8. JP Morgan/Tencent Holdings 0% of August 2022, issue size $400 million. Also, JP Morgan/Alibaba Group Holdings 0,125% of January 2023, issue size $500 million.

Conversion premium, along with the coupon rate and the issue size, is one of the three items that issuers and the underwriters focus on most when pricing a convertible new issue. Initial conversion premium in the range of 15% to 30% is most common, though some issues with investment grade rating and/or high volatility, and/or popularity of the underlying stock may price at higher premiums. The higher (lower) the conversion premium, the closer the convert is to a straight bond (equity).

- *Conversion price*: This is calculated as the price of the underlying stock at issue, that is, the reference price of $243 per share in this case, multiplied by (1 plus the conversion premium) = 243.00 × 1.275 = $309.83 per share.
- *Initial conversion ratio*: Issue price of par per note divided by the conversion price = $1000 / 309.63 = 3.2276 shares per note.

  As will be discussed below, this is an important number to which formulaic increments are conditionally made with a view to remedy corporate actions that may adversely impact the time value of the conversion option of the convertible.
- *Conversion option*: Freely convertible at the holder's option only commencing a calendar quarter prior to the maturity date of the note, that is, from February 15, 2024. However, it is *conditionally convertible* prior to the business day immediately preceding February 15, 2024, only if any of the following conditions apply: (a) Following the first full calendar quarter since issue, that is, September 30, 2019, if during any such following calendar quarter the last reported sale price of TSLA equals or is in excess of 130% of the applicable conversion price, for any 20 out of 30 consecutive trading days. This is called the *provisional conversion clause*. (b) The convertible note trades at greater than 2% discount to its then conversion value for an observation period, as defined. (c) Offer to sell the underlying stock at a discount of 10% or greater to substantially all holders of TSLA common shares, rights, warrants, or options. (d) Upon a fundamental change of ownership due to corporate events.

  While the above nonconversion period and conditional or contingent conversions[9] are particular to this issuer, it is not uncommon to find conversion restrictions and contingencies in other convertible notes too. They are driven by the issuer desire to avoid immediate share dilution recognition pertaining to the underlying number of shares of the note.

9. The term *contingent convertible*, or *CoCo,* in the context of an equity-linked security is not to be confused with identically named "CoCo" bonds issued by a bank as an Enhanced Capital Note. The latter is issued toward achieving conformance per banking regulatory requirements with respect to capital adequacy to address potential adverse financial conditions. Structurally, while issued as a debt obligation of the issuing bank, they may be converted at the option of the issuer or directed to do so by the regulatory body, into equity capital of the issuer bank and the debt obligation eliminated, most often with no compensation in any form to holders, when the bank has breached, or is close to breaching, the required minimum capitalization ratio.

Additionally, such conversions may adversely affect hedging transactions undertaken by the issuer in conjunction with the issue (discussed below). However, while these may be viewed as an abrogation of the holder's traditional right to freely convert, the nonconversion period and the conditional conversion rights, when inside of a no-call period, and taken together, do not adversely affect the value of the convertible since absent the above conditional conversion triggering events, it is suboptimal for the holder to truncate the time value of the conversion option.

- *Settlement upon conversion*: TSLA has the option to settle its obligation through delivery of shares—called *physical settle*—or cash, or a combination thereof. Further, cash payment, if any, shall be computed based on the 20-day *observation period* preceding the conversion effective date as the average daily computed conversion value that results from the multiplication of the then effective conversion ratio and the corresponding daily volume-weighted average price (VWAP) for that trading day.

  Identical, or closely approximate, terms feature in almost all convert note issues. A common method in this context is *Net Share Settlement* wherein an issuer satisfies its obligation to pay the conversion value by paying par in cash plus the overage in a number of shares calculated by dividing the overage amount due by the share price on payment date; the definition of the share price in this context is also specified.
- *Redemption*: The TSLA 2's of 24 is nonredeemable, that is, noncallable for life unless under a *fundamental corporate change* event, as defined, occurs. In that event, the incremental make-whole share additions matrix stated in the prospectus supplement is applied to the then applicable conversion ratio.

