest even if collateral losses exceed the amount of subordination below them in the capital structure. The benefit of coverage tests to senior tranches depends on how soon the tests are breached. The earlier the diversion of interest to senior tranches occurs, the greater the collateral interest diverted over the remaining life of the collateral. The amount of cash that can be diverted is smaller if tests fail late in the CLO's life.

However, there are strategies that a CLO manager can employ to circumvent the protection of cash-flow diversion. "Par building" trades artificially improve par coverage tests by replacing relatively high-price collateral with relatively low-price collateral. For example, suppose that a CLO manager sells \$6 million of loans at par and with the proceeds from the sale acquires \$7 million par of loans selling at 85%. This action would inflate Asset Par by \$1 million in the numerator of the par coverage test. Done in enough size, it could prevent a CLO from violating par coverage tests and keep cash flowing down the CLO's waterfall to the manager and equity holders.

MARKET SIZE, TRADING

As of 2019, the outstanding CLO market is approximately \$600 billion, which accounts for half of the \$1.2 trillion leveraged loan market. Annual new issuance volume averaged \$100 billion from 2014–2019, with a large number of new CLO asset managers appearing since 2018 as risk-retention rules were turned back by the courts.

CLO trading is still completed in a very decentralized, over-the-counter market. Due to the extensive work that must be completed by each potential buyer with respect to documentation, no electronic marketplace has yet developed for CLO's. In fact, most lower-rated CLO tranches and CLO equity trade in a multiday BWIC (bid wanted in competition) format to allow for the exchange of documentation between buyers and bidders.

HOW A CLO IS CREATED

The origins of a new CLO begin with a lengthy syndicate process that may last as long as six months to complete. The issuer (who in this case is the SPV represented by the asset manager teams) with an investment bank help find buyers for both the liabilities (funding) and the equity.

Months before a CLO is priced and created, the investment bank and the manager start the process by opening a warehouse facility that will allow the manager to begin purchasing collateral for the upcoming CLO. This process of purchasing collateral in anticipation of a new CLO deal is called the "ramp-up period."

As the investment banker and investment manager begin to collect orders for the liabilities, the deal becomes more likely to be finalized, or "printed." Normally, it is the two ends of the capital structure (AAA or equity) that are the most difficult to place, depending on market conditions. As soon as both parties agree that a deal is likely, the amount of assets in the warehouse will grow closer to the expected final size of the deal. Most CLO deals are in the range of $350 to $600 million.

On the final day the spreads for all liabilities are locked, and the funds are transferred from the liability buyers to the SPV. Simultaneously, the assets previously purchased in the warehouse are transferred into the SPV. The asset manager must then hurry to purchase the remaining amount of the needed collateral since the cash in the SPV may create a negative arbitrage between the assets and liabilities.

FEES

CLO fees are divided into three classes. The first is the Senior Management Fee, which is paid after administration and trustee fees but before interest on the liabilities. The next fee is the Junior Management Fee, which is paid after the liabilities but before any payments to the equity class. The last fee is the Equity Class Incentive Fee, which has properties like a hedge fund fee with a hurdle rate and fixed percentage of profits.

The sum of the first two fees is in a range of 30 to 35 basis points of deal assets as measured by liabilities. However, certain arrangements called "side letters" are offered to critical investors that have the effect of lowering these fees.

BUYERS

It is easy to think of the CLO stack in three parts. The senior, which includes the AAA and AA tranches; the subordinate, which includes the BBB and BB tranches; and last the equity, which is unrated.

Senior tranches are purchased by money center banks, endowments, and pension funds. Hedge funds will only purchase senior tranches by applying a great deal of leverage.

Subordinate tranches are usually purchased by mutual funds or hedge funds looking to diversify away from BBB corporate credit while hoping to obtain similar or higher returns for the same ratings.

Equity tranches are purchased by a special class of buyers, most often structured products experts working within a credit hedge fund or other investment manager with structured product experience.

TRADING OF CLO COLLATERAL

The trading of bank loans by CLO managers depends on three factors: (1) liquidity of the issuer, (2) size of the sale amount and number of names, and (3) style of the manager.

For a well-known name (e.g., Charter or Sprint), a good buy-side loan trader should know the market and understand the bid side. For lesser-known names, the trader has two options: (1) give a broker an order at an agreed-upon level and let the broker canvas the market on behalf of the buy-side trader, or (2) go the BWIC route, asking many dealers for a bid.

If the number of names to be sold is small and less liquid, the trader may go to two or three other possible dealers—so, a mini-BWIC, because some dealers are either going to be asked to buy or sell a particular name on a specific day. A good trader needs to figure this out. The CLO trader cannot expect that every dealer desk will want to buy the bank loan that the trader wants to sell. If, in contrast, the BWIC contained a large number of names, let's say $100 million or more, a BWIC with six or seven dealers is usually the way to go. During a BWIC, dealers can either search for buyers or bid on their own. A good broker/dealer could either need the loans on an order for another account or need the loans for inventory. This leads to some loans being sold on the BWIC as a broker transaction (dealer passes loans to another account immediately and collects the bid/offer) or a principal transaction where the loans simply go into the dealer's inventory.

As for style, some CLO managers like to talk to many broker/dealers and show no favors. Others have favorites based on different metrics and do a considerable percentage of their business with a few dealers. There is no right or wrong practice.

Also what should be kept in mind is that CLO managers cannot be just sellers. The yield on the CLO portfolio cannot sustain being in cash after a sale but must be reinvested in another bank loan. Consequently, many trades are effectively swaps. A good CLO trader is looking for the best sale-to-purchase net price, so a BWIC/OWIC (offer wanted in competition) may or may not accomplish that investment objective.

KEY POINTS

- A CLO is a type of CDO in which the pool of assets consists of levered, secured bank loans.
- A CLO's capital structure includes senior debt, mezzanine debt, subordinated debt, and equity.
- From a CLO investor's perspective, the purpose is the partitioning and allocation of the credit risk of the pool of loans among investor groups that have different risk appetites.
- CLOs rely on both an initial positive arbitrage and strong active portfolio management for the life of the deal to provide investors their expected returns.
- In addition to the protection afforded by seniority and subordination of the CLO's capital structure, there is another structural credit protection that allows the diversion of cash flow to the senior-most tranche outstanding if prescribed coverage tests are not satisfied.
- A new issue CLO can only exist when there is a positive arbitrage between the loans (collateral) and the notes (liabilities).

CHAPTER
THIRTY-ONE

OVERVIEW OF FORWARD RATE ANALYSIS

Antti Ilmanen, Ph.D.
Principal
AQR Capital Management

Over the years, advances have been made in both the theoretical and the empirical analysis of the term structure of interest rates. However, such analysis is often very quantitative, and it rarely emphasizes practical investment applications. In this chapter we briefly describe the computation of par, spot, and forward rates; present a framework for interpreting the forward rates by identifying their main determinants; and develop practical tools for using the information in forward rates in active bond portfolio management.

The three main influences on the Treasury yield-curve shape are (1) the market's expectations of future rate changes, (2) bond risk premiums (expected return differentials across bonds of different maturities), and (3) convexity bias. Conceptually, it is easy to divide the yield-curve (or the term structure of forward rates) into these three components. It is much harder to interpret real-world yield-curve shapes, but the potential benefits are substantial. For example, investors often wonder whether the curve steepness reflects the market's expectations of rising rates or a positive risk premium. The answer to this question determines whether a duration extension increases expected returns. It also shows whether we can view forward rates as the market's expectations of future spot rates. In addition, in this chapter we will explain how the market's curve reshaping and volatility expectations influence the shape of today's yield-curve. These expectations determine the cost of enhancing portfolio convexity via a duration-neutral yield-curve trade.[1]

This chapter is a revised version of a Citigroup (Salomon Brothers) research report. Such report remains the property of Citigroup, and its disclaimers apply. The author wishes to thank Larry Bader, Eduardo Canabarro, Ajay Dravid, Francis Glenister, Ray Iwanowski, Cal Johnson, Tom Klaffky, Rick Klotz, Stan Kogelman, Janet Showers, and Charlie Ye for their helpful comments.

1. Details on each of the three influences on the yield-curve can be found at Antti Ilmanen, "Market's Rate Expectations and Forward Rates," *Journal of Fixed Income* (September 1996), pp. 8–22; Antti Ilmanen, "Does Duration Extension Enhance Long-Term Expected Returns?" *Journal of Fixed Income* (September 1996), pp. 23–36; and Antti Ilmanen, "Convexity Bias in the Yield Curve," Chapter 3 in Narasimgan Jegadeesh and Bruce Tuckman (eds.), *Advanced Fixed-Income Valuation Tools* (New York: Wiley, 2000).

Forward rate analysis also can be valuable in direct applications. Forward rates may be used as break-even rates to which subjective rate forecasts are compared or as relative-value tools to identify attractive yield-curve sectors.[2]

COMPUTATION OF PAR, SPOT, AND FORWARD RATES

At the outset, it is useful to review the concepts yield-to-maturity, par yield, spot rate, and forward rate to ensure that we are using our terms consistently. Appendix 31A is a reference that describes the notation and definitions of the main concepts used in this chapter. Our analysis focuses on government bonds that have known cash flows (no default risk, no embedded options). *Yield-to-maturity* is the single discount rate that equates the present value of a bond's cash flows to its market price. *A yield-curve* is a graph of bond yields against their maturities. (Alternatively, bond yields may be plotted against their durations, as we do in many of the exhibits presented in this chapter.) The best-known yield-curves are the on-the-run Treasury curve and the interest-rate-swap curve. On-the-run bonds are the most recently issued government bonds at each maturity sector. Since these bonds are always issued with price near par (100), the on-the-run curve often resembles the *par yield-curve,* which is a curve constructed for theoretical bonds whose prices equal par. The swap curve based on receive-fixed, pay-floating contracts is by construction a par curve.

While the yield-to-maturity is a convenient summary measure of a bond's expected return—and therefore a popular tool in relative-value analysis—the use of a single rate to discount multiple cash flows can be problematic unless the yield-curve is flat. First, all cash flows of a given bond are discounted at the same rate, even if the yield-curve slope suggests that different discount rates are appropriate for different cash-flow dates. Second, the assumed reinvestment rate of a cash flow paid on a given date can vary across bonds because it depends on the yield of the bond to which the cash flow is attached. In this chapter we will show how to analyze the yield-curve using simpler building blocks—single cash flows and one-period discount rates—than the yield-to-maturity, an *average* discount rate of multiple cash flows with various maturities.

A coupon bond can be viewed as a bundle of zero-coupon bonds (zeros). It can be unbundled to a set of zeros that can be valued separately. Then these can be bundled back together into a more complex bond whose price should equal the

2. For a discussion of how to analyze many aspects of yield-curve trades, such as barbell-bullet trades, and a presentation of empirical evidence about their historical behavior, see Antti Ilmanen and Ray Iwanowski, "Dynamics of the Shape of the Yield Curve," *Journal of Fixed Income* (September 1997), pp. 47–60; and Chapter 32.

sum of the component prices.[3] The *spot rate* is the discount rate of a single future cash flow such as a zero. Equation (31-1) shows the simple relation between an n-year zero's price P_n and the annualized n-year spot rate s_n.

$$P_n = \frac{100}{(1+s_n)^n} \tag{31-1}$$

A single cash flow is easy to analyze, but its discount rate can be unbundled even further to one-period rates. A multiyear spot rate can be decomposed into a product of *one-year forward rates,* the simplest building blocks in a term structure of interest rates. A given term structure of spot rates implies a specific term structure of forward rates. For example, if the m-year and n-year spot rates are known, the annualized forward rate between maturities m and n, that is, $f_{m,n}$, is easily computed from Eq. (31-2).

$$(1+f_{m,n})^{n-m} = \frac{(1+s_n)^n}{(1+s_m)^m} \tag{31-2}$$

The forward rate is the interest rate for a loan between any two dates in the future, contracted today. Any forward rate can be "locked in" today by buying one unit of the n-year zero at price $P_n = 100/(1 + s_n)^n$ and by shortselling P_n/P_m units of the m-year zero at price $P_m = 100/(1 + s_m)^m$. (Such a weighting requires no net investment today because both the cash inflow and cash outflow amount to P_n.) The one-year forward rate ($f_{n-1,n}$ such as $f_{1,2}, f_{2,3}, f_{3,4}, \ldots$) represents a special case of Eq. (31-3) where $m = n - 1$. The spot rate represents another special case where $m = 0$; thus $s_n = f_{0,n}$.

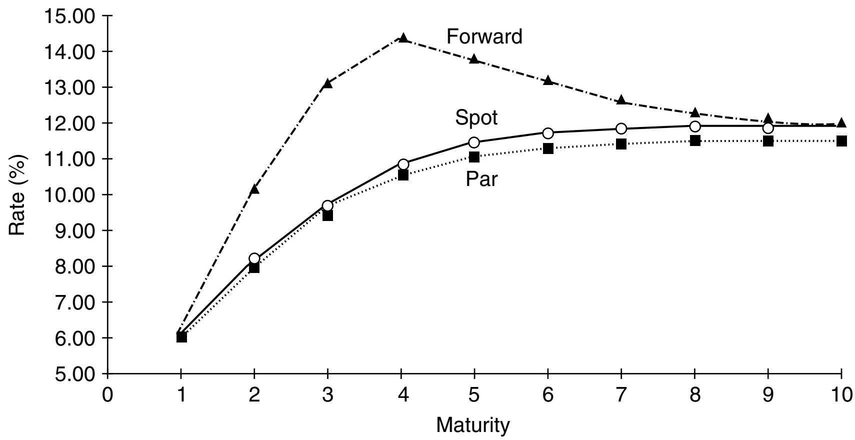
To summarize, a par rate is used to discount a set of cash flows (those of a par bond) to today, a spot rate is used to discount a single future cash flow to today, and a forward rate is used to discount a single future cash flow to another (nearer) future date. The par yield-curve, the spot-rate curve, and the forward-rate curve contain the same information about today's term structure of interest rates.[4]

3. Arbitrage activities ensure that a bond's present value is very similar when its cash flows are discounted using the marketwide spot rates as when its cash flows are discounted using the bond's own yield-to-maturity. However, some deviations are possible because of transaction costs and other market imperfections. In other words, the term structure of spot rates gives a consistent set of discount rates for all government bonds, but all bonds' market prices are not exactly consistent with these discount rates. Individual bonds may be rich or cheap relative to the curve because of bond-specific-liquidity, coupon, tax, or supply effects.

4. These curves can be computed directly by interpolating between on-the-run bond yields (approximate par curve) or between zero yields (spot curve). Because these assets have special liquidity characteristics, these curves may not be representative of the broad Treasury market. Therefore, the par, spot, or forward rate curve is typically estimated using a broad universe of coupon Treasury bond prices. There are many different curve-fitting techniques, but a common goal is to fit the prices well with a reasonably shaped curve. This chapter does not focus on yield-curve estimation but on the interpretation and practical uses of the curve once it has been estimated.

EXHIBIT 31-1

Par, Spot, and One-Year Forward Rate Curves



If one set of rates is known, it is easy to compute the other sets.[5] Exhibit 31-1 shows a hypothetical example of the three curves. In Appendix 31B, we show how the spot and forward rates were computed based on the par yields.

In this example, the par and spot curves are monotonically upward-sloping, whereas the forward rate curve[6] is first upward-sloping and then inverts (because of the flattening of the spot curve). The spot curve lies above the par curve, and the forward rate curve lies above the spot curve. This is always the case if the spot curve is upward-sloping. If it is inverted, the ordering is reversed: The par curve is highest, and the forward curve lowest. Thus loose characterizations of one curve (e.g., steeply upward-sloping, flat, inverted, humped) generally are applicable to the other curves. However, the three curves are identical only if they are horizontal. The forward rate curve magnifies any variation in the slope of the spot curve. One-year forward rates measure the *marginal* reward for lengthening the maturity of the investment by one year, whereas the spot rates measure an investment's *average* reward from today to maturity n. Therefore, spot rates are (geometric) averages of one or more forward rates. Similarly, par rates are averages of one or more spot rates; thus par curves have the flattest

5. Further, one can use today's spot rates and Eq. (31-2) to back out implied spot curves for any future date and implied future paths for the spot rate of any maturity. It is important to distinguish the implied spot curve one year forward ($f_{1,2}, f_{1,3}, f_{1,4}, \ldots$), a special case of Eq. (31-2) where $m = 1$, from the one-year forward rate curve ($f_{1,2}, f_{2,3}, f_{3,4}, \ldots$). Today's spot curve can be subtracted from the former curve to derive the yield changes implied by the forwards. (This terminology is somewhat misleading because these "implied" forward curves/paths do not reflect only the market's expectations of future rates.)

6. Note that all one-year forward rates actually have a one-year maturity even though in the x axis of Exhibit 31-1 each forward rate's maturity refers to the final maturity. For example, the one-year forward rate between $n - 1$ and n ($f_{n-1,n}$) matures n years from today.

shape of the three curves. In Appendix 31C, we discuss further the relation between spot and forward rate curves.

It is useful to view forward rates as *break-even rates*. The implied spot rates one year forward ($f_{1,2}$, $f_{1,3}$, $f_{1,4}$, . . .) are, by construction, equal to such future spot rates that would make all government bonds earn the same return over the next year as the (riskless) one-year zero. For example, the holding-period return of today's two-year zero (whose rate today is s_2) will depend on its selling rate (as a one-year zero) in one year's time. The implied one-year spot rate one year forward ($f_{1,2}$) is computed as the selling rate that would make the two-year zero's return [the left-hand side of Eq. (31-3)] equal to the one-year spot rate [the right-hand side of Eq. (31-3)]. Formally, Eq. (31-3) is derived from Eq. (31-2) by setting $m = 1$ and $n = 2$ and rearranging.

$$\frac{(1+s_2)^2}{1+f_{1,2}} = 1+s_1 \tag{31-3}$$

Consider an example using numbers from Exhibit 31B–1 in Appendix 31B, where the one-year spot rate (s_1) equals 6% and the two-year spot rate (s_2) equals 8.08%. Plugging these spot rates into Eq. (31-3), we find that the implied one-year spot rate one year forward ($f_{1,2}$) equals 10.20%. If this implied forward rate is exactly realized one year hence, today's two-year zero will be worth 100/1.1020 = 90.74 next year. Today, this zero is worth $100/1.0808^2 = 85.61$; thus its return over the next year would be 90.74/85.61 − 1 = 6%, exactly the same as today's one-year spot rate. Thus 10.20% is the break-even level of the future one-year spot rate. In other words, the one-year rate has to increase by more than 420 basis points (10.20% − 6.00%) before the two-year zero underperforms the one-year zero over the next year. If the one-year rate increases, but by less than 420 basis points, the capital loss of the two-year zero will not fully offset its initial yield advantage over the one-year zero.

More generally, if the yield changes implied by the forward rates are realized subsequently, all government bonds, regardless of maturity, earn the same holding-period return. In addition, all self-financed positions of government bonds (such as long a barbell versus short a bullet) earn zero return; that is, they break even. However, if the yield-curve remains unchanged over a year, each n-year zero earns the corresponding one-year forward rate $f_{n-1,n}$. This can be seen from Eq. (31-2) when $m = n - 1$; $1 + f_{n-1,n}$ equals $(1 + s_n)^n/(1 + s_{n-1})^{n-1}$, which is the holding-period return from buying an n-year zero at rate s_n and selling it one year later at rate s_{n-1}. Thus the one-year forward rate equals a zero's horizon return for an unchanged yield-curve. See Appendix 31C for details.

MAIN INFLUENCES ON THE YIELD-CURVE SHAPE

In this section we describe some economic forces that influence the term structure of forward rates or, more generally, the yield-curve shape. The three main influences are the market's rate expectations, the bond risk premiums (expected return differentials across bonds), and the so-called convexity bias. In fact, these three components fully determine the yield-curve; it can be shown that the difference between each one-year forward rate and the one-year spot rate is approximately equal to the sum of an expected spot-rate change, a bond risk premium, and the convexity bias.[7] We first discuss separately how each component alone influences the curve shape and then analyze their combined impact.

Expectations

It is clear that the market's expectations of future rate changes are one important determinant of the yield-curve shape. For example, a steeply upward-sloping curve may indicate market expectations of near-term Fed tightening or of rising inflation. However, it may be too restrictive to assume that the yield differences across bonds with different maturities *only* reflect the market's rate expectations. The well-known pure expectations hypothesis has such an extreme implication. The *pure expectations hypothesis* asserts that all government bonds have the same near-term expected return (as the nominally riskless short-term bond) because the return-seeking activity of risk-neutral traders removes all expected return differentials across bonds. Near-term expected returns are equalized if all bonds that have higher yields than the short-term rate are expected to suffer capital losses that offset their yield advantage. When the market expects an increase in bond yields, the current term structure becomes upward-sloping so that any long-term bond's yield advantage and expected capital loss (owing to the expected yield increase) exactly offset each other. Stated differently, if investors expect that their long-term bond investments will lose value owing to an increase in interest rates, they will require a higher initial yield as a compensation for duration extension. Conversely, expectations of yield declines and capital gains will lower current long-term bond yields below the short-term rate, making the term structure inverted.

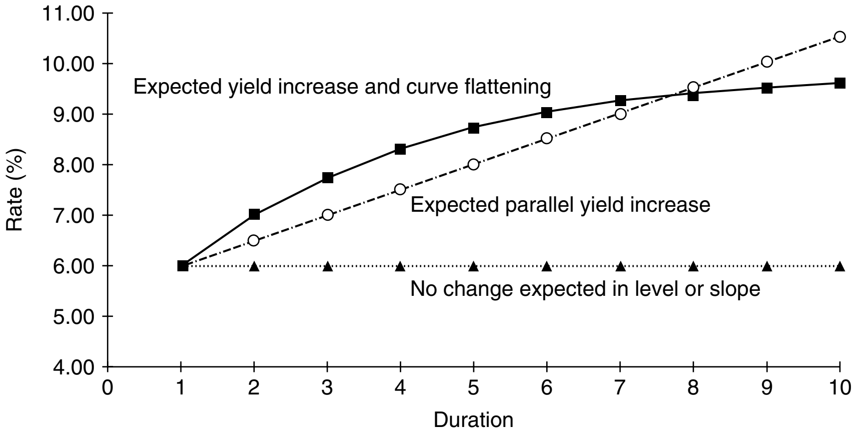
The same logic—that positive (negative) initial yield spreads offset expected capital losses (gains) to equate near-term expected returns—also holds for combinations of bonds, including duration-neutral yield-curve positions. One example is a trade that benefits from the flattening of the yield-curve between 2- and 10-year maturities: selling a unit of the 2-year bond, buying a duration-weighted amount (market value) of the 10-year bond, and putting the remaining proceeds from the sale to "cash" (very short-term bonds). Given the typical concave yield-curve shape, such a curve-flattening position earns a negative carry.[8] The trade will be profitable only if the curve flattens enough to offset the impact of the negative carry. Implied forward rates indicate how much

7. The proof is provided in the appendix to Chapter 37.

8. A concave shape means that the (upward-sloping) yield-curve is steeper in the front end than in the long end. The yield loss of moving from the two-year bond to cash is greater than the yield gain of moving from the two-year bond to the ten-year bond. Thus the yield earned from the combination of cash and tens is lower than the forgone yield from twos.

EXHIBIT 31-2

Yield-Curves Given the Market's Various Rate Expectations



flattening (narrowing of the two- to ten-year spread) is needed for the trade to break even.

In the same way as the market's expectations regarding the future level of rates influence the *steepness* of today's yield-curve, the market's expectations regarding the future steepness of the yield-curve influence the *curvature* of today's yield-curve. If the market expects more curve flattening, the negative carry of the flattening trades needs to be larger (to offset the expected capital gains), which makes today's yield-curve more concave (curved). Exhibit 31-2 illustrates these points. This figure plots coupon bonds' yields against their durations or, equivalently, zeros' yields against their maturities, given various rate expectations. Ignoring the bond risk premium and convexity bias, if the market expects no change in the level or slope of the curve, today's yield-curve will be horizontal. If the market expects a parallel rise in rates over the next year (but no reshaping), today's yield-curve will be linearly increasing (as a function of duration). If the market expects rising rates *and* a flattening curve, today's yield-curve will be increasing and concave (as a function of duration).[9]

Bond Risk Premium

A key assumption in the pure expectations hypothesis is that all government bonds, regardless of maturity, have the same expected return. In contrast, many theories and empirical evidence suggest that expected returns vary across bonds. We define the *bond risk premium* as a longer-term bond's expected one-period return in excess of the one-period bond's riskless return. A positive bond risk

9. For a detailed treatment of these issues, see Ilmanen, "Market's Rate Expectations and Forward Rates," *op. cit.*

premium would tend to make the yield-curve slope upward. Various theories disagree about the sign (+/−), the determinants, and the constancy (over time) of the bond risk premium. The classic liquidity premium hypothesis argues that most investors dislike short-term fluctuations in asset prices; these investors will hold long-term bonds only if they offer a positive risk premium as a compensation for their greater return volatility. Also, some modern asset-pricing theories suggest that the bond risk premium should increase with a bond's duration, its return volatility, or its covariance with market wealth. In contrast, the preferred-habitat hypothesis argues that the risk premium may decrease with duration; long-duration liability holders may perceive the long-term bond as the riskless asset and require higher expected returns for holding short-term assets. While academic analysis focuses on risk-related premiums, market practitioners often emphasize other factors that cause expected return differentials across the yield-curve. These include liquidity differences between market sectors, institutional restrictions, and supply and demand effects. We use the term *bond risk premium* broadly to encompass all expected return differentials across bonds, including those caused by factors unrelated to risk.

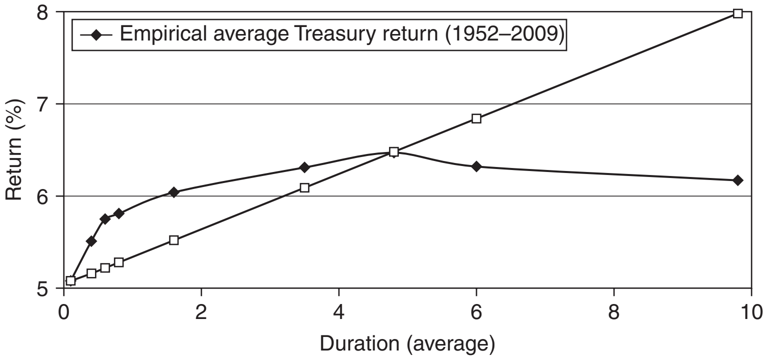
Historical data on U.S. Treasury bonds provide evidence about the empirical behavior of the bond risk premium. For example, the fact that the Treasury yield-curve has been upward-sloping more than 90% of the time in recent decades may reflect the impact of positive bond risk premiums. Historical average returns provide more direct evidence about expected returns across maturities than do historical yields. Even though weekly and monthly fluctuations in bond returns are mostly unexpected, the impact of unexpected yield rises and declines should wash out over a long sample period. Therefore, the *historical average returns* of various maturity sectors over a relatively trendless sample period should reflect the *long-run expected returns*.

Exhibit 31-3 shows the empirical average return curve as a function of average duration and contrasts it with a popular theoretical expected return curve, one that increases linearly with duration. The theoretical bond risk premiums are measured in the exhibit by the difference between the annualized expected returns at various duration points and the annualized return of the riskless one-month bill (the leftmost point on the curve). Similarly, the empirical bond risk premiums are measured by the historical average bond returns (at various durations) in excess of the one-month bill.[10] Historical experience suggests that the bond risk premiums are not linear in duration but that they increase steeply with duration in the

10. The empirical bond risk premiums are based on the compound average returns of various maturity-subsector portfolios of Treasury bills, notes, and bonds between 1952 and 2009. This period does not have an obvious bullish or bearish bias because long-term yields were at broadly similar levels at the beginning and end of the sample. Moreover, the sample period begins just after the "Treasury-Fed accord" ended a decade of regulated (capped) bond yields. Arithmetic average returns would be somewhat higher than these compound average returns (at the long-est maturities 0.2-0.4% higher). This evidence is from Chapter 9 in Antti Ilmanen, *Expected Return* (Hoboken, NJ: John Wiley & Sons, 2011), which discusses bond risk premiums but focuses mainly on forward-looking measures of such premiums.

EXHIBIT 31-3

Theoretical and Empirical Bond Risk Premiums



front end of the curve and much more slowly after two years. The concave shape may reflect the demand for long-term bonds from pension funds and other long-duration liability holders.

Exhibit 31-3 may give us the best empirical estimates of the long-run average bond risk premiums at various durations. However, empirical studies also suggest that the bond risk premiums are not constant but vary over time. That is, it is possible to identify in advance periods when the near-term bond risk premiums are abnormally high or low. These premiums tend to be high after poor economic conditions when the yield-curve is steep, amid high inflation expectations and related inflation uncertainty. These premiums tend to be lower and even turn negative when Treasury prices benefit from safe-haven premiums (amid equity market weakness and negative stock-bond correlation, as in 1998 and 2002) or from scarcity premiums (amid fiscal surpluses and expectations of dwindling government bond markets, as in 2000).[11]

Convexity Bias

The third influence on the yield-curve—convexity bias—is probably the least well known. Different bonds have different convexity characteristics, and the convexity differences across maturities can give rise to (offsetting) yield differences. In particular, long-term bonds exhibit very high convexity (see panel *a* of

11. Long-run average return differentials across bonds with different maturities are discussed in Ilmanen, "Does Duration Extension Enhance Long-Term Expected Returns?" *op. cit*. Near-term expected return differentials across bonds and the time variation in the bond risk premiums are discussed in Antti Ilmanen, "Forecasting U.S. Bond Returns," *Journal of Fixed Income* (June 1997), pp. 22–37. A more recent study, Antti Ilmanen, "Stock-Bond Correlations," *Journal of Fixed Income* (September 2003), pp. 55–66, focuses on stock-bond correlation as a determinant of bond risk premium but also discusses other determinants.

EXHIBIT 31-4 (a)

Illustration of Convexity Bias

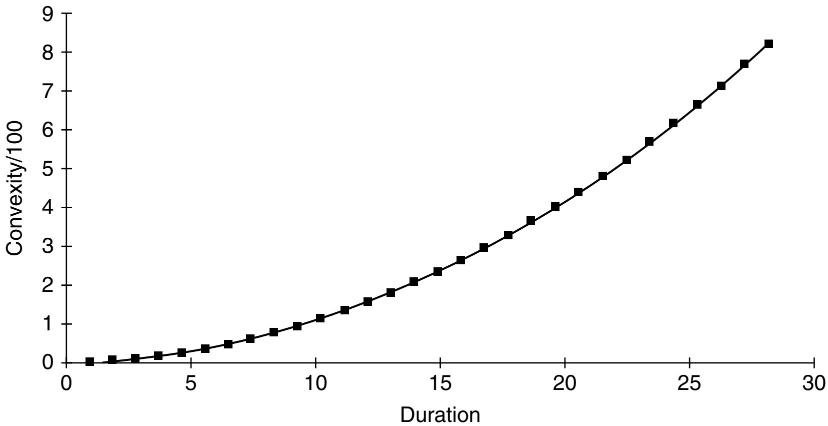


Exhibit 31-4), which tends to depress their yields. *Convexity bias* refers to the impact these convexity differences have on the yield-curve shape.

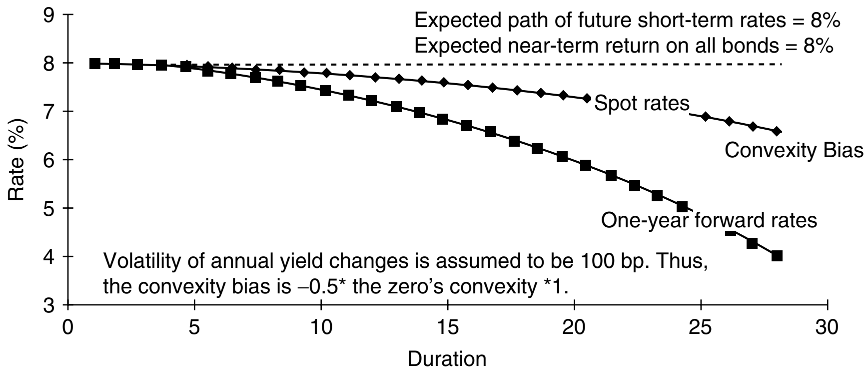
Convexity is closely related to the nonlinearity in the bond price–yield relationship. All noncallable bonds exhibit positive convexity; their prices rise more for a given yield decline than they fall for a similar yield increase. All else being equal, positive convexity is a desirable characteristic because it increases bond return (relative to return in the absence of convexity) whether yields go up or down—as long as they move somewhere. Because positive convexity can only improve a bond's performance (for a given yield), more convex bonds tend to have lower yields than less convex bonds with the same duration.[12] In other words, investors tend to demand less yield if they have the prospect of improving their returns as a result of convexity. Investors are primarily interested in expected returns, and these high-convexity bonds can offer a given expected return at a lower yield level.

Panel *b* of Exhibit 31-4 illustrates the pure impact of convexity on the curve shape by plotting the spot-rate curve and the curve of one-year forward rates when all bonds have the same expected return (8%) and the short-term rates are expected to remain at the current level. With no bond risk premiums and no expected rate

12. The degree of convexity varies across bonds, mainly depending on their option characteristics and durations. Embedded short options decrease convexity. For bonds without embedded options, convexity increases roughly as a square of duration (see Exhibit 31-4). There also are convexity differences between bonds that have the same duration. A barbell position (with very dispersed cash-flows) exhibits more convexity than a duration-matched bullet bond. The reason is that a yield rise reduces the relative weight of the barbell's longer cash-flows (because the present values decline more than those of the shorter cash-flows) and thereby shortens the barbell's duration. The inverse relation between duration and yield level increases a barbell's convexity, limiting its losses when yields rise and enhancing its gains when yields decline. Of all bonds with the same duration, a zero has the smallest convexity because its cash-flows are not dispersed, so its Macaulay duration does not vary with the yield level.

EXHIBIT 31-4 (b)

Pure Impact of Convexity on the Yield-Curve Shape



changes, one might expect these curves to be horizontal at 8%. Instead, they slope down at an increasing pace because lower yields are needed to offset the convexity advantage of longer-duration bonds and thereby to equate the near-term expected returns across bonds.[13] Short-term bonds have little convexity, so there is little convexity bias at the front end of the yield-curve, but convexity can have a dramatic impact on the curve shape at very long durations. Convexity bias can be one of the main reasons for the typical concave yield-curve shape (i.e., for the tendency of the curve to flatten or invert at long durations).

The value of convexity increases with the magnitude of yield changes. Therefore, increasing volatility should make the overall yield-curve shape more concave (curved) and widen the spreads between more and less convex bonds (duration-matched coupon bonds versus zeros and barbells versus bullets).[14]

Putting the Pieces Together

Of course, all three forces influence bond yields simultaneously, making the task of interpreting the overall yield-curve shape quite difficult. A steeply upward-sloping curve can reflect either the market's expectations of rising rates or a high required risk premium. A strongly humped curve (i.e., high curvature) can reflect

13. Convexity bias is closely related to the distinction between different versions of the pure expectations hypothesis. Earlier we referred to *the* pure expectations hypothesis. In fact, there are alternative versions of this hypothesis that are not exactly consistent with each other. The local-expectations hypothesis (LEH) assumes that "all bonds earn the same expected return over the next period" whereas the unbiased-expectations hypothesis (UEH) assumes that "forward rates equal expected spot rates." In panel *b* of Exhibit 31-4, the LEH is assumed to hold; thus UEH is not exactly true. The expected future short rates are flat at 8% even though the curve of one-year forward rates is inverted. In yield terms, the difference between the LEH and the UEH is the convexity bias.

14. For detailed discussion of this topic, see Ilmanen, "Convexity Bias in the Yield Curve," *op. cit.*

the market's expectations of either curve flattening or high volatility (which makes convexity more valuable) or even the concave shape of the risk premium curve.

In theory, the yield-curve can be neatly decomposed into expectations, risk premiums, and convexity bias. In reality, exact decomposition is not possible because the three components vary over time and are not observable directly but need to be estimated.[15] Even though an exact decomposition is not possible, the analysis in this chapter should give investors a framework for interpreting various yield-curve shapes. Furthermore, our survey of earlier literature and our new empirical work evaluate which theories and market myths are correct (consistent with data) and which are false. The main conclusions are as follows:

- We often hear that "forward rates show the market's expectations of future rates." However, this statement is true only if no bond risk premiums exist and the convexity bias is very small.[16] If the goal is to infer expected short-term rates one or two years ahead, the convexity bias is so small that it can be ignored. In contrast, our empirical analysis shows that the bond risk premiums are important at short maturities. Therefore, if the forward rates are used to infer the market's near-term rate expectations, some measures of bond risk premiums should be subtracted from the forwards, or the estimate of the market's rate expectations will be strongly upward-biased.
- The traditional term-structure theories make the assumption of a zero risk premium (pure expectations hypothesis) or of a nonzero but *constant* risk premium (liquidity premium hypothesis, preferred-habitat hypothesis), which is inconsistent with historical data. According to the pure expectations hypothesis, an upward-sloping curve should predict increases in long-term rates so that a capital loss offsets the long-term bonds' yield advantage. However, empirical evidence shows that, on average, small declines in long-term rates, which *augment* the long-term bonds' yield advantage, follow upward-sloping curves. The steeper the yield-curve, the higher is the expected bond risk premium. This finding clearly vio-

15. We show in other studies how interest-rate expectations can be measured using survey data, how bond risk premiums can be estimated using historical return data, and how the convexity bias can be inferred using option prices; see Ilmanen, "Market's Rate Expectations and Forward Rates," *op. cit.*; Ilmanen, "Does Duration Extension Enhance Long-Term Expected Returns?" *op. cit.*; and Ilmanen, "Convexity Bias in the Yield Curve," *op. cit.* Alternatively, all three components could be estimated from the yield-curve if one is willing to impose the structure of some term-structure model.

16. A related assertion claims that if near-term expected returns were not equal across bonds, it would imply the existence of *riskless arbitrage opportunities*. This assertion is erroneous. It is true that if forward contracts were traded assets, arbitrage forces would require their pricing to be consistent with zero prices according to Eq. (31-2). However, the arbitrage argument says nothing about the economic determinants of the zero prices themselves, such as rate expectations or risk premia. The experience of 1994 and 1999 shows that buying long-term bonds is not riskless even if they have higher expected returns than short-term bonds.

lates the pure expectations hypothesis and supports hypotheses about time-varying risk premiums.

- Modern term-structure models make less restrictive assumptions than the traditional theories just mentioned. Yet many popular one-factor models assume that bonds with the same duration earn the same expected return. Such an assumption implies that duration-neutral positions with more or less convexity earn the same expected return (because any convexity advantage is *exactly* offset by a yield disadvantage). However, if the market values very highly the insurance characteristics of positively convex positions, more convex positions may earn lower expected returns. Our analysis of the empirical performance of duration-neutral barbell-bullet trades will show that, in the long run, barbells tend to marginally underperform bullets.

USING FORWARD RATE ANALYSIS IN YIELD-CURVE TRADES

Recall that if the local expectations hypothesis holds, all bonds and bond positions have the same near-term expected return. In particular, an upward-sloping yield-curve reflects expectations of rising rates and capital losses, and convexity is priced so that a yield disadvantage exactly offsets the convexity advantage. In such a world, yields do not reflect value, no trades have favorable odds, and active management can add value only if an investor has truly superior forecasting ability. Fortunately, the real world is not quite like this textbook case because expected returns do vary across bonds (see Exhibit 31-3). The main reason is probably that most investors exhibit risk aversion and preferences for other asset characteristics; moreover, investor behavior may not always be fully rational. Therefore, yields reflect value, and certain relative value trades have favorable odds.

The preceding section provided a framework for thinking about the term-structure shapes. In this section we describe practical applications, that is, different ways to use forward rates in yield-curve trades. The first approach requires strong subjective rate views and faith in one's forecasting ability.

Forwards as Break-Even Rates for Active Yield-Curve Views

The forward rates show a path of break-even future rates and spreads. This path provides a clear yardstick for an active portfolio manager's subjective yield-curve scenarios and yield-path forecasts. It incorporates directly the impact of carry on the profitability of the trade. For example, a manager should take a bearish portfolio position only if she expects rates to rise by more than what the forwards imply. However, if she expects rates to rise, but by less than what the forwards imply (i.e., by less than what is needed to offset the positive carry), she should take a bullish portfolio position. If the manager's forecast is correct, the position will be profitable. In contrast, managers who take bearish portfolio positions whenever they expect bond yields to rise—ignoring the forwards—may find that their positions lose money, because of the negative carry, even though their rate forecasts are correct.

One positive aspect about the role of forward rates as break-even rates is that they do not depend on assumptions regarding expectations, risk premiums, or convexity bias. The rules are simple. If forward rates are realized, all positions earn the same return. If yields rise by more than the forwards imply, bearish positions are profitable, and bullish positions lose money. If yields rise by less than the forwards imply, the opposite is true. Similar statements hold for any yield spreads and related positions, such as curve-flattening positions.

Exhibit 31-5 shows the dollar-swap (par) yield-curve and the implied-swap curves 3 months forward and 12 months forward as of April 2004. If we believe that forward rates only reflect the market's rate expectations, a comparison of these curves tells us that the market expects rates to rise and the curve to flatten over the next year. Alternatively, the implied yield rise may reflect a bond risk premium, and the implied curve flattening may reflect the value of convexity. Either way, the forward yield-curves reflect the break-even levels between profits and losses.

The information in the forward rate structure can be expressed in several ways. Exhibit 31-5 is useful for an investor who wants to contrast his subjective view of the future yield-curve with an objective break-even curve at some future horizon. Another graph may be more useful for an investor who wants to see the break-even future path of any given-maturity yield (instead of the

Current and Forward Par Yield Curves Based on the Dollar-Swap Curve in April 2004

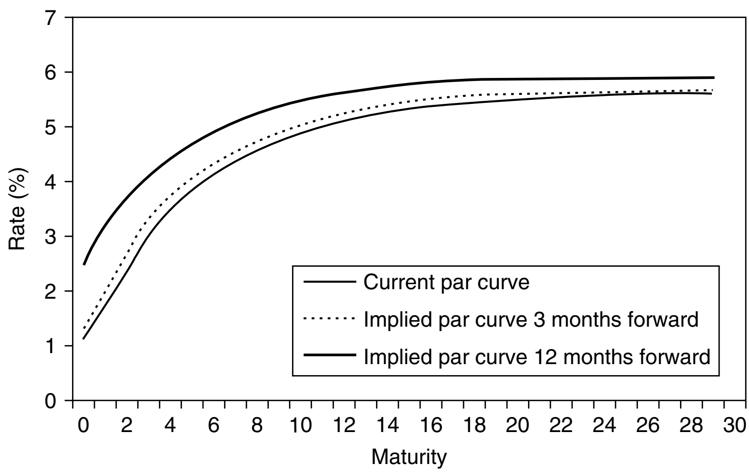

EXHIBIT 31-6

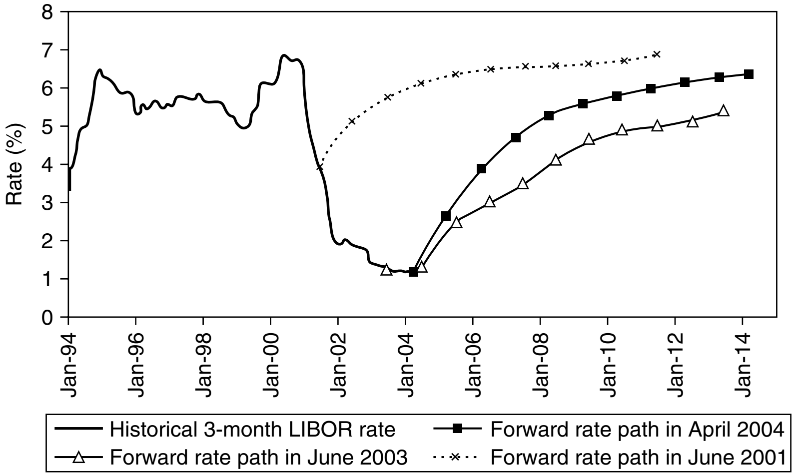
Historical Three-Month Rates and Implied Forward Rate Path Based on the Dollar Swap Curve in April 2004, June 2003, and June 2001



whole curve) and contrast it with his own forecast, which may be based on a macroeconomic forecast or on the subjective view about the speed of Fed tightening. As an example, Exhibit 31-6 shows such a break-even path of future three-month rates in April 2004. Note that the first point in each implied forward par curve in Exhibit 31-5 is the implied forward three-month rate at a given future date. Therefore, the forward path in Exhibit 31-6 can be constructed by tracing through the three-month points in the three curves of Exhibit 31-5 and through similar curves at other horizons. Because Exhibit 31-6 depicts a rate path over time, the horizontal axis is calendar years and not maturity.

To add perspective, the graph also contains the historical path of the three-month rate over the past decade and the break-even path of the future three-month rates in June 2003 when monetary policy expectations were much more bullish and in June 2001 when market's policy tightening expectations proved immature.

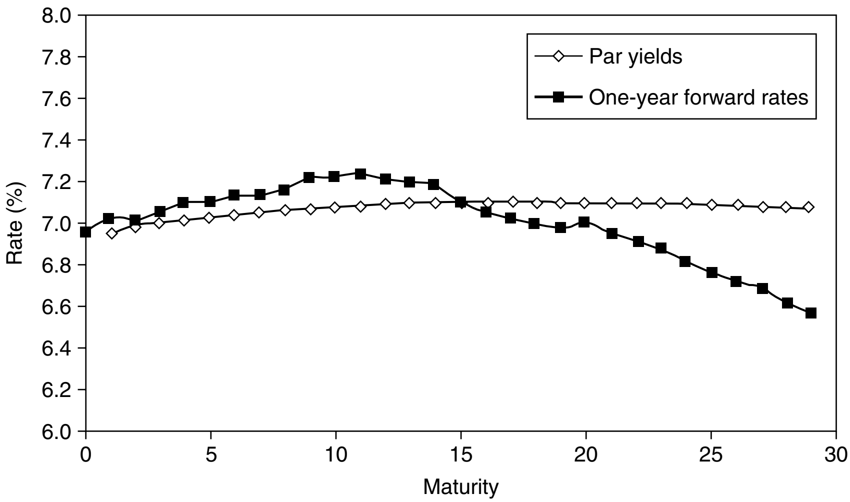
Forwards as Indicators of Cheap Maturity Sectors

The other ways to use forwards require less subjective judgment than the first one. As a simple example, the forward rate curve can be used to identify cheap maturity sectors visually. Abnormally high forward rates are more visible than high spot or par rates because the latter are averages of forward rates.

Exhibit 31-7 shows one real-world example from year 2000 when the par yield-curve was extremely flat (although forwards may be equally useful when the par curve is not flat). Even though the par yield-curve was almost horizontal (all par

EXHIBIT 31-7

Par Yields and One-Year Forward Rates Based on the Dollar-Swap Curve in August 2000



yields were within 15 basis points), the range of one-year forward rates was almost 100 basis points because the forward rate curve magnifies the cheapness/richness of different maturity sectors. High forward rates identify the 9- to 12-year sector as cheap. Forward rates are very low at the long maturities, but this characteristic probably reflects the convexity bias. Recall that forward rates are downward-biased estimates of expected returns because they ignore the convexity advantage, which is especially large at long maturities.