  If callable prior to maturity, all converts have a noncall period, usually three years, followed by a *provisional call* or *soft call* until maturity, conditioned on the underlying stock price exceeding a pre-stated threshold price, usually set at 130–160% above the initial conversion price. Typically, this threshold would need to be met or exceeded for a prespecified period, commonly for 20 out of 30 trading days, not necessarily continuous. To effect redemption, the issuer will need to provide written notification to holders with details of the prespecified notice period, usually 15 to 30 days, and note delivery instructions to effect conversion. Redemption notice is generally delayed by the issuer until confident that during the notice period the underlying stock price will not drop to an extent as to fail the redemption trigger test.[10]

10. The so-called freely redeemable bond with unconditional issuer redemption rights commencing following expiry of a "hard noncall period" and/or a "soft-call period," with its prespecified call price schedule, is increasingly rare.

Note that redemption option(s) benefit the issuer and would, therefore, need to be compensated for via the convertible's initial pricing terms through a lower conversion premium and/or a higher coupon rate and/or even a reduced offering size in some cases. As an alternate, a *make-whole adjustment matrix* to the conversion ratio is also used by some issuers.

- *Conversion rate adjustments*: Present. This conversion ratio adjustment feature is now standard for all newly issued convertibles. Although popularly known as *dilution protection adjustments,* they also include, in addition, *value conservation adjustments*. Together, through their respective conversion rate adjustment formulae, they are intended to mitigate conversion value erosion that would be expected to result from specified future corporate actions, should they transpire. As detailed in Appendix 38A at the end of the chapter, while the adjustment triggers generally result in upward revisions in the conversion ratio, a share consolidation through a reverse stock split would decrease it.
- *Fundamental change make-whole*: Present. This usually takes the form of a conversion ratio adjustment matrix with scenarios of underlying stock price on the horizontal axis and calendar dates pertaining to early conversion on the vertical axis. The cells populating the matrix represent incremental conversion ratio additions per note to the then current conversion ratio.

  This make-whole matrix feature is now a standard in all new convert issues and seeks to protect the interests of holders in the event of the corporate fundamental changes, as defined, that might otherwise adversely affect, or even truncate, the value of the convert. These are further detailed in Appendix 38B.
- *Conditional poison put*: Present. This clause is triggered when (using nonlegal language here) an external entity, not related to the issuer, files notice per regulatory requirements of its having directly acquired beneficiary ownership of greater than 50% of the issuer's underlying common stock or by acquiring a combination of assets and securities that lead to the same outcome. Upon exercise by the holder per instructions detailed in the prospectus, this requires the issuer to pay holders the principal amount of the note, plus accrued interest, as applicable, on the stipulated date per calculations specified.

  The poison put feature is yet another attribute that is increasingly found in new convert issues.[11]

11. A poison put feature is controversial from corporate governance perspective in that it is (potentially) additive to existing barriers to change of corporate control that favor entrenchment of current management. However, from a convertible security holder perspective, it could be of positive value when taken together with the fundamental make-whole clause. For example, if the acquiring entity is highly leveraged or is through a going-private transaction, in both cases due to the higher implied credit spread of the resulting convertible and the associated probability of default, the value of the convertible may decline and/or its conversion option truncated.

- *Concurrent hedging and warrant transaction by the issuer*: Present. Increasingly a common feature, this concurrent hedging—colloquially known as a *happy meal*—is aimed at reducing, if not eliminating, the potential dilution of common shares through trades with the underwriter(s) of the issue. The additional warrant transaction is aimed at effectively increasing the conversion price beyond that defined in the issue. This is elaborated in Appendix 38C.

  The immediate impact of these transactions is that the price of the underlying stock rises upon announcement of the convertible with these concurrent transactions, whereas absent these there would tend to be an immediate downward pressure on the underlying stock due to dilution effect further compounded by shorting by hedge funds.

CONVERTIBLE NOTE AS A CONTINGENT CLAIM

In its most general definition, a contingent claim is a security or contract whose future payoff is contingent on the occurrence, or not, of a prespecified state of an underlying asset. Payoff of convertibles fit the definition, with the state of the underlying common stock determining its payoff.

Consider a portfolio consisting of a long position in a European call option, C_t at time t, a short position in a European put option, P_t, with identical maturity date, T, and exercise price for both options, K, on the same underlying stock, S, and the present value of the exercise price, $Ke^{-r(T-t)}$ to the exercise date with $T > t$, where r is the discounting rate and assuming continuous compounding. That is,

$$\text{Portfolio}_t = \mathrm{C}_t - \mathrm{P}_t + Ke^{-r(T-t)}$$

At the maturity of the options, $t = T$, the present value grows to K. Denoting the stock price at maturity as S_T, if $S_T > K$, the put option expires worthless, and the call option is in-the-money and worth $(S_T - K)$ upon exercising it. Replacing this for the value of C_T in the above equation, the portfolio value at maturity of the options equates to S_T. Analogously, if $S_T < K$, then the call option expires worthless, and the put is in-the-money and worth $(K - S_T)$ and will exercised with K received as the exercise proceeds. Replacing the value of P_T in the above equation, the portfolio is once again worth = S_T. So also, the case when $S_T = K$.