Once an investor has identified a sector with abnormally high forward rates (e.g., between 9 and 12 years), she can exploit the cheapness of this sector by buying a bond that matures at the end of the period (12 years) and by selling a bond that matures at the beginning of the period (9 years). If equal market values of these bonds are bought and sold, or received and paid fixed in swaps, the position captures the cheap forward rate (in this case the 3-year rate 9 years forward). In par-curve terms, the position is exposed to a general increase in rates and a steepening yield-curve. More elaborate trades can be constructed (e.g., by selling both the 9- and 15-year bonds against the 12-year bonds with appropriate weights) to retain level and slope neutrality. To the extent that bumps and kinks in the forward curve reflect temporary local cheapness, the trade will earn capital gains when the forward curve becomes flatter and the cheap sector richens (in addition to the higher yield and rolldown the position earns).

Forwards as Relative-Value Tools for Yield-Curve Trades

Thus far in this chapter forwards are used quite loosely to identify cheap maturity sectors. A more formal way to use forwards is to construct quantitative cheapness indicators for duration-neutral flattening trades, such as barbell-bullet trades. We first introduce some concepts with an example of a market-directional trade.

When the yield-curve is upward-sloping, long-term bonds' yield advantage over the riskless short-term bond provides a cushion against rising yields. In a sense, duration extensions are "cheap" when the yield-curve is very steep and the cushion (positive carry) is large. These trades only lose money if capital losses caused by rising rates offset the initial yield advantage. Moreover, the longer-term bonds' rolling yield advantage[17] over the short-term bond is even larger than their yield advantage. The one-year forward rate ($f_{n-1,n}$) is, by construction, equal to the n-year zero's rolling yield (see Appendix 31C). Thus it is a direct measure of the n-year zero's rolling yield advantage. [Another forward-related measure, the change in the $(n-1)$-year spot rate implied by the forwards ($f_{1,n} - s_{n-1}$) tells how much the yield-curve has to shift to offset this advantage and to equate the holding-period returns of the n-year zero and the one-year zero.]

Because one-period forward rates measure zeros' near-term expected returns, they can be viewed as indicators of cheap maturity sectors. The use of such cheapness indicators does not require any subjective interest-rate view. Instead, it requires a belief, motivated by history, that an unchanged yield-curve is a good base-case scenario.[18] If this is true, long-term bonds have higher (lower) near-term expected returns than short-term bonds when the forward rate curve is upward-sloping (downward-sloping). In the long run, a strategy that adjusts the portfolio duration dynamically based on the curve shape should earn higher average return than constant-duration strategies.[19]

Similar analysis holds for curve-flattening trades. Recall that when the yield-curve is concave as a function of duration, any duration-neutral flattening trade earns a negative carry. Higher concavity (curvature) in the yield-curve indicates less attractive terms for a flattening trade (larger negative carry) and more "implied flattening" by the forwards (that is needed to offset the negative carry).

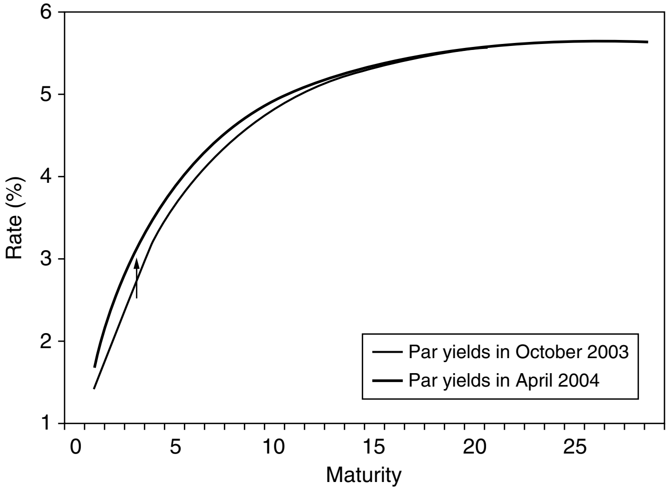
17. As bonds age, they roll down the upward-sloping yield-curve and earn some rolldown return (capital gain owing to this yield change) if the yield-curve remains unchanged. A bond's rolling yield, or horizon return, includes both the yield and the rolldown return given a scenario of no change in the yield-curve.

18. The one-period forward rate can proxy for the near-term expected return—albeit with a downward bias because it ignores the value of convexity—*if* the current yield-curve is not expected to change. Empirical studies show that the assumption of an unchanged curve is more realistic than the assumption that forward rates reflect expected future yields. Historically, current spot rates predict future spot rates better than current forward rates do because the yield changes implied by the forwards have not been realized, on average.

19. The historical performance of dynamic strategies that exploit the predictability of long-term bonds' near-term returns is evaluated in Antti Ilmanen, "Forecasting U.S. Bond Returns," *Journal of Fixed Income* (June 1997), pp. 22–37. The dynamic strategies have consistently outperformed static strategies that do not actively adjust the portfolio duration.

EXHIBIT 31-8

Dollar-Swap Curves in October 2003 and in April 2004



Therefore, the amount of spread change implied by the forwards is a useful cheapness indicator for yield-curve trades at different parts of the curve. If the implied change is wide historically, the trade is expensive, and vice versa.

Exhibit 31-8 shows a recent example of negative carry making curve-flattening positions expensive to hold. In October 2003, high yield-curve curvature indicated strong flattening expectations—forwards implied a 50 basis point decline in the 2- to 30-year spread over the coming six months—or high expected volatility (high value of convexity). The barbell (of the 30-year bond and six-month bill) over the duration-matched two-year bullet would become profitable only if the curve flattened even more than the forwards implied or if a sudden increase in volatility occurred. Purely on yield grounds, the two-year bullet (a steepening position) appeared cheap to the barbell. With the benefit of hindsight, we know that the carry/cheapness indicator gave a correct signal in this case. Exhibit 31-8 plots the dollar-swap curves in October 2003 and in April 2004; it is perhaps surprising that a steepening position outperformed amid curve flattening. Even though the yield-curve did flatten (the 2- to 30-year spread actually narrowed by 38 basis points by April 2004), the realized flattening did not match the forward-implied flattening. A steepener's (bullet's) initial carry and rolldown advantage did more than offset the capital losses owing to subsequent curve flattening.[20]

20. We show how to use forward rate analysis to evaluate opportunities like this in Ilmanen, "Market's Rate Expectations and Forward Rates," *op. cit.*; and Ilmanen and Iwanowski, "Dynamics of the Shape of the Yield Curve," *op. cit.*

APPENDIX 31A

Notation and Definitions

P	market price of a bond
P_n	market price of an n-year zero
C	coupon rate (in percent; other rates are expressed as a decimal)
y	annualized yield-to-maturity (YTM) of a bond
n	time-to-maturity of a bond (in years)
s_n	annualized n-year spot rate; the discount rate of an n-year zero
s_{n-1}	annualized (n – 1)-year spot rate next period; superscript * denotes next period's (year's) value
Δs_{n-1}	realized change in the (n – 1)-year spot rate between today and next period ($= s^*_{n-1} - s_{n-1}$)
$f_{m,n}$	annualized forward rate between maturities m and n
$f_{n-1,n}$	one-year forward rate between maturities (n – 1) and n; also, the n-year zero's rolling yield
$f_{1,n}$	annualized forward rate between maturities 1 and n; also called the implied (n – 1)-year spot rate one year forward
Δf_{n-1}	implied change in the (n – 1)-year spot rate between today and next period ($= f_{1,n} - s_{n-1}$); also called the break-even yield change (over the next period) implied by the forwards
Δfz_n	implied change in the yield of an n-year zero, a specific bond, over the next period ($= f_{1,n} - s_n$)
FSP	forward-spot premium ($\text{FSP}_n = f_{n-1,n} - s_1$)
h_n	realized holding-period return of an n-year zero [over one period (year)]

Rolling yield	a bond's horizon return given a scenario of unchanged yield-curve; sum of yield and rolldown return
Bond risk premium (BRP)	expected return of a long-term bond over the next period (year) in excess of the riskless one-period bond; for the n-year zero, $\text{BRP}_n = E(h_n - s_1)$
Realized BRP	realized one-year holding-period return of a long-term bond in excess of the one-year bond; also called excess bond return; realized $\text{BRP}_n = h_n - s_1$
Persistence factor (PF)	slope coefficient in a regression of the annual realized BRP_n on FSP_n
Term spread	yield difference between a long-term bond and a short-term bond; for the n-year zero, $= s_n - s_1$
Real yield	difference between a long-term bond yield and a proxy for expected inflation; our proxy is the recently published year-on-year consumer price inflation rate

Inverse wealth	ratio of exponentially weighted past wealth to the current wealth; we proxy wealth W by the stock market level; $= (W_{t-1} + 0.9^*W_{t-2} + 0.9^{2*}W_{t-3} + \cdots)^*0.1/W_t$
Duration (Dur)	measure of a bond price's interest rate sensitivity; Dur = $-(dP/\mathrm{d}y)^*(1/P)$
Convexity (Cx)	measure of the nonlinearity in a bond's P/y relation; Cx = $(d^2P/\mathrm{d}y^2)^*(1/P)$
Convexity bias (CB)	impact of convexity on the forward rate curve; $\mathrm{CB}_n = -0.5^*\mathrm{C}x_n{}^*(\text{volatility of } \Delta s_n)^2$

APPENDIX 31B

Calculating Spot and Forward Rates When Par Rates Are Known

A simple example illustrates how spot rates and forward rates are computed on a coupon date when the par curve is known (and coupon payments and compounding frequency are annual). The basis of the procedure is the fact that a bond's price will be the same, the sum of the present values of its cash flows, whether it is priced via yield-to-maturity—Eq. (31B.1)—or via the spot-rate curve—Eq. (31B.2).

$$P = \frac{C}{1+y} + \frac{C}{(1+y)^2} + \cdots + \frac{C+100}{(1+y)^n} \tag{31B.1}$$

$$P = \frac{C}{1+s_1} + \frac{C}{(1+s_2)^2} + \cdots + \frac{C+100}{(1+s_n)^n} \tag{31B.2}$$

where P is the bond price, C is the coupon rate (in percent), y is the annual yield-to-maturity (expressed as a decimal), s is the annual spot rate (expressed as a decimal), and n is the time-to-maturity (in years). We show only the computation for the first two years, which have par rates of 6% and 8%. For the first year, par, spot, and forward rates are equal (6%). Longer spot rates are solved recursively using known values of the par bond's price and cash flows and the previously solved spot rates. Every par bond's price is 100 (par) by construction, so its yield (the par rate) equals its coupon rate. Because the two-year par bond's market price (100) and cash flows (8 and 108) are known, as is the one-year spot rate (6%), it is easy to solve for the two-year spot rate as the only unknown in the following equation:

$$100 = \frac{C}{1+s_1} + \frac{C+100}{(1+s_2)^2} = \frac{8}{1.06} + \frac{108}{(1+s_2)^2} \tag{31B.3}$$

A little manipulation shows that the solution for s_2 is 8.08%. Equation (31B.3) also can be used to compute par rates when only spot rates are known. If the

EXHIBIT 31B–1

Par, Spot, and One-Year Forward Rate Curves

Maturity	Par Rate	Spot Rate	Forward Rate
1	6.00	6.00	6.00
2	8.00	8.08	10.20
3	9.50	9.72	13.07
4	10.50	10.86	14.36
5	11.00	11.44	13.77
6	11.25	11.71	13.10
7	11.38	11.83	12.55
8	11.44	11.88	12.20
9	11.48	11.89	11.97
10	11.50	11.89	11.93

spot rates are known, the coupon rate C—which equals the par rate—is the only unknown in Eq. (31B.3).

The forward rate between one and two years is computed using Eq. (31B.3) and the known one-year and two-year spot rates.

$$(1+f_{1,2}) = \frac{(1+s_2)^2}{1+s_1} = \frac{(1.0808)^2}{1.06} = 1.1020 \tag{31B.4}$$

The solution for $f_{1,2}$ is 10.20%. The other spot rates and one-year forward rates ($f_{2,3}$, $f_{3,4}$, etc.) in Exhibit 31B–1 are computed in the same way. These numbers are shown graphically in Exhibit 31-1.

APPENDIX 31C

Relations Between Spot Rates, Forward Rates, Rolling Yields, and Bond Returns

Investors often want to make quick "back of the envelope" calculations with spot rates, forward rates, and bond returns. In this appendix we discuss some simple relations between these variables, beginning with a useful approximate relation between spot rates and one-year forward rates.[21] Equation (31-2) showed exactly how the forward rate between years *m* and *n* is related to *m*- and *n*-year spot rates. Equation (31C.1) shows the same relation in an approximate but simpler form; this equation ignores nonlinear effects such as the convexity bias. The relation is exact if spot rates and forward rates are continuously compounded.

$$f_{m,n} \approx \frac{ns_n - ms_m}{n-m} \tag{31C.1}$$

For one-year forward rates ($m = n - 1$), Eq. (31C.1) can be simplified to

$$f_{n-1,n} \approx s_n + (n-1)(s_n - s_{n-1}) \tag{31C.2}$$

Equation (31C.2) shows that the forward rate is equal to an *n*-year zero's one-year horizon return given an unchanged yield-curve scenario: a sum of the initial yield and the rolldown return [the zero's duration at horizon ($n - 1$) multiplied by the amount the zero rolls down the yield-curve as it ages]. This horizon return is often called the *rolling yield.* Thus the one-year forward rates proxy for near-term expected returns at different parts of the yield-curve if the yield-curve is expected to remain unchanged. We can gain intuition about the equality of the one-year forward rate and the rolling yield by examining the *n*-year zero's realized holding-period return h_n over the next year, in Eq. (31C.3). The zero earns its initial yield s_n plus a capital gain/loss that is approximated by the product of the zero's year-end duration and its realized yield change.

$$h_n \approx s_n + (n-1) \times (s_n - s_{n-1}^*) \tag{31C.3}$$

where s_{n-1}^* is the ($n - 1$)-year spot rate next year. If the yield-curve follows a random walk, the best forecast for s_{n-1}^* is (today's) s_{n-1}. Therefore, the *n*-year zero's expected holding period return is exactly the one-year forward rate in Eq. (31C.2). The key question is whether it is more reasonable to assume that the current spot rates are the optimal forecasts of future spot rates than to assume that forwards are the optimal forecasts. Empirical evidence suggests that the "random walk" forecast of an unchanged yield-curve is more accurate than the forecast implied by the forwards.

Equation (31C.2) shows that the (one-year) forward rate curve lies above the spot curve as long as the latter is upward-sloping (and the rolldown return is positive). Conversely, if the spot curve is inverted, the rolldown return is negative, and the forward rate curve lies below the spot curve. If the spot curve is first rising and then declining, the forward rate curve crosses it from above at its peak. Finally, the forward rate curve can become downward-sloping even when the spot curve is upward-sloping if the spot curve's slope is first steep and then flattens

21. These relations are discussed in more detail in the appendix to Ilmanen, "Market's Rate Expectations and Forward Rates," *op. cit.*

(reducing the rolldown return). The following calculations illustrate this point and show that the approximation is good—within a few basis points from the correct values (10.20 – 13.07 – 14.36 – 13.77) in Exhibit 31B–1.

$$f_{1,2} \approx 8.08 + 1 * (8.08 - 6.00) = 8.08 + 2.08 = 10.16;$$

$$f_{2,3} \approx 9.72 + 2 * (9.72 - 8.08) = 9.72 + 3.28 = 13.00;$$

$$f_{3,4} \approx 10.86 + 3 * (10.86 - 9.72) = 10.86 + 3.42 = 14.28; \text{ and}$$

$$f_{4,5} \approx 11.44 + 4 * (11.44 - 10.86) = 11.44 + 2.32 = 13.76.$$

KEY POINTS

- Yield-curve or the term structure of interest rates can be depicted in several interchangeable ways, including the par curve, the spot curve, and the forward rate curve.
- The main drivers of the yield-curve are the market's rate expectations, required bond risk premiums, and convexity bias.
- A steeply upward-sloping yield-curve may reflect the market forecast of rising future short-term rates, or exceptionally high bond risk premiums, or some combination of these two. The pure expectations hypothesis assumes the first term drives yield-curve fluctuations, while empirical evidence suggests that the second term matters more. In reality, both matter.
- Forward rates can be useful tools for bond investors in break-even analysis (how much yields need to shift over a given horizon to just offset certain assets' initial yield advantage?) and in relative value analysis (what is the expected return of a zero-coupon bond if the curve remains unchanged?).
- Treasury analysis can focus on duration extensions and yield level changes or on duration-neutral strategies and yield-curve shape changes.

CHAPTER

THIRTY-TWO

A FRAMEWORK FOR ANALYZING YIELD-CURVE TRADES

Antti Ilmanen, Ph.D.
Principal
AQR Capital Management

In Chapter 31 it was explained that the shape of the yield-curve depends on three main determinants: the market's rate expectations, the required bond risk premia, and the convexity bias. In this chapter we show how to decompose the forward rate curve into these three determinants. Even though we cannot observe these determinants directly, the decomposition can clarify our thinking about the yield-curve.

Our analysis also produces direct applications—it provides a systematic framework for relative-value analysis of noncallable government bonds. Analogous to the decomposition of forward rates, the total expected return of any government bond position can be viewed as the sum of a few simple building blocks: (1) the yield income, (2) the rolldown return, (3) the value of convexity, and (4) the duration impact of the rate view. A further term should be added for bonds that trade "special" in the repo market and for bonds that trade very rich or cheap against the fitted curve.

The following observations motivate this decomposition. A bond's near-term expected return is a sum of its horizon return given an unchanged yield-curve and its expected return from expected changes in the yield-curve. The first item, the horizon return, is also called the *rolling yield* because it is a sum of the bond's yield income and the rolldown return (the capital gain that the bond earns because its yield declines as its maturity shortens and it "rolls down" an upward-sloping yield-curve). The second item, the expected return from expected changes in the yield-curve, can be approximated by duration and convexity effects. The duration impact is zero if the yield-curve is expected to remain unchanged, but it may be the main source of expected return if the rate predictions are based on an investor's or economist's market view or on a quantitative forecasting model.

This chapter is a revised version of a Citigroup (Salomon Brothers) research report. Such report remains the property of Citigroup, and its disclaimers apply.

The value of convexity is always positive and depends on the bond's convexity and on the perceived level of yield volatility.

We argue that both prospective and historical relative-value analysis should focus on near-term expected-return differentials across bond positions instead of on yield spreads. The former measures are more comprehensive in the sense that they take into account all sources of expected return. Moreover, they provide a consistent framework for evaluating all types of government bond positions. We also show, with practical examples, how various expected-return measures are computed and how our framework for relative-value analysis is related to the better-known scenario analysis.

FORWARD RATES AND THEIR DETERMINANTS

Chapter 31 shows that the yield-curve can be represented in either par rates, spot rates, or forward rates. Whichever representation is used, there are three main determinants of the yield-curve that we discuss next.

How Do the Main Determinants Influence the Yield-Curve Shape?

We describe here how the market's rate expectations, the required bond risk premia,[1] and the convexity bias influence the term structure of interest rates. The market's expectations regarding the future interest-rate behavior probably are the most important influences on today's term structure. Expectations for parallel increases in yields tend to make today's term structure linearly upward sloping, and expectations for falling yields tend to make today's term structure inverted. Expectations for future curve flattening induce today's spot- and forward-rate curves to be concave (functions of maturity), and expectations for future curve steepening induce today's spot- and forward-rate curves to be convex.[2] These are the facts, but what is the intuition behind these relationships?

The traditional intuition is based on the pure expectations hypothesis. In the absence of risk premia and convexity bias, a long rate is a weighted average of the expected short rates over the life of the long bond. If the short rates are expected to rise, the expected average future short rate (i.e., the long rate) is

1. The *bond risk premium* is defined as a bond's expected (near-term) holding-period return in excess of the riskless short rate. Historical experience suggests that long-term bonds command some risk premium because of their greater perceived riskiness. However, our term *bond risk premium* also covers required return differentials across bonds that are caused by other reasons than risk, such as liquidity differences, supply effects, or the market sentiment.

2. A concave (but upward-sloping) curve has a steeper slope at short maturities than at long maturities; thus a line connecting two points on the curve is always below the curve. A convex (but upward-sloping) curve has a steeper slope at long maturities than at short maturities; thus a line connecting two points on the curve is always above the curve.

higher than the current short rate, making today's term structure upward-sloping. A similar logic explains why expectations of falling rates make today's term structure inverted. However, this logic gives few insights about the relation between the market's expectations regarding future curve reshaping and the curvature of today's term structure.

Another perspective to the pure expectations hypothesis may provide a better intuition. The absence of risk premia means that all bonds, independent of maturity, have the same near-term expected return. Recall that a bond's holding-period return equals the sum of the initial yield and the capital gains/losses that yield changes cause. Therefore, if all bonds are to have the same expected return, initial yield differentials across bonds must offset any expected capital gains/losses. Similarly, each bond portfolio with expected capital gains must have a yield disadvantage relative to the riskless asset. If investors expect the long bonds to gain value because of a decline in interest rates, they accept a lower initial yield for long bonds than for short bonds, making today's spot- and forward-rate curves inverted. Conversely, if investors expect the long bonds to lose value because of an increase in interest rates, they demand a higher initial yield for long bonds than for short bonds, making today's spot- and forward-rate curves upward-sloping. Similarly, if investors expect the curve-flattening positions to earn capital gains because of future curve flattening, they accept a lower initial yield for these positions. In such a case, barbells would have lower yields than duration-matched bullets (to equate their near-term expected returns), making today's spot- and forward-rate curves concave. A converse logic links the market's curve-steepening expectations to convex spot- and forward-rate curves.

The preceding analysis presumes that all bond positions have the same near-term expected returns. In reality, investors require higher returns for holding long bonds than short bonds. Many models that acknowledge bond risk premia assume that they increase linearly with duration (or with return volatility) and that they are constant over time. Empirical evidence contradicts both assumptions.[3] Historical average returns increase substantially with duration at the front end of the curve but only modestly beyond intermediate durations. Thus the bond risk premia make the term structure upward-sloping and concave, on average. Moreover, it is possible to forecast when the required bond risk premia are abnormally high or low. Thus the time variation in the bond risk premia can cause significant variation in the shape of the term structure.

Convexity bias refers to the impact that the nonlinearity of a bond's price/yield-curve has on the shape of the term structure. This impact is very small at the front end but can be quite significant at very long durations. A positively convex price/yield-curve has the property that a given yield decline raises the bond price more than a yield increase of equal magnitude reduces it. All else

---

3. This evidence is discussed in Antti Ilmanen, "Does Duration Extension Enhance Long-Term Expected Returns?" *Journal of Fixed Income* (September 1996), pp. 23–36; and Antti Ilmanen, "Forecasting U.S. Bond Returns," *Journal of Fixed Income* (June 1997), pp. 22–37.

equal, this property makes a high-convexity bond more valuable than a low-convexity bond, especially if the volatility is high. It follows that investors tend to accept a lower initial yield for a more convex bond because they have the prospect of enhancing their returns as a result of convexity. Because a long bond exhibits much greater convexity than a short bond, it can have a lower yield and yet offer the same near-term expected return. Thus, in the absence of bond risk premia, the convexity bias would make the term structure inverted. In the presence of positive bond risk premia, the convexity bias tends to make the term structure humped—because the negative effect of convexity bias overtakes the positive effect of bond risk premia only at long durations. An increase in the interest-rate volatility makes the bias stronger and thus tends to make the term structure more humped.

The three determinants influence the shape of the term structure simultaneously, making it difficult to distinguish their individual effects. Despite a widespread misconception, the shape of the term structure does not reflect only the market's rate expectations. Forward rates are good measures of the market's rate expectations only if the bond risk premia and the convexity bias can be ignored. This is hardly the case, even though a large portion of the short-term variation in the shape of the curve probably reflects the market's changing expectations about the future level and shape of the curve. The steepness of the curve on a given day depends mainly on the market's view regarding the rate direction, but in the long run, the impact of positive and negative rate expectations largely washes out. Therefore, the average upward slope of the yield-curve is mainly attributable to positive bond risk premia. The curvature of the term structure may reflect all three components. On a given day, the spot-rate curve is especially concave (humped) if market participants have strong expectations of future curve flattening or of high future volatility. In the long run, the reshaping expectations should wash out, and the average concave shape of the term structure reflects the concavity of the risk premium curve and the convexity bias.

Decomposing Forward Rates into Their Main Determinants

Conceptually, each one-period forward rate can be decomposed to three parts: the impact of rate expectations, the bond risk premium, and the convexity bias. So far this statement is just an assertion. In this subsection we show intuitively why this relationship holds between the forward rates and their three determinants. We provide a more formal derivation in Appendix 32A (where we take into account the fact that the analysis is not instantaneous but that yield changes occur over a discrete horizon, during which invested capital grows). In Appendix 32B we tie some loose strings together by summarizing various statements about the forward rates and by clarifying the relations between these statements.

EXHIBIT 32-1

Splitting a Zero-Coupon Bond's One-Period Yield Change into Two Parts

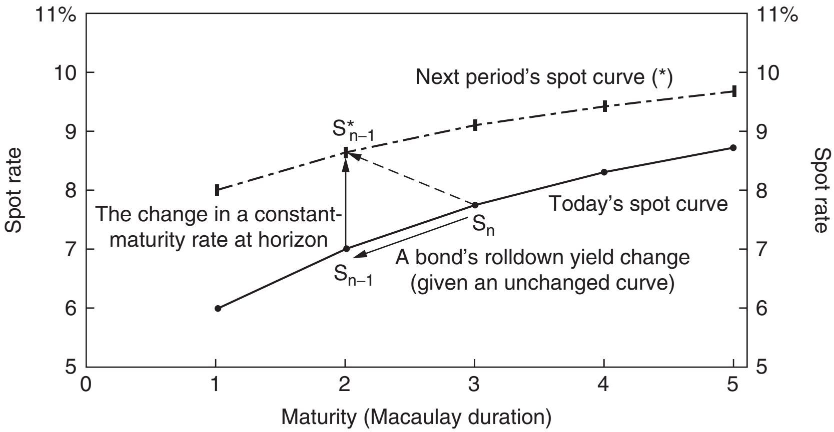

Exhibit 32-1 shows how the yield change of an n-year zero-coupon bond over one period (dashed arrow) can be split to the rolldown yield change and the one-period change in an $n - 1$ year constant-maturity spot rate $s_{n-1}(\Delta s_{n-1} = s^*_{n-1} - s_{n-1})$ (two solid arrows).[4] A zero-coupon bond's price can be split in a similar way (see Appendix 32A). Thus an n-year zero's holding-period return over the next period h_n is

$$\begin{aligned} h_n &= \text{return if the curve is unchanged} + \text{return from the curve changes} \\ &= \text{rolling yield} + \text{percentage price change (at horizon)} \\ &\approx \text{(one-period) forward rate} + [(-\text{duration} \times \Delta s_{n-1}) \\ &\quad + (0.5 \times \text{convexity} \times \Delta s_{n-1})^2] \end{aligned} \tag{32-1}$$

Equation (32-1) is based on the following relations. First, a bond's one-period horizon return given an unchanged yield-curve is called the *rolling yield*. A zero-coupon bond's rolling yield equals the one-period forward rate ($f_{n-1,n}$). For example, if the four-year (five-year) constant-maturity rate remains unchanged at 9.5% (10%) over the next year, a five-year zero bought today at 10% can be sold next year at 9.5% as a four-year zero; then the bond's horizon return is $1.10^5/1.095^4 - 1 = 0.1202 = 12.02\%$, which is the one-year forward rate between four- and five-year maturities [see Eq. (32-11) in Appendix 32B]. The second source of a zero's holding-period return, the price change caused by the yield-curve

4. All rates and returns in this chapter are expressed in percentage terms (200 basis points = 2%).

shift, is approximated very well by duration and convexity effects for all but extremely large yield-curve shifts.

It is more interesting to relate the forward rates to expected returns and expected rate changes than to the realized ones. We take expectations of both sides of Eq. (32-1), split the bond's expected holding-period return into the short rate and the bond risk premium, and recall that $E(\Delta s_{n-1})^2 \approx [\text{vol}(\Delta s_{n-1})]^2$. Then we can rearrange the equation to express the one-period forward rate as a sum of the other terms:

$$\begin{aligned}\text{Forward rate} \approx\ &\text{short rate} + \text{duration} \times E(\Delta s_{n-1}) \\ &+ \text{bond risk premium} + \text{convexity bias}\end{aligned} \tag{32-2}$$

where bond risk premium $= E(h_n - s_1)$, and convexity bias $\approx -0.5 \times$ convexity $\times$ $[\text{vol}(\Delta s_{n-1})]^2$.

If we move the short rate to the left-hand side of the equation, we decompose the "forward-spot premium" $(f_{n-1,n} - s_1)$ into a rate-expectation term, a risk-premium term, and a convexity term (see Eq. 32-10 in Appendix 32A). We interpret the expectations in Eq. (32-2) as the market's rate and volatility expectations and as the expected risk premium that the market requires for holding long-term bonds. The market's expectations are weighted averages of individual market participants' expectations.

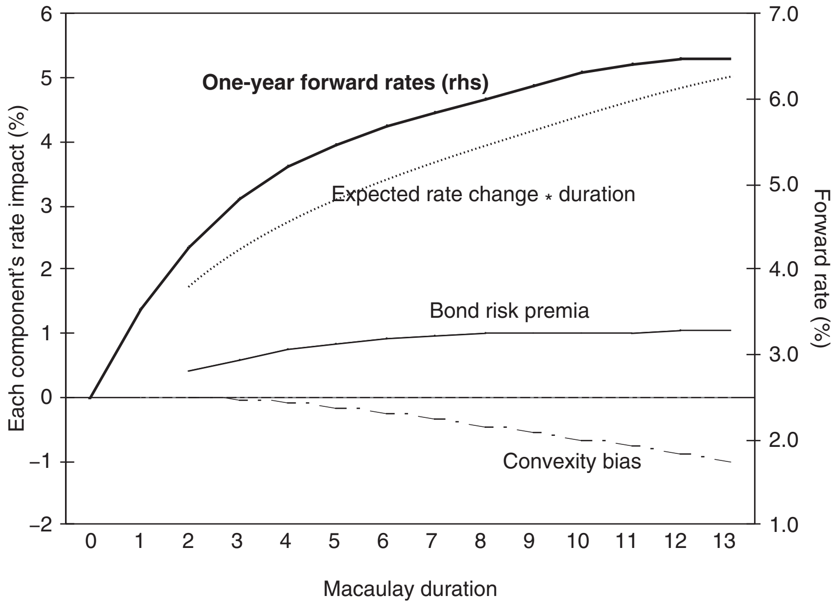
Some readers may wonder why our analysis deals with forward rates and not with the more familiar par and spot rates. The reason is the simplicity of the one-period forward rates. A one-period forward rate is the most basic unit in term-structure analysis, the discount rate of one cash flow over one period. A spot rate is the average discount rate of one cash flow over many periods, whereas a par rate is the average discount rate of many cash flows—those of a par bond—over many periods. All the averaging makes the decomposition messier for the spot rates and the par rates than it is for the one-period forward rate in Eq. (32-2). However, because the spot and the par rates are complex averages of the one-period forward rates, they too can be decomposed conceptually into the three main determinants.

Because the approximate decomposition in Eq. (32-2) is derived mathematically without making specific economic assumptions, it is true in general. In reality, however, it is hard to make this decomposition because the components are not observable and because they vary over time. Further assumptions or proxies are needed for such a decomposition. In Exhibit 32-2 we use historical average returns to compute the bond risk premia and historical rate volatilities to compute the convexity bias—together with the observable market forward rates (as of April 2004)—and back out the only unknown term in Eq. (32-2): the expected spot-rate change times duration. We also could divide this term by duration to infer the market's rate expectations. The rate expectations that we back out in Exhibit 32-2 suggest that the market expects rising short rates but less than forwards imply.

If bond risk premia vary over time, the use of historical average risk premia may be misleading. As an alternative, we can use survey data or rate predictions

EXHIBIT 32-2

Decomposing Forward Rates into Their Components Using Historical Average Risk Premia and Volatilities



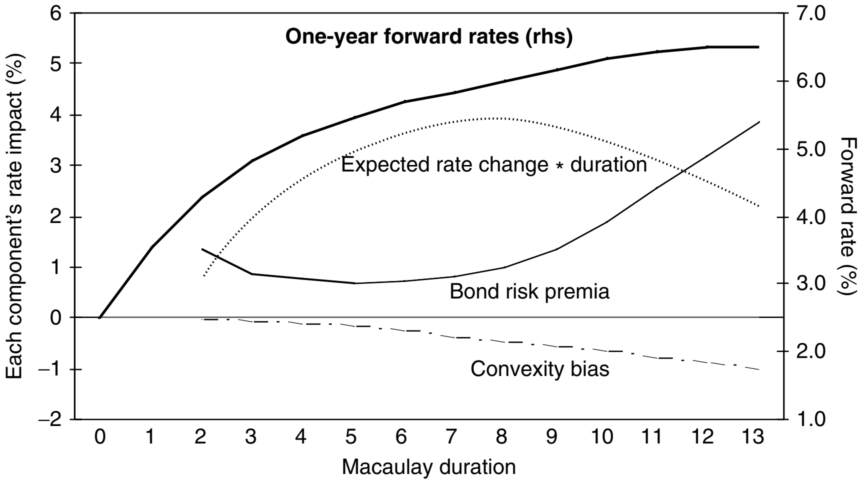
Note: The one-year forward rates are based on the dollar swap curve in April 2004. The bond risk premia are based on the historical arithmetic average returns of various maturity-subsector bond portfolios between 1972–2001, expressed in excess of the riskless one-year return. The convexity bias is based on the historical volatilities of various maturity swaps in 2004. The rate expectation term for each duration is then backed out as the difference—one-year forward rate – one-year spot rate – bond risk premium – convexity bias.

based on a quantitative forecasting model to proxy for the market's rate expectations. In Exhibit 32-3, we use a hypothetical consensus interest-rate forecast that predicts a bear flattening (yields rising 100 basis points at the two-year maturity and 20 basis points at 10 years). In addition, we use implied volatilities from swaption prices to compute the convexity bias. These components can be used together with the one-year forward rates to back out estimates of the unobservable bond risk premia.

A comparison of Exhibits 32-2 and 32-3 shows that the two decompositions look similar at short durations but different at intermediate and long durations. The similarity of the convexity bias components in these two exhibits suggests that the use of historical or implied volatilities makes little difference, at least in this case. The hypothetical survey's yield-curve view implies a relatively poor performance of intermediate-duration assets (low expected excess return) and a good performance by the longest assets (whose yields are expected to be stable). Because the forward-rate curve is the same

EXHIBIT 32-3

Decomposing Forward Rates into Their Components Using Hypothetical Survey Rate Expectations and Implied Volatilities



Note: The one-year forward rates are based on the dollar swap curve in April 2004. The market's rate expectations are proxied by a hypothetical consensus interest-rate forecast. The convexity bias is based on the implied basis point volatilities from swaption prices. The bond risk premium for each duration is then backed out as the difference—one-year forward rate – one-year spot rate – expected rate change × duration – convexity bias.

in both exhibits, any smaller predicted rate increases lead to higher bond risk premia in Exhibit 32-3 than in Exhibit 32-2.[5]

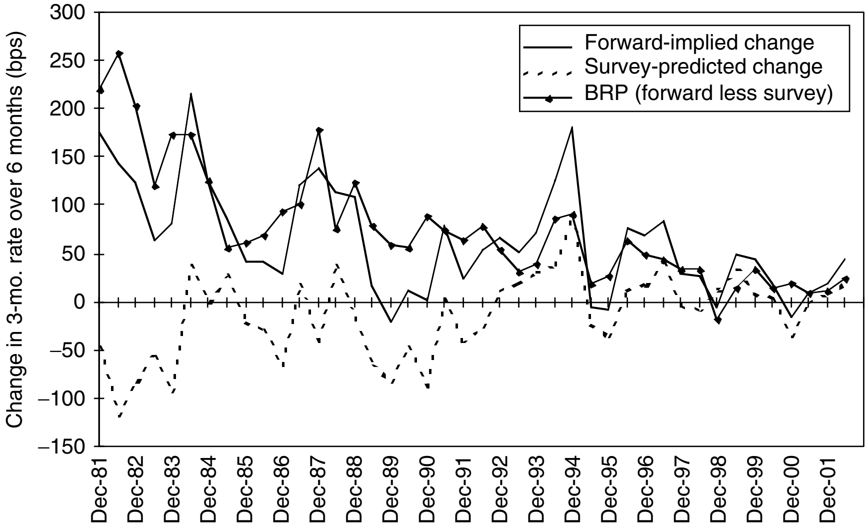
Exhibits 32-2 and 32-3 are snapshots of the forward rates and their components on one date. A comparison of similar decompositions over time would provide insights into the relative variability of each component. In Exhibit 32-4, we try to illustrate the impact of changing rate expectations and risk premia on the steepness of the U.S. Treasury bill curve based on a semiannual survey of economists' rate forecasts. The exhibit shows that the forwards almost always implied larger increases in the three-month rate than the market expected, based on surveys of bond market analysts. The difference is proportional to the required bond risk premium of longer bills over shorter bills (because bills exhibit negligible convexity, its impact can be ignored). This difference clearly varies over time.

The time variation in the survey-based bond risk premium in Exhibit 32-4 appears economically reasonable. It fell secularly from the early 1980s to late 1990s, perhaps reflecting the trend decline in inflation expectations and in level-dependent

5. We hasten to point out that these calculations are quite imprecise, especially at long durations. Even an error of a couple of basis points in our proxy for the market's rate expectation will have a large impact on any long bond's expected return (and thus on the estimated bond risk premium) because the expected yield change is scaled up by duration. Such sensitivity reduces the usefulness of this decomposition at long durations.

EXHIBIT 32-4

Forward-Implied Yield Changes versus Survey-Expected Yield Changes in the Treasury Bill Market, 1981–2002



Note: Forward-implied yield change is the difference between the implied three-month rate six months forward ($f_{0.5,\,0.75}$) and the current three-month rate ($s_{0.25}$) based on market data (fitted Treasury yield-curves). Survey-expected yield change is the difference between the expected three-month rate six months ahead [$E(s_{0.25})$] and the current three-month rate, where the market's rate expectation is proxied by the mean in the *Wall Street Journal's* semiannual survey of economist forecasts. The difference between the forward-implied yield change and the survey-expected yield change is proportional to the bond risk premium.

inflation uncertainty. Besides the lower inflation risk premium, improving fiscal prospects likely contributed to this trend decline. The bond risk premium also exhibited cyclic fluctuations that are related to the direction of consensus rate predictions and thus the central bank's policy tightening and easing cycles. Finally, the bond risk premium turned slightly negative during the flight to quality in late 1998, arguably reflecting government bonds' role as safe-haven assets.[6]

DECOMPOSING EXPECTED RETURNS OF BOND POSITIONS

Our framework for decomposing the yield-curve also provides a framework for systematic relative-value analysis of government bonds with known cash-flows. We can evaluate all bond positions' expected returns comprehensively yet with simple and intuitive building blocks. We emphasize that relative-value

6. Here we analyze the bond risk premium at money market maturities, but we find similar patterns for the 10-year Treasury in Antti Ilmanen, "Stock-Bond Correlations," *Journal of Fixed Income* (September 2003), pp. 55–66.

analysis should be based on near-term expected return differentials, not on yield spreads, which are only one part of them. That is, total-return investors should care more about expected returns than about yields. Thus our approach brings fixed income investors closer to mean-variance analysis in which various positions are evaluated based on the trade off between their expected return and return volatility.

Five Alternative Expected-Return Measures

Equation (32-1) shows that a zero's holding-period return is a sum of its return given an unchanged yield-curve and its return caused by the changes in the yield-curve. The return given an unchanged yield-curve is called the *rolling yield* because it is a sum of the zero's yield and the rolldown return. The return caused by changes in the yield-curve can be approximated well by duration and convexity effects. Taking expectations of Eq. (32-1) and splitting the rolling yield into yield income and rolldown return, the near-term expected return of a zero is

$$\begin{aligned}\text{Expected return} &= \text{yield income} + \text{rolldown return} + \text{value of convexity}\\ &\quad + \text{expected capital gain from the rate “view”}\end{aligned}$$

[For details, see Eq. (32-8) in Appendix 32A or the notes below Exhibit 32-5.] A similar relation holds approximately for coupon bonds, and we will describe the three-month expected return of some on-the-run Treasury bonds as the sum of the four preceding components.[7]

This framework is especially useful when evaluating positions of two or more government bonds, such as duration-neutral barbells versus bullets. We first compute expected return separately for each component and then compute the portfolio's expected return by taking a market-value weighted average of all the components' expected returns.

7. However, certain modifications are needed when we analyze coupon bonds' instead of zeros' expected returns—and the approximation will be somewhat worse. We use each bond's rolling yield to measure the horizon return given an unchanged yield-curve; this measure no longer equals the one-period forward rate. We also use the end-of-horizon duration and convexity, as well as the change in the constant-maturity rate of a constant-coupon curve at horizon, and we adjust the duration and convexity effects for the fact that the bond's value increases to (1 + rolling yield/100) by the end of the horizon. Besides the approximation error of ignoring higher-order terms than duration and convexity effects, another source of error exists for coupon bonds: The reinvestment-rate assumptions vary across bonds. Recall that the calculation of the yield-to-maturity implicitly assumes that all cash flows are reinvested at the bond's yield-to-maturity. This fact may lead to exaggerated estimates of yield income for long-term bonds if the yield-curve is upward-sloping, a problem common to all expected-return measures that use the concept of yield-to-maturity. Even though our approach of using bond-specific yields does not ensure internal consistency of the reinvestment-rate assumptions across bonds, any inconsistencies should have a relatively small impact on the overall level of bonds' expected returns.

It may be helpful to show step by step how the expected-return measures are improved, starting from simple yields and moving toward more comprehensive measures:

- A bond's *yield income* includes coupon income, accrued interest, and the accretion/amortization of price toward par value. Yield-to-maturity is the correct return measure if all interim cash flows can be reinvested at the yield and the bond can be sold at its purchasing yield.[8] Yield ignores the rolldown return the bond earns if the yield-curve stays unchanged.
- *Rolling yield* is a better expected-return proxy if an unchanged curve is a reasonable base case. Yet it ignores the value of convexity and thus implicitly assumes no rate uncertainty. Thus the rolling yield measures expected return if no curve change and no volatility are expected.
- Combining the rolling yield with the value of convexity improves the expected-return measure further. This is so because it can be shown that a bond's convexity-adjusted expected return equals the sum of the rolling yield and the value of convexity. This measure recognizes the impact of rate uncertainty but implies that no change is expected in the yield-curve.[9] Empirical evidence suggests that an unchanged yield-curve is often a reasonable base "view."[10]
- If investors want, they can replace the prediction of an unchanged curve with some other rate (or spread) "view." One possibility is to use survey-based information of the market's current rate forecasts; such an approach may be useful for backing out the market's required return for each bond. Alternatively, investors may ignore the market view and input either their own rate views or an economist's subjective rate forecasts or rate predictions from some quantitative model.[11] The impact of any rate view is approximated by the expected yield change scaled by duration [see Eq. (32-10) in Appendix 32A], which may be added

---

8. The yield-to-maturity of a single cash flow is unambiguous, whereas the yield of a portfolio of multiple cash flows is a more controversial measure. The duration-times-market-value weighted yield is a good proxy for a portfolio's true yield-to-maturity (internal rate of return). Capital gains are well-approximated by the product of minus duration and the change in such a yield measure. However, a portfolio's market-value weighted yield may be a better estimate of the portfolio's *likely yield income over a short horizon* (its near-term expected return) than is its yield-to-maturity. The yield-to-maturity weighs longer cash flows more heavily and is more influenced by the built-in reinvestment-rate assumptions.

9. See Antti Ilmanen, "Convexity Bias in the Yield Curve," Chapter 3 in Narasimgan Jegadeesh and Bruce Tuckman (eds.), *Advanced Fixed-Income Valuation Tools* (New York: Wiley, 2000).

10. See Antti Ilmanen, "Market's Rate Expectations and Forward Rates," *Journal of Fixed Income* (September 1996), pp. 8–22.

11. For example, one can use the predictors identified in Antti Ilmanen, "Forecasting U.S. Bond Returns," *Journal of Fixed Income* (June 1997), pp. 22–37.

to the convexity-adjusted expected return. The sum gives us the "expected return with a view"—the four-term expected return measure in Eq. (32-3). However, this equation is a perfect description of expected returns only for bonds that lie on the fitted curve. Thus the preceding relative-value measures ignore "local" or bond-specific richness or cheapness relative to the curve.

- Many technical factors can make a specific bond "locally" rich or cheap (relative to adjacent-maturity bonds), or they can make a whole maturity sector rich or cheap relative to the fitted curve. Such factors include supply effects (temporary price pressure on a sector caused by new issuance), demand effects (maturity limitations or preferences of important market participants—for example, the richness of quarter-end bills), liquidity effects (lower transaction costs for on-the-runs versus off-the-runs, for 10-year bonds versus 8-year bonds, for Treasury bills versus duration-matched coupon bonds, etc.), coupon effects (motivated by tax benefits, accounting rules, etc.), and above all, the financing effects (the "special" repo income that is common for on-the-runs).[12] Fortunately, it is easy to add to the four-term expected-return measures the financing advantage and two local cheapness measures—the spread off the fitted curve and the expected cheapening toward the fitted curve. The five-term expected-return measures are comprehensive measures of total expected returns—ignoring small approximation errors, they incorporate all sources of expected return for noncallable government bonds.[13]

As a numerical illustration, Exhibit 32-5 shows the various expected-return measures for three bonds (the three-month Treasury bill and the 5- and 10-year on-the-run Treasury notes) and for the barbell combination of the three-month bill and the 10-year bond. In this example we use as much market-based data as

12. Whether such local cheapness effects appear as deviations from a fitted yield-curve or as "wiggles" or "kinks" in the fitted curve depends on the curve-estimation technique. Recall that all curve-estimation techniques try to fit bond prices well while keeping the curve reasonably shaped. If the goodness of fit is heavily weighted, all bonds have small or no deviations from the fitted curve. However, a close fit may lead to "unreasonably" jagged forward-rate curves. Based on Eq. (32-2), the forward-rate curve should be smooth rather than jagged because maturity-specific expectations of rate or volatility behavior are hard to justify and because arbitrageurs presumably are quick to exploit any abnormally large expected-return differentials between adjacent-maturity bonds.

13. In our analysis we include the local effects into the expected bond returns separately as a fifth term. As an alternative, we could include the financing advantage (repo income) and the spread off the curve in the yield income, and we could include the expected cheapening in the rolldown return. "Rich" bonds, such as the on-the-runs, are unlikely to roll down the fitted curve if the overall curve remains unchanged. More likely, they eventually will lose their relative richness. It may be reasonable to assume that an on-the-run bond's yield advantage and *expected* cheapening roughly offset its *expected* financing advantage. For other issues than on-the-runs, it is often reasonable to assume (or better, estimate) some reversal toward the issue's "normal" cheapness spread versus the fitted curve.

NA, not available.

Note: Barbell is a combination of 0.56 unit of the ten-year par bond and 0.44 unit of the three-month bond; these weights duration-match the barbell with the five-year par bond bullet. Yield income is the return that a par bond earns over three months if it can be sold at its yield and if any cash flows are reinvested at the yield. The yields are compounded semiannually and based on the Citigroup Treasury Model's par yield-curve. Rolldown return is the capital gain that a bond earns from the rolldown yield change. Rolling yield is a bond's horizon return given an unchanged yield-curve. Value of convexity is approximated by 0.5 × convexity at horizon × (yield volatility)^2 × (1 + rolling yield/100), where yield volatility is the basis-point yield volatility over a three-month horizon. The latter is computed by multiplying the on-the-run bond's relative yield volatility—implied volatility based on the price of a three-month OTC option written on this bond—by its yield level and dividing by two (for deannualization). For the three-year bond, we interpolate between the implied volatilities of on-the-run twos and fives. Duration impact of the "view" is (– duration at horizon) × (expected change in a constant-maturity rate over the next three months) × (1 + rolling yield/100). In this example, the "view" reflects the market's yield-curve expectations, broadly based on a *Consensus Forecasts* report. The "expected return with a view" measures the expected return for a hypothetical par bond that lies exactly on the model curve, ignoring any local cheapness or financing advantage of actual bonds. We can add to this four-term measure a fifth component called the *total local rich/cheap effect*. It is the sum of three additional sources of return for specific bonds: (1) the financing advantage (the difference between the three-month term repo rate for general collateral and the three-month special term repo rate for the on-the-run bond, divided by four for deannualization), (2) the spread between the on-the-run bond yield and the model par yield, divided by four for deannualization, and (3) the bond's expected cheapening as it loses the richness associated with the on-the-run status.

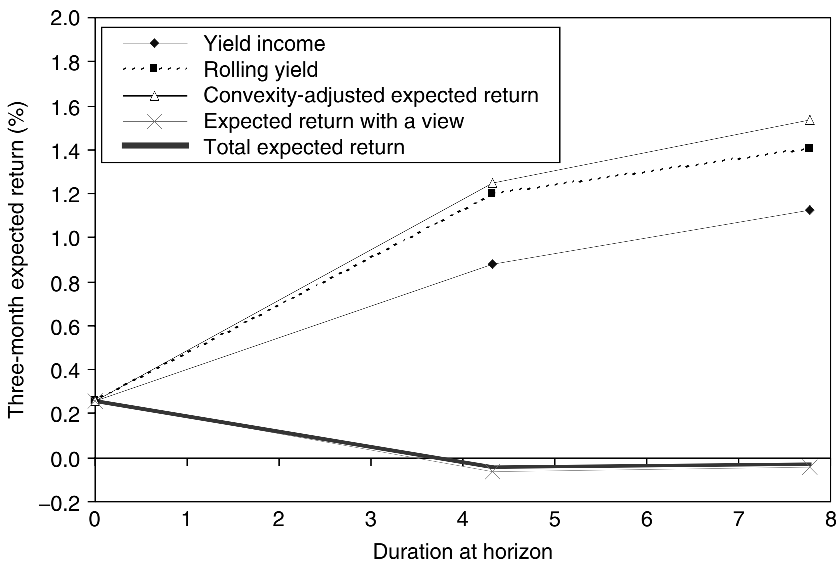
possible, for example, implied volatilities, not historical, to estimate the value of convexity and the "view" (rate predictions) based on survey evidence of the market's rate expectations, not on a quantitative forecasting model. All the numbers are based on the market prices as of April 22, 2004.

The top panel of Exhibit 32-5 shows how nicely the different components of expected returns can be added to each other. Moreover, the barbell's expected return measures are simply the market-value weighted averages of its components' expected returns. In this case, the yield income, the rolldown return, and the value of convexity are all higher for the longer bonds. In contrast, the duration impact of the market's rate view is negative because the consensus forecast indicates that the market expected rising rates over the next quarter. The local rich/cheap effect is marginally positive for the 5- and 10-year notes; the reason is that the negative yield spread and the expected cheapening are not sufficient to offset the high repo market advantage. Based on "viewless" expected-return measures, the five-year bullet looks more attractive than the barbell, thanks to its carry and rolldown advantage. However, if we impose a consensus curve-flattening view (30 basis point rise in 5-year rates versus 20 basis point rise in 10-year rates), the broad expected-return measures favor the barbell over the bullet.

Exhibit 32-6 shows the five different expected-return curves plotted on the three bonds' durations. In this case, the simplest expected-return measure (yield income) and the most comprehensive measure (total expected return) look very

EXHIBIT 32-6

Expected Returns of a Three-Month Bill, a 5-Year Bond, and a 10-Year Bond, in April 2004



different, thanks to the strong bear-flattening view on yield-curve reshaping. In general, the relative importance of the five components may be dramatically different from that in Exhibit 32-5. The longer the asset's duration and the shorter the investment horizon, the greater is the relative importance of the duration impact and the smaller is the impact of yield income. It is worth noting that realized returns can be decomposed in the same way as the expected returns and that the duration impact typically dominates the realized returns even more.[14]

The total expected returns, if estimated carefully, should produce the most useful signals for relative-value analysis because they include all sources of expected returns. Yield spreads may be useful signals, but they are only a part of the picture. Therefore, we advocate the monitoring of broader expected-return measures relative to their history as cheapness indicators—just as yield spreads often are monitored relative to their history.

The components of expected returns just discussed are not new. However, few investors have combined these components into an integrated framework and based their historical analysis on broad expected-return measures. An additional useful feature of this framework is that all types of government bond trades can be evaluated consistently within it: the portfolio-duration decision (market-directional view), the maturity-sector positioning and barbell-bullet decision (curve-reshaping view), and the individual-issue selection (local cheapness view). With small modifications, the framework can be extended to include the cross-country analysis of currency-hedged government bond positions. Other possible future extensions include the analysis of foreign-exchange exposure and the analysis of spread positions between government bonds and other fixed income assets.

We finish with some reservations. Even if two investors use the same general framework and the same type of expected-return measure, they may come up with different numbers because of different data sources and different estimation techniques. The whole analysis can be made with any raw material; we emphasize the importance of good-quality inputs. Various candidates for the raw material include on-the-run and off-the-run government bonds, STRIPS, Eurodeposits, swaps, and Eurodeposit futures. [This multitude, of course, opens the possibility of trading between these curves if we can assess how various characteristics (say, convexity) are priced in each curve.] The most common approach is first to estimate the spot curve (or discount function) using a broad universe of coupon government bonds as the raw material and then to compute the forward rates and other relevant numbers. In European bond markets, the liquid swap curve (using cash Eurodeposits and swaps as the raw material) has gained more of a benchmark status. Of course, some credit and tax-related

---

14. Realized returns can be split into an expected part and an unexpected part, and both parts can be decomposed further. Equation (32-3) describes the decomposition of the expected part, while the unexpected part can be split into duration and convexity effects. This type of return attribution can have a useful role in risk management and performance evaluation, but these two activities are not our focus in this chapter.

spread may exist between the swap curve and the government bond yield-curve. Recently, yet another approach has become popular: Eurodeposit futures prices are used as the raw material. In this case, the forward rates are computed by adjusting for the convexity difference between a futures contract and a forward contract, and only then are spot rates computed from the forwards. Some components of expected returns are easier to measure—and less debatable—than others. The yield income is relatively unambiguous. The rolldown return and the local rich/cheap effects depend on the curve-fitting technique. The value of convexity depends on the volatility input and thus on the volatility estimation technique. The rate "view," the fourth term, can be based on various approaches, such as quantitative modeling or subjective forecasting, that rely on fundamental or technical analysis. Even the quantitative approach is not purely objective because infinitely many alternative forecasting models and estimation techniques exist. Forecasting rate changes is, of course, the most difficult task, as well as the one with greatest potential rewards and risks. Forecasting changes in yield spreads may be almost as difficult. The short-term returns of most bond positions depend primarily on the duration impact (rate changes or spread changes). However, even if investors cannot predict rate changes, they may earn superior returns in the long run—and with less volatility—by systematically exploiting the more stable sources of expected-return differentials across bonds: yields, rolldown returns, value of convexity, and local rich/cheap effects. More generally, while the total expected return differentials are, in theory, better relative-value indicators than the yield spreads, in practice, measurement errors conceivably can make them so noisy that they give worse signals. Therefore, it is important to check with historical data that any supposedly superior relative value tools would have enhanced the investment performance, at least in the past.

Link to Scenario Analysis

Many active investors base their investment decisions on subjective yield-curve views, often with the help of scenario analysis. Our framework for relative-value analysis is closely related to scenario analysis. It may be worthwhile to explore the linkages further.

An investor can perform the scenario analysis of noncallable government bonds in two steps. First, the investor specifies a few yield-curve scenarios for a given horizon and computes the total return of her bond portfolio—or perhaps just a particular trade—under each scenario. Second, the investor assigns subjective probabilities to the different scenarios and computes the probability-weighted expected return for her portfolio. Sometimes the second step is not completed, and investors only examine qualitatively the portfolio performance under each scenario. However, we advocate performing this step because investors can gain valuable insights from it. Specifically, the probability-weighted expected return is the "bottom line" number a total return manager should care about. By assigning probabilities to scenarios, investors also can explicitly back out their implied views about the yield-curve reshaping and about yield volatilities and correlations.

In scenario analysis, investors define the mean yield-curve view and the volatility view implicitly by choosing a set of scenarios and by assigning them probabilities. In contrast, our framework for relative-value analysis involves explicitly specifying one yield-curve view (which corresponds to the probability-weighted mean yield-curve scenario) and a volatility view (which corresponds to the dispersion of the yield-curve scenarios). Either way, the yield-curve view determines the duration impact, and the volatility view determines the value of convexity.

Exhibit 32-7 presents a portfolio that consists of five equally weighted zero-coupon bonds with maturities of one to five years and (annually compounded) yields between 6% and 7%. The portfolio's maturity—and its Macaulay duration—initially

Neutral	0.00	0.00	0.00	0.00	0.00	
Bear-flattener	1.00	0.875	0.75	0.625	0.50	
Bull-steepener	–0.50	–0.375	–0.25	–0.125	0.00	
One-year returns in each scenario						
Bear	6.00	5.51	5.02	4.53	4.05	5.02
Bull	6.00	7.51	9.04	10.59	12.15	9.06
Neutral	6.00	6.50	7.00	7.50	8.01	7.00
Bear-flattener	6.00	5.51	5.26	5.26	5.51	5.51
Bull-steepener	6.00	7.01	7.76	8.26	8.51	7.51
Assign equal probability (0.2) to each scenario and back out various statistics						
Mean return	6.00	6.41	6.82	7.23	7.65	6.82
Vol. of return	0.00	0.80	1.52	2.17	2.78	1.45
Mean yield change	0.10	0.10	0.10	0.10	0.10	
Vol. of Yield Change	0.80	0.76	0.72	0.69	0.66	

is three. Over a one-year horizon, each zero's maturity shortens by one year. We specify five alternative yield-curve scenarios over the horizon: parallel shifts of +100 basis points and –100 basis points, no change, a yield increase combined with a curve flattening, and a yield decline combined with a curve steepening (see Exhibit 32-8). We compute the one-year holding-period returns for each asset and for the portfolio under each scenario. In particular, the neutral scenario shows the rolling yield that each zero earns if the yield-curve remains unchanged. We can evaluate each scenario separately. However, such analysis gives us limited insight—for example, the last column in Exhibit 32-7 shows just that bearish scenarios produce lower portfolio returns than bullish scenarios.

In contrast, if we assign probabilities to the scenarios, we can back out many numbers of potential interest. We begin with a simple example in which we use only the two first scenarios, parallel shifts of 100 basis points up or down. If we assign these scenarios equal probabilities (0.5), the expected return of the portfolio is 7.04% (= 0.5 × 5.02 + 0.5 × 9.06). On average, these scenarios have no view about curve changes, yet this expected return is 4 basis points higher than the expected portfolio return given no change in the curve (i.e., the 7% rolling yield computed in the neutral scenario). This difference reflects the value of convexity. If we use only one scenario, we implicitly assume zero volatility, which leads to downward-biased expected-return estimates for positively convex bond positions. If we use the two first scenarios (bear and bull), we implicitly assume a 100 basis point yield volatility; this assumption may or may not be reasonable, but it certainly is more reasonable than an assumption of no volatility. This example highlights the importance of using multiple scenarios to recognize the value of convexity. (The value is small here, however, because we focus on short-duration assets that have little convexity.)

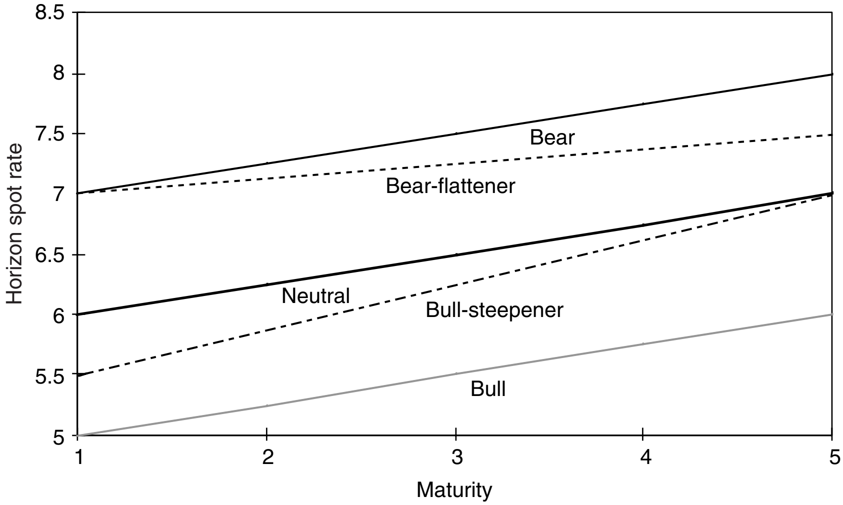
Now we return to the example with all five yield-curve scenarios in Exhibit 32-8. As an illustration, we assign each scenario the same probability (p_i = 0.2). Then it is easy to compute the portfolio's probability-weighted expected return:

$$E(h_p) = \sum_{i=1}^{5} p_i \times h_i = 0.2 \times (5.02 + 9.06 + 7.00 + 5.51 + 7.51) = 6.82 \tag{32-3}$$

Given these probabilities, we can compute the expected return for each asset, and it is possible to back out the implied yield-curve views. The lower panel in Exhibit 32-7 shows that the mean yield change across scenarios is +10 basis points for each rate (because the bear-flattener and the bull-steepener scenarios are not quite symmetric in magnitude in this example), implying a mild bearish bias but no implied curve-steepness views. In addition, we can back out the implied basis point yield volatilities (or return volatilities) by measuring how much the yield-change (or return) outcomes in each scenario deviate from the mean. These yield volatility levels are important determinants of the value of convexity. The last line in Exhibit 32-7 shows that the volatilities range from 80 to 66 basis points, implying an inverted term structure of volatility. Finally, we can compute implied correlations between

EXHIBIT 32-8

Various Yield-Curve Scenarios



various maturity-yield changes; the curve behavior across the five scenarios is so similar that all correlations are 0.92 or higher (not shown). Note that all correlations would equal 1.00 if only the first three scenarios were used; the imperfect correlations arise from the bear-flattener and the bull-steepener scenarios.

Whenever an investor uses scenario analysis, he should back out these implicit curve views, volatilities, and correlations—and check that any biases are reasonable and consistent with his own views. Without assigning the probabilities to each scenario, this step cannot be completed; then the investor may overlook hidden biases in his analysis, such as a biased curve view or a very high or low implicit volatility assumption that makes positive convexity positions appear too good or too bad. If investors use quantitative tools—such as scenario analysis, mean-variance optimization, or the approach outlined in this chapter—to evaluate expected returns, they should recognize the importance of their rate views in this process. Strong subjective views can make *any* particular position appear attractive. Therefore, investors should have the discipline and the ability to be fully aware of the views that are input into the quantitative tool.

In addition to the implied curve views, we can back out the four components of expected returns discussed earlier. In this example, we only analyze bonds that lie "on the curve" and thus can ignore the fifth component, the local rich/cheap effects. First, we measure the yield income from the portfolio by a market-value weighted-average yield of the five zeros, which is 6.50%. Second, each asset's rolldown return is the difference between the horizon return given an unchanged yield-curve and the yield income. Exhibit 32-7 shows that the horizon return for the portfolio is 7% in the neutral scenario; thus the portfolio's (market-value weighted average) rolldown return is 50 basis points (= 7% – 6.5%). Note that the rolldown return is larger for longer bonds, reflecting the fact that the same rolldown yield change (25 basis points) produces larger capital gains for longer bonds. Third, the value of convexity for each zero can be approximated by 0.5 × convexity at horizon × (basis point yield volatility)^2 × (1 + rolling yield/100). Using the implicit yield volatilities in Exhibit 32-7, this value varies between 0.6 and 4.5 basis points across bonds. The portfolio's value of convexity is a market-value weighted average of the bond-specific values of convexity, or roughly 2 basis points. Fourth, the duration impact of the rate "view" for each bond equals (– duration at horizon) × (expected yield change) × (1 + rolling yield/100). The last term is needed because each invested dollar grows to (1 + rolling yield/100) by the end of horizon when the repricing occurs. The core of the duration impact is the product of duration and expected yield change. The expected yield change refers to the change (over the investment horizon) in a constant-maturity rate of the bond's horizon maturity. In Exhibit 32-7, all rates are expected to increase by 10 basis points, and the duration impact on specific bonds' returns varies between 0 and –40 basis points. The portfolio's duration impact is a market-value weighted average of bond-specific duration impacts, or about –20 basis points.

The four components add up to the total probability-weighted expected return of 6.82% (= 6.50% + 0.50% + 0.02% – 0.20%). Decomposing expected returns into these components should help investors to better understand their own investment positions. For example, they can see what part of the expected return reflects static market conditions and what part reflects their subjective market view. Unless they are extremely confident about their market view, they can emphasize the part of expected-return advantage that reflects static market conditions. In our example, the duration effect is small because the implied rate view is quite mild (10 basis points), and the one-year horizon is relatively long (the "slower" effects need time to accrue). With a shorter horizon and stronger rate views, the duration impact easily would dominate the other effects.

APPENDIX 32A

Decomposing the Forward Rate Structure into Its Main Determinants

In this appendix we show how the forward rate structure is related to the market's rate expectations, bond risk premia, and convexity bias. In particular, the holding-period return of an n-year zero-coupon bond can be described as a sum of its horizon return given an unchanged yield-curve and the end-of-horizon price change that is caused by a change in the n – 1 year constant-maturity spot rate (Δs_{n-1}). The horizon return equals a one-year forward rate, and the end-of-horizon price change can be approximated by duration and convexity effects. These relations are used to decompose near-term expected bond returns and the one-period forward rates into simple building blocks. All rates and returns used in the following equations are compounded annually and expressed in percentage terms

$$\frac{h_n}{100} = \frac{P^*_{n-1} - P_n}{P_n} = \frac{(P^*_{n-1} - P_{n-1}) + (P_{n-1} - P_n)}{P_n}$$
$$= \left(\frac{\Delta P_{n-1}}{P_{n-1}} \times \frac{P_{n-1}}{P_n} - 1\right) + \left(\frac{P_{n-1}}{P_n} - 1\right) \tag{32-4}$$

where h_n is the one-period holding-period return of an n-year bond, P_n is its price (today), P^*_{n-1} is its price in the next period (when its maturity is $n-1$), and $\Delta P_{n-1} = P^*_{n-1} - P_{n-1}$. The second term on the right-hand side of Eq. (32-4) is the bond's rolling yield (horizon return). The first term on the right-hand side of Eq. (32-4) is the instantaneous percentage price change of an $n-1$ year zero multiplied by an adjustment term P_{n-1}/P_n.[15]

Equation (32-5) shows that the zero's rolling yield (P_{n-1}/P_n) equals, by construction, the one-year forward rate between $n-1$ and n. Moreover, the adjustment term equals one plus the forward rate.

$$1 + \frac{f_{n-1,n}}{100} = \frac{\left(1 + \frac{s_n}{100}\right)^n}{\left(1 + \frac{s_{n-1}}{100}\right)^{n-1}} = \frac{P_{n-1}}{P_n} \tag{32-5}$$

Equation (32-6) shows the well-known result that the percentage price change ($\Delta P/P$) is closely approximated by the first two terms of a Taylor series expansion, duration and convexity effects

$$100 \times \frac{\Delta P}{P} \approx -\text{dur} \times (\Delta s) + 0.5 \times Cx \times (\Delta s)^2 \tag{32-6}$$

where

$$\text{dur} \equiv -\frac{dP}{ds} \times \frac{100}{P} \qquad \text{and} \qquad Cx \equiv \frac{d^2P}{d^2s} \times \frac{100}{P}$$

Plugging Eqs. (32-5) and (32-6) into Eq. (32-4), we get

$$h_n \approx f_{n-1,n} + \left(1 + \frac{f_{n-1,n}}{100}\right)[-\text{dur}_{n-1}(\Delta s_{n-1}) + 0.5Cx_{n-1}(\Delta s_{n-1})^2] \tag{32-7}$$

15. The adjustment term is needed because the bond's instantaneous price change occurs at the end of horizon, not today. The value of the bond position grows from one to P_{n-1}/P_n at the end of horizon if the yield-curve is unchanged. The end-of-horizon value (P_{n-1}/P_n) would be subject to the yield shift at horizon.

Even if the yield-curve shifts occur during the horizon, for performance calculation purposes, the repricing takes place at the end of horizon. This disparity causes various differences between the percentage price changes in Eqs. (32-6) and (32-7). First, the amount of capital that experiences the price change grows to $(1 + f_{n-1,n}/100)$ by the end of horizon. Second, the relevant yield change is the change in the $n - 1$ year constant-maturity rate, not in the n-year zero's own yield (the difference is the rolldown yield change).[16] Third, the end-of-horizon (as opposed to the current) duration and convexity determine the price change.

The realized return can be split into an expected part and an unexpected part. Taking expectations of both sides of Eq. (32-7) gives us the n-year zero's expected return over the next year:

$$E(h_n) \approx f_{n-1,n} + \left(1 + \frac{f_{n-1,n}}{100}\right)[-\text{dur}_{n-1}E(\Delta s_{n-1}) + 0.5Cx_{n-1}E(\Delta s_{n-1})^2] \tag{32-8}$$

Recall from Eq. (32-5) that the one-period forward rate equals a zero's rolling yield, which can be split to yield and rolldown return components. In addition, the expected yield change squared is approximately equal to the variance of the yield change or the squared volatility $E(\Delta s_{n-1})^2 \approx [\text{vol}(\Delta s_{n-1})]^2$. This relation is exact if the expected yield change is zero. Thus the zero's near-term expected return can be written (approximately) as a sum of the yield income, the rolldown return, the value of convexity, and the expected capital gains from the rate "view" (see Eq. 32-3).

We can interpret the expectations in Eq. (32-8) to refer to the market's rate expectations. Mechanically, the forward rate structure and the market's rate expectations on the right-hand side of Eq. (32-8) determine the near-term expected returns on the left-hand side. These expected returns should equal the required returns that the market demands for various bonds if the market's expectations are internally consistent. These required returns, in turn, depend on factors such as each bond's riskiness and the market's risk-aversion level. Thus it is more appropriate to think that the market participants, in the aggregate, *set the bond market prices* to be such that given the forward rate structure and the consensus rate expectations, each bond is expected to earn its required return.[17]

16. If we used bonds' own yield changes in Eq. (32-7), these yield changes would include the rolldown yield change. In this case, we should not use the forward rate (which includes the impact of the rolldown yield change on the return, in addition to the yield income) as the first term on the right-hand side of Eq. (32-7). Instead, we would use the spot rate.

17. Individual investors also can use Eq. (32-8), but the interpretation is slightly different because most of them are so small that they cannot influence the market rates; thus they are "price takers." Any individual investor can plug her subjective rate expectations into Eq. (32-8) and back out the expected return given these expectations and the market-determined forward rates. These expected returns may differ from the required returns that the market demands; this discrepancy may prompt the investor to trade on her view.

Subtracting the one-period riskless rate (s_1) from both sides of Eq. (32-8), we get

$$E(h_n - s_1) \approx (f_{n-1,n} - s_1) + \left(1 + \frac{f_{n-1,n}}{100}\right)[-\text{dur}_{n-1}E(\Delta s_{n-1}) + 0.5Cx_{n-1}\text{vol}(\Delta s_{n-1})^2] \quad (32\text{-}9)$$

We define the bond risk premium as $BRP_n \equiv E(h_n - s_1)$ and the forward-spot premium as $FSP_n \equiv f_{n-1,n} - s_1$. The forward-spot premium measures the steepness of the one-year forward rate curve (the difference between each point on the forward rate curve and the first point on that curve), and it is closely related to simpler measures of yield-curve steepness. Rearranging Eq. (32-9), we obtain

$$FSP_n \approx BRP_n + \left(1 + \frac{f_{n-1,n}}{100}\right)[\text{dur}_{n-1}E(\Delta s_{n-1}) - 0.5Cx_{n-1}\text{vol}(\Delta s_{n-1})^2] \quad (32\text{-}10)$$

In other words, the forward-spot premium is approximately equal to a sum of the bond risk premium, the impact of rate expectations (expected capital gain/loss caused by the market's rate "view"), and the convexity bias (expected capital gain caused by the rate uncertainty). Unfortunately, none of the three components is directly observable.

The analysis thus far has been very general, based on accounting identities and approximations, not on economic assumptions. Various term-structure hypotheses and models differ in their assumptions. Certain simplifying assumptions lead to well-known hypotheses of the term-structure behavior by making some terms in Eq. (32-10) equal zero—although fully specified term-structure models require even more specific assumptions. First, if constant-maturity rates follow *a random walk,* the forward-spot premium mainly reflects the bond risk premium but also the convexity bias [$E(\Delta s_{n-1}) = 0 \Rightarrow FSP_n \approx BRP_n + CB_{n-1}$]. Second, if the *local-expectations hypothesis* holds (all bonds have the same near-term expected return), the forward-spot premium mainly reflects the market's rate expectations but also the convexity bias [$BRP_n = 0 \Rightarrow FSP_n \approx \text{dur}_{n-1}E(\Delta s_{n-1}) + CB_{n-1}$]. Third, if the *unbiased-expectations hypothesis* holds, the forward-spot premium only reflects the market's rate expectations [$BRP_n + CB_{n-1} = 0 \Rightarrow FSP_n \approx \text{dur}_{n-1}E(\Delta s_{n-1})$]. The last two cases illustrate the distinction between two versions of the pure expectations hypothesis.

APPENDIX 32B

Relating Various Statements About Forward Rates to Each Other

We make several statements about forward rates—describing, interpreting, and decomposing them in various ways. The multitude of these statements may be confusing; therefore, we now try to clarify the relationships between them.

We refer to the spot curve and the forward curves on a given date as if they were unambiguous. In reality, different analysts can produce somewhat different estimates of the spot curve on a given date if they use different curve-fitting techniques or different underlying data (asset universe or pricing source). We acknowledge the importance of these issues—having good raw material is important to any kind of yield-curve analysis—but here we ignore these differences. We take the estimated spot curve as given and focus on showing how to interpret and use the information in this curve.

In contrast, the relations between various depictions of the term structure of interest rates (par, spot, and forward rate curves) are unambiguous. In particular, once a spot curve has been estimated, any forward rate can be computed mathematically by using Eq. (32-11):

$$\left(1+\frac{f_{m,n}}{100}\right)^{n-m} = \frac{\left(1+\frac{s_n}{100}\right)^n}{\left(1+\frac{s_m}{100}\right)^m} \tag{32-11}$$

where $f_{m,n}$ is the annualized $n - m$ year interest rate m years forward and s_n and s_m are the annualized n-year and m-year spot rates, expressed in percent. Thus a one-to-one mapping exists between forward rates and *current* spot rates. The statement "the forwards imply rising rates" is equivalent to saying that "the spot curve is upward sloping," and the statement "the forwards imply curve flattening" is equivalent to saying that "the spot curve is concave." Moreover, an unambiguous mapping exists between various types of forward curves, such as the implied spot curve one year forward ($f_{1,n}$) and the curve of constant-maturity one-year forward rates ($f_{n-1,n}$).

The forward rate can be the agreed interest rate on an *explicitly* traded contract, a loan between two future dates. More often the forward rate is defined *implicitly* from today's spot curve based on Eq. (32-11). However, arbitrage forces ensure that even the explicitly traded forward rates would equal the implied forward rates and thus be consistent with Eq. (32-11). For example, the implied one-year spot rate four years forward (also called the one-year forward rate four years ahead, $f_{4,5}$) must be such that the equality $(1 + s_5/100)^5 = (1 + s_4/100)^4(1 + f_{4,5}/100)$ holds. If $f_{4,5}$ is higher than this, arbitrageurs can earn profits by short selling the five-year zeros and buying the four-year zeros and the one-year forward contracts four years ahead, and vice versa. Such activity should make the equality hold within transaction costs.

Forward rates can be viewed in many ways: the arbitrage interpretation, the break-even interpretation, and the rolling yield interpretation. According to the arbitrage interpretation, implied forward rates are such rates that would ensure the absence of riskless arbitrage opportunities between spot contracts (zeros) and forward contracts if the latter were traded. According to the break-even interpretation of forward rates, implied forward rates are such *future* spot rates that would equate holding-period returns across bond positions. According to the rolling-yield interpretation, the one-period forward rates show the one-period horizon returns that various zeros earn if the yield-curve remains unchanged. Each interpretation is useful for a certain purpose: active view taking relative to the forwards (break-even), relative-value analysis given no yield-curve views (rolling yield), and valuation of derivatives (arbitrage).

All these interpretations hold by construction (from Eq. 32-11). Thus they are not inconsistent with each other. For example, the one-period forward rates can be interpreted and used in quite different ways. The implied one-year spot rate four years forward ($f_{4,5}$) can be viewed as either the break-even one-year rate *four years into the future* or the rolling yield of a five-year zero *over the next year*. Both interpretations follow from the equality $(1 + s_5/100)^5 = (1 + s_4/100)^4(1 + f_{4,5}/100)$. This equation shows that the forward rate is the break-even one-year reinvestment rate that would equate the returns between two strategies (holding the five-year zero to maturity versus buying the four-year zero and reinvesting in the one-year zero when the four-year zero matures) over a five-year horizon. [Rewriting the equality as $(1 + s_4/100)^4 = (1 + s_5/100)^5/(1 + f_{4,5}/100)$ gives a slightly different viewpoint; the forward rate also is the break-even selling rate that would equate the returns between two strategies (holding the four-year zero to maturity versus buying the five-year zero and selling it after four years as a one-year zero) over a four-year horizon.] Finally, rewriting the equality as $1 + f_{4,5}/100 = (1 + s_5/100)^5/(1 + s_4/100)^4$ shows that the forward rate is the horizon return from buying a five-year zero at rate s_5 and selling it one year later as a four-year zero at rate s_4 (thus the constant-maturity four-year rate is unchanged from today). Our analysis focuses on the last (rolling-yield) interpretation.

Interpreting the one-period forward rates as rolling yields enhances our understanding about the relation between the curve of one-year forward rates ($f_{0,1}, f_{1,2}, f_{2,3}, \ldots, f_{n-1,n}$) and the implied spot curve one year forward ($f_{1,2}, f_{1,3}, f_{1,4}, \ldots, f_{1,n}$). The latter "break-even" curve shows how much the spot curve needs to shift to cause capital gains/losses that exactly offset initial rolling-yield differentials across zeros and thereby equalize the holding-period returns. Thus a steeply upward-sloping curve of one-period forward rates requires, or "implies," a large offsetting increase in the spot curve over the horizon, whereas a flat curve of one-period forward rates only implies a small "break-even" shift in the spot curve.[18] A similar link exists for the rolling-yield differential between a duration-neutral barbell versus bullet and the break-even yield-spread change (curve-flattening) that is needed to offset the bullet's rolling-yield advantage. These examples provide insight as to why an upward-sloping spot curve implies rising rates and why a concave spot curve implies a flattening curve.

18. In Chapter 31 we describe one common way to use the break-even forward rates. Investors can compare their subjective views about the yield-curve at some future date (or about the path of some constant-maturity rate over time) to the forward rates and directly determine whether bullish or bearish strategies are appropriate. If the rate changes that the forwards imply are realized, all bonds earn the riskless return [because $(1 + s_n/100)^n/(1 + f_{1,n}/100)^{n-1} = 1 + s_1/100$]. If rates rise by more than that, long bonds underperform short bonds. If rates rise by less than that, long bonds outperform short bonds because their capital losses do not quite offset their initial yield advantage.

Appendix 32A showed that forward rates can be decomposed conceptually into three main determinants (rate expectations, risk premia, and convexity bias). One might hope that the arbitrage, break-even, or rolling-yield interpretations could help us in backing out the relative roles of rate expectations, risk premia, and convexity bias in a given day's forward rate structure. However, such hope is in vain. The three interpretations hold quite generally because of their mathematical nature. Thus they do not guide us in decomposing the forward rate structure.

Therefore, even when two analysts agree that today's forward rate structure is an approximate sum of three components, they may disagree about the relative roles of these components. We can try to address this question empirically. It is closely related to the question about the forward rates' ability to forecast future rate changes and future bond returns. Ignoring convexity bias, if the forwards primarily reflect rate expectations, they should be unbiased predictors of future spot rates (and they should tell little about future bond returns). However, if the forwards mainly reflect required bond risk premia, they should be unbiased predictors of future bond returns (and they should tell little about future rate changes).[19,20]

Finally, our analysis does not reveal the fundamental economic determinants of the required risk premia or the market's rate expectations—nor does it tell us to what extent the nominal rate expectations reflect expected inflation and expected real rates. Macroeconomic news about economic growth, inflation rates, budget deficits, and so on can influence both the required risk premia and the market's rate expectations. More work clearly is needed to improve our understanding about the mechanisms of these influences.

19. We present some empirical evidence indicating that the forward rates are better predictors of future bond returns than of future rate changes in Antti Ilmanen, "Market's Rate Expectations and Forward Rates," *Journal of Fixed Income* (September 1996), pp. 8–22. This evidence also suggests that the current spot curve is a better predictor of the next-period spot curve than is the implied spot curve one period forward. These findings imply that the rolling yields are reasonable proxies for the near-term expected bond returns—although even rolling yields capture a very small part of the short-term realized bond returns. Note that the poorer the forwards are in predicting future rate changes, the better they are in predicting bond returns—because then the implied rate changes that would offset initial yield advantages tend to occur more rarely. Note also that some investors may not care whether the forwards' ability to predict bond returns reflects rational risk premia or the market's inability to forecast rate changes; they want to earn any predictable profit irrespective of its reason.

20. One common misconception is that the forward rates are used in the valuation of swaps, options, and other derivative instruments *because* the forwards are good predictors of future spot rates. In fact, the forwards' ability to predict future spot rates has nothing to do with their usefulness in derivatives pricing. Unlike forecasting returns, the valuation of derivatives is based on arbitrage arguments. For example, traders theoretically can construct, by dynamic hedging, a riskless combination of a risky long-term bond and an option written on it. The price of the option should be such that the hedged position earns the riskless rate—otherwise, a riskless arbitrage opportunity arises. The forward rates are central in this valuation because the traders can lock in these rates for future periods in their hedging activity. This arbitrage argument implies that the yield-curve option pricing models should be calibrated to be consistent with the market forward rates *in spite of* the fact that the forwards are quite poor predictors of future spot rates.

KEY POINTS

- Yield-curve or forward rates can be decomposed into three main determinants: the market's rate expectations, required bond risk premiums, and convexity bias.
- In an analogous fashion, the expected return of a position in a (default-free) bond—or in a long-short position across such bonds—can be decomposed into a few building blocks: the yield income and so-called rolldown return, the value of convexity, and the duration impact of a curve view.
- The first three components of the expected return amount to the reasonably predictable "viewless" part, while the last component is the least certain but dominates realized returns.
- The above decompositions provide a useful framework for analyzing the attractiveness of yield-curve trades. For analyzing the attractiveness of individual issues, the local richness of a bond relative to the curve and its richness in the repo market are important additional considerations.

CHAPTER
THIRTY-THREE

EMPIRICAL YIELD-CURVE DYNAMICS AND YIELD-CURVE EXPOSURE

Wesley Phoa, Ph.D.
Partner
Capital Group

While there are many factors that can influence the return on a specific bond, one of the most important influences—especially for high-quality bonds—is the behavior of the benchmark (Treasury) yield curve. Individual bond yields tend to move along with the yield curve. For example, if the 10-year Treasury yield moves up or down, other high-quality bonds with maturities close to 10 years will tend to follow suit. This sensitivity to yield-curve changes is referred to as the yield-curve exposure or the interest rate risk of a bond or a portfolio of bonds; in order to measure and manage this risk, we first need to understand the ways in which the yield curve can move.

The goals of this chapter are therefore as follows. First, to explain how most yield-curve movements can be empirically captured by a small number of standard yield-curve shifts. Second, to discuss the theoretical reasons why yield curves behave in this way, that is, how the standard shifts arise. Third, to sketch the implications for risk management of a bond portfolio, and when the usual concept of bond duration is—or is not—applicable. And along the way, to illustrate some techniques in exploratory data analysis that are helpful in interpreting the data and applying the results of the analysis appropriately.

Before diving into the analysis, some intuition may be helpful. The yield curve is determined by Treasury bonds of different maturities, which are closely linked to each other: nearby bonds have similar cash flows and should therefore behave in a similar way—they should be correlated with each other, and the yield curve as a whole should be somewhat "rigid." What could this mean?

In the physical world, rigid bodies do not vibrate in arbitrary ways, but tend to have "vibration modes" or "natural frequencies." For example, consider a thin plank on wheels (i.e., a *dolly*) rolling over rough ground. As it is shaken around, it will tend to vibrate in a few specific ways: up and down, tilting back and forth,

The author thanks Henry Schellhorn and Tom Hollenberg for their useful comments.

and flexing in the middle, as shown in Exhibit 33-1. It will also have additional vibration modes, but these will be much smaller. Compare this to a thin beam with one end fixed to a wall (i.e., a *cantilever*), as shown in Exhibit 33-2. Parallel up-and-down movements are now impossible, and the beam will only be able to tilt and flex. We will see that the first situation is roughly comparable to a yield curve that can shift freely, while the second situation resembles a yield curve whose short end is pinned down by monetary policy.

EXHIBIT 33-1

Vibration Modes of a Plank on Wheels

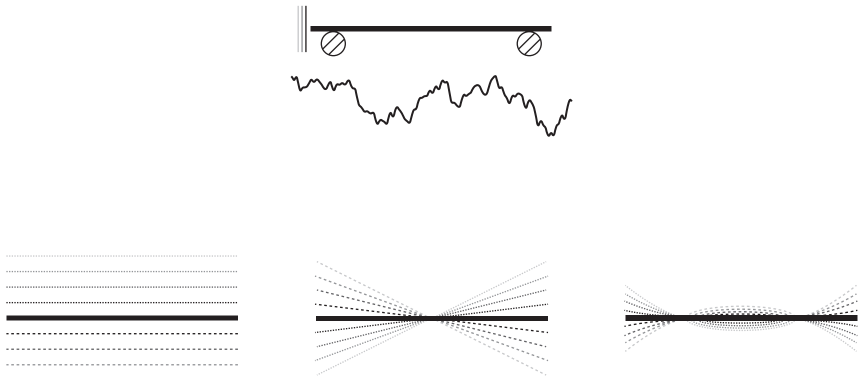

EXHIBIT 33-2

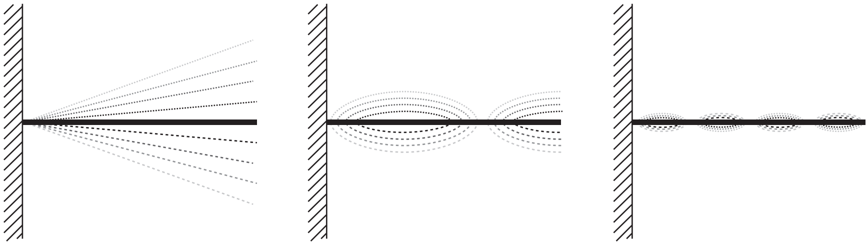
Vibration Modes of a Thin Beam Attached to a Wall



Note that if the plank (or beam) can only vibrate in one way, all the points on the plank will be perfectly correlated, but if it has several vibration modes, the correlations between different points will be less than one; for example, the endpoints of the plank in Exhibit 33-1 will not be perfectly correlated with the middle, since when the plank tilts back and forth, the endpoints move but the middle doesn't. This suggests that the correlations encode information about the vibration modes.

EMPIRICAL ANALYSIS OF YIELD-CURVE DYNAMICS

The "vibration modes" of the yield curve can be identified using a statistical method known as *principal component analysis*, invented in 1901 by Pearson.[1] It was first applied to analyze yield-curve dynamics in 1991 by Litterman and Scheinkman.[2] Since the method is completely standard,[3] we give only a brief description here before moving on to the results.

The intuition is as follows. Given a predefined shift in the yield curve (such as a parallel shift), any observed shift can be written as a multiple of the predefined shift plus some residual. Define the shift in order to make these residuals—measured over some historical data set of yield-curve observations—as small as possible. The resulting yield-curve shift is referred to as the first principal component: it can be regarded as the "first vibration mode," that is, the most important type of shift. We can proceed iteratively to define the second, third, and so on, principal components.

It turns out that there is a simple way to calculate these principal components: they are simply the eigenvectors of the correlation matrix. The first principal component is the eigenvector corresponding to the biggest eigenvalue the second principal component is the eigenvector corresponding to the second biggest eigenvalue, and so on.[4]

Since a correlation matrix is positive definite, all its eigenvalues are real and positive. The relative size of the eigenvalues indicates the relative contribution of each principal component to the overall variance of yields along the yield curve. Usually there are just a few eigenvalues that are much bigger than all the rest. Also, note that since the eigenvectors are orthogonal, they can be regarded as describing independent factors. This means that one can take a large and unpromising correlation matrix, like the ones shown in Exhibit 33-3, and extract a small number of independent risk factors that capture most of the information in it.

We should note at this point two features of principal component analysis that can be regarded as both limitations and advantages. First, it assumes that each factor is symmetric (i.e., up and down shifts have the same shape, and the same

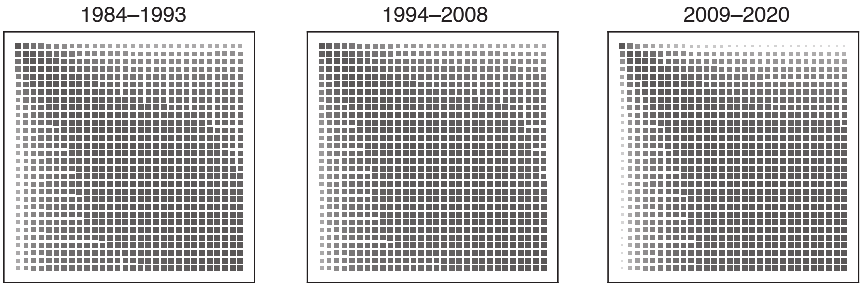
4. There is a subtlety here about whether to use the correlation matrix, which implicitly weights different points on the yield curve equally, or the covariance matrix, which weights them by their volatilities. The convention—adopted in many statistical software packages—is to use the former, which is appropriate when different units of measurement are involved. The calculations in this chapter use the covariance matrix, which has some theoretical advantages but leads to similar results. See Mike Tipping and Christopher Bishop, "Probabilistic Principal Component Analysis," *Journal of the Royal Statistical Society* B 61(3), 1999, pp. 611–622.

EXHIBIT 33-3

Correlation Matrices for 1-Year to 30-Year U.S. Treasury Yields



loadings).[5] Second, it assumes that the shape of each factor is independent of the level of the yield curve—which, as we will see below, is not true when yields are near the lower bound. These oversimplifications are clearly limitations, but they are also advantages in practice, because the results are easy to interpret and use—as we'll see at the end of this chapter.

Principal Component Analysis of Yield-Curve Shifts

Exhibit 33-4 shows the results of applying principal component analysis to daily U.S. Treasury yield date from 1984 to 2020, covering evenly spaced maturities from 1 year to 30 years.[6]

- Most of the observed variance in bond yields is explained by the first four principal components: the 1st principal component explains about 92%,[7] the 2nd explains about 5%, the 3rd about 1%, the 4th explains 0.5%, and the rest very little.
- The first line plot shows the first four principal components. The first two principal components look quite intuitive: the 1st (solid line) is a nearly parallel shift in the level of the yield curve, while the 2nd (dashed line) is a change in the slope of the yield curve, that is, a steepening or flattening.

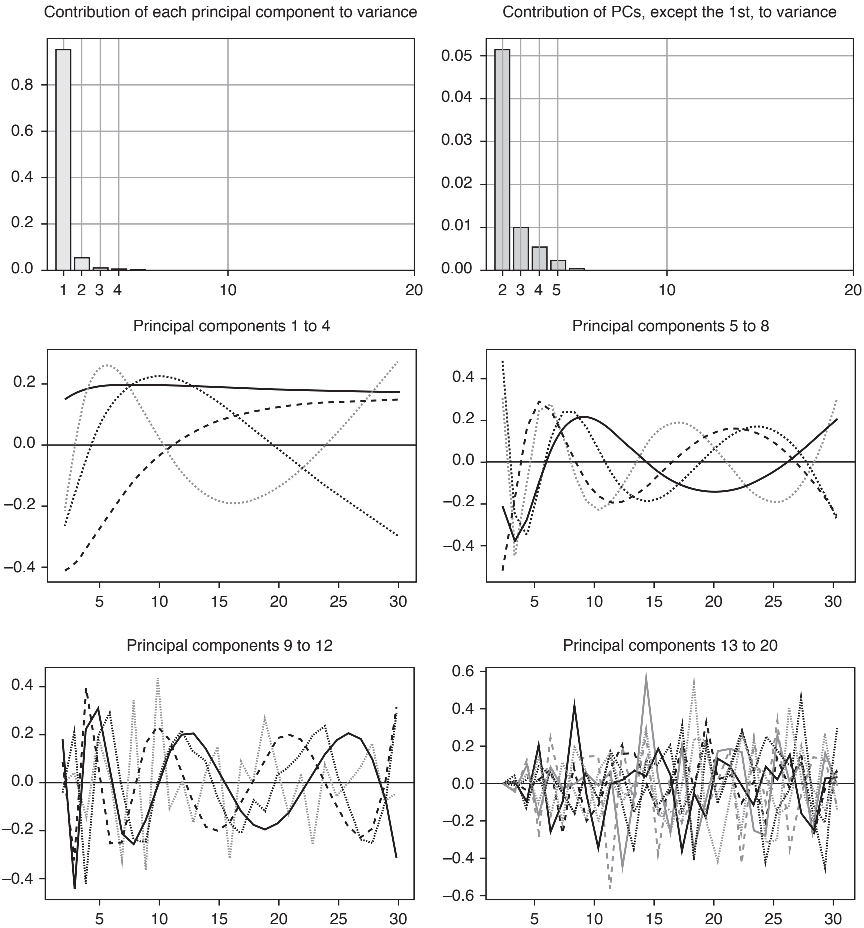
5. Thanks to Henry Schellhorn for noting the potential importance of asymmetry.

6. All U.S. yield-curve data are from the Federal Reserve Board. See Refet Gurkaynak, Brian Sack an,d Jonathan Wright, "The U.S. Treasury Yield-Curve: 1961 to the Present," *FEDS Working Paper* 2006-28 (2006).

7. It can be hard for finance practitioners, who are used to thinking in terms of volatility, to interpret statements like "explains 92% of variance." A simple example may help. Suppose a security's returns are driven by two uncorrelated factors, with volatilities of 3% and 1%, respectively. Then even though the first factor is only 3× as volatile, it explains $\frac{0.03^2}{0.03^2+0.01^2} = 90\%$ of the variance in returns.

EXHIBIT 33-4

Principal Component Analysis, U.S. Treasury Yields, 1984–2020



- The 3rd principal component (dark dotted line) is a hump-shaped shift with the peak of the hump at around the 10-year maturity point; the 4th (light dotted line) is a "snake shift," which seems less intuitive.
- The remaining three line plots show the remaining principal components up to the twentieth. The next half dozen look vaguely like Fourier modes, while the remainder appear to be just noise. None seem intuitive or meaningful.

The 1st principal component is particularly interesting, since it vindicates the notion of bond duration. When we compare the interest rate risk of different bonds by comparing their durations, we are implicitly assuming that all their yields move one-for-one; that is, the duration of a bond is its sensitivity to a parallel shift in the yield curve, which affects all bonds equally. This is almost the same thing as its sensitivity to the 1st principal component, that is, to the empirically most important kind of yield-curve shift.

Beyond the 1st, though, which of these principal components are meaningful and useful? The answer is more subtle than it seems, but we begin with a very important observation: *The principal components you identify will depend on the set of maturities you look at.*[8]

This is illustrated by Exhibit 33-5, which shows the results of a principal component analysis to data from the same historical time period, but considering only intermediate Treasuries, that is, those with maturities of 10 years or less.

- Again, only the first four principal components look significant.
- The first two principal components again look like a level shift and a slope shift, and have similar weights, explaining about 93% and 5% of variance, respectively.
- The 3rd principal component is a hump-shaped shift, but this time peaking at around the 2.5-year maturity point, and it now has a 2% weight; the 4th is a snake shift, but peaking around the one-year point.
- The next three or so principal components look like wavy Fourier modes, and the rest once again look like noise.

Here is our first indication that, while the first two principal components are fairly robust, the shape and significance of the third (often called the "curvature shift") are much more dependent on the data we choose to focus on. That is, while the level shift and slope shift seem to have some universal significance, the other shifts we identify can vary depending on the maturities we include.[9]

Another robustness check is to compare the results of analyzing yield-curve shifts observed in different historical periods. Exhibit 33-6 splits the 1962–2020 data into five different periods.[10]

---

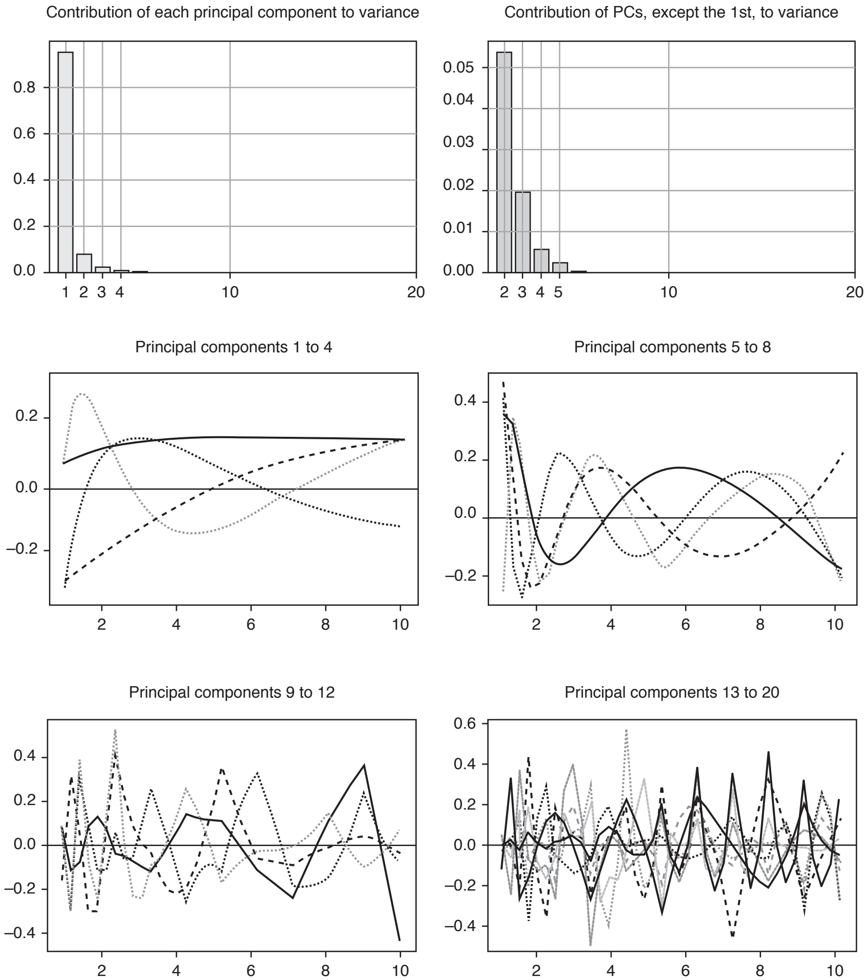
8. So do the weights. If the data set includes large gaps between maturities, the 1st and 2nd principal components will appear relatively more important. Since diversified bond portfolios tend to populate the full range of maturities rather than leaving gaps, the analysis in this chapter uses equally spaced maturities.

9. Many empirical studies of interest rate dynamics have focused solely on Treasury bill yields or Eurodollar futures yields. A principal component analysis of these data only sheds light on the dynamics at the short end of the yield curve, and the results may have little relevance for an investor in intermediate or long maturity bonds.

10. These were chosen to correspond to different monetary policy regimes: 1962–1979 is the early period; 1979–1983 is the period when the Fed targeted the money supply; 1984–1993, when it targeted the Fed funds rate but did not disclose the target; 1994–2008, when it had a public target for the Fed funds rate; and 2009–2020, when Fed funds was near the zero bound and it employed quantitative easing.

EXHIBIT 33-5

Principal Component Analysis, U.S. Treasury Yields (Intermediate Maturities Only), 1984–2020



- In most periods, the 1st principal component is a level shift. The exception is the most recent period 2009–2020, where it looks like a flattened-out slope shift, with no movement in short maturities. We will return to this observation later.
- In most periods, the 2nd principal component is a slope shift. However, it seems to change shape over time, becoming more "linear." The exceptions are the early period where it is parallel beyond the one-year

point, and the QE period where it looks like a slope shift for maturities two years and longer, but is pinned near zero at the very short end.

- The hump of the 3rd principal component has moved around in different periods, as has the peak of the 4th principal component, which seems to have been even less stable.

A further check, which is independently useful, is to analyze yield-curve data from other countries, shown in Exhibit 33-7.[11] We observe the following:

- Canada and the United Kingdom show similar results to the United States.
- The level shift in Germany is similar, but is not parallel at maturities shorter than two years. The slope shift is also somewhat different, as are the 3rd and 4th principal components, though there is a qualitative resemblance.
- For Japan, where yields have been low for much longer, the 1st principal component looks a little more like a slope shift (cf. the QE period results for the United States). The 2nd principal component looks like Germany's. The 3rd and 4th principal components are completely different.
- In all four countries, the relative importance of the 1st principal component is a little lower than it is in the United States. That is, duration does a slightly worse job of capturing overall yield-curve risk in other countries, especially Japan, than it does in the United States.

It is also possible to use principal component analysis to study the *joint* dynamics of yield curves in different countries. For example, it turns out that in a data set spanning advanced economies, the 1st principal component is a "global level shift."[12]

Is the Analysis Vacuous?

At this point, we might feel some satisfaction for identifying a small number of important yield-curve shifts that explain most interest rate risk: the level shift, which justifies the traditional notion of duration; the slope shift, which suggests an additional, important risk measure (see the end of this chapter); and the third/fourth principal components, which may be important as well. After all, a priori these principal components could all have turned out to have complicated and unintuitive shapes—like the less significant ones actually do.

11. U.K. data is from the Bank of England; Canadian data from the Bank of Canada; German and Japanese data from Bloomberg.

EXHIBIT 33-6

Principal Component Analysis, Intermediate U.S. Treasury Yields, Different Time Periods

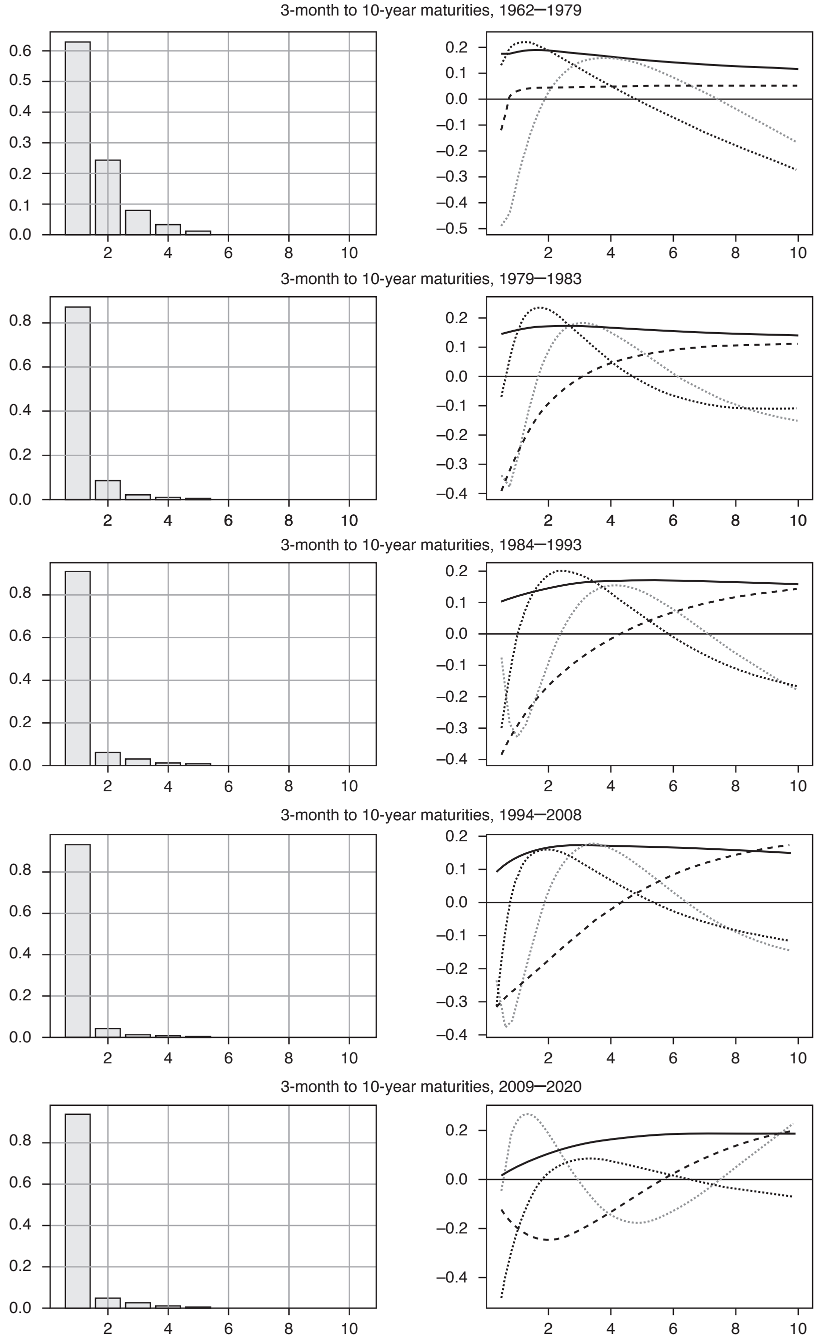

EXHIBIT 33-7

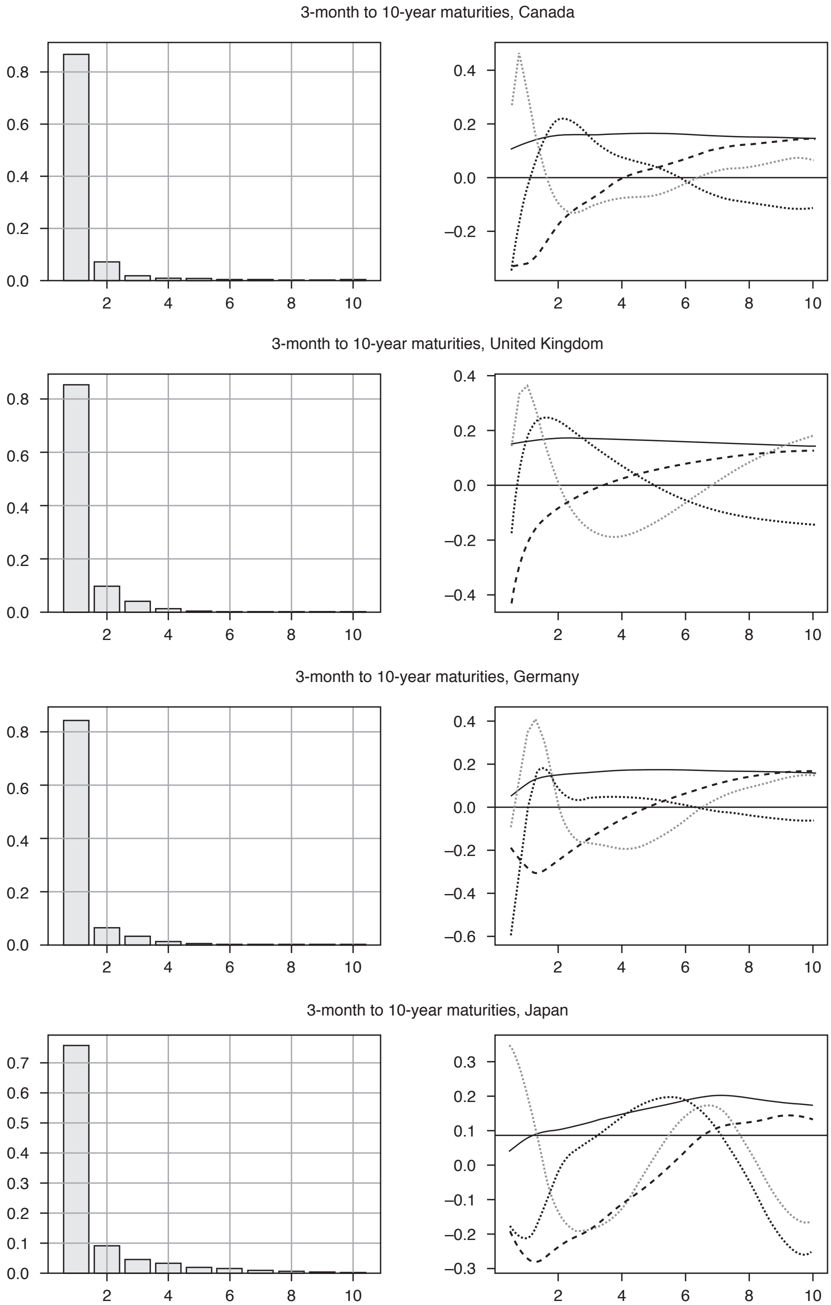
Principal Component Analysis, Other Countries



But we should first ask ourselves whether this really was a discovery emerging from hidden, special features of the data, or whether it was a statistical artefact—whether the principal components *must* look like that, for general reasons; that is, whether there are theorems that dictate their form.

The answer is somewhere in between. Lord and Pelsser describe the general characteristics of a correlation matrix that ensure that a principal component analysis *must* generate level, slope, and curvature shifts.[13] To explain their results, fix a data set and define the *correlation curve* for a specified maturity M to consist of the correlation between each maturity point of the yield curve and the specified M-year yield. It is simply the corresponding row of the correlation matrix, interpreted as a function of maturity (e.g., see the solid lines in Exhibit 33-20 later in this chapter).

Lord and Pelsser define a yield-curve shift to be a *level shift* if it does not change sign, that is, yields at all maturities move in the same direction; it is a *slope shift* if it changes sign exactly once, and a *curvature shift* if it changes sign exactly twice. Then they prove precise versions of the following theorems:

- The 1st principal component will look like a *level shift* provided every entry in the correlation matrix is strictly positive.
- The 2nd principal component will look like a *slope shift* provided each correlation curve is flatter on the right than on the left.
- The 3rd will look like a *curvature shift* provided the "derivative" of each correlation curve is flatter on the right than on the left.

A glance at Exhibit 33-20 shows that the first two conditions hold for the full Treasury yield curve in various time periods. The third condition is harder to visualize, but we can also verify that it holds in all the time periods shown. The same is true for most other yield-curve data sets.

We should not interpret this negatively, as saying that yield-curve principal component analysis is simply a tautology. Viewed more positively, these results show that the first few principal components are qualitatively robust, in the sense that their form is not overly dependent on the specific details of the correlation matrix, but on its general features.

Also, note that a "level shift" in Lord and Pelsser's sense need not be a parallel shift, and indeed empirically the 1st principal component is not always parallel. This illustrates that, even though yield-curve correlation matrices usually satisfy the general conditions spelled out in their paper, the principal components analysis still yields necessary quantitative information about the precise form of the shifts.

Time Variation and Other Sources of Uncertainty

Let's take a closer look at the stability of the principal components—or, to put it differently, their time variation. Exhibit 33-8 overlays a principal component analysis for each individual year in the period 1984-2020, to show how much the results varied; Exhibit 33-9 does the same, but for maturities up to 10 years.

- The 1st principal component varied quite a bit from being nearly parallel to being distinctly sloped at the short end. It was generally flat, or slightly downward-sloping, for maturities longer than five years.
- The 2nd principal component had a surprisingly consistent shape over time, but occasionally deviated quite a bit—though never for long.
- The 3rd and 4th principal components had the same general form over time but tended to peak at different maturities in different periods.
- The remaining principal components seem less meaningful, and inconsistent over time.

This is a strong indication that the first two principal components are fairly stable and therefore meaningful; that the 3rd, and perhaps the 4th, may be relevant, but should be interpreted with caution due to their instability; and that the rest should probably be ignored.[14]

Now that we've observed that the 1st principal component is not always a parallel shift, it's reasonable to ask what determines its shape. A reasonable guess would be: when bond yields are well above zero, the yield curve is free to move (like the plank/dolly), and parallel shifts are possible; whereas when short-term interest rates are static, the yield curve is anchored at one end (like the beam/cantilever), and the 1st principal component cannot be parallel.[15]

Evidence for this is shown in Exhibit 33-10, which plots the short-term interest rate in the United States and the slope of the 1st principal component, again measured over one-year periods. In the period prior to 2008, short-term interest rates remained well above zero, and the 1st principal component was quite flat on average. By contrast, once short-term interest rates reached the zero lower bound and remained there, the 1st principal component became upward-sloping. Note that when short-term rates started to rise above zero in 2016–2019, the 1st principal component started to flatten; if this had continued, it might have returned to being parallel.

14. However, more components may be relevant when analyzing forward rates rather than coupon yields: Ilias Lekkos, "A Critique of Factor Analysis of Interest Rates," *Journal of Derivatives* 8(1), 2000, pp. 72–83.

15. One might also suspect that the fundamental shifts might not be symmetric in nature, e.g., because it is possible to have a parallel yield-curve shift upward but not downward. As noted earlier, principal component analysis is not able to capture this kind of asymmetry. Practitioners tend to use more ad hoc methods to analyze it.

EXHIBIT 33-8

Variation in Shapes of Principal Components, U.S. Treasury Yields

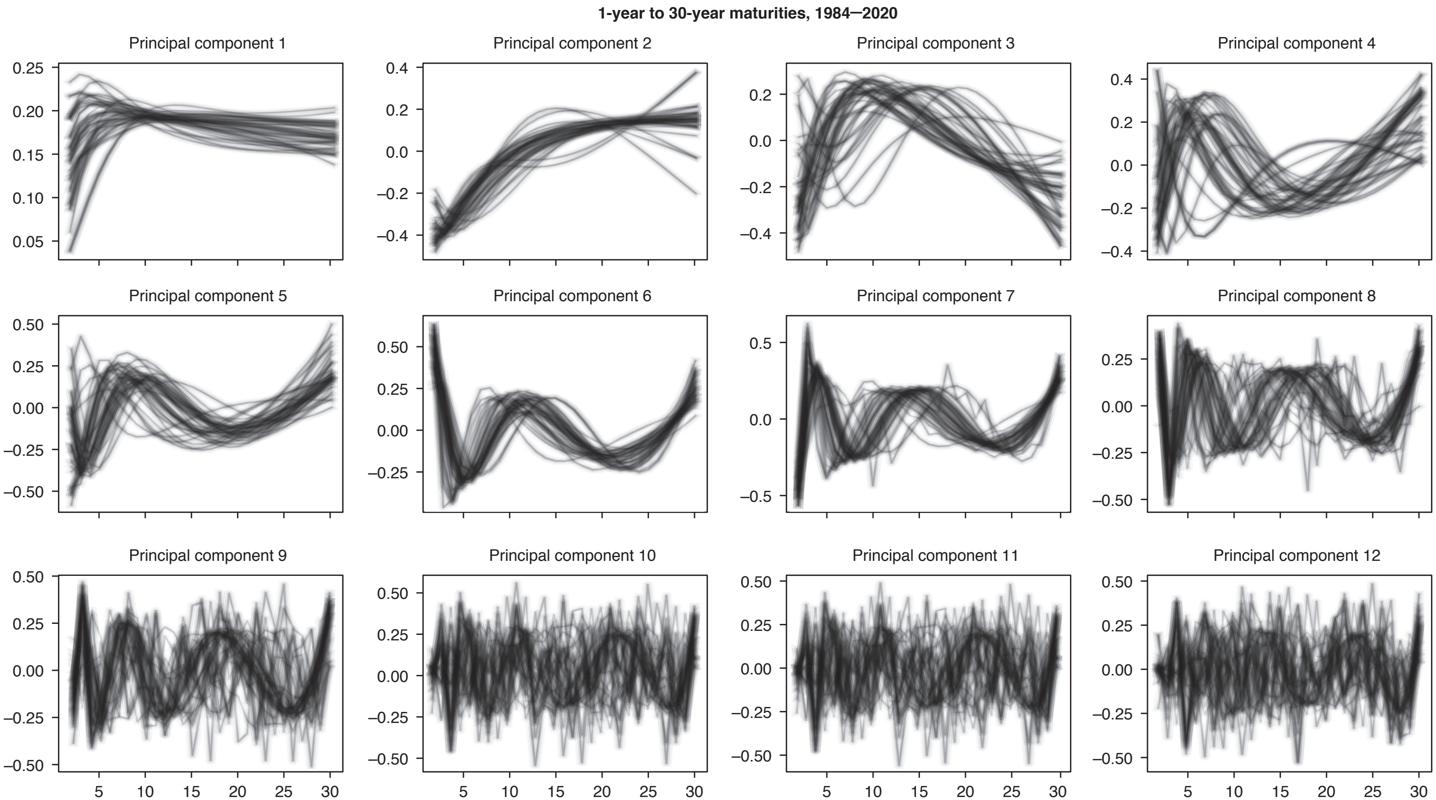

EXHIBIT 33-9

Variation in Shapes of Principal Components, Intermediate U.S. Treasury Yields

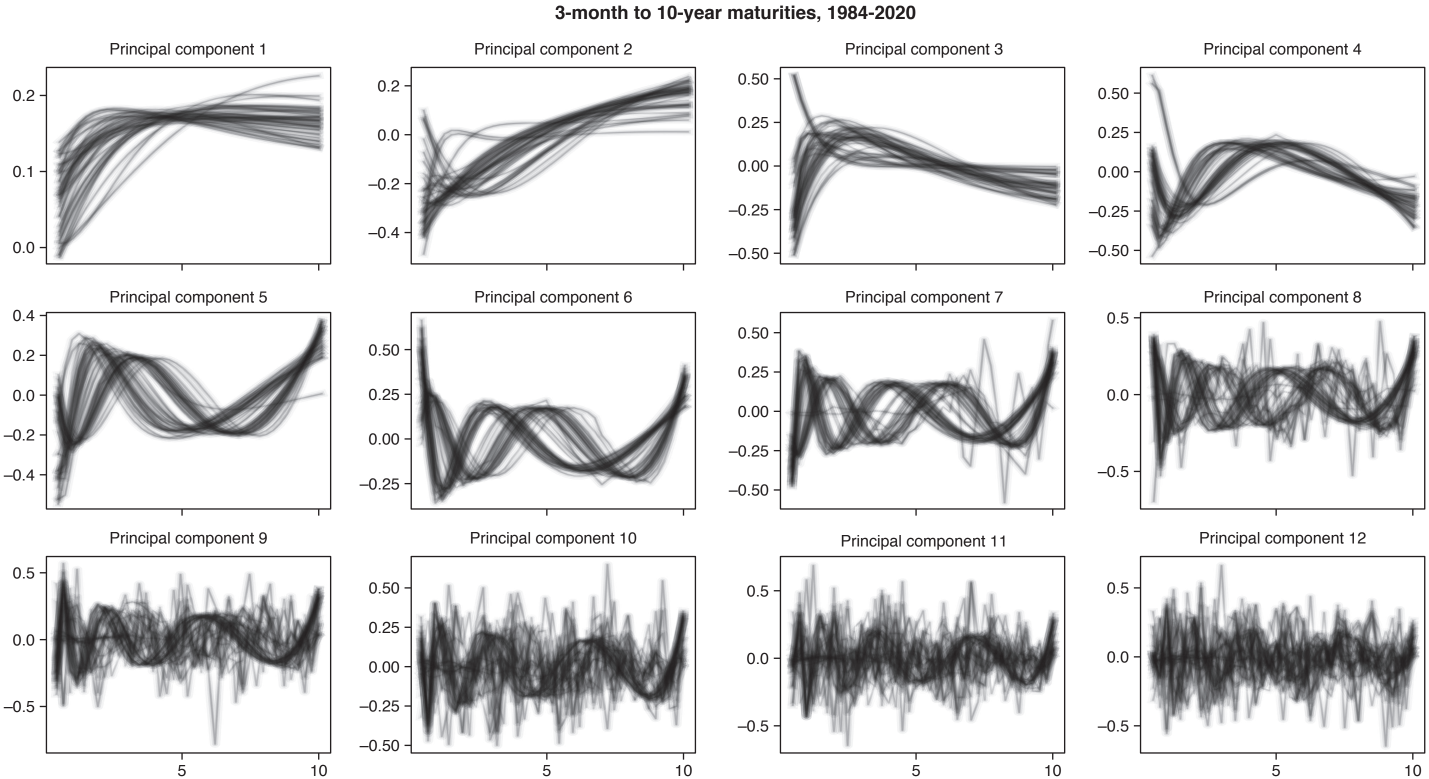

EXHIBIT 33-10

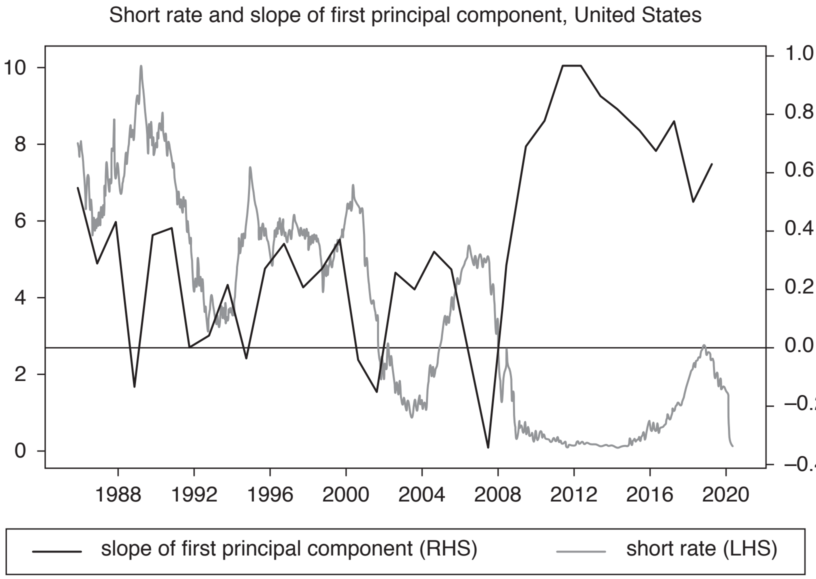
Historical Variation in 1st Principal Component, United States



However, this simple story, linking the nature of the 1st principal component with the zero lower bound on short-term rates, is unfortunately a bit too simple, as Exhibit 33-11 shows. In the United Kingdom, the 1st principal component started to exhibit a distinct upward slope in the mid-1990s, more than a decade before short-term interest rates approached zero. In Canada, the slope of the 1st principal component was trending upward from around 2004, again well before short-term rates approached zero.

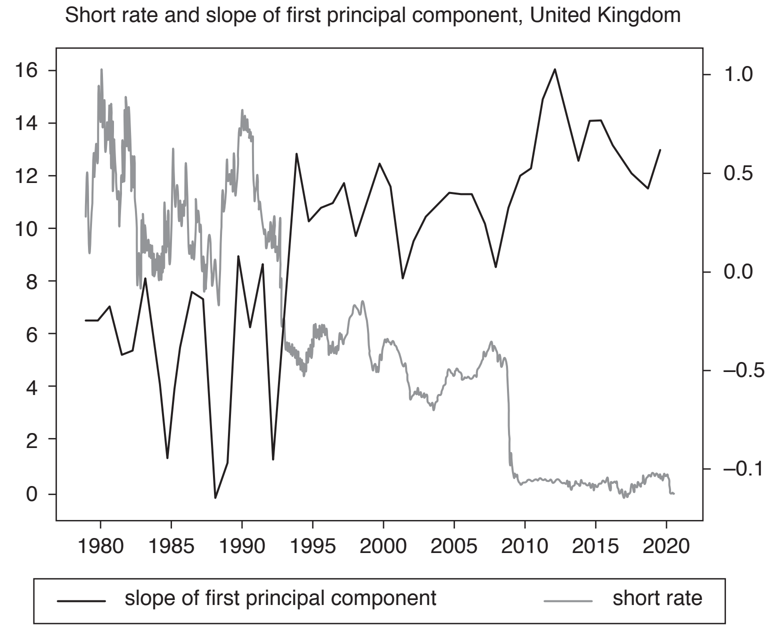
In both cases there is a possible explanation. The Bank of England became independent in 1998; the monetary policy regime in Canada may have changed in 2004.[16] However, it is difficult to make a rigorous connection between these less clear-cut regime switches and the change in yield-curve dynamics.

Another aspect of time variation involves the relative importance of each principal component. Exhibit 33-12 shows that, for the full U.S. Treasury yield curve, the importance of each principal component was somewhat stable during the 1984–2020 period: for example, the 1st principal component accounted for 86% to 97% of variation in yields throughout that period, while the 2nd principal component accounted for 2% to 9%.

16. David Andolfatto and Paul Gomme, "Estimating Canadian Monetary Policy Regimes, preprint (2008).

EXHIBIT 33-11

Historical Variation in 1st Principal Component, Other Countries



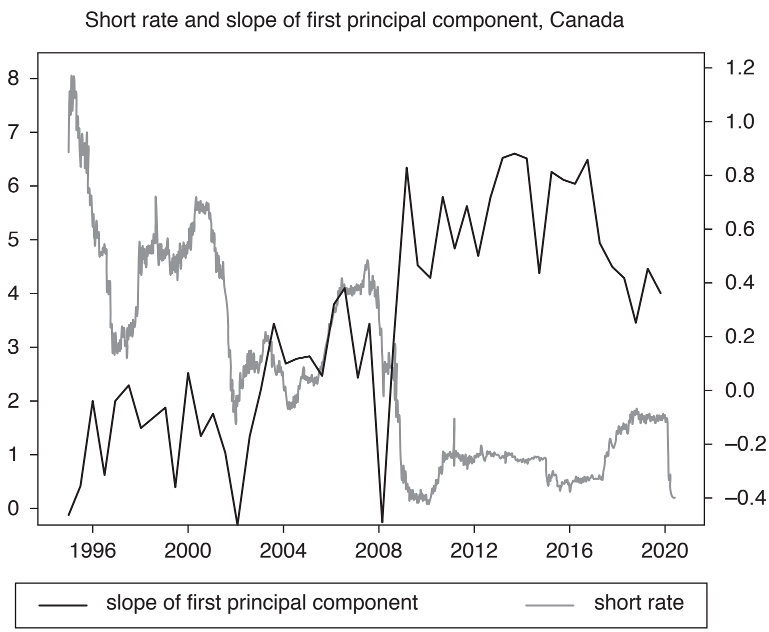


EXHIBIT 33-12

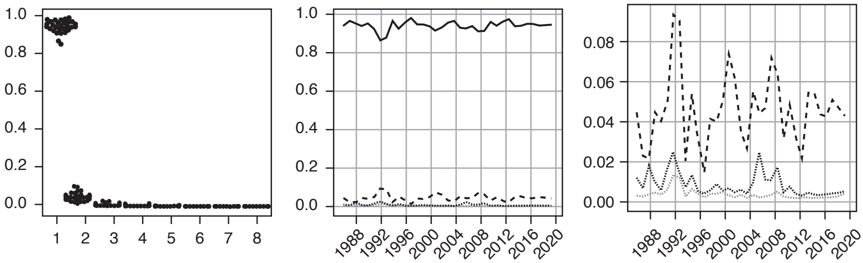
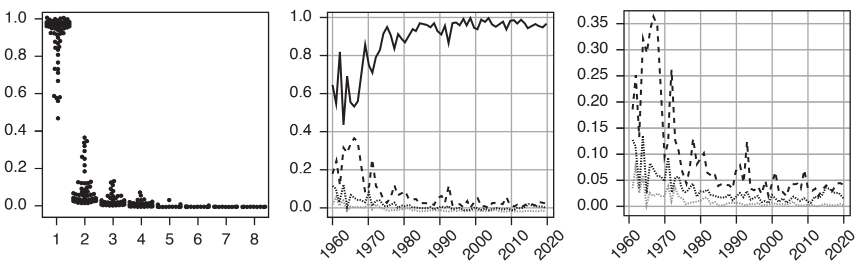
Variation in Importance of Principal Components, U.S. Treasury Yields



Looking at the longer 1962–2020 period, using intermediate Treasury yields, reveals a different picture (see Exhibit 33-13). Prior to the mid-1980s, the 1st principal component was much less important, initially accounting for only 60% of variation in yields on average. It seemed to become more important as Fed policy acquired more independence and clarity between the mid-1970s and the mid-1980s. At the same time, the importance of the 2nd, 3rd, and 4th principal components gradually declined.

EXHIBIT 33-13

Variation in Importance of Principal Components, Intermediate U.S. Treasury Yields



At this point, one might wonder about the relationship between any two principal components. Are they substitutes, with one gaining importance as the other loses it? Conversely, are they linked, both becoming more or less important together? Or are they just unrelated? The answer to these questions is relevant to risk management, once we acknowledge that the importance of each shift is not static.

Exhibit 33-14 shows that the answer is, unfortunately, not simple. It looks at both the full yield curve (upper charts) and maturities up to 10 years (lower chart), again for the 1984–2020 period.

- The 1st and 2nd principal components seem to be substitutes: when level shifts are more important, slope shifts are less important, and vice versa.
- For the analysis using intermediate maturities, the 3rd and 4th principal components seem to be linked: they tend to be more (or less) important at the same time. However, this is less clear in the analysis using all maturities; remember that this analysis identifies different 3rd and 4th principal components.
- The relationship between the 2nd and 3rd principal components is unclear in both data sets.

A final practical remark. The 3rd and 4th principal components are each significantly less important than the 2nd, but their combined importance is comparable. It can be useful to combine them into the shift shown in Exhibit 33-15, which is a hump shift peaking at intermediate maturities, and fairly flat beyond 15 years maturity. While this combined shift has no special significance—it is not itself a principal component—it can be a useful tool. When fixed income risk models incorporate a "curvature" or "hump" shift like this, it is often defined to roughly involve no shift at long maturities; this can be straightforward to specify using standard parametric yield-curve models.[17]

THEORETICAL DETERMINANTS OF YIELD-CURVE DYNAMICS

Now that we have empirically identified the different kinds of yield-curve shifts that dominate the dynamics of the yield curve, we should ask where they come from, and what this means for bond risk management and bond investing. This is a theoretical, rather than empirical, question.

Macroeconomic Determinants

Economic expectations are a key driver of yield-curve fluctuations; this is obvious from the fact that the yield-curve responds to economic surprises. Can we interpret level and slope shifts in terms of economic expectations? Do level and slope shifts emerge naturally from an economic account of the yield curve? Is this what distinguishes them from the other principal components? We sketch an affirmative answer to these questions as follows.

17. Ram Willner, "A New Tool for Portfolio Managers: Level, Slope and Curvature Durations," *Journal of Fixed Income* 6(1), 1996, pp. 48–59.

E X H I B I T 33-14

Historical Relationship Between Importance of Principal Components, U.S. Treasury Yields

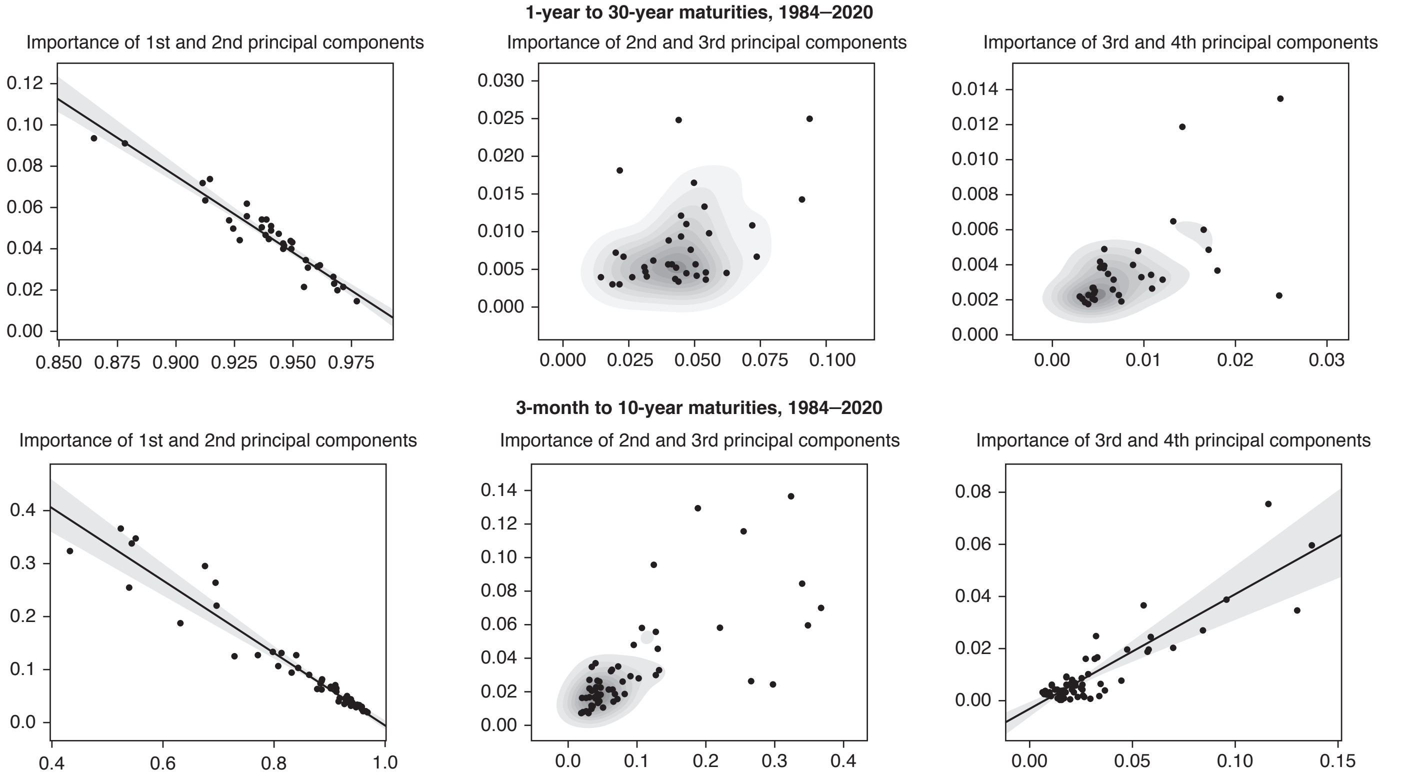


EXHIBIT 33-15

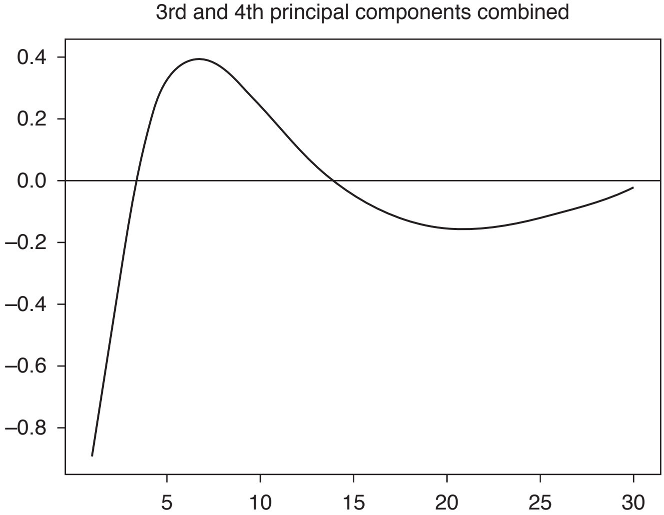
Combining the Problematic Principal Components



The simple intuition is shown schematically in Exhibit 33-16. Nominal yields are determined by expected real interest rates plus expected inflation. These both have long-run expected values but can deviate from those in the short run. The yield curve shifts whenever there is a change in either long-run or short-run expectations, about either future real interest rates or future inflation. (Note that in the long run, real interest rates are generally thought to be determined by the real growth rate of the economy.)

That intuition can be made a bit more formal: Let r_0 be the current short-term nominal interest rate, let $\overline{\pi}$ be the expected long-term inflation rate, and let $\overline{e}$ be the expected long-term real interest rate. Then the expected long-term nominal interest rate is $\overline{\pi}+\overline{e}$. This usually differs from the current short-term rate r_0, but it seems reasonable to assume that investors expect the future short-term rate $r = r_t \ (t > 0)$ to approach $\overline{\pi}+\overline{e}$ as time passes, at least in the absence of future shocks. In fact, under some simple assumptions about how the economy works, one can show that there is a constant κ such that, in expectation,

$$\frac{dr}{dt} = -\kappa\left(r - \left(\overline{\pi}+\overline{e}\right)\right)$$

More precisely, we can derive this from a formal macroeconomic model. The simple model that Frankel used to derive this relationship[18] is shown in

18. Jeffrey Frankel, *Financial Markets and Monetary Policy*, MIT Press (1995).

EXHIBIT 33-16

Economic Determinants of the (Short-Run Equilibrium) Nominal Rate

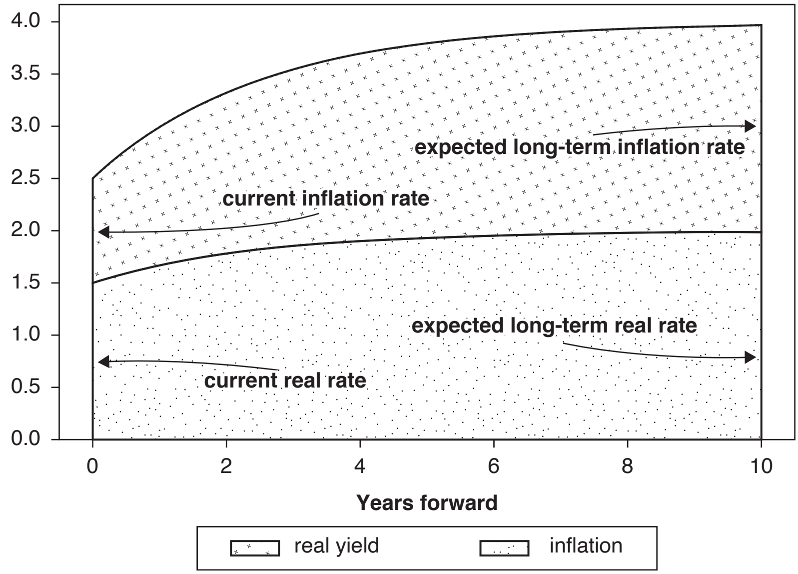


Exhibit 33-17; it corresponds fairly closely to "standard undergraduate macroeconomics." In that model, some algebraic manipulation yields the above formula with $\kappa = \dfrac{\rho\gamma}{\omega\gamma + \lambda}$, where $\gamma := \dfrac{\psi}{1 - \psi\rho}$.

This result is not special: a similar relationship appears to hold in a fairly wide variety of models of the economy, including more complex ones that permit random shocks to the level and trend of the money supply. Thus, the conclusion seems to be quite general. The basic intuition is that interest rates take time to adjust to their expected long-term level, since output and prices take time to adjust.

Given the above expression for the expected rate of change $\dfrac{dr}{dt}$ of the short-term interest rate, it is easy to derive a formula for the expected short-term interest rate at time t:

$$E\left[r_t\right] = \left(1 - \exp\left(-\kappa t\right)\right)\left(\bar{\pi} + \bar{e}\right) + r_0 \exp\left(-\kappa t\right)$$

It is convenient to write this in the form:

$$E\left[r_t\right] = \left(\bar{\pi} + \bar{e}\right) - \exp\left(-\kappa t\right)\left(\left(\bar{\pi} + \bar{e}\right) - r_0\right)$$

That is, a rational investor with conventional beliefs about how the economy works would expect the short-term interest rate to asymptotically approach some

"money supply growth is determined by potential output growth and long-run inflation"

long-term equilibrium level $\bar{\kappa} + \bar{e}$, and the expected future path of short-term rates can be described by a simple exponential curve. There are also other ways to arrive at this functional form, via arbitrage arguments rather than economic arguments.[19] The coefficient κ determines the shape of the yield curve, and could thus be estimated empirically by looking at observed yield curves.

We can see from the above expression that the model predicts two kinds of observable shifts in the yield curve due to changes in economic expectations:

19. Herbert F. Ayres and John Y. Barry, "The Equilibrium Yield Curve for Government Securities," *Financial Analysts Journal* 35(3), 1979, pp. 31–39.

1. *Level shifts*, which arise either from a change in the expected long-term rate of inflation $\overline{\pi}$, or in the expected long-term real rate $\overline{e}$. Thus, level shifts are linked to the expected long-run behavior of the economy.
2. *Slope shifts*, which result from short-term changes in r—in terms of the model, this might occur because an economic shock creates a sudden change in the output gap $y-\overline{y}$. Thus, slope shifts are linked to the cyclical behavior of the economy.

These can be regarded as separate economic factors because changes to long-run expectations and short-run shocks to the output gap can happen at different times for separate reasons.[20]

In addition, if investors expect that κ has changed (e.g., because the structural parameters ψ, λ, ρ have changed), then this would imply a change in the curvature of the yield–curve, that is, a hump-shaped shift resembling the 3rd empirical principal component. However, in practice, hump-shaped shifts in the yield curve mainly occur for quite different reasons.

Other Determinants

In practice we know that the yield curve is not determined entirely by economic expectations (long-term inflation and real rates) and current economic conditions (the output gap and current inflation). There are usually more factors at play. Two particularly important factors are:

- The *term premium*. This is the compensation that bond investors require for assuming interest rate risk, that is, for being willing to invest for a fixed term of years rather than continually rolling over short-term investments.[21] The term premium was positive during most periods in history, but can be negative if investors actually prefer locking in yields.
- The central bank's *policy bias*. This refers to the fact that the short-term interest rate is controlled by the central bank's discretionary policy, rather than being determined by a simple economic model. Over a horizon of a year or two, the expected policy rate can thus differ from what the model says it "should" be.

(Note that the term premium should not be confused with the "term spread," which is the observable difference between long-term and short-term yields. The term spread is the sum of two unobservable quantities: the market's

20. A *caveat* is that the first two principal components are orthogonal by construction, but the two economic factors just described need not be uncorrelated. So the relationship is a bit more subtle than implied here.

21. Don Kim, "The Bond Market Term Premium: What Is It, and How Can We Measure It?" *BIS Quarterly Review*, June 2007: 27–40.

expected change in short-term yields between now and the future, and the term premium. See the reference cited for a more detailed explanation.)

An interesting case of negative term premium is when the central bank is buying bonds aggressively, that is, engaging in quantitative easing, so that net supply is negative. An interesting case of policy bias is when the model says the short-term nominal rate should be large and negative. In many countries the policy rate cannot fall below zero, and in the remaining countries it can only be modestly negative. Thus, in this situation there will be a positive policy bias.

Exhibit 33-18 shows two conceptual illustrations of how economic and other determinants fit together to determine the overall nominal yield curve. In each row in Exhibit 33-18, the left-hand plot shows the economic determinants only (see Exhibits 33-16 and 33-17), while the right plot chart shows the adjustments due to the term premium and policy bias. The upper row illustrates the situation in the mid-2000s, when the term premium was positive; the lower row illustrates the early 2020s, with a negative term premium.

The term premium and policy bias are important for yield-curve dynamics because they are both time-varying. For example, the previous discussion noted that central bank policy actions can affect both the term premium (e.g., via quantitative easing) and the policy bias (e.g., via forward guidance).

Note that the term premium is a problematic concept, because—like other market risk premia—it is not directly observable. Therefore, the term premium must be estimated using a model, and different models can give quite different results. That problem is beyond the scope of this chapter, so we simply note that some central banks publish their own estimates of the term premium, which are a useful resource for investors who are not in a position to build and maintain these models themselves.

If a model is used to decompose the observed yield curve into short rate expectations (i.e., the economic model plus the policy bias) plus the term premium, then we can ask how the principal components can be interpreted in terms of this decomposition. For example, if there is a slope shift in the yield curve, how was this driven by changes in expected short rates, and in (the term structure of) the term premium? What about a curvature shift?

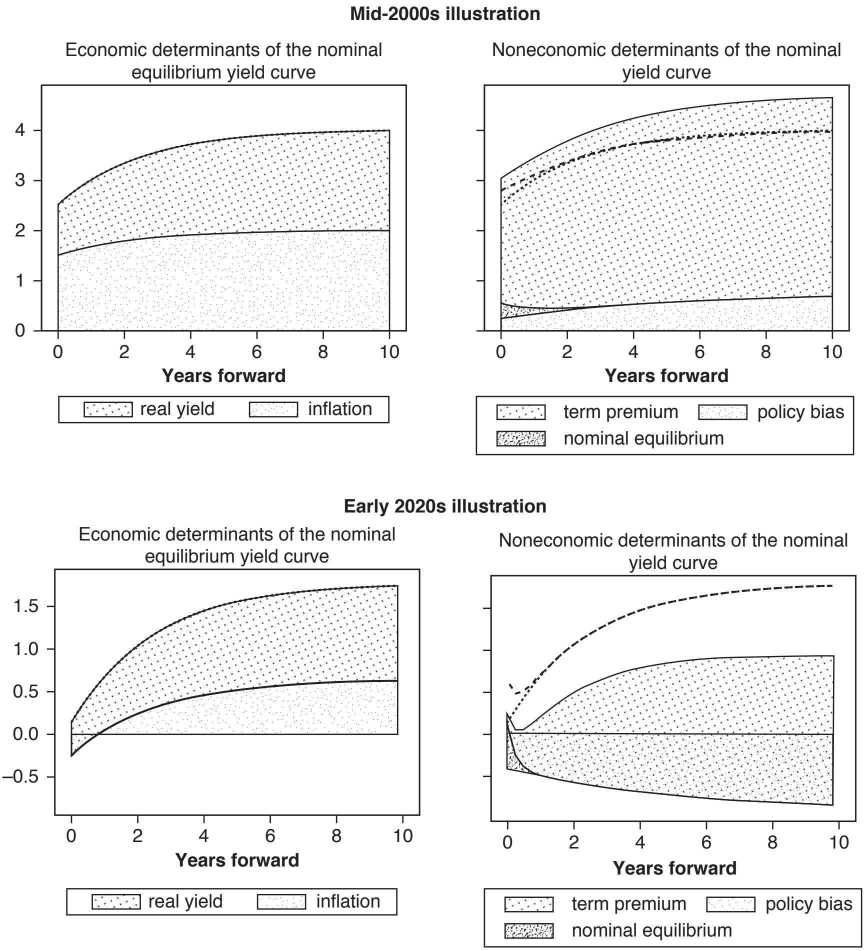
Exhibit 33-19 shows the results based on (a proprietary version of) a well-known term premium model.[22] The model decomposes slope and curvature shifts into their separate impact on short rate expectations and on the term structure of term premia.

- A slope shift (2nd factor) is decomposed into a bull steepening of the expected short rate curve, plus a bear steepening of the term premium curve.

22. Don Kim and Jonathan Wright, "An Arbitrage-Free Three-Factor Term Structure Model and Recent Behavior of Long-Term Yields and Distant Horizon Forward Rates," *FEDS Working Paper* 2005-33 (2005).

EXHIBIT 33-18

Economic and Other Determinants of the Yieldurve

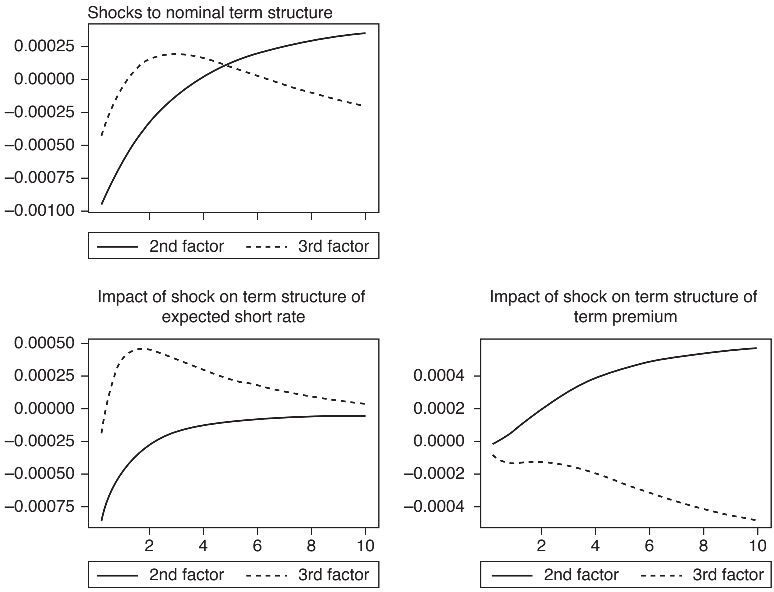


- A curvature shift (3rd factor) is decomposed into a hump shift of the expected short rate curve, plus a bull flattening of the term premium curve (for maturities over three years).

While this kind of decomposition is not so important for pure risk management, it can have investment implications: it affects whether we interpret an observed shift as due to changing expectations or changing compensation for risk. For example, it suggests that a slope shift generally leads to lower expected returns on longer maturity bonds, while a hump shift generally leads to higher expected returns.

EXHIBIT 33-19

Decomposition of Model-Implied Shocks to Nominal Yields



YIELD-CURVE DYNAMICS AND RISK MANAGEMENT

What does all this mean for the practical risk management of a bond portfolio? The analysis has shown that the first two principal components—interpreted as level and slope shifts—capture 80% or more of the variance in bond yields along the yield curve.

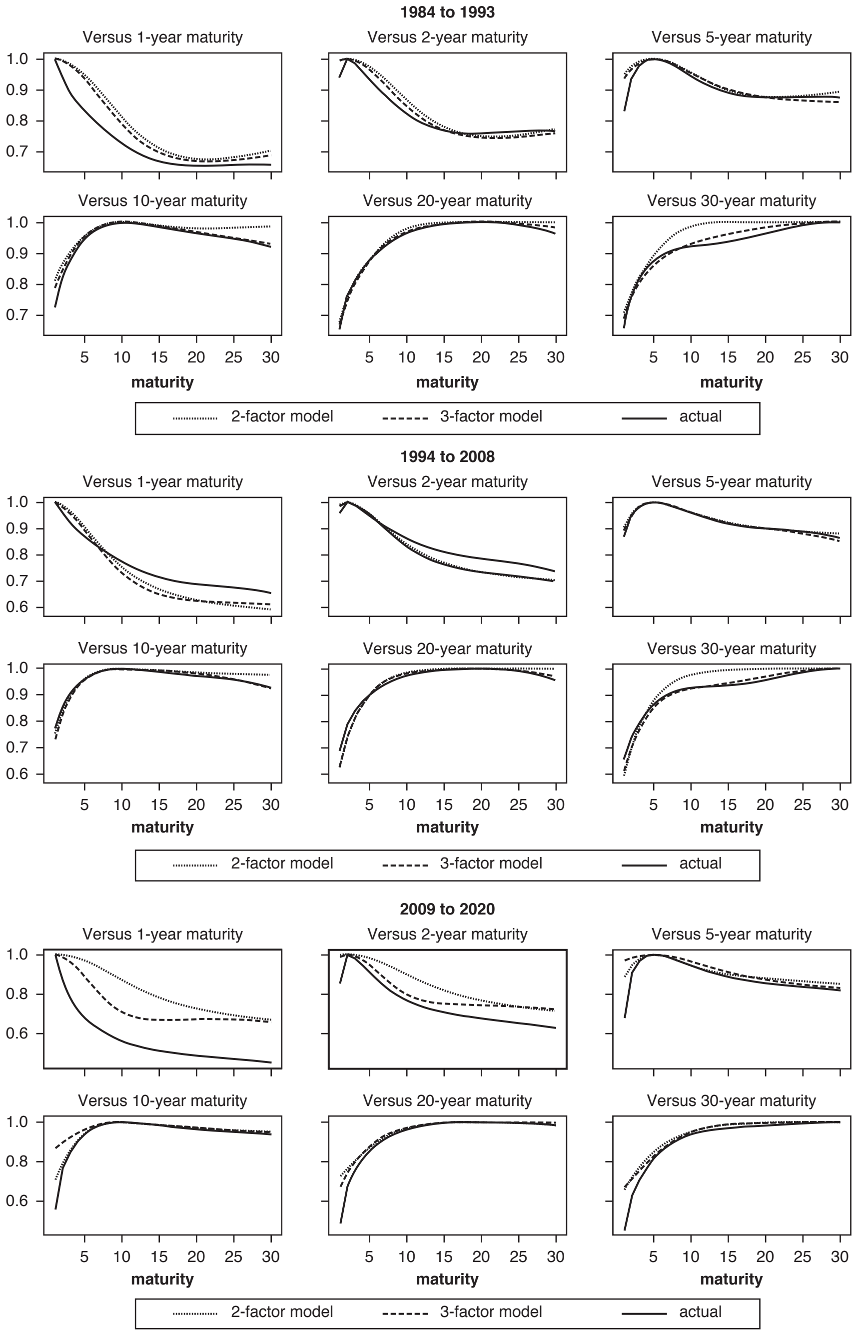
This has two important implications. First, it suggests that just two risk measures—the sensitivities to level and slope shifts—can capture most of the yield-curve risk in a bond or a portfolio. Second, it suggests that only two instruments (e.g., two different Treasury futures contracts) suffice to hedge most of that risk. But these conclusions must be heavily qualified. While the residual risk may seem small, it may be extremely important to investors who are very sensitive to relative returns or who have highly leveraged yield-curve positions. And importantly, this residual risk can change over time: for some investors, it has risen substantially in recent years.

Correlation Structure

One way to see this is to compare the actual correlations between different maturities with the correlations that we would have seen if only the first two (or the first three) principal components mattered. This is illustrated, for three different historical time periods, by the correlation curves show in Exhibit 33-20.

EXHIBIT 33-20

Empirical Correlation Curves vs. Those Implied by Risk Model



For example, for each period the top middle chart shows the correlation between the two-year yield and the yields at other maturity points. The solid line shows the actual correlations, while the dotted (dashed) line shows what they would have been if yields had been driven entirely by the first two (first three) principal components.

- In most cases, the solid, dashed, and dotted lines are close: the actual correlation structure of the Treasury yield curve was well captured by just three or even two factors.
- This is not true for the one-year maturity point, whose correlations with longer maturity bonds drop off much more rapidly in all three time periods. This illustrates the fact that the behavior of the short end of the yield curve can be very idiosyncratic.
- During 1984–2008, a two-factor model overstated the correlation between 10-year and 30-year yields, that is, understated the risk of a long-short position. However, this has been much less the case since 2009.
- On the other hand, since 2009, the two-factor and three-factor models have overstated the correlation between 2-year yields and 5–30-year yields. The idiosyncratic behavior that was formerly confined to the very short end of the yield curve seemed to extend to the two-year maturity point.[23]

It has been known for a long time that the empirical correlation structure of the yield curve cannot be fully reconstructed from just two or three kinds of yield curve shift.[24] Investors need to focus on specific data sets, and compare time periods, to understand the practical implications of this. For example, the results will vary depending on the relevant range of maturities.

Bond Risk Measures

We close this chapter by illustrating how to apply the analysis to the practical activity of managing the yield-curve risk of a high-quality bond portfolio. Exhibit 33-21 shows a typical yield-curve risk report for an illustrative portfolio of bonds, including U.S. Treasuries and TIPS, agency mortgage-backed securities, corporate bonds, asset-backed securities, and municipal bonds.[25] The risk measures shown are:

- *Effective duration*, which measures the sensitivity of the bond's price to a parallel shift in the yield curve—roughly corresponding to the 1st principal component.[26]
- *Slope duration*, which measures the sensitivity of the bond to a change in the slope of the yield curve—corresponding to the 2nd principal component.[27]
- *Key rate durations* for the 3-month, 1-year, 2-year, . . . 50-year points, which measure the sensitivity of the bond to shifts at specific points in the yield-curve.[28]
- *Convexity*, which is negative for most mortgages and callable bonds, such as callable municipals.

Not all risk management systems provide slope duration by default, but it is easily calculated from the key rate durations.[29] Note that since the 2nd principal component is a twist around the 10-year point on the yield curve, the slope duration is positive for bonds with longer durations, but negative for bonds with shorter durations (see Exhibit 33-22). Also, two bonds with the same duration can have different slope durations if their cash flows are different. Finally, while the slope shift is monotonic, the slope duration is most negative for bonds with around a five-year duration; these are the bonds whose price rises (falls) the most when the yield-curve steepens (flattens).

Key rate durations have relevance beyond being used to calculate derived risk measures such as slope duration. As noted above, two-factor or even three-factor yield-curve modeling overstates the correlation between different points on the yield curve, that is, the idiosyncrasies of specific maturities. Investors who are especially sensitive to yield-curve risks—for example, investors implementing asset-liability matching strategies—need to monitor key rate durations independently.

There are several important caveats to bear in mind when interpreting this kind of report:

- Duration is not a perfect measure of a bond's sensitivity to the 1st principal component, since it is not precisely a parallel shift. This discrepancy was relatively minor before 2009, but has become more significant

26. It would be a mistake to think that because the 1st principal component explains 95% of variance in yields, duration is the only risk measure that is important. Recall our earlier example in footnote 7, of a security whose returns are driven by two uncorrelated factors, with volatilities of 3% and 1%, respectively. The first factor accounts for 90% of variance, but hedging it out only reduces volatility from 3.2% to 1%, i.e., by only two-thirds. So the second factor is important too!

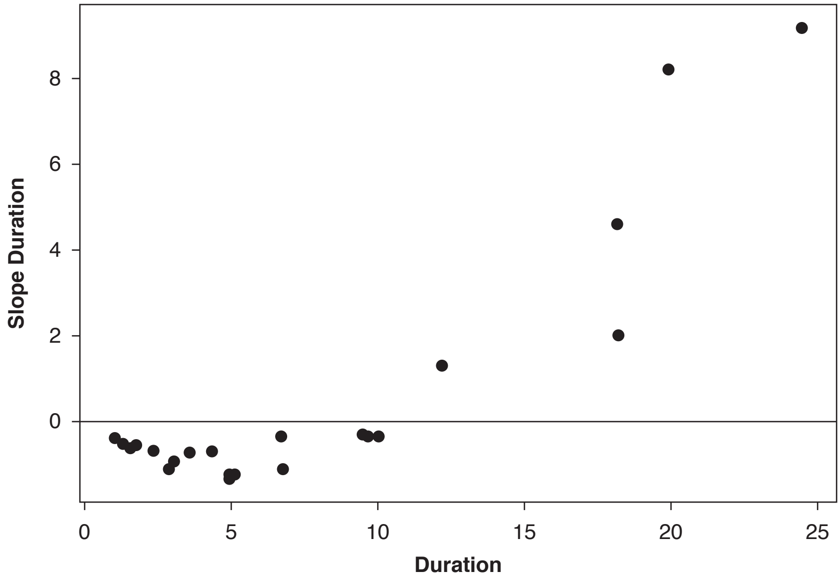
27. Note that defining the slope duration measure involves an arbitrary scaling (and shifting), which should be borne in mind when comparing results from different vendor systems.

28. Thomas Ho, "Key Rate Durations: Measures of Interest Rate Risks," *Journal of Fixed Income* 2(2), 1992, pp. 29–44. Key rate durations are sometimes called partial durations.

29. Wesley Phoa and Michael Shearer, "A Note on Arbitrary Yield-Curve Reshaping Sensitivities Using Key Rate Durations," *Journal of Fixed Income* 7(3), 1997, pp. 67–71.

EXHIBIT 33-22

Duration and Slope Duration of Selected Bonds



in recent years when the 1st principal component has been far from parallel (see Exhibit 33-6). Using standard duration will overstate the yield-curve risk of short maturity bonds.

- The above yield-curve risk measures overstate the yield-curve risk of TIPS. Yields on TIPS are not sensitive to changes in the expected long-term rate of inflation, but only the expected long-term real rate (see Exhibit 33-16).
- Similarly, they may overstate the yield-curve risk of municipal bonds. Under normal conditions, a shift in Treasury yields affects municipal bond yields less than one-for-one, since yields must be compared on an after-tax basis.
- Most importantly, yield-curve risk is not the only relevant risk that bond investors must manage. For example, corporate bonds have credit spread risk, MBS have prepayment uncertainty, TIPS are subject to a varying illiquidity premium, and so on. A full risk report would contain many other risk measures in addition to the ones shown.

KEY POINTS

- Yield-curve shifts are not always parallel. It is thus inadvisable to use the conventional notion of duration as the sole measure of interest rate risk.
- Both empirical and theoretical analyses suggest that the two most important kinds of yield-curve shifts are parallel shifts and slope shifts.
- The forms and relative importance of these shifts can be identified using principal component analysis. They are more or less uniform over time, except during periods when short-term interest rates are at the zero bound.
- The risk measures corresponding to these two kinds of yield-curve shifts are conventional (parallel) duration and slope duration. Taken together, these capture most, but not all, of a portfolio's yield-curve risk exposure.
- "Curvature shifts" appear to be important, but do not have a clear economic interpretation and are less uniform over time; a more practical way to monitor exposure to more complex yield-curve shifts is via key rate durations.
- In a period of structural change in bond markets, overreliance on off-the-shelf risk analytics can lead to blind spots in risk management. Investors should supplement standardized risk measures with exploratory data analysis and conceptual analysis that can shed light on the possibility of structural changes in yield-curve dynamics.

CHAPTER
THIRTY-FOUR

TERM STRUCTURE MODELING WITH NO-ARBITRAGE INTEREST RATE MODELS

Gerald W. Buetow, Jr., Ph.D., CFA,CIPM
President and Owner
BFRC Services, LLC

Brian J. Henderson, Ph.D., CFA
Associate Professor of Finance
The George Washington University

Interest rate models are important tools used by practitioners for purposes including pricing of fixed income securities, pricing interest rate contingent claims, and evaluation of interest rate risk. Although there are many interest rate models, the models vary by their assumptions regarding interest rate dynamics and their degree of specificity. Due to differing assumptions about the interest rate process, each model has different properties that have important implications for their use in valuation. The models range from fairly simplistic to highly mathematical and complex, reflecting the tradeoff between analytical tractability and how closely the model captures interest rate dynamics.

The focus in this chapter is on *no-arbitrage* interest rate models. This term means that the models are fit to the current term structure so that valuing bonds with the model results in prices that are consistent with market prices. In addition to no-arbitrage models, another class of interest rate models called *equilibrium models,* begin with a stochastic differential process and develop pricing mechanisms under a general equilibrium framework. Our focus on no-arbitrage models stems from the fact that these models seem to be the most widely accepted among practitioners.

In general, interest rate models begin with a stochastic differential equation (SDE) to describe the dynamics of an interest rate. One-factor models represent the short rate of interest, whereas multifactor models incorporate a SDE for additional interest rates. Obtaining closed-form solutions to interest rate models requires the use of stochastic calculus. Instead of assuming the reader is versed in stochastic calculus, we present the models in the most tractable way possible.

In this chapter, we illustrate several no-arbitrage interest rate models. Our presentation focuses on the important characteristics of each model with an emphasis on the key assumptions driving the models and the properties of the models that reflect these assumptions. Although more sophisticated models exist, the models presented in this chapter are built on the same intuition and algebraic properties as more sophisticated models.

For interest rate models to be useful for practical purposes, it is helpful to adapt them to a recombining lattice structure. This usually translates into binomial or trinomial trees. After presenting the models and highlighting their important properties, we illustrate the models using lattices. The lattice approach is a useful tool for pricing interest rate contingent claims such as callable bonds and swaptions and for evaluating interest rate risk exposure.

INTRODUCTION TO MODELS OF THE SHORT RATE

We present five no-arbitrage models of the short rate in this section. Our focus is on the assumptions behind each of the models and the implications of those assumptions on the resulting rate scenarios. In the next section we build on these ideas by presenting the models fit to binomial lattices to illustrate the important properties.

Ho-Lee Model

The first no-arbitrage interest rate model was that of Ho and Lee.[1] The model assumes that the short-rate follows the stochastic process:

$$dr = \theta(t)dt + \sigma dz \tag{34-1}$$

This continuous-time process expresses the short-rate dynamics as a combination of an expected component and a random shock. The term $\theta(t)dt$ is the expected change component that is also referred to as the drift in the short rate. This component is the source of important characteristics, such as mean reversion, driving the expected change in interest rates. The drift parameter is a function of time and its value comes from the current term-structure through the process of fitting the model to the no-arbitrage constraints, which we will illustrate below.

The second component in the continuous time process is the source of risk and is the product of σ and dz. This component is important since it drives the distributional characteristics of the interest rate. The Ho-Lee interest rate model assumes the level of risk is constant through time and is referred to as a normal process since z is a Weiner process that is distributed normally. The term $dz = \varepsilon\sqrt{dt}$ is distributed normally since ε comes from a standard normal distribution with zero mean and unit standard deviation. Thus, the Ho-Lee process models the short

1. Thomas Ho and Sang Lee, "Term Structure Movements and Pricing Interest Rate Contingent Claims," *Journal of Finance* (1986), pp. 1011–1029.

rate as normally distributed. As we will see shortly, this means that negative interest rates are possible in the model.

We develop a discrete numerical approximation to generate approximate interest rates. Denoting the exact solution to the stochastic differential equation at time t_k as $r(t_k)$, the numerical algorithm generates solutions denoted r_k that approximate the exact solutions $r(t_k)$. For very small discrete time steps, where Δt is close to zero, we have $dt \approx \Delta t = t_{k+1} - t_k$. This leads to an approximation for the interest rate where $dr \approx \Delta r = r(t_{k+1}) - r(t_k) \approx r_{k+1} - r_k$. Using the discrete approximation, we are able to write the approximation for the Ho-Lee model for the interest rate movement from time k to $k + 1$ as:

$$r_{k+1} = r_k + \theta_k \tau + \sigma_k \Delta z_k \tag{34-2}$$

where $t_k = k\tau$, and Δz_k is a numerical (discrete) approximation of dz. Substituting $dz = \varepsilon\sqrt{dt}$, the equation becomes:

$$r_{k+1} = r_k + \theta_k \tau + \sigma_k \varepsilon_k \sqrt{\tau} \tag{34-3}$$

where ε_k is a random number drawn from the standard normal distribution $N(0,1)$. We denote the time step between time t_k and the starting point as τ. Examining the above equation, it is clear that the short rate's mean may grow very large over time; this happens for certain θ where $\theta_k \tau$ can become large. Additionally, it is clear that for large volatility shocks, the short rate dynamics can be heavily influenced by volatility and the random shock component may be very large. Thus, the Ho and Lee allows for interest rates to grow without bound.

Hull-White Model

The stochastic process for the Hull-White interest rate model is[2]:

$$dr = (\theta - \phi r)dt + \sigma dz \tag{34-4}$$

The process in (34-4) is similar to the Ho-Lee process in (34-1) in that the volatility is assumed to be constant through time and the rates are distributed normally. Additionally, negative interest rates are also possible in the Hull-White model. The drift term in the Hull-White process differs from Ho-Lee process. Note that if θ equals zero, then the Hull-White model reduces to the Ho-Lee model. The drift term in the Hull-White model captures the mean-reversion property of interest rates and is an attempt to control the uncontrolled growth of the short rate that is possible in the Ho-Lee model.

2. John Hull and Alan White, "Pricing Interest Rate Derivative Securities," *Review of Financial Studies* (1990), 3, pp. 573–592, and "One Factor Interest Rate Models and the Valuation of Interest Rate Derivative Securities," *Journal of Financial and Quantitative Analysis* (1993), pp. 235–254.

If we define the long run target short rate as $\mu = \theta/\phi$, then we can rearrange the drift term in equation (34-4) to be $\phi(\mu - r)$. When the short rate is below the target rate μ, then in future periods the rate drifts upward toward that target rate. Conversely, in periods when the short rate is greater than the target rate, the drift term pulls future rates back toward the target rate. The parameter ϕ controls the speed of mean reversion. If ϕ is close to zero, the speed at which the short rate tends toward the target rate is slower than cases in which ϕ is close to one. Positive mean reversion occurs when ϕ takes a positive value. Negative mean reversion is possible when ϕ takes a negative value, but results in exponential growth in the short rate through time. Another important feature of mean reversion is that the drift toward the target rate is determined partially by how far the short rate is from the target rate, the drift being larger when the short rate is further from the target. In the case of negative mean reversion, this second effect amplifies the exponential growth of the short rate.

Applying the discrete approximation for the Hull-White stochastic process, as described for the Ho-Lee model, we obtain the following approximation:

$$r_{k+1} = r_k + (\theta_k - \phi_k r_k)\tau + \sigma_k \varepsilon_k \sqrt{\tau} \tag{34-5}$$

The numerical approximation for the Hull-White process, like the Ho-Lee process, models the short rate as normally distributed. The normality assumption is evident since ε_k is a random number drawn from the standard normal distribution $N(0,1)$. Additionally, it is clear that short rates can become negative, particularly when the assumed level of volatility is large.

Due to the additional parameters of the model, the algebra required to fit the Hull-White process to the lattice involves a variable time step. The variable time step is an undesirable property, requiring a spline methodology to engineer equal time steps. Using a trinomial lattice instead of a binomial lattice will introduce an additional degree of freedom allowing the solutions to have fixed time steps between nodes. Thus, when we present the model lattices, we will present the trinomial model for the Hull-White model.

Kalotay-Williams-Fabozzi Model

The Kalotay-Williams-Fabozzi (KWF) model is analogous to the Ho-Lee model as the stochastic process has a constant drift, does not include mean reversion, and exhibits constant volatility.[3] However, the incremental distinction is that the model treats the natural logarithm of the interest rate as normally distributed. Although the natural logarithm of the short rate may be negative, the short rate itself does not turn negative in this model, unlike the Ho-Lee and Hull-White models. Specifically, the differential process for the KWF model is:

$$d\ \ln(r) = \phi dt + \sigma dz \tag{34-6}$$

3. Andrew Kalotay, George Williams, and Frank J. Fabozzi, "A Model for the Valuation of Bonds and Embedded Options," *Financial Analysts Journal* (May-June 1993), pp. 35-46.

We can see that this equation is identical to the Ho-Lee model if $\mu = \ln(r)$ and we re-write the process as:

$$d\mu = \phi dt + \sigma dz \tag{34-7}$$

Since μ follows a normal process, $\ln(r)$ follows a normal process, implying that r follows a lognormal process. Although μ may become negative as in the Ho-Lee and Hull-White processes, r may not become negative. To illustrate, note that since $\mu = \ln(r)$ then $r = e^{\mu}$, which shows that r is always positive and the KWF model does not allow for negative interest rates like the Ho-Lee or the Hull-White models.

The discrete form approximation for the KWF model is:

$$\mu_{k+1} = \mu_k + \theta_k \tau + \sigma_k \varepsilon_k \sqrt{\tau} \tag{34-8}$$

Since $\mu = \ln(r)$ we re-write the equation as:

$$r_{k+1} = r_k e^{\theta_k \tau + \sigma_k \varepsilon_k \sqrt{\tau}} \tag{34-9}$$

From this equation, we see that when θ is positive, the short rate grows through time and is unbounded. Similarly, if θ is negative, the short rate decays toward zero. Like the Ho-Lee model, short rates in the KWF model exhibit potential unbounded growth, but the KWF model circumvents the negative short rates plaguing the Ho-Lee and Hull-White models. Additionally, the short rate is distributed log normally as opposed to normally.

Black-Karasinski Model

The interest rate process in the Black-Karasinski model takes the following form[4]:

$$d\ \ln(r) = (\theta - \phi\ \ln(r))dt + \sigma dz \tag{34-10}$$

If we again let $\mu = \ln(r)$ and re-write the process, we obtain:

$$d\mu = (\theta - \phi\ \mu)dt + \sigma dz \tag{34-11}$$

Note that this expression is the Hull-White interest rate process, and that since μ has those same properties as the rate in the Hull-White model, it is distributed normally and r is distributed log normally. Since $r = e^{\mu}$, the interest rate in the Black-Karasinski process is greater than zero, which is the advantage of this model over the Hull-White model.

4. F. Black and P. Karasinski, "Bond and Option Pricing when Short Rates are Lognormal," *Financial Analyst Journal* (July-August 1991), pp. 52–59.

Compared with the Kalotay-Williams-Fabozzi model, the Black-Karasinski model also includes mean reversion of the interest rate. Similar to the Hull-White model's extension of the Ho-Lee model, the Black-Karasinski model is an extension of the log normal KWF model to incorporate the mean-reversion property of interest rates. Similar to the Hull-White model, the parameter ϕ controls the growth of the short rate. The drift in the short term rate from each period to the next is determined by the speed of mean-reversion parameter and the distance of the rate from the target rate.

Next, we discretize the process using the same approach illustrated above for the other models:

$$\mu_{k+1} = \mu_k + (\theta_k - \phi_k r_k)\tau + \sigma_k \varepsilon_k \sqrt{\tau} \tag{34-12}$$

Since $\mu = \ln(r)$ we re-write the equation as:

$$r_{k+1} = r_k e^{(\theta_k - \phi_k \ln r_k)\tau + \sigma_k \varepsilon_k \sqrt{\tau}} \tag{34-13}$$

Note the similarity of these equations and Equation (34-5) for the Hull-White model. Both models incorporate mean reversion in the drift term but the main difference comes from the distributional assumption since the Hull-White is normal and Black-Karasinski is lognormal.

Black-Derman-Toy Model

Similar to the Black-Karasinski model, the Black-Derman-Toy (BDT) interest rate model combines mean reversion and the lognormal distribution of the short rate.[5] The important incremental contribution is that in the BDT model, mean reversion is determined endogenously, which is to say that it is determined based on the model's input parameters. The mathematics behind this model make it the most complicated of the models we present. The short rate in the model follows the following process:

$$d\ \ln(r) = \left(\theta(t) + \frac{\sigma'(t)}{\sigma(t)}\ln(r)\right)dt + \sigma(t)dz \tag{34-14}$$

If we again let $\mu = \ln(r)$ and re-write the process, we obtain:

$$\mu = \left(\theta(t) + \frac{\sigma'(t)}{\sigma(t)}\mu\right)dt + \sigma(t)dz \tag{34-15}$$

Equation (34-15) is strikingly similar to the Black and Karasinski model in Equation (34-11), and the only difference between the two comes from the mean

5. Fischer Black, Emanuel Derman, and William. Toy, "A One Factor Model of Interest Rates and Its Application to the Treasury Bond Options," *Financial Analyst Journal* (January-February 1990), pp. 33–39.

reversion parameter. In this model, mean reversion is endogenous to the model since it is determined by the assumed volatility of the short rate. The mechanics of mean reversion in this model should be similar, where the short rate is mean reverting when the term $\sigma'(t)$ is less than zero. Conversely, when $\sigma'(t)$ is positive, implying $\sigma(t)$ is increasing, the short rate grows without mean reverting. Note that if the volatility is constant, the derivative is zero and the mean-reversion term is zero. In the case of constant volatility, the KWF model is a special case of the BDT model.

Next, we discretize the BDT interest rate process using the same approach as for the other models:

$$\mu_{k+1} = \mu_k + \left(\theta_k - \frac{\sigma'(t)}{\sigma(t)} r_k\right)\tau + \sigma_k \varepsilon_k \sqrt{\tau} \tag{34-16}$$

Since $\mu = \ln(r)$ we re-write the equation as:

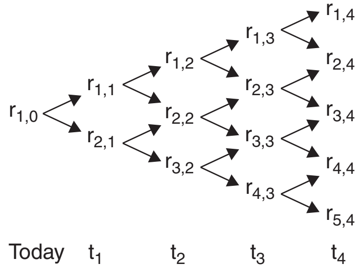
$$r_{k+1} = r_k e^{\left(\theta_k - \frac{\sigma'(t)}{\sigma(t)} \ln r_k\right)\tau + \sigma_k \varepsilon_k \sqrt{\tau}} \tag{34-17}$$

BINOMIAL INTEREST RATE LATTICES

In this section, we present binomial lattice representations of the interest rate models. In the binomial lattice, the interest rate may make one of two possible moves over discrete points in time. For our purposes, we present lattices where the length of each time step is six months. Exhibit 34-1 illustrates a four-period binomial tree. Note that at each node the interest rate takes either an up-step or a down-step. The size of each step is determined by the properties of the interest rate model. Additionally, notice that the tree recombines, meaning that an up-step followed by a down-step produces the same rate as a down-step followed by an up-step. Recombination is a common assumption in binomial trees and results from the imposition of additional algebraic constraints. The numerical methods required to fit the interest rate models to binomial trees are beyond the scope of

EXHIBIT 34-1

The Binomial Lattice of Forward Rates



this chapter, but we present binomial lattice representations of the model to illustrate the important features of the interest rate models. Buetow and Sochacki present a thorough discussion of the numerical methodologies involved with fitting the models to binomial trees.[6]

The no-arbitrage property of the term structure models presented in this chapter comes from the fact that the model rates match the properties of the current term structure. For example, denoting the current one-period (six-month) spot rate as $r_{1,0}$, the two-period spot rate as z, and the implied forward rate as f_1, we can illustrate the no-arbitrage property using the binomial lattice. The two possible values for the interest rate next period in the binomial lattice are $r_{1,1}$ and $r_{2,1}$, and the no-arbitrage property is satisfied by the following constraint, which requires the one-period spot rate, followed by the one-period rate at the next time step, $r_{1,1}$ or $r_{2,1}$, to be equal to the two-period spot rate:

$$\left(1+\frac{1}{2}z\right)^2 = \left(1+\frac{1}{2}r_{1,0}\right)\left[p_u\left(1+\frac{1}{2}r_{1,1}\right)+p_d\left(1+\frac{1}{2}r_{2,1}\right)\right] \tag{34-18}$$

where p_u and p_d are the probabilities of the up and down move, respectively. Imposing the no-arbitrage constraint ensures that pricing straight bonds using the interest rate lattice generates prices that are consistent with the observed spot curve produced from market prices. Due to this property, the no-arbitrage models have practical appeal and are useful for pricing and risk-management purposes.

Exhibit 34-2 presents the Ho-Lee binomial lattice where the term structure is flat at 2% and volatility is constant. In panel A of the exhibit, volatility is 1% and in panel B, volatility is 10%. There are several important features of the Ho-Lee model evident in the binomial lattices. First, the one-period interest rate may be negative, which results from the fact that in the Ho-Lee process, the rate is distributed normally and is unbounded. In fact, it can be demonstrated that the spread between the high and low rates in the Ho-Lee lattice equals $2\times k\times\sigma\sqrt{\tau}$, where k is time (in years) and τ is the length of the time step. This algebraic relation demonstrates that the spread, or distance, between the highest possible rate and the lowest at each time step is an increasing function of time and often produces negative rates. Additionally, the level of volatility drives the spread. To illustrate, panel B of Exhibit 34-2 presents the Ho-Lee lattice where volatility is 10%. The greater dispersion of rates resulting from the greater volatility is immediately evident and illustrates that rates in this model may be very large and frequently negative. Despite the undesirable economic interpretation of negative rates, they are not detrimental to the model since bond prices computed from the binomial trees are the average over the possible future short paths, averaging across all rates.

The Ho-Lee process models the short rate as distributed normally. This is evident in the binomial lattice representation since the rates are symmetrical around the mean rate. For example, the distance between rates $r_{1,2}$ and $r_{2,2}$ is identical to the distance between $r_{2,2}$ and $r_{3,2}$.

Another important property of the Ho-Lee model is that the drift term is related to the slope of the current term structure. This property is illustrated in panel A of Exhibit 34-3 where the term structure slopes upward and the forward curve is increasing by 15 basis points each period and volatility is constant at 10%. This example corresponds to a "normal" term structure since it is positively sloped. The positive drift term is evident and we note that the spread or dispersion between the nodes is identical to that in panel B of Exhibit 34-2. The difference comes from the positive drift term. In some cases, since the drift is proportional to time and grows unboundedly, this term can become quite large. Correspondingly, when the drift term is positive, there are fewer negative interest rates in the lattice. Panel B of Exhibit 34-3 presents the Ho-Lee model for an inverted term structure where the forward curve decreases by 15 basis points each period and volatility is again 10%. Again, the spread between the highest and lowest rate is identical since the volatility is 10% and volatility drives the spread in the Ho-Lee model. Additionally, we can see that the drift term is negative and all rates in the Ho-Lee model shift down by that negative drift term compared with the flat or normal term structure scenarios.

We now turn to the KWF binomial lattice. Recall that this model is analogous to a log-normal version of the Ho-Lee model. It is also a special case of the BDT model when volatility is assumed to be positive and constant. Panel A of Exhibit 34-4 presents the KWF binomial lattice for the scenario where the term structure is flat at 2% and volatility is a constant 10%. This scenario is directly comparable to the scenario is Exhibit 34-2 panel B for the Ho-Lee model and there are two important distinctions between the two lattices. First, the log-normal distribution in the KWF model restrains the interest rate paths from becoming negative. Since the Ho-Lee model is distributed normally, negative rates are possible, but the log-normal distribution of the KWF model restricts rates to be positive. Second, the spread of possible rates at the same volatility level are smaller than in the Ho-Lee model. Whereas the rates are distributed normally around the center nodes in the Ho-Lee model, in the KWF model the rates are distributed asymmetrically around the center node and are skewed toward higher rates. This property illustrates the importance of the distributional assumptions stemming from the models' differential processes.

Exhibit 34-5 presents the KWF lattices for two additional scenarios to cover a normal term structure and an inverted term structure. Panel A presents the normal term structure scenario in which rates are increasing at 15 basis points per period and volatility is constant at 10%. Note that the rates grow larger over time, which is the impact of the drift term. Panel B presents the lattice for the inverted term structure scenario in which the rates decrease by 10 basis points per period and volatility is again constant at 10%. Note that the rates

grow smaller over time, illustrating the impact of negative drift under the inverted term structure. Additionally, we notice that the spread from the highest to the lowest rate on the lattice at each time step is noticeably smaller for the inverted term structure scenario than for the normal term structure. This observation is in stark contrast to the Ho-Lee model in which the spread is determined solely by volatility.

Next, we turn to the BDT binomial lattice. Recall that the differential process in this model is lognormal and incorporates endogenous mean reversion in which the slope of the volatility curve drives mean reversion in the model. Exhibit 34-6 presents the binomial lattice for the normal interest rate tree scenario where the current rate is 2% and the rate increases by 0.15 basis points each period. Panels A, B, and C present three scenarios for a normal term structure across different volatility structures. In panel A, the volatility structure is decreasing from 20% by 0.5% each period, in panel B it is increasing from 20% by 0.5% each period, and in panel C it is constant. When volatility is constant, the model reduces to the KWF model. Note that the rates are all positive and are not extreme as in the normally distributed Ho-Lee model.

The shape of the volatility curve drives the model's mean reversion. This is evident in panels A, B, and C of Exhibit 34-6 since the only change across the panels is the shape of the volatility structure. Comparing panel A to panel C, it is clear that the decreasing volatility structure has the effect of increasing mean-reversion. Note that the upward drift and the spread from high to low rates at each time step are different. The upward drift is checked by the mean reversion when the volatility structure is decreasing and similarly the spread is lower. Comparing panel B to panel C, it is clear that under the positively sloped volatility structure, the upward drift is larger and the spread at each time step is greater.

Exhibit 34-7 presents the BDT interest rate lattices for an inverted term structure where the current short rate is 2% and decreases by 10 basis points each period. The pattern that emerges is similar to the previous exhibit. Comparing panel A to panels B and panel C, it is clear that the mean reversion from the decreasing volatility structure has the effect of reducing the spread across rates at each time step.

Turning to the Black-Karasinski model, Exhibit 34-8 presents the interest rate lattice for this model for a flat term structure of rates when volatility is initially 20% but decreases by 0.5% each period. To illustrate the importance of mean reversion in this model, the table contains two panels; panel A illustrates the lattice with the mean-reversion parameter equal to 0.015 and panel B illustrates the lattice when the mean-reversion parameter equals 0.005. The figures illustrate that larger mean reversion impacts the rates by narrowing the spread between the rates at each time step. Additionally, it must be noted that in order to fit the model to a binomial lattice the ttime step must be allowed to vary for this model. Interpolation is necessary to adjust this tree to equally spaced time steps. The larger mean reversion leads to a decreasing time step. One way to circumvent the uneven time step in this model is to use a trinomial lattice since it allows for an extra degree of freedom.

TRINOMIAL LATTICE

Turning to the Hull-White model, Exhibit 34-9 presents the Hull-White trinomial lattice. The trinomial structure is identical to the binomial lattice except there are three possible time steps from each node instead of two. Similar to the binomial lattice, the solutions impose restrictions to ensure that the trinomial lattice recombines and that the rates in the tree satisfy the necessary conditions. Exhibit 34-9 presents the Hull-White trinomial lattice when the term structure is flat at 2%, 10% constant volatility, and zero mean reversion. The important properties of the Hull-White process are evident in the lattice: Interest rates become negative for the bottom nodes, the spread between high and low rates at each time step is large, and the rates are distributed normally. Additionally, an upward drift is evident in the middle nodes.

Since the Hull-White model incorporates mean reversion, Exhibit 34-10 presents the Hull-White model with the same term structure and volatility as Exhibit 34-9, but incorporates 5% mean reversion. We expect the mean reversion will have the effect of pulling rates back toward the mean, or that the lattice tree should be "pruned." The mean-reversion property is evident as the spread at each time step is reduced and each rate is pulled back toward the target rate, compared to the tree in Exhibit 34-9.

In summary, the lattice representations of the no-arbitrage interest rate models discussed in this chapter demonstrate the importance of the model assumptions about the short-rate process on the model output. It is of critical importance that users of these models understand the model assumptions and the impact those assumptions have on any results (pricing or risk metrics) based on model outputs.

KEY POINTS

- Interest rate models are important tools for practitioners and are useful for pricing fixed income securities, valuing interest-rate contingent claims, and risk management purposes.
- There exist many interest rate models. One-factor models of the short rate make important assumptions about its dynamics through time. Understanding these assumptions and their implications is critical for practitioners.
- Interest rate models specify a stochastic differential equation to capture the dynamics of the models.
- Early models (Ho-Lee and Hull-White) assume the short rate is distributed normally. Interest rates in those models may be negative. Other models (Kalotay-Williams-Fabozzi, Black-Derman-Toy, and Black-Karasinski models) assume the short rate is distributed log-normally, restricting the short rate to be positive.
- Mean reversion is the tendency for interest rates to tend toward a long-term target rate. Absent mean reversion, an interest rate model may allow the short rate to grow unbounded.
- The no-arbitrage models incorporate the information in the current term structure and produce identical prices for option-free bonds.
- When pricing bonds with embedded option features, the interest rate model assumptions are critically important and may result in meaningful differences across different models.

CHAPTER

THIRTY-FIVE

RELATIVE VALUE TRADING

Jordan Hu

Marc Seah
Fixed Income Trading Strategist
RiskVal Financial Solutions

Xu Gao
Fixed Income Quantitative Developer
RiskVal Financial Solutions

Relative value (RV) trading has been a cornerstone of fixed income trading. However, in the current low interest rate environment, RV trading has proliferated to become an even more important tool for investors to boost their returns. The beauty of RV trading is that it is less dependent on the absolute level of yields compared to traditional investing methods. The result is that investors are now less reliant on the general market environment to generate alpha.

Traditional strategies like macro trading tend to require high leverage and often result in large risk exposure to the market. In contrast, RV trading exploits the opportunity between securities, and because the risk exposure of an RV trade is the spread between securities, an investor is exposed to less tail risk to worry about than on a traditional directional trade.

In this chapter, we help define RV in the investment sense in fixed income securities and show how traders and portfolio managers look at it to generate alpha in any market environment.

WHAT IS FIXED INCOME RELATIVE VALUE?

Relative value analysis relies on creating different models and fair value baselines in which an investor can compare assets. Having a fair value baseline is essential in creating an RV measure to ensure that you can compare these assets relatively to each other.

Building an RV trading model in the fixed income space is fairly challenging as there are many moving parts. First, an effective trading model must calibrate to the market in real time so that an investor can trade off it. This requires an accurate live data feed. On top of that, an investor needs reliable historical data to see how the strategy has performed as well as to calculate some performance metric. On top of that, there is also no one perfect model to look at RV as all models have their own assumptions along with their pros and cons. Most traders use multiple models simultaneously to inform each trading decision. The hallmark of a good trading model is one that can consistently identify rich and cheap securities with strong mean reversion.

An even greater challenge besides sourcing for data and building the right model is that the financial markets tend toward being more and more efficient. As each trading model propagates through the industry and is used by more people, security prices tend to converge to fair value. Therefore, models must consistently be tweaked and refined, and new models built if an investor intends to consistently generate positive returns.

In the 1980s, the largest bond trading house Salomon Brothers created the "2+ term structure fair value model" to quantify the richness and cheapness of U.S. government bonds. In a period where mathematical models were practically absent on trading floors, they made a fortune. Over time, as older models have become less effective, newer ones have become more numerous and more sophisticated in nature.

Building a Fair Value Baseline Curve

RV measures involve building a baseline and looking at the spread of each security to this baseline. In fixed income, a fair value curve can be created that represents this baseline. Much like running a regression on two variables and looking at the spread from the current position (residual) to the regression curve to get an idea of whether the point is an outlier, the spread in yield from the security in question to this baseline curve gives investors an idea of the richness or cheapness of these securities.

In the fixed income world, the yield curve derived from all of a country's government bonds is commonly used in this fair value analysis. A bootstrapped curve is derived from carefully selecting multiple instruments.[1] This term structure of yields is created from bond yields by solving for them recursively, by forward substitution, in ascending order of maturity.

Recent Practice of Curve Construction

The number of curve-building choices are consistently increasing in the industry. Before the 2008 Global Financial Crisis, the LIBOR curve was used as both the forward curve and discounting curve for swap traders. However, in the post-crisis

1. Ken Adams, "Smooth Interpolation of Zero Curves," *Algo Research Quarterly*, 4(1/2), 2001, pp. 11–22.
Patrick S. Hagan and Graeme West, "Methods for Constructing a Yield Curve," *Wilmott Magazine*, 3, 2008, pp. 70–81.

period, a new "multi-curve and collateral" framework has become more common. The overnight index swap (OIS) curve has proven to be a better choice for the discounting curve since it is the rate paid on the collateral posted by counterparties on most Credit Support Annexes (CSAs).

There are multiple listed indices that market participants think would be good discounting curves, such as the Secured Overnight Financing Rate (SOFR) in the United States, the Euro Short Term Rate (€STR) in Europe, and the Sterling Overnight Interbank Average Rate (Sonia) in Britain.

Besides having different curves to choose from, the curve construction methodologies are also evolving. In 2006, Hagan and West introduced a new "Monotone Convex Spline Interpolation" of the forward rates as a curve construction method.[2] This spline method uses piecewise quadratic polynomials chosen carefully to preserve the geometric properties such as local monotonicity and convexity.

Now that we understand how to construct a curve, we next look at how a security is valued against the chosen baseline curve.

Z-SCORE, MEAN REVERSION, AND EXPECTED RETURN

Bond prices move inversely to yields. In order to compare bond values relative to each other, their yields should be compared as prices largely differ depending on when they were issued. In the previous section, we discussed how to construct a curve. We can then use this methodology to create a fair value curve based on where all the bonds are currently trading. Because the live prices are always changing, the spread to the fair value curve, or RV spread, is constantly changing as well. What is important is this distance to the fair value curve, as well as its standard deviation from the curve, which gives an investor a good idea of how rich or cheap a bond is. If the yield is higher than the fair value curve, the bond is cheap relative to its estimated fair value curve, and if the yield is lower than the estimated fair value curve, the bond is richer to the fair value curve.

In the fixed income world, each security has its own characteristics. Some bonds tend to stay consistently rich or cheap on multiple RV metrics. For example, the high-coupon U.S. Treasury bonds with a coupon of up to 8.75% consistently trade rich on different RV metrics. These original-issue 30-year bonds were auctioned in the 1990s during a time of high interest rates. This systematic issue highlights the problem of purely looking only at the spread to a fair value curve. Consequently, investors need to look at this spread as a function of historical levels: the Z-score.

2. Patrick S. Hagan and Graeme West, "Interpolation Methods for Curve Construction," *Applied Mathematical Finance*, 13(2), 2008, pp. 89–129.

Z-Score

The Z-score measures how far above or below the mean the live level is in standard deviations. This allows investors to quantify the relative value while taking historical levels and volatilities into account. The Z-score is calculated as follows:

$$\text{Z-score} = \frac{\text{Current value} - \text{Mean value}}{\text{Standard deviation}}$$

The larger the absolute Z-score, the further the current level is deviated from the historical mean and the higher statistical probability of mean reversion.

Mean Reversion and Expected Return

Mean reversion is the main assumption of relative value analysis. It assumes the current level of a trade will converge to its average level or the moving average level. Expected return is defined here as the value an investor would obtain if the strategy were to revert to the mean from current levels. Quantifying the expected return allows investors to easily compare trades side by side in basis points. Trading signals to enter into a trade are usually set by a certain level of deviation from the mean. For example, an investor can set an alert and threshold for the absolute value of the Z-score as a point to enter or exit a trade.

Mean Reversion Assumption

The mean reversion assumption assumes that the current level of a trade would converge to the mean, although this is not always the case. Changes in macroeconomic paradigms or structural curve moves will result in the violation of mean reversion. When there are structural market changes or extreme market shocks like the recent financial crisis, assuming mean reversion becomes much more dangerous and an investor might have to sit on a trade for a longer period of time before current levels return to the mean. This is why traders and portfolio managers like carry and roll down in addition to expected return.

Carry

Carry is broadly defined as the component of return obtained from the receipts and payments associated with holding an asset. In the fixed income space, this is the coupon payment an investor receives from being long the bond, and the funding charges paid to borrow the capital needed to purchase the bond. If we assume a bond is trading at par and the coupon is higher than the funding cost (repo rate), then the carry is positive because the investor is receiving more from the coupon than paying in funding to hold the position. If the cost to fund the position is higher than the coupon, then carry is negative, and the investor will be paying interest to hold onto the position.

Roll Down

The roll down in fixed income markets refers to the component of return that an investor would obtain when a bond's yield changes as it matures. Calculating roll down assumes that the yield curve's shape does not change over time and is dependent on the steepness of the yield curve. An upward-sloping yield curve would result in positive roll down, and vice versa. For example, suppose that the 10-year point is at 2.00% and the 7-year point is 1.7%. If an investor bought the 10-year bond and held on to it for 3 years, it will become a 7-year bond. Assuming the yield curve's shape does not change, the bond's price has risen 0.3% as the yield has fallen from 2.00% to 1.70%, allowing the investor to now sell it at a higher price. This roll down return is independent from the carry return described earlier.

Estimating roll down on the curve is also a bit of an art. There is no perfect way to do it. Calculating roll down involves constructing or picking a curve to estimate the yield change for a given change in maturity. Some traders believe in using the market curve that consists of all the bonds in that space, but this rarely gives rise to a consistent roll down across the curve due to kinks from rich or cheap bonds and sectors. One option is using the CMT curve to estimate roll down because it is smoother and gives rise to a more uniform roll down across the curve.

Total Return

Traders and portfolio managers look holistically at the total return of a trade. The best trades are those with a high expected return as well as positive carry and roll down. The assumptions of mean reversion and a stable yield curve must be considered as well to ensure all the relevant risks are properly understood.

The total return from a position is calculated as follows:

$$\text{Total return} = \text{Expected return} + \text{Carry} + \text{Roll down}$$

Expected return is usually the largest return component of a trade, although that is not always the case. An investor needs to take into consideration all components of the total return. Expected return may also not materialize. To compensate for this, investors generally like to get paid to sit on a trade, and this is possible by entering into trades with positive carry and roll down. With the total return metric to compare trades in mind, investors next need to pick an RV model.

MARKET-BASED VS. MODEL-BASED RELATIVE VALUE

RV models can broadly be classified into two distinct groups: model based and market based. Market-based RV models utilize current market levels to create the fair value baseline. The biggest advantage of the market-based model is that they are directly tradable. We list here several popular models, as well as their pros and cons.

Market-Based RV Models

There are three main market-based RV models: bond asset swap spread, true swap, and Z spread.

Bond Asset Swap (ASW) Spread

Interest rate swaps provide unrivaled flexibility in that an investor can construct a swap with any start and end date, notional amount, and benchmark fixed rate. This flexibility makes these swaps one of the most traded fixed income derivatives, which gives rise to a liquid market and accurate prices. Because of this, many traders like to use RV models that assume the swap curve is the fair value baseline curve for measuring a bond's richness and cheapness. The most common swap curve that traders look at as a fair baseline curve is the LIBOR curve, but as the industry slowly moves away from LIBOR, the OIS curve and SOFR curve have gained prominence.

There are several popular ASW spreads, including the Yield-to-Yield asset swap spread and True-Spread against the LIBOR, OIS, and SOFR curves. The Yield-to-Yield asset spread (YY) is popular as it is easily tradable and simple to calculate. It is calculated by the bond yield minus the matched maturity par swap rate. That is,

$$\text{YY spread} = \text{Bond yield} - \text{Matched maturity par swap rate}$$

To trade this spread, an investor would buy a bond and sell the equivalent amount of a matched maturity par swap that would make the position market neutral (based on the dollar value of a basis point, DV01). Looking at the YY spread lets the investor evaluate a bond's performance against the swap curve relative to each other.

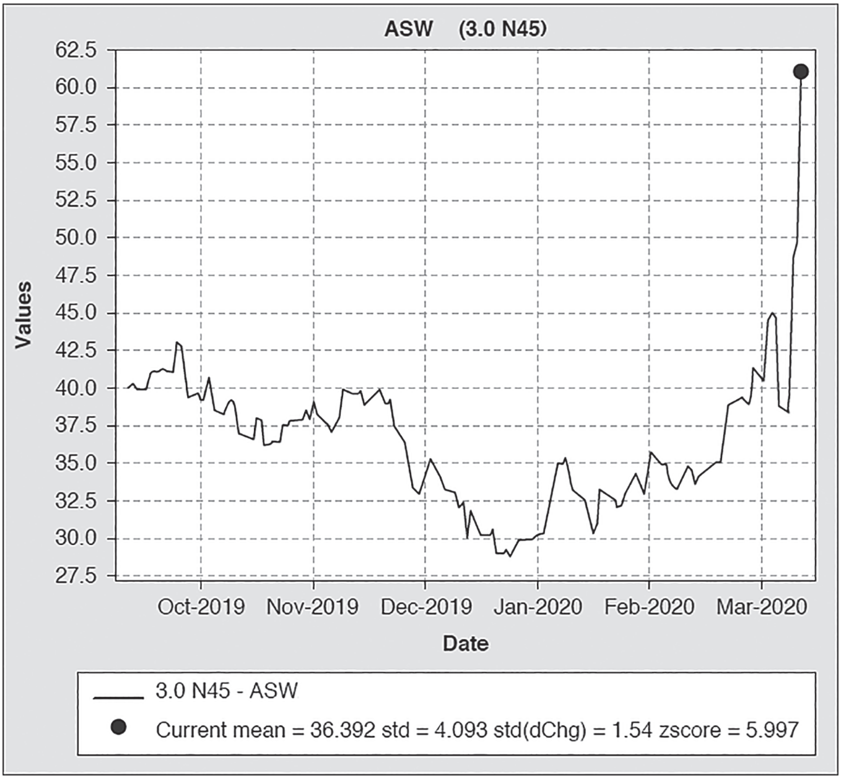
We can illustrate this with a specific case. The cheapest-to-deliver (CTD) bond for the WNM0 contract is the "Treasury 3% 11/15/2045." On 3/12/2020, the yield dropped 1.4 bps to 1.346%. At the same time, the match-maturity swap rate became 0.742%, giving a YY spread of 60.9 bps, as seen in Exhibit 35-1. Taking the last three-month history into account, the Z-score, which is the number of standard deviations the current level is from the mean, was around 6, as shown in Exhibit 35-1, which indicates a strong signal and attractive entry point. If we assume mean reversion and that there was not a good catalyst for this move, an investor should take the opportunity to enter into a short ASW or long bond position here. Assuming mean reversion and a mean of 36.4 as seen in Exhibit 35-1, this trade could produce 24.5 bps in value.

True Spread

To calculate the true asset swap spread, an investor should create a matched maturity interest rate swap, where the swap fixed cash flows are equivalent to the bond cash flows. The investor would then set the net present value (NPV) of the

EXHIBIT 35-1

Historical Yield-Yield Asset Swap Spread for 3.0% 11/15/2045



Source: RiskVal Financial Solutions, LLC

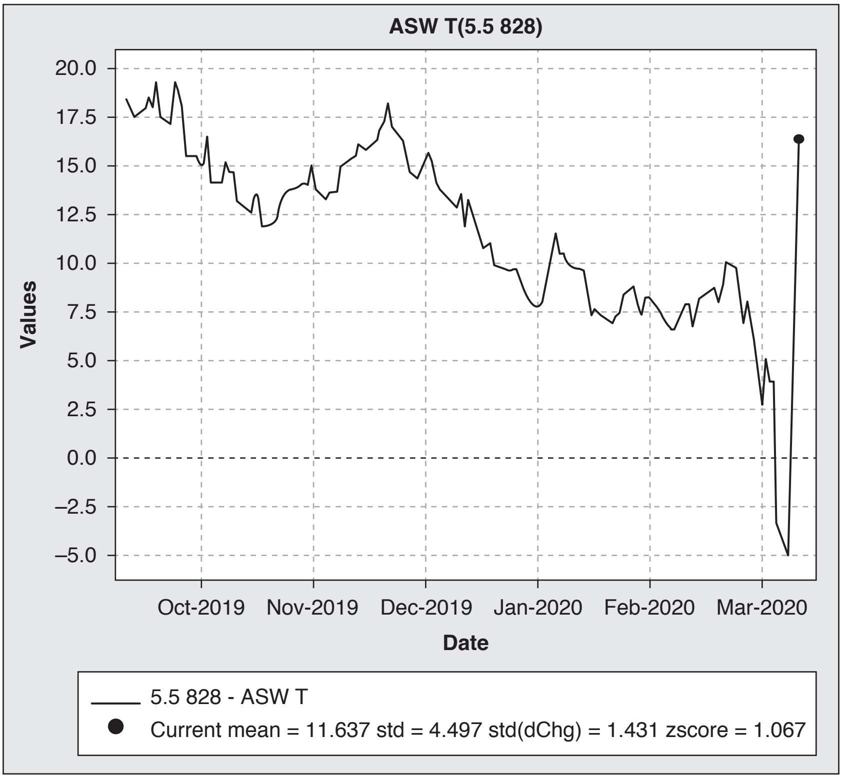
swap to match the bond's dirty price minus par value and solve for the spread to LIBOR. That is,

$$\text{Bond Dirty Price} - 100 = \sum_{i=1}^{n} \frac{\text{bond cash flow}_i}{(1+\text{discount rate})^i} - \sum_{i=1}^{n} \frac{\text{swap floating index}_i + \text{true spread}}{(1+\text{discount rate})^i}$$

As an example, for the 5.5% 8/15/2028 USD Treasury on 3/12/2020, the true spread on that day showed a strong bounce back from its historical low point in the three-month period. With a mean of 11.6 bps as seen in Exhibit 35-2, an investor could enter into a short at current levels of 16.4. However, looking at these levels, investors would have wished that they knew of this trade on 3/9/2020, where the level was (5.0) bps (as seen in Exhibit 35-2) and instead entered into a long position at that point. Assuming mean reversion and a current mean of 11.6 bps, a long position at (5.0) bps would give an investor 16.6 bps of return.

EXHIBIT 35-2

Historical True Asset Swap Spread for 5.5% 8/15/2028



Source: RiskVal Financial Solutions, LLC

As with any trading model, there are assumptions that need to be considered for asset swap spread models. These models assume that the swap curve used is liquid and that the rates derived from the curves are fair. This is not always the case, as the swap curve can also display systematic dislocations for various reasons, including large flows in the financial markets. However, given these assumptions, the Yield-to-Yield and True asset swap spreads are easily understandable and tradable, making them important metrics to look at when trading RV.

Z-Spread

The Z-spread, also called the static spread, is the constant spread to the yield curve is solved for that makes all the discounted cash flows of a bond (which are discounted at their respective yields plus the Z-spread) equivalent to the current dirty price of the bond. That is,

$$\text{Bond Dirty Price} = \sum_{i=1}^{n} \text{cashflow}_i \,/\left(1 + r_i + \text{Z spread}\right)^i, \text{where } i = 1, 2, 3, \ldots n$$

The Z-spread is not a tradable level, but looking at this metric allows an investor to evaluate a bond's performance against the current yield curve relative to other bonds.

The Z-spread can also be looked at in a similar way to the YY and true spread. Looking at the three-month Z-score (ASW Z ZS) of the Z-spread, traders can quickly identify the rich or cheap securities in each sector. As the Z-spread is not a tradable or market quoted level, traders utilize this information to trade these bonds outright or on a spread to each other. In Exhibit 35-3, this sector of bonds maturing from 2026 to 2029 looks rich on a Z-spread basis as seen in the ASW Z column, but it is more important to look at each security relative to other securities in the sector. Hence, it is a good trade to be short a rich bond like the 2.375% 5/15/2027, which is 3.8 standard deviations rich, and going long a cheaper bond like the 2.625% 2/15/2029, which is just 1.5 standard deviations rich.

The Z-spread model assumes that the bond yield curve is the fair value baseline model and hence that the yield curve rates are fair. As mentioned earlier in this chapter, this is not necessarily the case, especially with high-coupon bonds. It is also not a market tradable level. However, the benefit of just using the bond curve here is that this model only uses one type of instrument, Treasury bonds, and so isolates any idiosyncrasies in the valuations to be from one type of financial instrument and market only.

Model-Based RV Models

Model-based RV models usually require significantly fewer market observable inputs and puts them through a predefined model to construct a fair value baseline. The resulting RV spreads of the bond to the baseline curve are not directly tradable but are often used to determine the richness or cheapness of that bond. We list several models we have found effective, as well as their pros and cons.

Constant Maturity Treasury (CMT) Curve[3]

The traditional Constant Maturity Treasury (CMT) curve uses all the bonds in the U.S. government universe as fitting points to build the baseline fair value curve. This ensures that the curve incorporates all the information from the bond market, including the outright level, curvature, and liquidity profile of each point. To fit all 300 bonds from the U.S. Treasury universe, the Nelson-Siegel-Svensson (NSS) multifactor model and weighted least square method are usually combined as the fitting procedure.

The fitting points take the entire bond universe into account. Since the bond maturity distributions are very tight, excluding some bonds do not have a material effect on the overall curve construction. This allows more flexibility as the real-world liquidity of each bond is not identical, which reduces the effectiveness of the model in real-time analysis

One limitation of the NSS model often cited by investors suggests that the model's accuracy is sacrificed at either the long end or short end of the yield curve. This limitation is a result of model parameter assumptions, which are significantly different at each end of the yield curve. Therefore, selecting the best parameters is unique to each situation and should be reconsidered as interest rate regimes change.

To deal with this limitation, two NSS curves are used to fit the discount curve. One curve is used for the short-term fit, while the other is used for long-term fit. This results in a closed-form formula for the discounting factor, which is calculated from the negative natural log of the discount factor denoted as logDF as follows:

$$\text{DiscountFactor}_{\text{double}}(m) = \exp\left(-\log DF_{\text{double}}(m)\right)$$

3. Hana Hladíková and Jarmila Radová,H Hladíková, "Term Structure Modelling by Using Nelson-Siegel Model," *European Financial and Accounting Journal* 7(2), 2012, pp. 36–55, and Hana Hladíková, "Term Structure Modelling by Using Nelson-Siegel Model," *European Financial and Accounting Journal*, 7, 2012, pp. 36–55.

There is an overlapping period [T_{short}, T_{long}] between the short-term curve and long-term curve. For this period, a time-weighted method is introduced to join these two curves and derive the following double-curve model:

$$\log DF_{\text{double}}(m) = \begin{cases} \log DF_{\text{short}}(m)\, \mathit{if}\ m \le \mathrm{T}_{\text{short}} \\ w * \log DF_{\text{short}}(m) + (1-w)\log DF_{\text{long}}(m)\ \mathit{if}\ \mathrm{T}_{\text{short}} < m < \mathrm{T}_{\text{long}} \\ \log DF_{\text{long}}(m)\, \mathit{if}\ m >= \mathrm{T}_{\text{long}} \end{cases}$$

where

$$w = \frac{(m - T_{\text{short}})}{(T_{\text{long}} - T_{\text{short}})}.$$

Using an optimization method to minimize the model error, we get the CMT curve.

The CMT curve model uses all the bonds in their respective country's universe as the fitting pool. This ensures that the constructed curve indeed captures the characteristics of the bond market, from the short end to the long end. There are benefits to not introducing multiple products into the same model as this isolates any market nuances that arise.

The disadvantages of the CMT curve is its sensitivity to the quality of data. Most long-term bonds are not as frequently traded as short-term bonds. This does not apply to the U.S. Treasury market as it is the most liquid market in the world, but this liquidity issue is more prominent in the markets of other less liquid countries. Because of this, the last or mid prices used to fit these curves may be biased. Additionally, the double-curve method cannot guarantee all real-world nuances. For example, in a low interest rate environment, some governments may decide to lock in low borrowing costs and issue ultra-long-term bonds. Austria, for instance, issued 100-year bonds in 2017. These new bonds, being outside the original curve tenor and having lower sizes and liquidity, tend to deteriorate the quality of the constructed curve. This requires investors to customize the used bonds, which is less of a science and more of an art.

Looking at this particular sector of the CMT curve in Exhibit 35-4 and specifically at the three-month CMT standard deviation (CMT RVS ZS), investors could go long a cheap bond like the 1.875 7/15/2026, which is 0.9 standard deviations cheap, while shorting a rich bond like the 1.75 12/31/2026, which is 4.2 standard deviations rich, to create a profitable spread trade.

Some swap traders like to use the CMT curve to calculate the carry and roll down as CMT curves tend to be smoother. Additionally, the CMT curve can used in principal component analysis calculations and can applied this analysis to other instruments.

Hull-White Two-Factor Model

The traditional Hull-White two-factor model, also called the "2+ model," describes the short-rate dynamics of the Treasury yield curve. In this model, it is assumed that the short rates satisfy the following differential equations:

$$dZ(t) = k\left(X(t)+Y(t)-Z(t)\right)dt$$

$$dX(t) = \mu dt + \sigma_x dW_x$$

$$dY(t) = -\alpha Y(t)\,dt + \sigma_y dW_y$$

where

X is the risk-neutral process for the long-term rate factor

Y is the risk-neutral process of the short-term spread factor, such that the "equilibrium" instantaneous rate is *X*+

Z is the risk-neutral process for the actual instantaneous rate

How to use the 2+ model: Using the 2+ model, we construct a fair value Treasury curve. We then discount a specific bond's cash flow on this fair baseline curve to derive the theoretical fair price and yield of the bond. Comparing this fair yield with the current market yield of the bond shows investors the richness or cheapness of each specific issue as seen by the RV spread to the 2+ model curve (2+ RVS) and the resultant Z-score (2+ RVS ZS) in Exhibit 35-5.

The 2+ model is particularly useful in looking at the benchmark points on the Treasury curve and especially so when there are significant moves. In the USD Treasury RVS shown in Exhibit 35-6, the second and larger bar chart of each benchmark point represents the change in yield for each benchmark and future point across the curve. The 2+ model quantifies how rich or cheap each point is based on the movement for that day. In Exhibit 35-6, as shown from the second bar chart of each benchmark point, the WN future, which is the ultra 30-year bond futures contract, has not rallied as much as the U.S. ultra 10-year bond futures or the 30-year benchmark point. The 2+ model is used to quantify how cheap the WN contract is, concluding it is 3 bps cheap given the move of the rest of the benchmark points. This graph gives investors a quick look at the daily yield changes of each point, as well as the resulting richness or cheapness of each point using the 2+_model. Investors could go long the WN contract, which looks to be 3 bps cheap, while short the US contract which looks to be 1.1 bps rich, as represented by the first bar charts for the respective benchmark points.

The Hull-White two-factor model assumes that the rate factors follow a random walk and that there is constant volatility in both the *X* and *Y* processes. The advantage of two-factor model is that it better captures the dynamics in both the short- and long-term rate regimes. It also allows two different volatilities instead of just one, which provides more flexibility.

In practice, a normal distribution and constant volatility are not particularly realistic. Additionally, fat tails are another topic heavily debated in the academic world.

Once the different RV models are understood, investors can then pick and choose how they want to construct their fair value model, how to look at rich and cheap, and how to start constructing trades.

Spread Trades

Trading a single bond outright carries much higher risk than trading two bonds as a spread. This is because when trading a single outright bond, an investor would have duration risk and would be exposed to a parallel shift in the yield curve. By entering into a spread trade and being long one bond and short the other, and if hedged correctly, an investor would be DV01 neutral. This removes the parallel curve move risk as the profits attained from one bond in a market rally would perfectly offset the losses on the other bond.

The remaining risk would be the spread risk, or relative risk between the two securities, which is what investors set out in the first place to gain exposure to. Additionally, constructing a butterfly trade where investors are long the middle issue while short both wings and vice versa would achieve similar relative risk exposure. Constructing these RV spread strategies can also boost an investor's returns by both being long a cheap issue with high expected total return and pairing this with being short a bond that is perceived to be rich.

Constructing a Trade—CMT Curve

Earlier we discussed using the CMT curve as a fair value baseline curve. We will now construct an example spread trade using the CMT curve.

Looking at the basket of bonds in Exhibit 35-7, the 2.375 15-May-2029 is 3.2 standard deviations cheap from the CMT RV Z-score (CMT RVS ZS) column. Investors can pair this with the 2.375 15-May-2027, which is 6.9 standard deviations rich. Again, it is not the actual spread to the fair value baseline curve (CMT RVS) that matters as much, but rather the standard deviation of the RV spread, which takes the past three-month level into account. We can also see that there is positive carry and roll down (3M C+ R) of 0.3 bps on the 2.375 15-May-2027 and negative carry and roll down of (0.4) bps on the 2.375 15-May-2029. Presented graphically in Exhibit 35-8, the yield spread level for the last three months further confirms that there has been a dislocation from previous trading levels.

Source: RiskVal Financial Solutions, LLC

Putting the two trades together as a strategy as shown in Exhibit 35-9—being long the 2.375 15-May-2027 and short the 2.375 15-May-2029 produces a 1.6 standard deviation (Sprd Zs) cheap trade. This strategy also gives investors a total carry and roll down of 0.6 bps (3M C+R), expected return of 1.5 bps, and a total return of 2.1 bps. This means that an investor who puts this position on now will get paid 0.6 bps to sit on this trade for three months while waiting for the trade level to revert to the mean. Reversion to the mean would result in an additional 1.5 bps of return. All in all, a pretty good position to have.

SCENARIO AND HORIZONTAL ANALYSIS

Scenario Analysis

In the context of the assessment of an RV trade, scenario analysis involves estimating the new expected value of a portfolio after a given time period assuming specific market changes. It is commonly used to estimate changes to a portfolio's value in response to an unfavorable event and may be used to examine the theoretical worst-case scenario. For example, the 9/11 terrorist attacks and the 2008 global financial crisis are two commonly used scenarios today by investors to understand the potential impact of such events on their portfolios. Common scenario changes include parallel curve moves or curvature changes.

A parallel curve bump assumes that each point on the curve moves up or down in unison (i.e., by the same number of basis points). Any profit and loss generated from a parallel move would be due to duration risk. Thus, a DV01 neutral strategy can be used in such scenarios.

A curvature change reflects a change in convexity of the yield curve. As illustrated in Exhibit 35-10, there are four general cases: bull steepener, bull flattener, bear flattener, and bear steepener. A bull market refers to when the Treasury market richens, and a bear market refers to Treasuries cheapening and hence an opposite move in the yield curve.

Running different scenarios including those of extreme events allows an investor to better understand the risks of their portfolio and provides an event with information to make more informed investment decisions.

Horizontal Analysis

In fixed income analysis, horizontal analysis is an extension of scenario analysis, assessing the change in portfolio value in different scenarios and time periods. Horizontal analysis provides an understanding of how a portfolio will perform under multiple scenarios and time periods. It is useful for traders to compare their different portfolios against the same change in parameters to understand which portfolio might perform better in a rate environment they believe might occur. In Exhibit 35-11, the profit and loss for a given range in curve moves and time period are shown.

DATA AND THE FUTURE OF RELATIVE VALUE

The most important building block in constructing and using models is data, and having clean and reliable historical data is absolutely essential. Without it, it would be impossible to build and calibrate an effective model, much less use it. As a data provider and analytics company, we maintain massive databanks of historical data. This has allowed us the rare opportunity to explore automation in the data space.

RV Analysis

RV analysis, as seen in Exhibit 35-12, helps investors automatically generate trades with the highest total return based on the parameters that they define. Investors can choose the basket of instruments to run the analysis on. For instance, they can filter by sector or remove high-coupon bonds. They can also pick the RV model they want like in yield or true asset swap and generate the best long and short trades taking carry and roll down into consideration. Investors can also use this in the swap space, which reduces trade identification time by magnitudes due to the vast amount of combinations.

Automation

This was the first step in automation, but we do not believe in stopping here. We are always testing new ways to define and identify trades with the most risk–reward ratio and realized return. With the large swathes of available data being generated everyday, the industry has moved toward using machine learning and artificial intelligence to identify the best trades. Additionally, as computers become more powerful and sophisticated, our models can start using multiple dimensions in the analysis as well. We might be several years away, but quantum computing is also favored to completely reengineer how these financial models work.

From the rising importance of RV trading and how to build a fair value baseline curve model to creating RV trades with high expected value and building and testing these fixed income portfolios, we hope that this chapter has given you a foundational step in understanding fixed income RV. However, investors must keep in mind that no trade or investment is without risk, and model limitations and assumptions should be fully understood. Long-Term Capital Management (LTCM) was a good example of what could happen if investors blindly follow these models.

LTCM was a wildly successful hedge fund from 1994 to 1998 that ran arbitrage and RV strategies including the 2+ model. They had $5 billion in assets but had positions worth over $1 trillion by using leverage to increase returns. In 1998, their position in Russian government bonds plummeted as the Russian government defaulted on its debt. LTCM's models continued to recommend holding their positions and losses approached $4 billion. The U.S. government had to

organize a bailout as they deemed LTCM's disorderly collapse a systematic risk. At that time, their positions totaled about 5% of the global fixed income market.

LTCM's downfall was in their inability to fully understand the limitations of their models. The models performed exactly as expected but did not account for fat tail risks, which LTCM did not fully take into consideration. In order to prevent this type of recurrence, model users need to both fully understand the models' limitations and also have proper risk controls in place.

The RV path is littered with many dangers, but hopefully this chapter provides you with a better understanding of how to navigate it, because with no risk, there is no reward.

KEY POINTS

- Relative value trading has grown in importance in the current low rate and low volatility environment.
- There are numerous market-based and model-based relative value models, each with its own assumptions, advantages, and disadvantages.
- Understanding the Z-score, mean reversion assumption, and total return is essential in constructing relative value trades.
- Scenario and horizontal analysis can be used to better understand the rate and time sensitivities of a strategy or portfolio.
- Relative value trading concepts can be applied to many other financial securities.
- Big data and machine learning pave the way for automation of relative value trading.

The complication in building a model to value bonds with embedded options and option-type derivatives is that cash flows will depend on interest rates in the future. Academicians and practitioners have attempted to capture this interest rate uncertainty through various models, often designed as single or multi-factor models. These models attempt to capture the stochastic behavior of rates.

In practice, these elegant mathematical models must be converted to numeric applications. Here we focus on one such model—a single-factor model that assumes a stationary variance or, as it is more often called, volatility. We demonstrate how to move from the yield curve to a valuation lattice. Effectively, the lattice is a representation of the model, capturing the distribution of rates over time. In our illustration we will present the lattice as a binomial tree, the most simple lattice form.

The lattice holds all the information required to perform the valuation of certain option-like interest rate products. First, the lattice is used to generate cash flows over the life of the security. Next, the interest rates on the lattice are used to compute the present value of those cash flows.

There are several interest rate models that have been used in practice to construct an interest rate lattice. These are described in other chapters. In each case, interest rates can realize one of several possible rates when we move from one period to the next. A lattice model where it is assumed that only two rates are possible in the next period given the current rate is called a *binomial model*. A lattice model where it is assumed that interest rates can take on three possible rates in the next period is called a *trinomial model*. There are even more complex models that assume more than three possible rates in the next period can be realized.

Regardless of the underlying assumptions, each model shares a common restriction. The interest rate tree generated must produce a value for an on-the-run optionless issue that is consistent with the current par yield curve. In effect, the value estimated by the model must be equal to the observed market price for the optionless instrument. Under these conditions, the model is said to be "arbitrage free." A lattice that produces an arbitrage-free valuation is said to be "fair." The lattice is used for valuation only when it has been calibrated to be fair. More on calibration below.

In this chapter we show how to value bonds with embedded options using the lattice methodology. We begin by demonstrating how an interest rate lattice is constructed. Then we use the model to value bonds with an embedded option. The lattice methodology also can be used to value floating-rate securities with option-type derivatives, options on bonds, caps, floors, swaptions, and forward-start swaps.[1]

THE INTEREST RATE LATTICE

Exhibit 36-1 provides an example of a binomial interest rate tree, which consists of a number of "nodes" and "legs." Each leg represents a one-year interval over time. A simplifying assumption of one-year intervals is made to illustrate the key principles. The methodology is the same for smaller time periods. In fact, in practice, the selection of the length of the time period is critical, but we need not be concerned with this nuance here.

The distribution of future interest rates is represented on the tree by the nodes at each point in time. Each node is labeled as N and has a subscript, a combination of L's and H's. The subscripts indicate whether the node is lower or higher on the tree, respectively, relative to the other nodes. Thus node N_{HH} is reached when the one-year rate realized in the first year is the higher of the two rates for that period, then the highest of the rates in the second year.

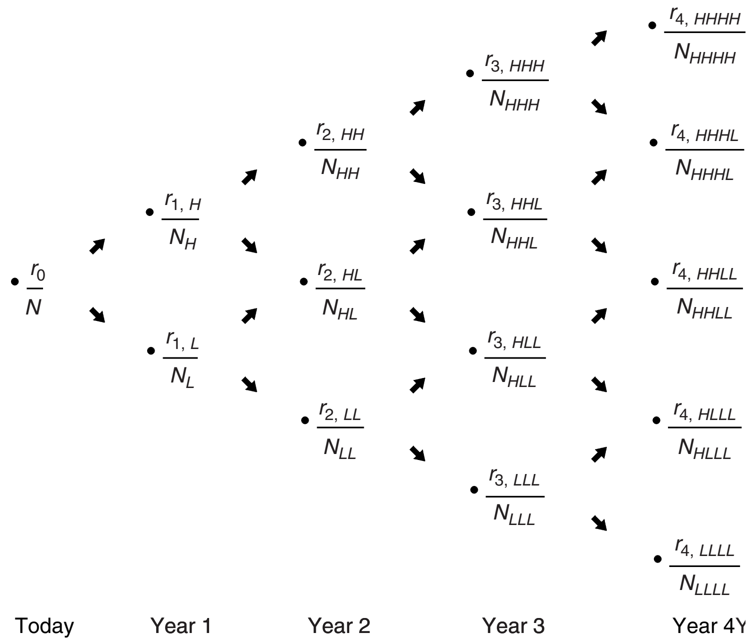
The root of the tree is N, the only point in time at which we know the interest rate with certainty. The one-year rate today (i.e., at N) is the current one-year spot rate, which we denote by r_0.

We must make an assumption concerning the probability of reaching one rate at a point in time. For ease of illustration, we have assumed that rates at any point in time have the same probability of occurring; in other words, the probability is 50% on each leg.

1. These applications of the lattice methodology are presented in Frank J. Fabozzi, Andrew Kalotay, and Michael Dorigan, "Yield Curves and Valuation Lattices" and "Using the Lattice Model to Value Bonds with Embedded Options, Floaters, Options, and Caps/Floors," Chapters 13 and 14 in Frank J. Fabozzi (ed.), *Interest Rate, Term Structure, and Valuation Modeling* (Hoboken, NJ: Wiley, 2002).

EXHIBIT 36-1

Four-Year Binomial Interest Rate Tree



The interest rate model we will use to construct the binomial tree assumes that the one-year rate evolves over time based on a log-normal random walk with a known (stationary) volatility. Technically, the tree represents a one-factor model. Under the distributional assumption, the relationship between any two adjacent rates at a point in time is calculated via the following equation:

$$r_{1,H} = r_{1,L}e^{2\sigma\sqrt{t}}$$

where σ is the assumed volatility of the one-year rate, t is time in years, and e is the base of the natural logarithm. Since we assume a one-year interval, that is, $t = 1$, we can disregard the calculation of the square root of t in the exponent.

For example, suppose that $r_{1,L}$ is 4.4448% and σ is 10% per year, then

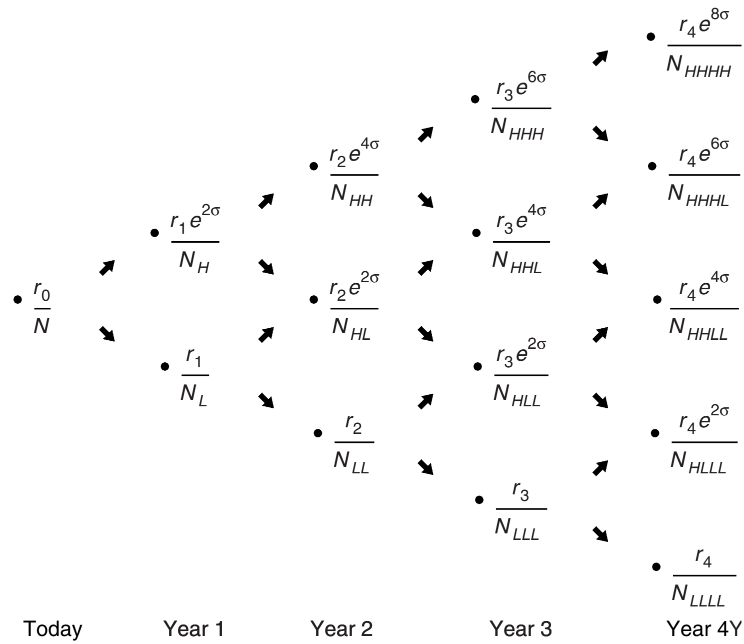
$$r_{1,H} = 4.4448\%(e^{2\times 0.10}) = 5.4289\%$$

In the second year, there are three possible values for the one-year rate. The relationship between $r_{2,LL}$ and the other two one-year rates is as follows:

$$r_{2,HH} = r_{2,LL}\,(e^{4\sigma}) \qquad \text{and} \qquad r_{2,HL} = r_{2,LL}(e^{2\sigma})$$

EXHIBIT 36-2

Four-Year Binomial Interest Rate Tree with One-Year Rates*



*r_t is the lowest one-year rate at each point in time.

Thus, for example, if $r_{2,LL}$ is 4.6958%, and assuming once again that σ is 10%, then

$$r_{2,HH} = 4.6958\%(e^{4\times0.10}) = 7.0053\%$$

and

$$r_{2,HL} = 4.6958\%(e^{2\times0.10}) = 5.7354\%$$

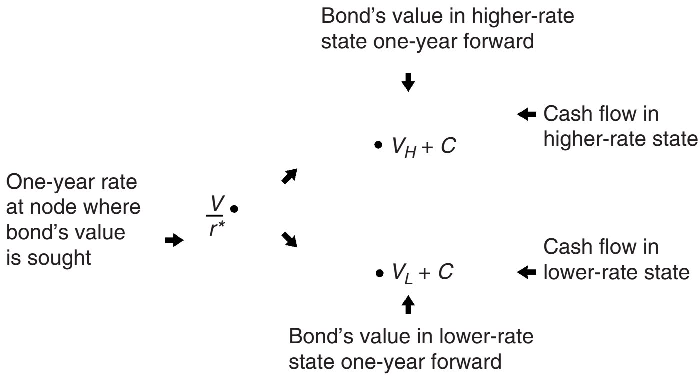
This relationship between rates holds for each point in time. Exhibit 36-2 shows the interest rate tree using this new notation.

Determining the Value at a Node

In general, to get a security's value at a node, we follow the fundamental rule for valuation: The value is the present value of the expected cash flows. The appropriate discount rate to use for cash flows one-year forward is the one-year rate at the node where we are computing the value. Now there are two present values in this case: the present value of the cash flows in the state where the one-year rate is the higher rate and one where it is the lower-rate state. We have assumed that the probability of

EXHIBIT 36-3

Calculating a Value at a Node



both outcomes is equal. Exhibit 36-3 provides an illustration for a node assuming that the one-year rate is r^* at the node where the valuation is sought and letting

V_H = the bond's value for the higher one-year rate state
V_L = the bond's value for the lower one-year rate state
C = coupon payment

From where do the future values come? Effectively, the value at any node depends on the future cash flows. The future cash flows include (1) the coupon payment one year from now and (2) the bond's value one year from now, both of which may be uncertain. Starting the process from the last year in the tree and working backward to get the final valuation resolves the uncertainty. At maturity, the instrument's value is known with certainty—par. The final coupon payment can be determined from the coupon rate or from prevailing rates to which it is indexed. Working back through the tree, we realize that the value at each node is calculated quickly. This process of working backward is often referred to as *recursive valuation*.

Using our notation, the cash flow at a node is either

$V_H + C$ for the higher one-year rate
$V_L + C$ for the lower one-year rate

The present value of these two cash flows using the one-year rate at the node, r^*, is

$$\frac{V_H + C}{(1 + r^*)} = \text{present value for the higher one-year rate}$$

$$\frac{V_L + C}{(1 + r^*)} = \text{present value for the lower one-year rate}$$

Then the value of the bond at the node is found as follows:

$$\text{Value at a node} = \frac{1}{2}\left[\frac{V_H + C}{(1+r^*)} + \frac{V_L + C}{(1+r^*)}\right]$$

CALIBRATING THE LATTICE

We noted earlier the importance of the no-arbitrage condition that governs the construction of the lattice. To ensure that this condition holds, the lattice must be calibrated to the current par yield curve, a process we demonstrate here. Ultimately, the lattice must price optionless par bonds at par.

Assume the on-the-run par yield curve for a hypothetical issuer as it appears in Exhibit 36-4. The current one-year rate is known, 3.50%. Hence the next step is to find the appropriate one-year rates one-year forward. As before, we assume that volatility σ is 10% and construct a two-year tree using the two-year bond with a coupon rate of 4.2%, the par rate for a two-year security.

Exhibit 36-5 shows a more detailed binomial tree with the cash flow shown at each node. The root rate for the tree r_0 is simply the current one-year rate, 3.5%. At the beginning of year 2, there are two possible one-year rates, the higher rate and the lower rate. We already know the relationship between the two. A rate of 4.75% at N_L has been chosen arbitrarily as a starting point. An iterative process determines the proper rate (i.e., trial-and-error). The steps are described and illustrated below. Again, the goal is a rate that, when applied in the tree, provides a value of par for the two-year 4.2% bond.

Step 1. Select a value for r_1. Recall that r_1 is the lower one-year rate. In this first trial, we arbitrarily selected a value of 4.75%.

Step 2. Determine the corresponding value for the higher one-year rate. As explained earlier, this rate is related to the lower one-year rate as follows: $r_1 e^{2\sigma}$. Since r_1 is 4.75%, the higher one-year rate is 5.8017% (= 4.75% $e^{2\times 0.10}$). This value is reported in Exhibit 36-5 at node N_H.

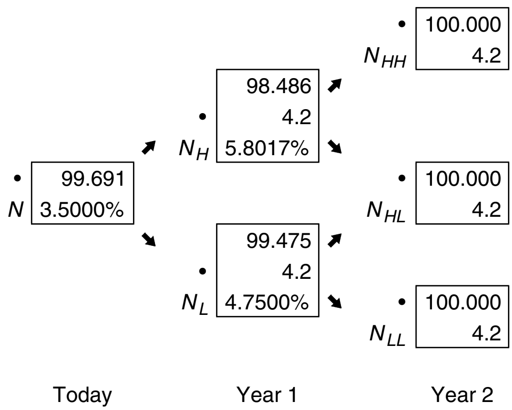
EXHIBIT 36-4

Issuer Par Yield Curve

Maturity	Par Rate	Market Price
1 year	3.50%	100
2 years	4.20%	100
3 years	4.70%	100
4 years	5.20%	100

EXHIBIT 36-5

The One-Year Rates for Year 1 Using the Two-Year 4.2% On-the-Run Issue: First Trial



Step 3. Compute the bond's value one year from now. This value is determined as follows:

a. Determine the bond's value two years from now. In our example, this is simple. Since we are using a two-year bond, the bond's value is its maturity value ($100) plus its final coupon payment ($4.2). Thus it is $104.2.

b. Calculate V_H. Cash flows are known. The appropriate discount rate is the higher one-year rate, 5.8017% in our example. The present value is $98.486 (= $104.2/1.058017).

c. Calculate V_L. Again, cash flows are known—the same as those in step 3b. The discount rate assumed for the lower one-year rate is 4.75%. The present value is $99.475 (= $104.2/1.0475).

Step 4. Calculate *V*.

a. Add the coupon to both V_H and V_L to get the cash flow at N_H and N_L, respectively. In our example we have $102.686 for the higher rate and $103.675 for the lower rate.

b. Calculate *V*. The one-year rate is 3.50%. (*Note:* At this point in the valuation, r^* is the root rate, 3.50%.) Therefore, $99.691 = 1/2($99.214 + $100.169)

Step 5. Compare the value in step 4 to the bond's market value. If the two values are the same, then the r_1 used in this trial is the one we seek. If, instead, the value found in step 4 is not equal to the market value of the bond, this means that the value r_1 in this trial is not the one-year rate that is consistent with the current yield curve. In this case, the five steps are repeated with a different value for r_1.

When r_1 is 4.75%, a value of \$99.691 results in step 4, which is less than the observed market price of \$100. Therefore, 4.75% is too large, and the five steps must be repeated trying a lower rate for r_1.

Let's jump right to the correct rate for r_1 in this example and rework steps 1 through 5. This occurs when r_1 is 4.4448%. The corresponding binomial tree is shown in Exhibit 36-6. The value at the root is equal to the market value of the two-year issue (par).

We can "grow" this tree for one more year by determining r_2. Now we will use the three-year on-the-run issue, the 4.7% coupon bond, to get r_2. The same five steps are used in an iterative process to find the one-year rates in the tree two years from now. Our objective is now to find the value of r_2 that will produce a bond value of \$100. Note that the two rates one year from now of 4.4448% (the lower rate) and 5.4289% (the higher rate) do not change. These are the fair rates for the tree one-year forward.

The problem is illustrated in Exhibit 36-7. The cash flows from the three-year 4.7% bond are in place. All we need to perform a valuation are the rates at the start of year 3. In effect, we need to find r_2 such that the bond prices at par. Again, an arbitrary starting point is selected, and an iterative process produces the correct rate.

The completed version of Exhibit 36-7 is found in Exhibit 36-8. The value of r_2, or equivalently $r_{2,LL}$, that will produce the desired result is 4.6958%. The corresponding rates $r_{2,HL}$ and $r_{2,HH}$ would be 5.7354% and 7.0053%, respectively.

EXHIBIT 36-6

The One-Year Rates for Year 1 Using the Two-Year 4.2% On-the-Run Issue

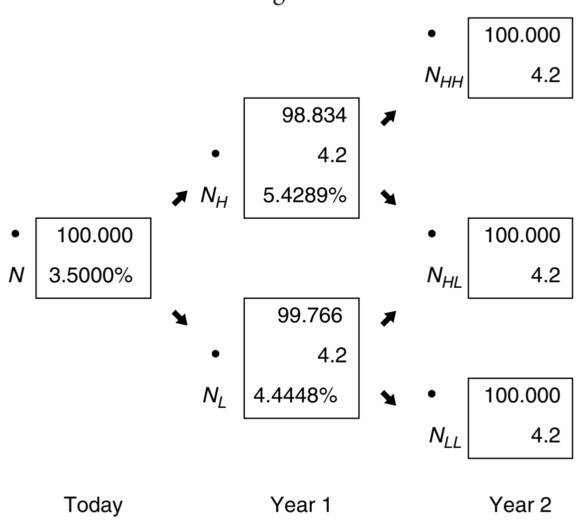


EXHIBIT 36-7

Information for Deriving the One-Year Rates for Year 2 Using the Three-Year 4.7% On-the-Run Issue

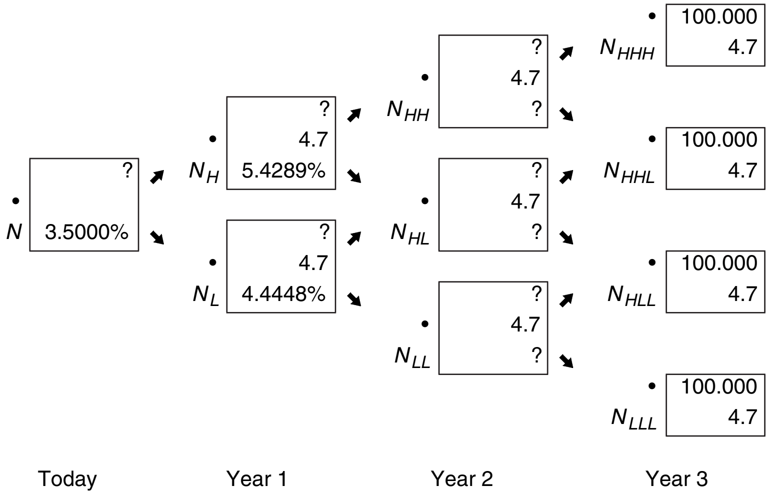

EXHIBIT 36-8

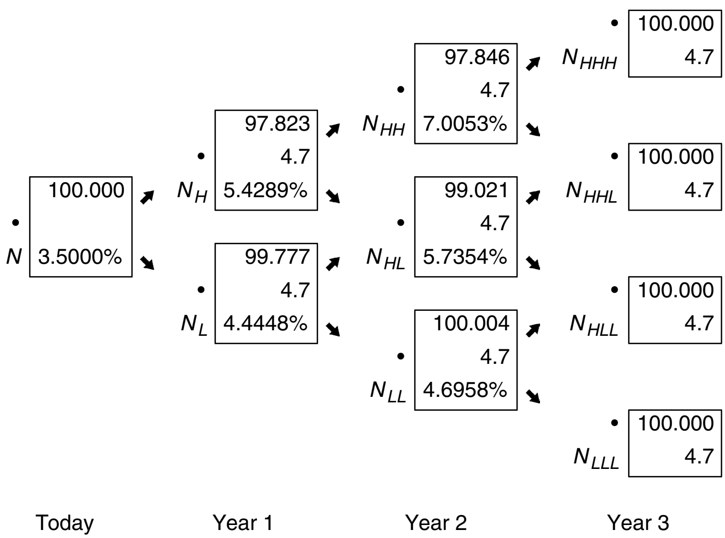
The One-Year Rates for Year 2 Using the Three-Year 4.7% On-the-Run Issue



To verify that these are the correct one-year rates two years from now, work backward from the four nodes at the right of the tree in Exhibit 36-8. For example, the value in the box at N_{HH} is found by taking the value of \$104.7 at the two nodes to its right and discounting at 7.0053%. The value is \$97.846. Similarly, the value in the box at N_{HL} is found by discounting \$104.70 by 5.7354% and at N_{LL} by discounting at 4.6958%.

USING THE LATTICE FOR VALUATION

To illustrate how to use the lattice for valuation purposes, consider a 6.5% option-free bond with four years remaining to maturity. Since this bond is option-free, it is not necessary to use the lattice model to value it. All that is necessary to obtain an arbitrage-free value for this bond is to discount the cash flows using the spot rates obtained from bootstrapping the yield curve shown in Exhibit 36-4. The spot rates are as follows:

1 year	3.5000%
2 years	4.2147%
3 years	4.7345%
4 years	5.2707%

Discounting the 6.5% four-year option-free bond with a par value of \$100 at the above spot rates would give a bond value of \$104.643.

Exhibit 36-9 contains the fair tree for a four-year valuation. Exhibit 36-10 shows the various values in the discounting process using the lattice in Exhibit 36-9. The root of the tree shows the bond value of \$104.643, the same value found by discounting at the spot rate. This demonstrates that the lattice model is consistent with the valuation of an option-free bond when using spot rates.

FIXED-COUPON BONDS WITH EMBEDDED OPTIONS

The valuation of bonds with embedded options proceeds in the same fashion as in the case of an option-free bond. However, the added complexity of an embedded option requires an adjustment to the cash flows on the tree depending on the structure of the option. A decision on whether to call or put must be made at nodes on the tree where the option is eligible for exercise. Examples for both callable and putable bonds follow.

Valuing a Callable Bond

In the case of a call option, the call will be made when the present value (PV) of the future cash flows is greater than the call price at the node where the decision to exercise is being made. Effectively, the following calculation is made:

$$V_t = \min[\text{call price, PV(future cash flows)}]$$

EXHIBIT 36-9

Binomial Interest Rate Tree for Valuing Up to a Four-Year Bond for Issuer (10% Volatility Assumed)

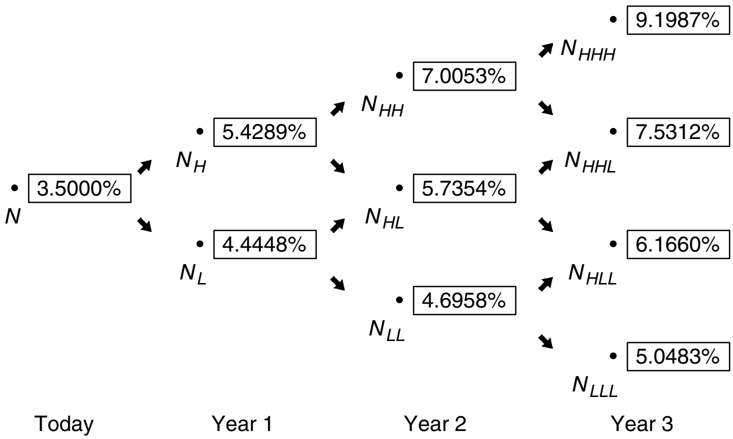


EXHIBIT 36-10

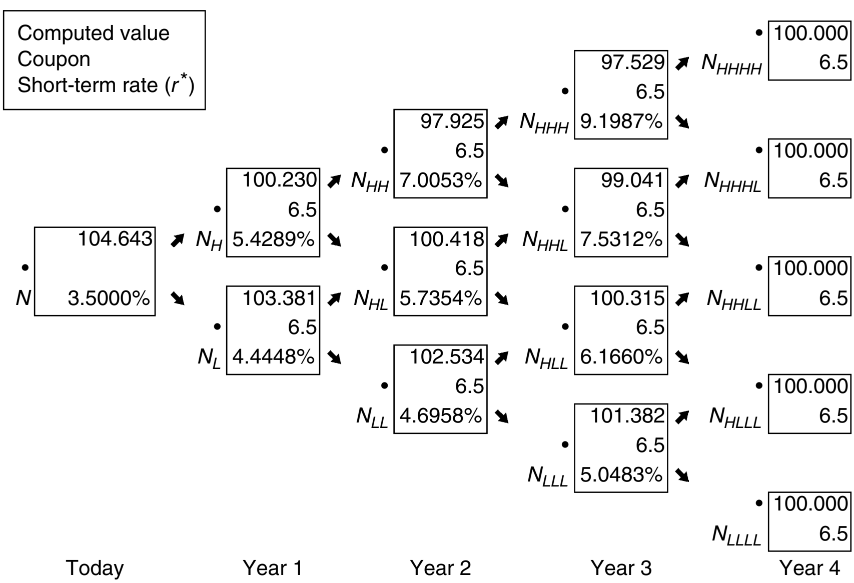
Valuing an Option-Free Bond with Four Years to Maturity and a Coupon Rate of 6.5% (10% Volatility Assumed)



where V_t represents the PV of future cash flows at the node. This operation is performed at each node where the bond is eligible for call.

For example, consider a 6.5% bond with four years remaining to maturity that is callable in one year at \$100. We will value this bond, as well as the other instruments in this chapter, using a binomial tree. Exhibit 36-9 is the binomial interest rate tree that was derived earlier in this chapter and then used to value an option-free bond. In constructing the binomial tree in Exhibit 36-9, it is assumed that interest rate volatility is 10%. This binomial tree will be used throughout this chapter.

Exhibit 36-11 shows that two values are now present at each node of the binomial tree. The discounting process explained earlier is used to calculate the first of the two values at each node. The second value is the value based on whether the issue will be called. Again, the issuer calls the issue if the PV of future cash flows exceeds the call price. This second value is incorporated into the subsequent calculations.

In Exhibits 36-12 and 36-13, certain nodes from Exhibit 36-11 are featured. Exhibit 36-12 shows nodes where the issue is not called (based on the simple call rule used in the illustration) in years 2 and 3.[2] The values reported in this case are the same as in the valuation of an option-free bond. Exhibit 36-13 shows some nodes where the issue is called in years 2 and 3. Notice how the methodology changes the cash flows. In year 3, for example, at node N_{HLL} the recursive valuation process produces a PV of 100.315. However, given the call rule, this issue would be called. Therefore, 100 is shown as the second value at the node, and it is this value that is then used as the valuation process continues. Taking the process to its end, the value for this callable bond is 102.899.

The value of the call option is computed as the difference between the value of an optionless bond and the value of a callable bond. In our illustration, the value of the option-free bond is 104.643 (calculated earlier in this chapter). The value of the callable bond is 102.899. Hence the value of the call option is 1.744 (=104.634 − 102.899).

Valuing a Putable Bond

A putable bond is one in which the bondholder has the right to force the issuer to pay off the bond prior to the maturity date. The analysis of the putable bond follows closely that of the callable bond. In the case of the putable, we must establish the rule by which the decision to put is made. The reasoning is similar to that for the callable bond. If the PV of the future cash flows is less than the put price (i.e., par), then the bond will be put. In equation form,

$$V_t = \max[\text{put price, PV(future cash flows)}]$$

Exhibit 36-14 is analogous to Exhibit 36-3. It shows the binomial tree with the values based on whether or not the investor exercises the put option at each node.

2. We assume cash flows occur at the end of the year.

EXHIBIT 36-11

Valuing a Callable Bond with Four Years to Maturity, a Coupon Rate of 6.5%, and Callable After the First Year at 100 (10% Volatility Assumed)

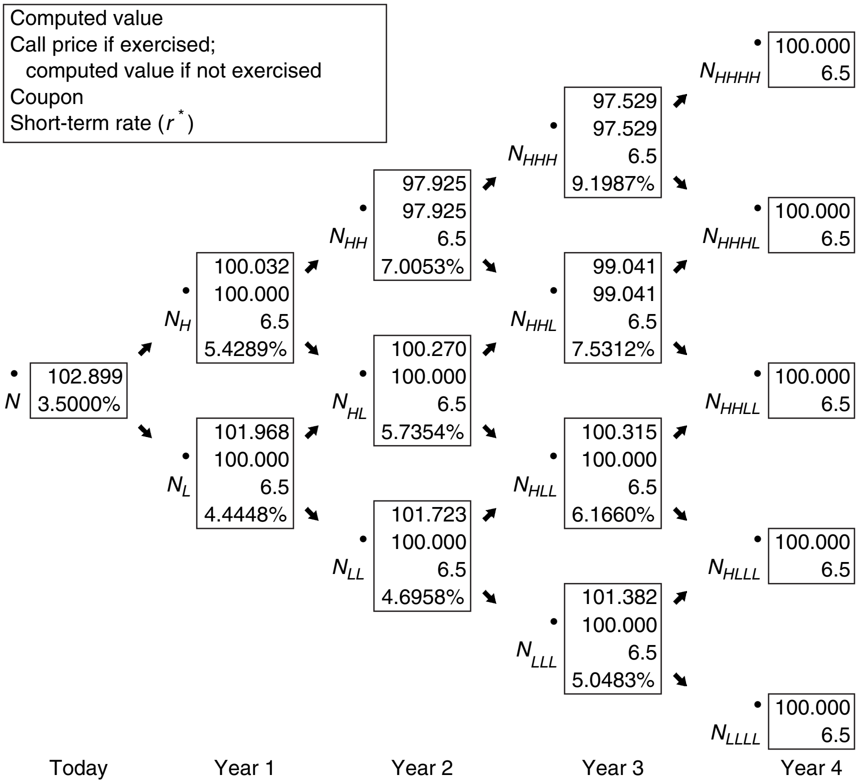


EXHIBIT 36-12

Featured Nodes in Years 2 and 3 for a Callable Bond: Nodes Where Call Option Is Not Exercised

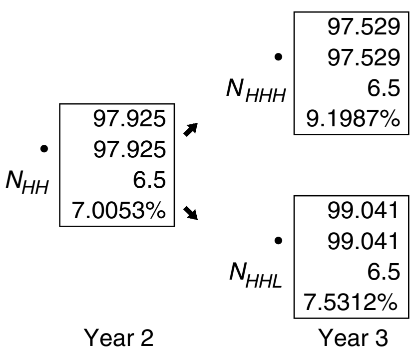

EXHIBIT 36-13

Featured Nodes in Years 2 and 3 for a Callable Bond: Selected Nodes Where the Call Option Is Exercised

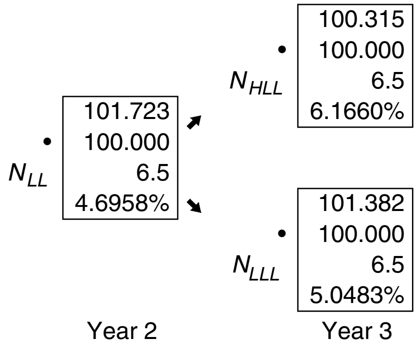

EXHIBIT 36-14

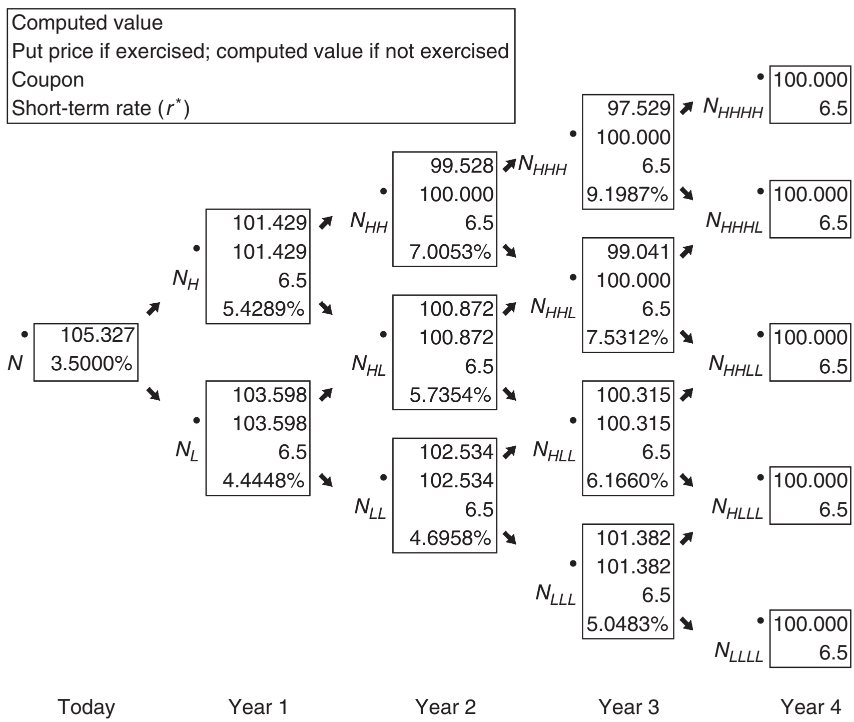
Valuing a Putable Bond with Four Years to Maturity, a Coupon Rate of 6.5%, and Putable after the First Year at 100 (10% Volatility Assumed)



The bond is putable any time after the first year at par. The value of the bond is 105.327. Note that the value is greater than the value of the corresponding option-free bond.

With the two values in hand, we can calculate the value of the put option. Since the value of the putable bond is 105.327 and the value of the corresponding option-free bond is 104.643, the value of the embedded put option purchased by the investor is effectively 0.684.

Suppose that a bond is both putable and callable. The procedure for valuing such a structure is to adjust the value at each node to reflect whether the issue would be put or called. Specifically, at each node there are two decisions about the exercising of an option that must be made. If it is called, the value at the node is replaced by the call price. The valuation procedure then continues using the call price at that node. If the call option is not exercised at a node, it must be determined whether or not the put option will be exercised. If it is exercised, then the put price is substituted at that node and is used in subsequent calculations.

VALUATION OF TWO MORE EXOTIC STRUCTURES

The lattice-based recursive valuation methodology is robust. To further support this claim, we address the valuation of two more exotic structures—the step-up callable note and the range floater.

Valuing a Step-Up Callable Note

Step-up callable notes are callable instruments whose coupon rate is increased (i.e., "stepped up") at designated times. When the coupon rate is increased only once over the security's life, it is said to be a *single step-up callable note*. A *multiple step-up callable note* is a step-up callable note whose coupon is increased more than one time over the life of the security. Valuation using the lattice model is similar to that for valuing a callable bond described earlier except that the cash flows are altered at each node to reflect the coupon characteristics of a step-up note.

Suppose that a four-year step-up callable note pays 4.25% for two years and then 7.5% for two more years. Assume that this note is callable at par at the end of year 2 and year 3. We will use the binomial tree given in Exhibit 36-9 to value this note.

Exhibit 36-15 shows the value of the note if it were not callable. The valuation procedure is the now familiar recursive valuation from Exhibits 36-12 and 36-13. The coupon in the box at each node reflects the step-up terms. The value is 102.082. Exhibit 36-16 shows that the value of the single step-up callable note is 100.031. The value of the embedded call option is equal to the difference in the optionless step-up note value and the step-up callable note value, 2.051.

EXHIBIT 36-15

Valuing a Single Step-Up Noncallable Note with Four Years to Maturity (10% Volatility Assumed)

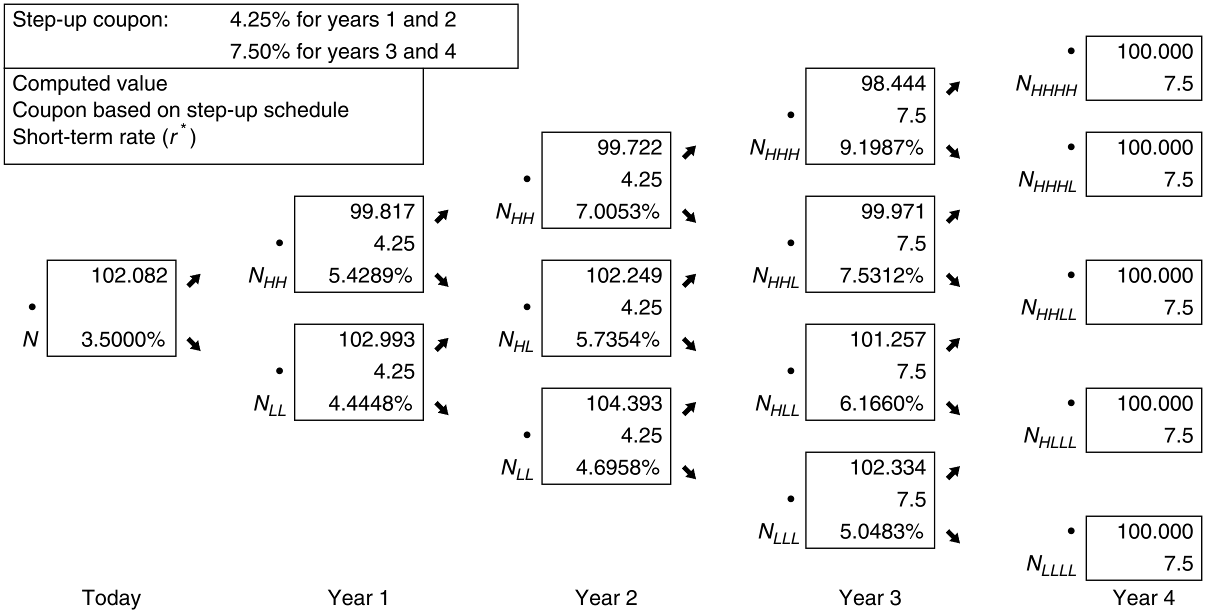


EXHIBIT 36-16

Valuing a Single Step-Up Callable Note with Four Years to Maturity, Callable in Two Years at 100 (10% Volatility Assumed)

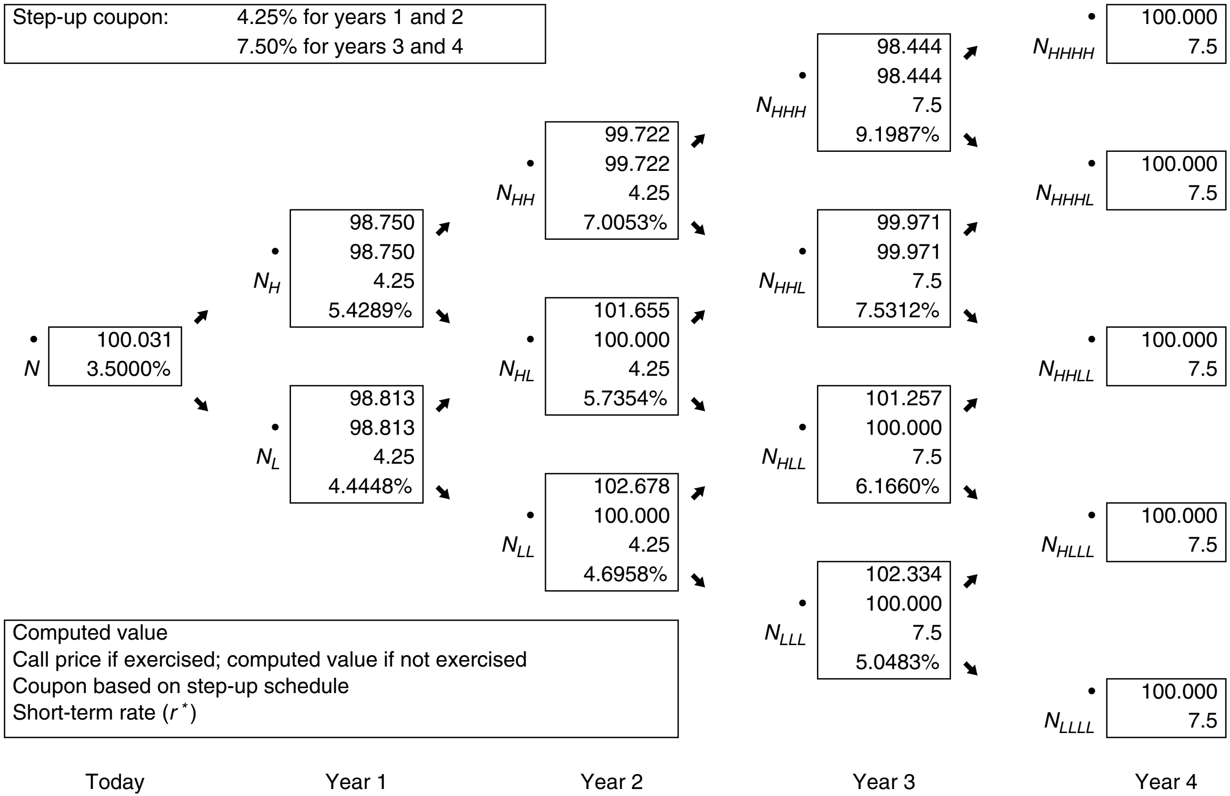

EXHIBIT 36-17

Coupon Schedule (Bands) for a Range Note

	Year 1	Year 2	Year 3
Lower limit	3.00%	4.00%	5.00%
Upper limit	5.00%	6.25%	8.00%

Now we move to another structure where the coupon floats with a reference rate but is restricted. In this next case, a range is set in which the bond pays the reference rate when the rate falls within a specified range, but outside the range no coupon is paid.

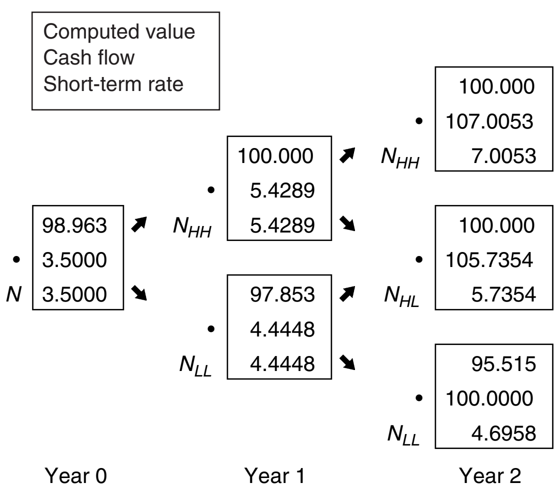
Valuing a Range Note

A *range note* is a security that pays the reference rate only if the rate falls within a band. If the reference rate falls outside the band, whether the lower or upper boundary, no coupon is paid. Typically, the band increases over time.

To illustrate, suppose that the reference rate is, again, the one-year rate and the note has three years to maturity. Suppose further that the band (or coupon schedule) is defined as in Exhibit 36-17. Exhibit 36-18 holds our tree and the cash

EXHIBIT 36-18

Valuation of a Two-Year Range Floater



flows expected at the end of each year. Either the one-year reference rate is paid, or nothing. In the case of this three-year note, there is only one state in which no coupon is paid. Using our recursive valuation method, we can work back through the tree to the current value, 98.963.

EXTENSIONS

We next demonstrate how to compute the option-adjusted spread, effective duration, and the convexity for a fixed income instrument with an embedded option.

Option-Adjusted Spread

We have concerned ourselves with valuation to this point. However, financial market transactions determine the actual price for a fixed income instrument, not a series of calculations on an interest rate lattice. If markets are able to provide a meaningful price (usually a function of the liquidity of the market in which the instrument trades), this price can be translated into an alternative measure of value, the option-adjusted spread (OAS).

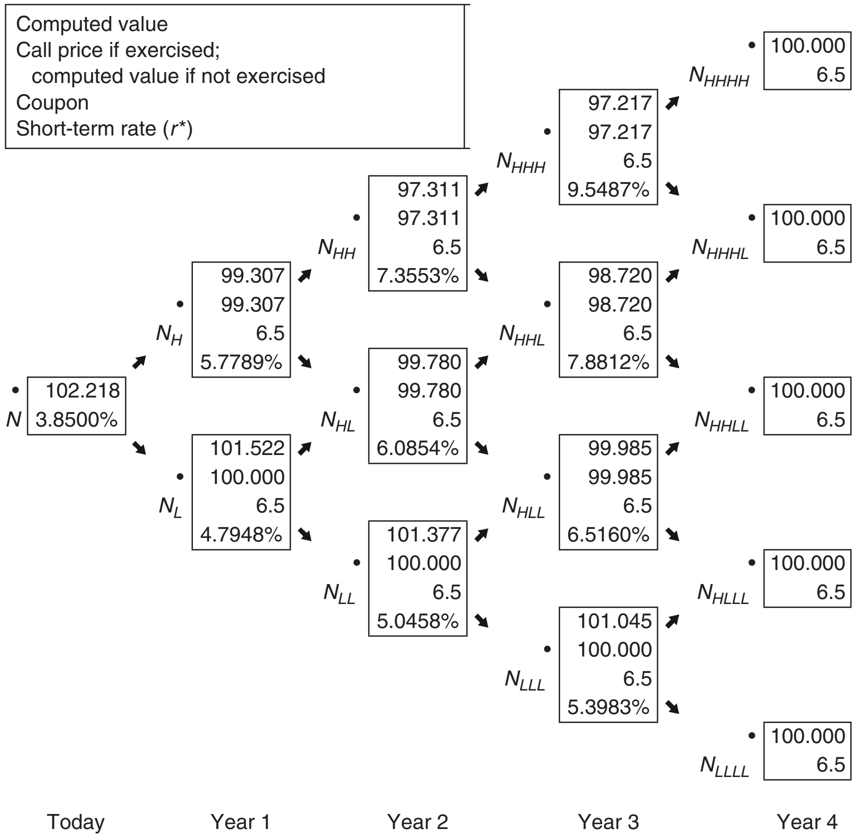
The OAS for a security is the fixed spread (usually measured in basis points) over the benchmark rates that equates the output from the valuation process with the actual market price of the security. For an optionless security, the calculation of OAS is a relatively simple, iterative process. The process is much more analytically challenging with the added complexity of optionality. And just as the value of the option is volatility-dependent, the OAS for a fixed income security with embedded options or an option-like interest-rate product is volatility-dependent.

Recall our illustration in Exhibit 36-11, where the value of a callable bond was calculated as 102.899. Suppose that we had information from the market that the price is actually 102.218. We need the OAS that equates the value from the lattice with the market price. Since the market price is lower than the valuation, the OAS is a positive spread to the rates in the exhibit, rates that we assume to be benchmark rates.

The solution in this case is 35 basis points, which is incorporated into Exhibit 36-19 that shows the value of the callable bond after adding 35 basis points to each rate. The simple binomial tree provides evidence of the complex calculation required to determine the OAS for a callable bond. In Exhibit 36-11, the bond is called at N_{HLL}. However, once the tree is shifted 35 basis points in Exhibit 36-19, the PV of future cash flows at N_{HLL} falls below the call price to 99.985, so the bond is not called at this node. Hence, as the lattice structure grows in size and complexity, the need for computer analytics becomes obvious.

EXHIBIT 36-19

Demonstration That the Option-Adjusted Spread Is 35 Basis Points for a 6.5% Callable Bond Selling at 102.218 (Assuming 10% Volatility)*



*Each one-year rate is 35 basis points greater than in Exhibit 36-11.

Effective Duration and Effective Convexity

Duration and convexity provide a measure of the interest rate risk inherent in a fixed income security. We rely on the lattice model to calculate the effective duration and effective convexity of a bond with an embedded option and other option-like securities. The formulas for these two risk measures are given below:

$$\text{Effective duration} = \frac{V_- - V_+}{2V_0(\Delta r)}$$

$$\text{Effective convexity} = \frac{V_+ + V_- - 2V_0}{2V_0(\Delta r)^2}$$

where V_- and V_+ are the values derived following a parallel shift in the yield curve down and up, respectively, by a fixed spread. The model adjusts for the changes in the value of the embedded call option that result from the shift in the curve in the calculation of V_- and V_+.

Note that the calculations must account for the OAS of the security. Below we provide the steps for the proper calculation of V_+. The calculation for V_- is analogous.

Step 1. Given the market price of the issue, calculate its OAS.

Step 2. Shift the on-the-run yield curve up by a small number of basis points (Δr).

Step 3. Construct a binomial interest-rate tree based on the new yield curve from step 2.

Step 4. Shift the binomial interest-rate tree by the OAS to obtain an "adjusted tree." That is, the calculation of the effective duration and convexity assumes a constant OAS.

Step 5. Use the adjusted tree in step 4 to determine the value of the bond, V_+.

We can perform this calculation for our four-year callable bond with a coupon rate of 6.5%, callable at par selling at 102.218. We computed the OAS for this issue as 35 basis points. Exhibit 36-20 holds the adjusted tree following a shift in the yield curve up by 25 basis points and then adding 35 basis points (the OAS) across the tree. The adjusted tree is then used to value the bond. The resulting value V_+ is 101.621.

To determine the value of V_-, the same five steps are followed except that in step 2, the on-the-run yield curve is shifted down by a small number of basis points (Δr). It can be demonstrated that for our callable bond, the value for V_- is 102.765.

The results are summarized below:

$$\Delta r = 0.0025$$
$$V_+ = 101.621$$
$$V_- = 102.765$$
$$V_0 = 102.218$$

Therefore,

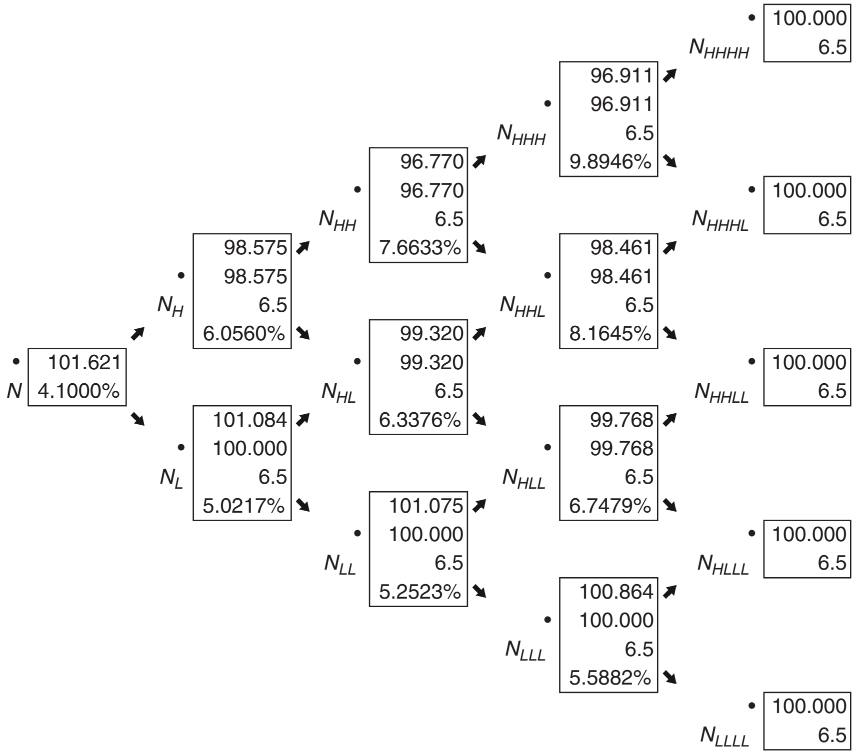
$$\text{Effective duration} = \frac{102.765 - 101.621}{2(102.218)(0.0025)} = 2.24$$

$$\text{Effective convexity} = \frac{101.621 + 102.765 - 2(102.218)}{2(102.218)(0.0025)^2} = -39.1321$$

Notice that this callable bond exhibits negative convexity.

EXHIBIT 36-20

Determination of V_+ for Calculating Effective Duration and Convexity*



*+25 basis point shift in on-the-run yield curve.

KEY POINTS

- For bonds with embedded options, the expected cash flow will depend on future interest-rate levels, which in turn depend on expected interest-rate volatility.
- An interest rate lattice provides a robust means for the valuation of a number of fixed income securities and derivatives.
- Given the market price of a bond, a lattice model can be used to obtain the option-adjusted spread to a benchmark yield curve based on an assumed interest rate volatility.

- A bond's OAS is the fixed spread (usually measured in basis points) over the benchmark rates that equates the output from the valuation process with the actual market price of the security.
- Effective duration and convexity can be computed for a bond by changing the yield-curve up and down by a given number of basis points and calculating what the new prices would be on the revised interest rate tree. These new prices are then used in the standard duration and convexity formula.

CHAPTER

THIRTY-SEVEN

VALUATION OF MORTGAGE-BACKED SECURITIES

Rajashri (Priya) Joshi, Ph.D.
Senior Quantitative Researcher, Mortgages and Structured Products
FactSet Research Systems

Debra Chen, CFA, Ph.D.
Associate Director, Mortgage and Structured Products Research
FactSet Research Systems

Tom P. Davis, CFA, Ph.D.
Director, Fixed Income and Derivatives Research
FactSet Research Systems

The valuation of a mortgage-backed security (MBS) is a complex undertaking that requires a variety of inputs and models, including an interest rate process, a prepayment model for projecting speeds along a given interest rate path, and numerous assumptions on the various macro drivers that can influence MBS cash flows. In this chapter, we describe the elements of MBS valuation and the steps involved in pricing an MBS. We start the chapter by reviewing the traditional static valuation techniques that are used for analyzing fixed income securities and explain why they are of limited use when valuing bonds with embedded options, like MBS. We then introduce Monte Carlo simulation and describe several popular interest rate models used for valuing mortgage products. Next, we provide an overview of the overall mortgage modeling framework. This section includes a brief introduction to prepayment models and how they are used in conjunction with term structure models to project the cash flows on mortgage-backed securities. We then introduce option-adjusted spread (OAS) and related analytical measures. We conclude the chapter with an illustrative example.

STATIC VALUATION AND ITS LIMITATIONS

The value of a bond is the present value of its expected future interest and principal payments, that is, its total cash flows, as shown in Equation 37-1:

$$V=\sum_{n=1}^{N}\frac{CF_n}{\left(1+r_n\right)^n}, \tag{37-1}$$

where CF_n is the total cash flow in the nth period, r_n is the discount rate corresponding to a tenor of n periods, and N is the remaining term. Using Equation 37-1, we can back out the **yield to maturity** (YTM) given the market price P of the bond, as illustrated in Equation 37-2. YTM is the anticipated rate of return on a bond if the bond is held until maturity and all intermediate cash flows are reinvested at that same rate, which is unlikely to occur in practice:

$$P=\sum_{n=1}^{N}\frac{CF_n}{\left(1+YTM\right)^n}. \tag{37-2}$$

Yield to maturity has a few common variations to better handle bonds that have embedded options. *Yield to call* assumes that the bond will be called as soon as permitted, and it is therefore calculated using a shorter set of cash flows than is used in the calculation of yield to maturity. *Yield to worst* is used when a bond has multiple embedded options—it is the lowest yield based on all call dates listed in the prospectus.

It is also useful to measure the excess return that a bond offers over a selected benchmark in order to gauge relative value. The simplest such measure is *nominal spread*, which is simply the difference between the yield of the bond and the yield of a similar-maturity Treasury. Mortgage-backed securities return principal to investors throughout the life of the pool. So, the nominal spread on an MBS is typically computed as the difference between yield to maturity and interpolated Treasury yield at the mortgage bond *weighted average life* (WAL). The weighted average life is the average time to receipt of principal, as shown as in Equation 37-3:

$$WAL=\frac{1}{12}\frac{\sum_{n=1}^{N}n\times P_n}{\sum_{n=1}^{N}P_n} \tag{37-3}$$

where P_n is the principal received in month n. In other words, WAL is the time it takes for half of the face value to be returned to the investor. Prepayments (defined below) on mortgage-backed securities reduce the WAL and can hurt or help returns, depending on whether the bond was purchased at a premium or at a discount.

Nominal spread, though simple, has limited value because it is computed with reference to a single point on the benchmark yield curve and therefore does not account for the fact that MBS principal is returned to investors throughout the life of the pool. A better measure of incremental return versus a benchmark is z-spread, which can be found by solving Equation 37-4:

$$P=\sum_{n=1}^{N}\frac{CF_n}{\left(1+y_n+z\right)^n} \tag{37-4}$$

where y_n is the interpolated Treasury/swap yield corresponding to a tenor of n periods. Note that the z-spread may be computed off of the spot yield curve, as shown above, or off of the forward curve, as shown in Equation 37-5:

$$P = \sum_{n=1}^{N} \frac{CF_n}{\prod_{m=1}^{n} \left(1 + f_m + z\right)} \tag{37-5}$$

where f_m is the one-month forward rate for month m. The z-spread is sometimes referred to as the zero vol OAS.

Investors are also interested in gauging how much the value of their portfolio will change in response to a given change in yield. *Modified duration* measures the percentage change in the price of a bond in response to a change in interest rates, as shown in Equation 37-6:

$$ModD = -\frac{1}{P}\frac{dP}{dy} = \frac{\sum_{n=1}^{N} \frac{n \times CF_n}{(1+y)^{n+1}}}{\sum_{n=1}^{N} \frac{CF_n}{(1+y)^{n}}} = \frac{\frac{1}{(1+y)} \sum_{n=1}^{N} n \times PV(CF_n)}{\sum_{n=1}^{N} PV(CF_n)} \tag{37-6}$$

Two related measures are *dollar duration*, which measures the change in the value of a bond for a 100 bps change in rates and *DV01*, which measures the change in the value of a bond for a 1 bp change in rates. *Key rate durations* are extensions of bond duration—they measure the sensitivity of bond price to a change in yield at a specific maturity point on the curve. Collectively, the various measures of duration help fixed income investors design effective investment strategies and gauge risk when managing their portfolios.

Drawbacks of Static Valuation for MBS Analysis

The static valuation metrics described above are widely used in the industry for evaluating many types of bonds and assessing relative value. But a complexity arises in the valuation of mortgage-backed securities because the collateral cash flows are sensitive to the interest rate environment and its evolution. Mortgage loans are usually prepayable by the borrower at any time, so the total principal paid on an MBS pool in any month is the sum of scheduled principal and prepaid principal. In fact, prepayments typically constitute the dominant component of principal payments over the life of the pool.

Prepayment rates or speeds can be measured in terms of a *single monthly mortality* (SMM) rate, which is the ratio of unscheduled principal to the "prepayable" balance. More precisely, the SMM in month n is given by Equation 37-7:

$$SMM_n = \frac{P_n - SP_n}{Bal_{n-1} - SP_n} \tag{37-7}$$

where Bal_{n-1} is the actual balance at the *end* of month $n-1$ while P_n and SP_n are the total and scheduled principal payments occurring *during* month n. Prepayment speeds are usually reported as an annualized percentage rate called the "conditional prepayment rate" (CPR), as shown in Equation 37-8:

$$CPR = 100 \times \left(1 - \left(1 - SMM\right)^{12}\right) \tag{37-8}$$

Perhaps the most obvious limitation of the static approach for MBS analysis is that the prepayment projections, cash flows, and associated valuation metrics are contingent on the single assumed primary mortgage rate path being realized. Any deviation of realized primary mortgage rates from this projected path can dramatically alter the MBS cash flows and any assessments of relative value.

Another drawback of the static approach is that the static yield may significantly overstate the return that the investor will achieve. As mentioned above, yield equals return only if the bond is held to maturity and the reinvestment rate on all intermediate cash flows equals the yield itself. However, in the case of an MBS, this shortcoming is amplified by the impact of the embedded prepayment option. When rates rally, prepayment rates increase, and more principal is returned to the investor, which must be reinvested at a lower rate, resulting in a lower return than implied by the static yield. Conversely, when rates rise, prepayment rates decrease, and less principal is returned to the investor, which cannot be reinvested at a higher rate, again resulting in a lower return than implied by static yield.

An MBS usually offers a higher static yield than duration-matched Treasury securities or swaps. This makes sense, because an unhedged MBS investor is taking a view not only on interest rate levels but also on interest rate volatility. If rates do not move much over the holding period, an MBS position that is duration-hedged with an appropriately sized short position in Treasuries or swaps should provide a positive return, as predicted by the nominal yield spread. But if rates move significantly and prepayments vary, an MBS will likely underperform its duration hedge. Static yield fails to alert the investor to this dynamic behavior. Likewise, z-spread tends to overstate the excess return that an investor can achieve because the impact of the embedded prepayment option is ignored under a static rate assumption.

Yet another limitation of the static valuation approach is that modified duration (defined back in Equation 37-6) cannot be used to accurately gauge the sensitivity of MBS prices to interest rates. This simple method for calculating duration is unable to account for the sensitivity of the cash flows themselves to interest rates and the resulting "price compression" that occurs when yields fall. When rates rally, prepayment speeds increase, leading to a lower price than on an otherwise identical option-free bond.

To be sure, static valuation techniques can be useful for evaluating certain types of mortgage-backed securities with limited prepayment risk—for example, call-protected CMO classes, certain types of nonagency RMBS and CMBS, or

MBS pools backed by adjustable-rate mortgages. But the static metrics are of limited value in analyzing most other types of MBS, including fixed-rate mortgage pass-throughs, interest rate-sensitive CMO classes such as support tranches, and mortgage derivatives (such as IO and PO classes, floaters, and inverse floaters). Indeed, the static metrics are likely to lead to unreliable assessments of relative value across much of the MBS universe.

In contrast with the static valuation approach, the MBS valuation process is quite involved and computationally intensive because it requires the use of several complex models, numerous market inputs and assumptions, and a wide range of borrower and loan attributes. Prepayment models and the speed projections that they produce are at the center of mortgage security valuation and analysis. But mortgage valuation also calls for an option pricing model that can handle the unique characteristics of MBS cash flows, including interest rate sensitivity and path dependence (introduced later in this chapter). So, before we dive into the elements of prepayment modeling, we review several popular interest rate models and introduce Monte Carlo simulation for valuing mortgage-backed securities.

MONTE CARLO MODELS FOR VALUING MBS

MBS valuation calls for a methodology that accounts for the impact of interest rate volatility and fully adjusts for the value of the embedded option. So, how can we go about valuing the option? A closed-form solution, when available is ideal. But closed-form valuation formulas, like the one provided by the Black-Scholes option pricing model, only exist for the simplest types of options such as plain vanilla European-style options on stocks or swap rates. These closed-form formulas are based on arbitrage freedom and dynamic hedging and are certainly not available for valuing options as complex as the prepayment option that is embedded within mortgage-backed securities.

Monte Carlo is a statistical method wherein the set of financial observables required for pricing are simulated many times—each simulation is known as a "path." The security cash flows are then determined on each path and the price is determined as the average of the discounted cash flows over all paths.

Broadly speaking, there are four steps in the Monte Carlo process. First, a model of interest rates must be selected, where the choice of model is determined by characteristics of the security—a balance must be struck between sufficient realism to capture the dynamics that drive the variability in the security price and computational complexity. Second, the model must be calibrated, which amounts to selecting the parameters based on some predetermined criteria. At this point, if the model is too computationally expensive, factor reduction must be employed. Factor reduction is a method of reducing the model complexity such that the price of the security can be determined in a reasonable amount of time with limited resources. The final step is to generate the paths by using the calibrated model to evolve the financial observables and price the security.

We briefly describe each of these steps in the next sections. Our goal here is not to provide a full exposition on term structure modeling and Monte Carlo methods, but rather to give the reader a sense of the various types of term structure models, the considerations that go into selecting a model, and the elements of Monte Carlo simulation.

Choosing an Interest Rate Model

The 10-year swap rate is closely correlated with the primary mortgage rate that is a key driver of MBS cash flows and valuations. The swap rate is a weighted average of observable forward rates where the weightings are determined by the prices of zero-coupon bonds throughout the entire 10-year tenor of the swap. Therefore, as expected LIBOR rates rise, the swap rate correspondingly rises. However, as the shape of the yield curve changes to inverted or to hump-shaped, the corresponding swap rate changes are harder to intuit. It is clear that any model of the evolution of expected LIBOR rates must contain sufficient structure to model the covariances that exist between the LIBOR rates in a realistic way.[1]

Modeling the future evolution of interest rates can be done in a number of ways. The simplest class of models are econometric models, most notably the Nelson-Siegel parameterization, which uses economic motivation to parameterize the yield curve. The parameters are determined for each of a series of dates in the past, and the future values are predicted by using the historical covariances of the parameters. This type of evolution is known as the "real-world measure" approach and is widely used in risk modeling where the future evolution of the yield curve must closely reflect the past evolution, as well as economic forecasting by central banks. However, a drawback of this method is that it does not fit today's term structure exactly and therefore would not correctly price hedging instruments.

The preferred alternative is to use an arbitrage-free model of the term structure. Arbitrage freedom guarantees that the securities that are used to hedge MBS (such as Treasuries and swaps) are correctly priced on all future paths, making it less likely that the target security is mis-hedged. Arbitrage freedom is guaranteed by the Heath-Jarrow-Morton (HJM) condition, which is a relationship between the drift and volatility of the evolution of the forward curve. There are two general classes of HJM models: continuous-rate models and market models.

In continuous-rate models, the yield curve is represented by the instantaneous forward rate, that is, the rate at a specific time for lending over an infinitesimally short time horizon. The most well-known of the continuous-rate models are

1. Tier 1 banks will no longer be required to respond to the LIBOR poll after December 2021, implying that LIBOR may cease to be a valid index after that date. It is expected that the swap market will still be active and liquid but will be based on an alternative index: SOFR in the United States, SONIA in the United Kingdom, ESTR in the Eurozone, and SARON in Switzerland.

the short-rate models such as those due to Ho-Lee,[2] Black-Karasinski,[3] Vasicek,[4] and Hull-White.[5] These are models of the instantaneous short rate, and this one factor drives the dynamics of the entire forward rate curve. No single-factor model will perform adequately for applications to MBS, since their use will inevitably lead to high static correlations between forward rates. There also exist multifactor extensions to these single-factor models that can capture a more realistic structure of the correlations and covariances between the observable forward rates. However, a drawback of all continuous-rate models is that the short rate is not a true financial observable since there is no market security that transacts which depends on this hypothetical rate.

The other classes of HJM models are market models, where the underlying factors are the observable rates themselves. The most popular model in this class is the LIBOR market model,[6] where the set of forward LIBOR rates spanning a time horizon are the stochastic factors.

Exhibit 37-1 summarizes the benefits and drawbacks of several popular interest rate models. The continuous-rate models have the benefit of simplicity and, in the case of some models, admit closed-form solutions for the prices of certain types of securities. Closed-form solutions can greatly enhance the accuracy (as well as the speed) of the Monte Carlo simulations. However, the drawback of all one-factor models is that they cannot adequately simulate the covariance structure necessary to generate realistic dynamics for the swap rate.

The LIBOR Market Model: The preferred interest rate model for pricing mortgage-backed securities is the LIBOR market model (LMM), since it has many underlying factors and therefore can accurately capture the swap rate dynamics. Another benefit of the LMM is that the stochastic factors are financial observable quantities, rendering the calibration process and results much more intuitive. The underlying factors in the LMM are the forward LIBOR rates that span the time from today to the last required simulated date. Typically for mortgages, this is 30 years into the future, which means the LMM can have hundreds of stochastic factors. Therefore, after calibration is performed, a factor reduction step is necessary.

Each individual forward rate is assumed to be lognormally distributed, with a drift that is calculated via the HJM condition to ensure arbitrage freedom. Each

EXHIBIT 37-1

Benefits and Drawbacks of Popular Interest Rate Models

Model	*Benefits*	*Drawbacks*
Ho-Lee	Closed-form solutions for bond options, caps/floors, swaptions.	Unrealistic modeling of the interest rate, no mean reversion.
Hull-White	Closed-form solutions for bond options, caps/floors, swaptions. Mean reversion, implying a humped structure for the volatility term structure, something usually seen in market data.	Single-factor models lead to a much higher forward rate correlation than is seen in the market.
Black-Karasinski	Lognormal rates, meaning rates cannot go negative. Until recently, the nonnegative rates assumption was heralded as a benefit of interest rate models. However, in 2015 many non-U.S. rates were seen to go negative.	Leads to nonsensical results for Eurodollar futures, due to its lognormality of rates.
LIBOR Market Model	Driving factors are financial observables. Approximate closed form for swaptions.	High dimensionality of the model can lead to large computational runtime.

of the forward LIBOR rates has a volatility $\sigma_j(t)$, and every pair of forward LIBOR rates has a correlation ρ_{jk}. The dynamics of the forward LIBOR rates are described by the following stochastic differential equation:

$$dL_j(t) = \begin{cases} -L_j(t)\sum_{k=1}^{i-1}\frac{\tau L_k(t)}{1+\tau L_k(t)}\sigma_j(t)\sigma_k(t)\rho_{jk}dt + \sigma_j(t)L_j(t)dW_i & j < i \\ L_j(t)\sigma_j(t)dW_i & j = i \\ L_j(t)\sum_{k=i+1}^{N}\frac{\tau L_k(t)}{1+\tau L_k(t)}\sigma_j(t)\sigma_k(t)\rho_{jk}dt + \sigma_j(t)L_j(t)dW_i & j > i \end{cases} \tag{37-9}$$

Although as written, the LMM cannot handle negative rates, adding a shift parameter is straightforward,[7] and necessary in today's global low-rate environment. This parameter can be calibrated, but typically is set to a small negative level. Alternatively, the LMM can be written such that the forward LIBOR rates follow a normal distribution. There also exist other extensions of the LMM:

7. Eymen Errais, Gianvittorio Mauri, and Fabio Mercurio. "Capturing the Skew in Interest Rate Derivatives: A Shifted Lognormal LIBOR Model with Uncertain Parameters." *Banca IMI Internal Report* (2004).

constant elasticity of variance,[8] stochastic volatility,[9] and jump diffusion.[10] However, these extensions greatly increase the computational complexity of Monte Carlo simulation and are therefore not used as often as the parsimonious normal and shifted lognormal variations.

Calibrating the Model

The parameters required to calibrate the LMM are the initial term structure of interest rates and the covariance matrix containing the volatilities and pairwise correlations of all forward LIBOR rates. There are two approaches to determining the parameters of the model.

The first approach is based exclusively on the historical data. The entries in the covariance matrix are estimated by looking at the relevant historical time series. However, historical time series analysis typically produces covariance matrices that render the model internally inconsistent. Furthermore, if a purely historical approach is used, then the model is not guaranteed to reflect the information on the future evolution of interest rates implied by the current prices of securities.

The preferred approach is to calibrate the covariance and correlation to the current prices of market instruments. Market-implied calibration begins with the current prices of traded securities and the initial term structure of interest rates: short-term cash instruments, forward-rate agreements, swaps, caps/floors, and swaptions. As with all HJM models, the initial term structure of interest rates is an input and therefore the prices of zero-coupon bonds are guaranteed to be exactly reproduced on average by the Monte Carlo simulation. Collectively, caps and floors contain the information about the volatility of the set of forward rates. Swaptions are used to extract the correlations between the forward rates. The output of the calibration process is the covariance matrix that is implied by the market prices of currently traded securities. The entire calibration process can be tested by so-called round tripping, where the calibrated model is used to reproduce the prices of the instruments used in calibration, either exactly or in a least-squares sense.[11]

11. In some parametric forms of the volatility term structure, the prices of market securities cannot all be exactly matched. In this case, the best fit is produced by minimizing the error between the market and model prices.

Factor Reduction

For LIBOR market models, there can be dozens to hundreds of underlying factors that need to be simulated. By choosing even a modest number of Monte Carlo paths, this could result in the need to generate millions of correlated random numbers, which is untenable in terms of computational time as well as storage requirements. Factor reduction techniques help to mitigate this issue.

The goal of factor reduction is to reduce the number of stochastic factors of the model in such a way that the covariance structure is preserved as much as possible. This is accomplished by performing a principal component analysis (PCA) on the calibrated covariance matrix. The calculation is iterative in nature and finds the linear combination of factors with the maximal variance; the first principal component explains the greatest fraction of covariance in the original model, the second explains the next greatest fraction, and so on. Typically, the first few principal components contribute a high fraction of the covariance, and therefore only a small number are retained. Increasing the number of principal components leads to a more faithful model, but at the expense of greater computational complexity.

For interest rate movements, the first three principal components are directly related to the three well-known movements of the yield curve: parallel shift, twist, and buckle. These three principal components will generally explain a large share of the entire covariance of the yield curve. Since the amount of covariance explained can be quantified, it can be used as the decision criterion to determine how many principal components to use in the Monte Carlo simulation. Usually the first three principal components suffice, as they typically account for over 70% of the total covariance.

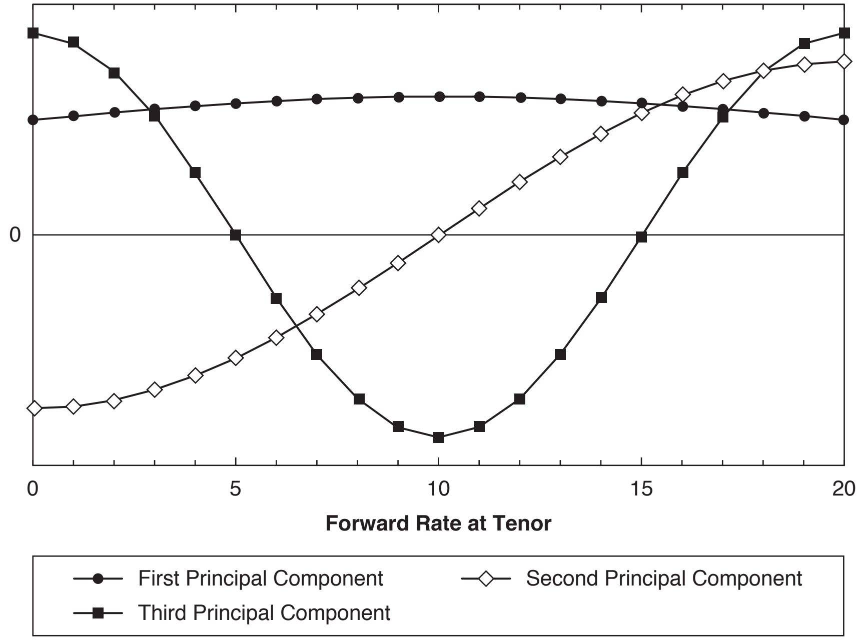
Exhibit 37-2 displays a typical principal component analysis showing the first three principal components of a covariance matrix describing forward rates. The largest contribution to the covariance of the forward curve comes from the first principal component, which is represented by a linear combination of LIBOR rates with all positive contribution—it therefore represents parallel shifts of the yield curve. The linear combination corresponding to the second largest contribution changes sign representing a twist effect. The third largest contribution is seen to change sign twice, and this contribution is known by various names such as "shape effect" or "buckle."

Path Generation

The final step is to generate correlated random numbers and construct the arbitrage free paths of the future observable rates. Exhibit 37-3 shows 200 possible interest rate paths from the shifted LIBOR Market Model. On each path, the prepayment model and the cash-flow engine (both of which are discussed in the next section) are used to generate the speeds and corresponding cash flows. Given the cash flows, the bond can be priced. The error in the Monte Carlo estimate decreases as the number of paths increases. Therefore, choosing a large number

EXHIBIT 37-2

Largest Principal Components of the Forward Curve—Shift, Twist, and Buckle

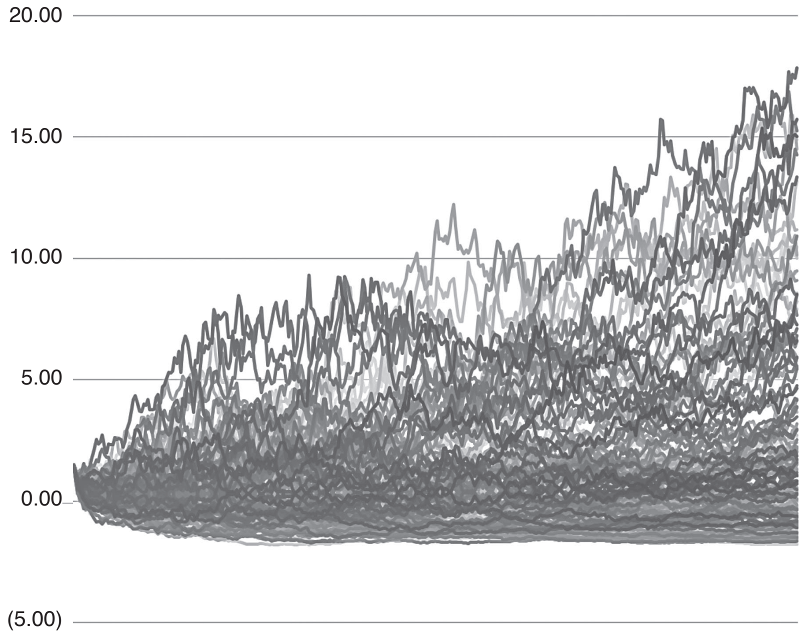


of paths is desirable, but this choice must be balanced against the constraint that the pricing calculation needs to complete in a reasonable time. This is of particular concern in the analysis of mortgage-backed securities since computing the cash flows on each individual path takes a relatively long time due to the complex relationship between interest rates and prepayments. Furthermore, in the case of CMOs, the cash-flow waterfall (which is itself path dependent) must be applied along each path.

Since Monte Carlo is a statistical technique, the resulting price has a distribution; each simulation (performed using a different set of random numbers) results in a different price. Therefore, the price has an associated variance that can be reduced in two ways. Increasing the number of paths will certainly reduce the variance. Alternatively, variance reduction techniques can be applied that can produce a more accurate result for a given number of paths. These techniques typically use knowledge of the specific problem under consideration. However, there is one variance reduction technique that can be applied to any Monte Carlo problem—for every vector of random numbers used to generate a Monte Carlo path, the complement of this path is also generated by using the negative of the original random numbers. This eliminates any bias in the paths that could be introduced by the random nature of the sampling process.

EXHIBIT 37-3

Monte Carlo Paths Generated Using the Shifted LIBOR Market Model (Shift = 200 Bps)



MBS MODELING FRAMEWORK

Next, we turn to the problem of projecting the future cash flows on a mortgage pool given a primary mortgage rate path. This requires a prepayment model as well as a mechanism for projecting the primary mortgage rate, a forecast for home price appreciation (HPA), and finally a cash-flow calculator. We describe each of these components next.

Projecting the Primary Mortgage Rate

Any forecast of MBS prepayments is contingent on a specified path of the primary mortgage rate. While primary mortgage rates are closely correlated with other market rates such as Treasury yields or swap rates, mortgage rates are also influenced by drivers unique to the mortgage market (such as pricing in the secondary mortgage market) as well as by certain non-market-driven factors. Because of this, a nontrivial methodology is required to translate the interest rate paths generated by Monte Carlo simulation into primary mortgage rate paths. A useful first step is to decompose the primary rate into the current coupon yield and the primary–secondary spread. The current coupon yield is the yield on a (likely hypothetical) par priced MBS and the primary–secondary spread is the difference between the prevailing primary mortgage rate and the current coupon yield. The goal here is to isolate the secondary market component that moves more tightly with swap or Treasury yields from the spread component that is less market driven.

There are two main approaches used in the market for estimating the current coupon yield: a regression-based approach and a risk-neutral approach. The regression-based method is simple and intuitive—the historical data is regressed on one or more market rates, say, for example, the 2-year and 10-year swap or Treasury yields. But this methodology ignores the fact that mortgage rates are driven by all tenors on the yield curve. An alternative is to utilize a risk neutral method like Citi's Mortgage Option-Adjusted Term Structure (MOATS) model methodology.[12] In this approach, the current coupon yield is calculated within the Monte Carlo generator itself via a backward-induction algorithm that accounts for the prepayment option. This approach results in a more dynamic and realistic model of the primary rate but is much more computationally intensive. Both methods are widely used in the market, but one model may be more suitable than the other depending on the prevailing market environment.

The other component of the primary rate, the primary–secondary spread, consists of two components: the guarantee fee (or "g-fee") that is charged by the agency and the servicing spread, which is compensation to the loan servicer. The guarantee fee itself consists of an upfront component and an ongoing component. Upfront fees are paid to the agency at origination and they are a function of a variety of loan attributes such as loan-to-value ratio, borrower attributes such as credit score, and several other factors. The ongoing component of the guarantee fee is built into the primary rate that is offered to potential borrowers. But lenders also will typically convert the upfront component of the g-fee to an ongoing basis and add it to the mortgage rate that the borrower pays.

Turning to the servicing spread, the government sponsored enterprises (GSEs), that is, Fannie Mae and Freddie Mac, usually require a minimum of 25 bps of retained servicing for 30-year fixed loans. The remainder of the servicing spread beyond the mandated minimum is known as excess servicing and lenders have some discretion in setting the level. Excess servicing can rise significantly in response to market conditions, especially during periods of housing market distress or when delinquency rates begin to rise.

The risk of loan putback can also lead to a widening in the level of excess servicing. The GSEs have the right to put back to lenders loans that violate any of the reps and warrants (R&W). Reps and warrants allow the GSEs to purchase and guarantee loans without having to perform a thorough credit evaluation on each loan—therefore, they help to support credit availability. But putback costs

12. Ranjit Bhattacharjee and Lakhbir S. Hayre, "The Term Structure of Mortgage Rates," *The Journal of Fixed Income* (Spring 2006), pp. 34–47.

skyrocketed during the financial crisis as defaults surged and the GSEs became more aggressive in terms of enforcing the reps and warrants. To mitigate the risk of putback, originators began applying credit overlays and expending more time and effort into underwriting, leading to higher underwriting costs. Putback risk has eased over the past few years as the GSEs have taken steps to provide rep and warrant relief, including the introduction of sunset provisions.

Finally, the level of excess servicing is also influenced by mortgage lending capacity vis-à-vis demand. When rates drop quickly, the demand for refinancing loans (as well as purchase loans) tends to spike and overwhelm the origination pipeline, leading to "capacity constraints" in the mortgage lending system. It takes time for the industry to add loan origination capacity to meet the increased demand. In the interim, lenders' pricing power increases, which can lead to a widening of the level of excess servicing. As the industry gradually staffs up and capacity constraints ease, excess servicing gradually reverts to more "normal" levels.

Modeling Mortgage Prepayments

Practitioners generally rely on econometric prepayment models, and associated auxiliary models, to generate speed forecasts. These models project speeds based on a selected set of explanatory variables and make many assumptions on the future evolution of the drivers of prepayments along with the interrelationships between the various sources of prepayments. A good model is based on intuitive relationships that are likely to persist over time. But a modeling framework must also be dynamic and flexible enough for the modeler to quickly react to regime shifts or changes in the macro backdrop. Given the amount of judgment and the wide range of assumptions that go into a model, any set of prepayment projections clearly contains an element of subjectivity. In short, MBS prepayment modeling and valuation is part science, part art.

Practitioners should take the time to fully understand the model assumptions and the implications on valuations. A practitioner should also be aware of the scope of the model in use, recent market changes that the model may not be capturing, and any other limitations. The practitioner should ask questions such as the following:

- Are there important prepayment drivers that the model excludes?
- Is the model capturing the impact of recent regulatory initiatives?
- Is the projected primary mortgage rate path reasonable?
- Is the model assumption on home price growth realistic?
- Are baseline speeds appropriate, given the economic environment and housing fundamentals?

Most prepayment models expose certain dials that the practitioner can adjust in order to express a difference of opinion versus the model assumptions or to extend the model to handle out-of-scope collateral types. Common user-facing dials include refi and turnover multipliers, refi S curve steepener/flattener and elbow shift, length of the turnover seasoning ramp, and overrides on external economic drivers such as home price growth.

With these considerations in mind, we examine the sources of prepayments in MBS pools and their key drivers.

Rate-driven refinancings: Refinancings are the most volatile component of prepayments, with speeds surging when rates decline and falling sharply when rates increase. From this perspective, an MBS pool can be likened to a callable corporate bond. However, rate-driven refis are much harder to predict than corporate bond redemptions for several reasons:

- Mortgage-backed securities have embedded within them hundreds or thousands of individual prepayment options—the investor has in effect sold a call option to each underlying borrower. So, it is necessary to project the collective responsiveness of numerous borrowers versus a single entity (typically the chief financial officer of the issuing corporation).
- The economics of refinancing differs across borrowers because of factors such as variation in the note rate, expected home tenure, and credit profile.
- Redemption efficiency also varies across borrowers as the most financially savvy borrowers tend to refinance relatively promptly, while less savvy or more credit-impaired borrowers are more likely to delay exercise.

The refi response function is modeled as an S curve representing the relationship between refi speeds and interest rate incentive. A pool's aggregate S curve is not static—it represents the rate sensitivity of prepayment speeds at a particular point in time, based on the composition of the pool at that time and prevailing market conditions. The shape of the S curve (slope, amplitude, and elbow) gradually changes over time as the pool composition evolves, in part because of the difference in realized speeds across the fast and slow populations within the pool. The economic environment, underwriting standards, and policy initiatives also drive the overall shape of the S curve. Seasoning also plays a role—pools backed by newly originated loans tend to be less responsive to interest rates, as borrowers who have just refinanced or recently purchased a home are less likely to immediately move or refinance again, regardless of rate levels. Reactivity gradually increases, or equivalently, the S curve becomes steeper, as the pool seasons. But responsiveness tends to be lower on very seasoned pools, as the most reactive borrowers have already exited the pool.

Cashout refis: Borrowers who have accumulated significant equity since loan origination (via amortization or an increase in home value) may refinance the existing loan to extract some of that equity—this is known as a cashout refi. The borrower may be facing financial hardship or may wish to use the cash for home improvements or to pay down non-tax-deductible consumer debt. As the name implies, cashouts are primarily motivated by a desire for cash rather than a lower rate. Cashouts do usually result in a lower mortgage rate, but under certain circumstances, a borrower may choose to extract built-up equity even if it does not lead to a lower mortgage rate.

Home price growth, housing market sentiment, and easing lending standards are key determinants of cashout refi speeds, which can be very significant under favorable market conditions. Cashouts were popular in the years leading up to the financial crisis, but almost disappeared during the crisis as home prices plummeted and underwriting standards tightened. In recent years, the share of cashout refis has picked up again fueled by an improving macro backdrop, strong home price growth, and gradually easing underwriting standards.

Credit-driven refis: Borrowers whose credit profile has measurably improved since loan origination may be able to qualify for cheaper financing, even if overall interest rates have not declined—this is known a credit-driven refi. In theory, credit-driven refi rates should be negligible for several months after loan origination and tend to gradually rise as the pool seasons and the underlying borrowers continue to make on-time payments on their mortgages and other financial obligations.

Housing turnover: Housing turnover is the second most significant source of prepayments in agency MBS pools and generally becomes the dominant component of total speeds when a pool is out of the money. Conventional mortgage loans typically contain a "due on sale" clause, so a property sale leads to a prepayment of the outstanding loan balance. Turnover speeds tend to be very slow early in the life of a mortgage pool, especially in the case of purchase loans, as borrowers who have recently moved are unlikely to do so again for a while. Turnover speeds typically rise to their fully seasoned level over the course of two to three years. Turnover speeds also show a strong seasonal pattern with speeds peaking during the summer months and dropping off in winter.

Turnover does show mild dependence on interest rates—mortgage rates influence affordability, so higher rates can make it harder for borrowers to trade up. Furthermore, a borrower with a below-market note rate may be reluctant to relinquish that rate and may delay moving. This phenomenon is known as "lock-in." However, home sales are much less dependent on interest rates than refinancings because they are often motivated by necessity (e.g., marriage, divorce, growing family, and job change), placing a floor on turnover speeds as well as total prepayment speeds.

Curtailments: Debt aversion or the desire to build equity faster may lead some borrowers to accelerate loan paydown by remitting more than the scheduled monthly payment. This is known as a curtailment and is passed through to investors as a partial prepayment of the outstanding balance. Curtailments, as well as full payoffs, tend to be very low early in the life of a pool, but become significant late in the life of a pool as borrowers grow older and wish to eliminate mortgage debt prior to retirement. Older borrowers may also be more financially stable than their younger counterparts and are more likely to have spare cash available that can be used to reduce mortgage debt.

Involuntary prepayments: When a borrower stops making timely mortgage payments, the owner of the mortgage note has the right to foreclose on the property, leading to a prepayment, principal write-down, or some combination of the two. Regardless of whether the defaulted loan backs an agency or nonagency pool, it flows through the same process of moving from foreclosure to real estate–owned (REO) or other form of liquidation. But there is a difference in how losses are recognized on defaulted loans within agency versus nonagency mortgage pools. In agency pools, a loan default is passed through to investors as a full prepayment of the principal balance. In nonagency pools, a default isn't recognized until loan liquidation and it may result in a partial or full write-down of the outstanding loan balance if the net sales proceeds are insufficient to pay off the loan.

Current LTV as well as the borrower's credit profile are the key determinants of default. In theory, default should not occur so long as the current LTV is under 100%, because the borrower can simply sell the property to avoid default. But in practice, financial hardship also plays a role—therefore, the borrower's credit profile and external macro factors are also important default drivers.

Path Dependence and Its Implications

This discussion on the sources and drivers of prepayments brings to light a critical difference between mortgage-backed securities and callable corporates. While both types of investments have embedded optionality, MBS cash flows are path dependent. This means that the future cash flows on an MBS at any point in time are a function not just of prevailing interest rate levels but also of the path along which interest rates (and other driving variables) reached their current level. Path dependence largely dictates the appropriate valuation methodology for mortgage-backed securities. To correctly price an MBS and fully account for the embedded prepayment option, we must generally look beyond closed-form solutions and lattice-based methods that can be used in the valuation of less complex financial instruments.

Burnout is a well-known example of how path dependence manifests itself in MBS prepayment behavior. The responsiveness of a mortgage pool at any point in time is a function of the degree of past exposure to refi opportunities. When a pool moves into the money, the most reactive borrowers refinance and exit the pool, leaving behind the less reactive borrowers. Therefore, all else equal, a pool that has been deep in the money for an extended period in the past is likely to be much less reactive than an otherwise similar pool that moves into the money for the first time since origination.

The interaction between voluntary and involuntary prepayments is another manifestation of path dependence—fast early refis in a mortgage pool are likely to reduce lifetime cumulative defaults, since fewer loans remain outstanding that can default in the future.

Housing Market Outlook

Mortgage valuation requires practitioners to take a view on housing market fundamentals. An MBS cash flow forecast is contingent on an assumed path of home price appreciation (HPA), the pace of future home sales, the availability of mortgage credit, and other housing-related drivers. Cumulative HPA is a key determinant of current LTV, which is the main driver of mortgage defaults. HPA is also a determinant of loss severity and the recovery lag on nonagency loans. Likewise, the frequency of cashout refis is also directly tied to HPA, as it determines the pace at which borrowers build extractable equity.

Housing fundamentals are also a key driver of turnover speeds. Turnover can be estimated as the ratio of existing home sales to the total single-family housing stock. The correlation between the two metrics is not perfect, as the existing home sales/housing stock ratio is based on the entire housing market, consisting of properties backing agency loans, nonagency loans, and whole loans, as well as foreclosed properties and homes without a mortgage. However, this ratio still provides a good sense of aggregate turnover trends.

Moreover, HPA encourages trade-ups, leading to a shorter turnover seasoning ramp and faster aggregate speeds. Strong home price growth can also encourage lenders to loosen underwriting standards, which can help to support home sales, especially for first-time buyers. But the availability of housing and the pace of building can also influence turnover. The inventory of homes for sale currently stands near record low levels—limited availability can make it harder for borrowers to trade up or to relocate for other purposes.

Cash-Flow Engine

The projected voluntary and involuntary prepayment speeds and other required assumptions described above are passed to a cash-flow model to generate the principal and interest payments on the mortgage-backed security. The projected cash flows can then be used for further analysis and for computing a variety of valuation and sensitivity measures. Cash-flow modeling involves two main steps: (1) projecting the cash flows on the underlying asset pool and (2) modeling the waterfall, that is, the collection of rules that determine the order in which principal and interest payments are distributed to the various tranches in the deal. The deal structure can be as simple as a pass-through, in which all the principal and interest payments are remitted to investors on a pro rata basis. The structure can also be much more complex with a variety of tranche types and variable principal and interest waterfalls.

OPTION-ADJUSTED VALUATION METRICS

Armed with a methodology for producing the Monte Carlo interest rate paths, as well as a prepayment model as described above, we are now ready to produce MBS analytics that account for the dynamic evolution of interest rates and the optionality embedded within mortgage-backed securities.

Option-Adjusted Spread

Option-adjusted spread (OAS) is defined as the unique spread over the forward rates on each Monte Carlo path that is required for the option pricing model to reproduce the market observable price, as shown in Equation 37-10. Unlike z-spread, which is calculated over a single path of forward rates, OAS takes into account the potential for the cash flows to change in differing interest rate environments. OAS is computed iteratively by starting with an initial guess and adjusting it until the resulting price matches the market price to within some tolerance.

$$P = E\left[\sum_{n=1}^{N} \frac{CF_n}{\prod_{m=1}^{n}\left(1+f_m+OAS\right)}\right] \tag{37-10}$$

The value of the embedded option is calculated as the difference between z-spread to forward rates and OAS, as shown in Equation 37-11:

$$\text{Option Cost} = z - OAS. \tag{37-11}$$

A positive option cost implies that the investor is short the option whereas a negative option cost implies that the investor is long the option. Mortgage-backed securities always have nonnegative option cost, since the investor is short the prepayment option.

OAS is a useful indicator of relative value and excess returns over Treasuries or swaps and is a key tool that is widely used by investors for deciding whether a mortgage-backed security is rich or cheap versus historical levels or versus other bonds. It is a significant improvement over the static valuation metrics described earlier. Nevertheless, investors should keep in mind that OAS is an extremely model-dependent valuation metric. This should be clear from the large number of assumptions and steps that go into its calculation. The strong model dependency means that the excess return implied by the OAS will not be precisely realized in practice unless all of the model assumptions are realized, which is of course, extremely unlikely. Model dependency also implies that option-adjusted spreads produced by different models are extremely unlikely to match each other. Therefore, OAS comparisons should be only be made *within* a specified modeling framework, never across different modeling frameworks.

Effective Duration and Effective Convexity

As mentioned earlier in this chapter, the traditional measures of interest rate sensitivity, such as modified duration, assume that the cash flows remain unchanged when yields change—these metrics are therefore unsuitable for the analysis of mortgage-backed securities. Effective duration (also known as option-adjusted duration) is computed using simulated Monte Carlo paths and therefore accounts for the change in the cash flows (based on the prepayment model) under the shocked rate scenarios.

Effective and modified duration are generally close on securities whose cash flows do not change with interest rates, such as noncallable fixed-rate bonds, and when the interest rate curve is relatively flat. However, for securities with optionality, rational issuers (or borrowers, in the case of MBS) will alter their decisions based on interest rates and exercise the option when it is beneficial. The deviation between effective and modified duration on mortgage-backed securities is driven by the interest-rate-sensitive nature of the cash flows.

The procedure for computing effective duration is as follows. The OAS is first computed based on the market price of the bond. The interest rate curve is then shocked up by adding a fixed number of basis points, Δr, to the entire term structure of interest rates. The shifted interest rate curve is then used with the arbitrage-free term structure model to generate a new set of Monte Carlo paths and the bond is repriced, holding OAS constant. Subsequently, the interest rate curve is shocked downward by the same number of basis points, a new set of Monte Carlo paths is generated, and the bond is priced again. Effective duration is defined as follows:

$$\text{Effective duration} = \frac{P_- - P_+}{2P_0 \Delta r} \tag{37-12}$$

where P_0 is the price of the bond based on the prevailing yield curve and P_- and P_+ are the values of the bond when yields are shifted down and up, respectively, by Δr.

Duration is a linear measure and therefore the predicted price change is a good approximation to the true price change for small shifts in interest rates but starts to diverge when the rate shift grows. For larger interest rate shifts, the linear approximation breaks down and one needs to introduce a second-order, or parabolic, correction. This second-order correction is known as convexity. For securities with positive convexity, the linear approximation underestimates the true price increase when rates fall and overestimates the true price decrease when rates rise. Conversely, for securities with negative convexity, the linear approximation overestimates the true price increase when rates fall and underestimates the price decrease when rates rise.

Effective convexity is calculated by an identical process to the one that is used to calculate effective duration, that is, the interest rate curve is shifted up and down by a fixed number of basis points and the full recalculation of the security price is performed using the option pricing model. Effective convexity is defined as follows:

$$\text{Effective convexity} = \frac{P_{+} - 2P_{0} + P_{-}}{P_{0}\Delta r^{2}}. \tag{37-13}$$

In contrast with noncallable bonds, convexity on many types of mortgage-backed securities is negative over a wide range of interest rates because the investor is short the embedded prepayment option. The price compression mentioned earlier in this chapter is a direct result of the negative convexity of MBS.

Extensions to Effective Duration

Effective duration has embedded within it a number of implicit assumptions that can limit its utility. It represents the sensitivity to a parallel shift of the yield curve and also assumes that volatilities and OAS remain fixed when rates change. In practice, the yield curve may change in much more unpredictable ways and may be accompanied by changes in volatility, spreads, and other drivers of MBS valuations.

The option-adjusted valuation approach described above can be used to compute many different kinds of price sensitivities beyond a parallel curve shift. Collectively, these sensitivities are known as "partial effective durations." Each such measure describes the sensitivity of bond price to a specific driver of value. The methodology is similar to the one that is used to compute effective duration, given in Equation 37-12. That is, a particular factor is shocked up and down, new Monte Carlo paths are generated, and the bond is repriced, holding OAS constant. The effective partial duration with respect to a factor F is given by the following:

$$\text{Effective partial duration} = \frac{P_{-}^{F} - P_{+}^{F}}{2P_{0}\Delta F}, \tag{37-14}$$

where P_{-}^{F} and P_{+}^{F} are the values of the security when the factor F is shifted down and up, respectively, by ΔF units.

Equation 37-14 can be used to compute key rate effective durations (KRD) by shocking individual tenors or sections of the yield curve while the rest of the curve is held constant. Exposure to other types of yield-curve movements such as twist and buckle can also be computed using this methodology. Moreover, price sensitivities to factors beyond interest rate levels can also be calculated. For instance, vol duration is the sensitivity of bond price to changes in the interest rate volatility assumptions that are used in the generation of the simulated Monte Carlo paths. Likewise, spread duration can be computed by perturbing only the bond's option-adjusted spread, holding all else constant.

AN ILLUSTRATIVE EXAMPLE

In this section, we review a set of analytical results on Fannie Mae 30-year 3.0s of 2019 using static analysis and using two different term structure models. The purpose of this example is to illustrate the steps involved in computing selected static and option-adjusted analytics, compare the analytics under different approaches, and understand how the analytics change as the underlying assumptions shift.

The process to produce selected static and option-adjusted valuation metrics is summarized below:

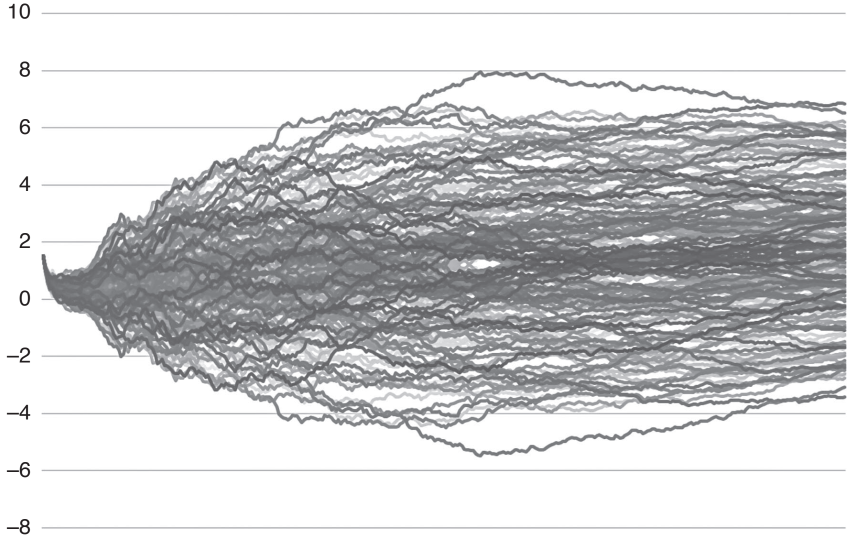
1. Select a term structure model and generate a set of interest rate paths (as illustrated in Exhibit 37-4)
2. For each path,
   - **a.** Determine the cash flows along this path (see Exhibit 37-5).
     1. Compute the sequence of prepayment speeds.
     2. Compute scheduled and unscheduled principal payments and interest payments on the collateral and on the bond.
   - **b.** Discount the cash flows using an initial guess for OAS to obtain the price on this path.
3. Compute the yield, WAL, and z-spread based on the cash flows along the forward path of interest rates (see Exhibit 37-6)
4. Find the OAS that makes the computed average price across all Monte Carlo paths equal to the market price of the security (see Exhibit 37-6)

Regarding the selection of a term structure model, the normal LLM (illustrated in Exhibit 37-4) may be preferable when market interest rates are approaching zero and negative rate paths become more plausible. Of course, a shifted lognormal process (illustrated in Exhibit 37-3) can generate negative rates—but the value of the shift, 200 bps in our example, limits how far below zero rate paths can go.

Along each Monte Carlo path, the prepayment model is used to produce a sequence of single monthly mortality rates. Likewise, the prepayment model also projects speeds along the forward curve. The cash-flow engine then computes along each path the principal, interest, and total cash flows on the underlying collateral and on the mortgage bond. Exhibit 37-5 shows the projected bond cash flows for the next 18 months along the forward curve. Readers may notice that prepayment speeds ramp up rapidly over the next few months, in part due to seasoning and turnover seasonality, but mostly due to a sharply lower primary mortgage rate. The table illustrates how a decline in interest rates can lead to a significant rise in prepayment speeds especially in the case of recent-vintage collateral that sits near the "cusp" of the refi S curve.

EXHIBIT 37-4

Monte Carlo Paths Generated Using the Normal LIBOR Market Model



Once the cash flows have been generated, the various valuation metrics can be calculated, as described in this chapter. Exhibit 37-6 shows the results of our analysis—WAL and z-spread along the forward curve and option-adjusted analytics based on the shifted lognormal LMM and the normal LLM.

The table illustrates the large difference between the z-spread and the option-adjusted spread (computed using either of the two term structure models). As mentioned above, z-spread typically overstates MBS return as it ignores the impact of the embedded option that the investor has sold. Nevertheless, z-spread and the other static valuation metrics can be useful for certain applications because of their relative simplicity.

All of the metrics, especially OAS and related measures like effective duration, are highly dependent on the underlying models and assumptions. In our example, changing only the term structure model while using the same prepayment model leads to big movements in OAS and effective duration. These results highlight the importance of utilizing a consistent analytical framework when evaluating mortgage-backed securities or gauging relative value. For investors who want to measure relative performance or compute tracking errors, it is important to assess both the benchmark and the portfolio within the same modeling framework. Otherwise, any measures of relative performance are likely to be distorted and the tracking errors are likely to be overstated.

EXHIBIT 37-5

Projected Cash Flows (First 18 Months) on Fannie Mae 30-Yr 3.0s of 2019 Along the Forward Curve

Month	Balance	Scheduled Principal	Prepaid Principal	Total Principal	Interest	Total Payment	CPR
25-Apr-20	$949,030	$1,461	$8,279	$9,740	$2,397	$12,137	9.9

Analytical Results (as of March 27, 2020)

	Forward Curve	Shifted Lognormal LMM	Normal LMM
WAL/Effective Duration	3.83	2.14	1.71
Z-spread/OAS (bps)	82	16	31
Option Cost (bps)	NA	66	51
Effective Convexity	NA	–1.35	–0.76

KEY POINTS

- A complete mortgage valuation framework includes a prepayment model, a cash-flow engine, a methodology for forecasting house prices, a term structure model, and a mechanism for translating Monte Carlo interest rate paths into a primary mortgage rate projection.
- Econometric prepayment models are at the center of mortgage security valuation and analysis. These models predict the collective response of borrowers using a wide range of borrower and loan attributes and macroeconomic drivers. A good model is based on intuitive relationships that are likely to persist over time. But every model needs to be reassessed from time to time to determine if the methodology needs to be updated based on prevailing market conditions.
- Monte Carlo simulation is generally used to price mortgage-backed securities due to the path-dependent nature of their cash flows; variance reduction techniques must also be utilized, since the entire valuation process, which may include modeling a cash-flow waterfall, can be computationally intensive.
- The preferred interest rate model for pricing mortgage-backed securities is the LIBOR market model (LMM), since it is calibrated based on observable market instruments and has a sufficient number of underlying factors to accurately capture the swap rate dynamics. Although the standard LMM is a lognormal model of forward LIBOR rates, other variants exist that can handle negative rates, such as the shifted lognormal LMM and the normal LMM.
- The traditional static valuation metrics, such as yield and z-spread, have the benefit of simplicity and can be useful for certain applications. However, the option-adjusted analytics, including OAS, effective duration, and effective convexity, offer a significant improvement over the static measures as they account for the embedded optionality and sensitivity of MBS cash flows to interest rates.

- Given the wide range of assumptions and the amount of subjectivity involved in mortgage valuation, investors should take care to utilize a consistent analytical framework when evaluating bonds or gauging relative value. It is also important for investors to understand the strengths and weaknesses of the different valuation metrics, while keeping in mind that there is no single best measure of value. A variety of analysis techniques, taken together as part of a consistent framework, help the savvy investor build an intuition as to the drivers of return and associated risks of the target security.

CHAPTER

THIRTY-EIGHT

CONVERTIBLE SECURITIES

Mihir Bhattacharya, Ph.D.

Convertible notes or debentures are hybrid equity-linked securities that span the space from common stock on the one hand to nonconvertible (straight) debt on the other, and analogously for convertibles in their preferred share forms. The popularity of their structural variations wax and wane, largely driven by macro factors and market conditions under which issuer needs are balanced against investor participation and preferences, most often through intermediary investment banks. Specifically, during periods of attractive arbitrage opportunities, typically associated with moderate to high volatility in equities, interest rates, and credit spreads (and currencies, if applicable) concurrent with accompanying liquidity, participation by hedge funds tends to dominate. Under these conditions, convertible structures have emerged with several embedded options, path dependencies, and hence complexities. On the other hand, absent these conditions, to wit, during periods of low interest rates, low volatility, and low liquidity, *long-only investors*, also known as *outright investors*, who do not short the underlying stock and/or undertake other hedging trades, tend to be the principal investors with preference for relatively simpler or traditional structures.[1]

In any event, the balancing of issuer needs against preferences of the holders is achieved through varying the levels of the available structural descriptors of this hybrid asset class. The volume and structure selection of convertible issuance each year, therefore, depend on the aforementioned macro factors. In the current context, they have coalesced around relatively short-dated convertible obligations, notes in particular—the so-called *plain vanilla convertible note*—and *mandatorily convertible preferred shares*, with the former in preponderance.

Perpetual convertible preferred shares, that is, with no maturity date and hence no obligation to pay back par, were also considered a "traditional" structure with banks being the principal issuers but were also issued by nonbanks. As a result of their perpetual nature, they used to be considered equity substitutes to some degree with their preferred dividends distributions deferrable though usually not tax deductible. However, updated capital adequacy standards per

1. While exact estimates are difficult, it is believed that prior to the financial crisis of 2008, hedge funds accounted for approximately 80% of convertible asset class. Currently, in the low-volatility and low-rate environments as of this writing, the role of long-only holders is estimated to be a touch above 50%.

Basle III—aimed at member banks' ability to deal with financial stress—now excludes preferred shares in the computation of Core Equity Tier 1, a primary metric of banks' financial stability. Consequently, the issuance of perpetual preferred shares, including of the convertible variety, is now rare.[2]

This chapter will focus on prototypes of the plain vanilla convertible note[3] and a traditional mandatorily convertible. The discussion will address the descriptors and variables—the knobs, so to speak—that provide the flexibility and together define the underpinnings for their theoretical valuation. Post-issuance structural adjustments to reflect corporate actions, the most notable of which, the *Make Whole Conversion Ratio Adjustment Matrix,* is elaborated upon.

CONVERTIBLE NOTE

As a prototype, consider the "Tesla 2's of 24"as it is referenced in common trader language; its formal name is "Tesla Inc. 2.00% Convertible Senior Notes due May 15, 2024," CUSIP: 88160RAG6. It was priced at the close of trading day on Tuesday May 2, 2019, with settlement date of Thursday May 7, 2019, designated at T+2 (i.e., trade date plus 2 days).

The May 2, 2019, closing price for the TSLA common stock, which trades on the NASDAQ Exchange, was $244.10 per share. However, simultaneously with the convertible note issuance, Tesla also sold $862.5 million of common stock at a price of $243 per share. This $243 per share price is the base price or *reference price* for the convertible off of which the conversion price and the initial conversion ratio for the convertible are calculated.

Convertible Note Descriptors

Each of these *descriptors*, or simply, *terms*—in conjunction with the applicable variables—helps determine the value of a convertible. Comments on the terms and their *ceteris paribus* impacts follow:

- *Aggregate amount (also known as the principal amount, par amount*, *or deal size*): $1.6 billion, subject to an additional 15% if the underwriters' option to sell additional notes is exercised within a stipulated period, usually 30 days. This option was exercised, and the total issue size increased to $1.84 billion.

2. Issuance of notes at the prevailing low level of interest rates, along with their tax deductibility feature, has further contributed to the decline in the issuance of perpetual convertible preferred. Hence although not discussed in this chapter, the valuation principles for convertible bonds also apply to convertible preferred shares.

3. Despite the maturity differences between debt notes and bonds, since their valuation logic is identical, this chapter uses the two terms—notes and bonds—interchangeably. Also, using common parlance, a convertible security is called a "convertible" or, simply, a "convert."

Typically, large issue size, which usually occurs for large, attractive issuers with strong research and investor following, is usually accompanied by greater trading liquidity in the secondary market.[4,5]

- *Issue Price*: 100% of principal amount, at $1,000 per note.

  While issuance at par is most common, in countries with very low or negative nominal interest rates, convertible notes may be issued at a premium to par, say, 102% of par, with redemption at par at maturity, if not converted.[6]
- *Coupon rate*: 2.0% per annum, payable semi-annually, on May 15 and November 15, beginning on November 15, 2019. Note that the first coupon payable on November 15, 2019, is longer than six months by a few days from the settlement date of May 7, 2019, and is called a *long coupon date*.

  The higher the coupon rate, the higher the value of the note. Tesla common share pays zero dividends. So, the *yield advantage* at issue, defined as the coupon rate divided by purchase price of the convert minus dividend yield of the stock; at the time of issue, the yield advantage of the TSLA note was 2%. The higher the yield advantage, the more attractive the convert.[7]
- *Maturity date*: With its Maturity Date of May 15, 2024, its time to maturity is five years plus a few days from the date of issue, this convertible is still deemed as a "five-year note."

  While the five-year maturity notes are most common, seven-year notes are also issued. The longer the time to maturity, the lower the present value of par when interest rates are positive, and hence the higher the note's duration and, consequently, its interest-rate risk. Credit spread also features in to adversely impact value if, as expected under normal conditions, credit spread for the note widens with longer time

4. According to Kynex, Inc., convertible issues of less than $100 million aggregate amount, while present, are not very liquid. In calendar year 2019, of the 106 U.S. convertible debt issues larger than $50 million, of the total U.S. raise of $53 billion, the median issue was in the $200 million to $300 million range.
5. As an aside, according to Bank of America Merrill Lynch Global research, an estimated $44 billion of U.S. convertible issues were retired, thereby bringing about the net new issuance at $9 billion.
6. A variant seldom used now is a *discount convertible bond* issued at below par value that, in lieu of paying a cash coupon, accreted to par at maturity at the prespecified deemed coupon rate; taxable holders had to consider the accretion amount as deemed income. This structure resulted in a conversion price rising continuously to maturity date at the accretion rate. Some Asian issues were a modified version of this structure, issued at par but accreting to beyond par at maturity, the so-called *premium redemption convertible bonds*.
7. Notable exceptions being convertibles issues by real estate investment trusts (REITs) with their already high common share dividend yield. Dedicated convertible funds seeking high-yielding securities tend to buy these despite the negative yield advantage as their fund structure usually prohibits them from holding common shares. Other justifications are that they are senior to the common in bankruptcy proceedings and for dividend distribution. Further, that as a convertible, per the *Put–Call Parity theorem*, they may also be viewed equivalently as a stock with a put option.

to maturity. Offsetting this latter negative impact to some degree is the conversion option, which is commensurately longer, particularly in the absence of diminution of value due to earlier redemption or "*provisional redemption*" of the note (see below).

- *Seniority*: Senior Unsecured.

  This seniority level is now the most frequent for newly issued convertible notes, while others have been issued as Senior Subordinated Unsecured, and less frequently as Subordinated Unsecured. When issued at the holding company level, they are also most commonly subordinated to debt issued at the subsidiary level, and also to trade debt.

  Unlike straight debt, convertible debt is generally issued without typical financial covenants or tests pertaining to minimum net worth, maximum leverage, coverage of fixed obligations, or working capital.
- *Issue Rating*: Unrated by Moody's; B– by S&P.

  The overwhelming majority of convertibles issued are either noninvestment-grade-rated or are unrated. In calendar year 2019, of the 105 convertible notes issued in the United States with issue size of at least $50 million, only four were rated as investment grade.
- *SEC Registration*: Yes, off of a prior "shelf registration," with registration supplement. This was to be expected considering the concurrent secondary equity offering.

  SEC-registered securities can be purchased by all potential investors, whereas those issued under Rule 144A can only be purchased or transferred between Qualified Institutional Buyers ("QIBs"). Nearly two-thirds of the 106 convertible notes issued in the United States in 2019 were under Rule 144A.
- *Underlying common stock*: TSLA.

  Although not relevant in the current TSLA note context, convertible notes can also be in an *exchangeable* structure wherein the underlying share for the conversion option is not that of the issuer but into another stock in which, usually, the issuer has a holding and the convertible being used to potentially divest this holding at a premium to its current price. Another variation is a *structured convert* such as the one issued by JP Morgan, cash-settled conversion option linked to the share price of the Chinese company, Tencent Holdings. This exchangeable followed a familiar pattern of issuance motivated by investor interest in convertible structure exposure to specific equities otherwise not available to the convertible asset class investors.[8]
- *Conversion premium*: 27.5%.