Assuming the absence of arbitrage and market frictions, the above Equation for the case of European options can be stated as

$$S_t = C_t - P_t + Ke^{-r(T-t)} \tag{38-1}$$

Or, equivalently as

$$S_t + P_t = Ke^{-r(T-t)} + C_t \tag{38-2}$$

This is the *Put–Call Parity theorem* for European options for a stock that pays no dividends.[12] In the case of the underlying common stock paying dividends at a continuously compounded dividend yield rate, d, Equation 38-2 can be modified as

$$S_t + P_t = Ke^{-(r-d)(T-t)} + C_t \tag{38-3}$$

Viewed through this lens, from the right-hand side of Equation 38-3, which is a fixed income investor's perspective, a convertible note may be viewed as a combination of a straight bond of the same tenor and a call option to convert into the underlying common share. From equity investors' perspective, which is the left-hand side of Equation 38-3, it may be viewed as a long position in the underlying share with a put option to exchange the share for a straight bond with a swap to receive the bond coupons for the common share's dividends. Hence, another frequently cited manner of describing a convertible note is that it provides exposure to equity upside with downside protection.

Despite the complexities introduced through additional features, including conditional call and put, into even the plain vanilla convertible note—as seen in the prototype Tesla 2's of 24—the above viewpoints are still conceptually valid.

The value diagram in Exhibit 38-1 depicts changes in the character of the convertible note in relation to changing underlying stock price. The x-axis represents the *conversion value* or *parity value,* or, simply, *parity,* which is the conversion ratio times the price of the underlying common. This is also represented by the ODQ (which is a line 45% to the x-axis as both axes represent parity). ACVS represents the theoretical valuation curve for the convertible note, while ACDB, the bond value representing the present value of the debt obligation of the convertible note with respect to its obligation to pay the stipulated coupons and par in the event the convertible is not converted into equity.

The value difference between any point on the convertible note valuation curve, ACVS, and its projection on the parity value line, represented by ODQ, is the *conversion premium* expressed in percent over parity value, or equivalently, in bond points over parity value, called the *points premium*. Analogously, the value difference between the same point on the convertible valuation curve and bond floor, ACDB, expressed in percentage terms, is the *investment premium.*

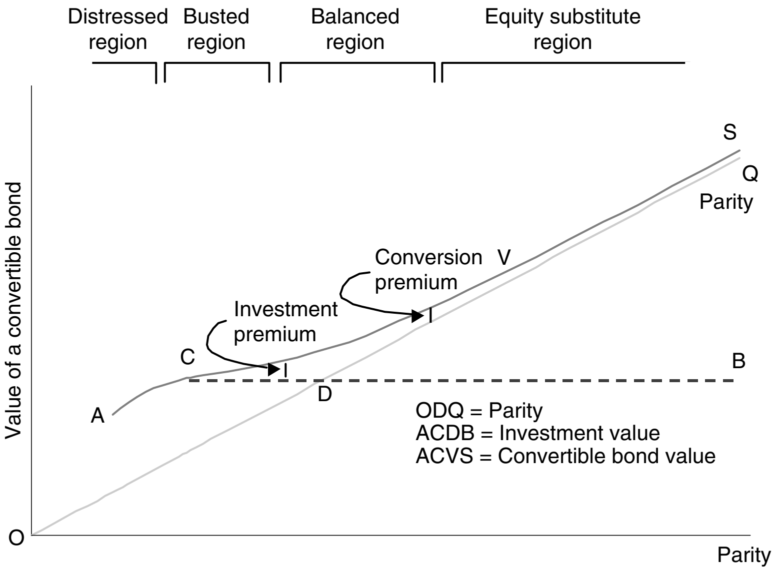
The convertible value curve is above the parity line. The value difference between their corresponding points represents the time value of the embedded long call option in the convertible that benefits the holder. The conversion premium, the investment premium, and *delta,* also called the *neutral hedge ratio* of the convertible, help characterize the changes in the value of a convertible in response to changing value of the underlying common share.

For illustration, consider a convertible note with par at \$1000 issued at 100% of par, with the underlying stock price at issue = \$20 per share, conversion

12. See J. Cox and M. Rubinstein, *Option Markets* (Englewood Cliffs, NJ: Prentice Hall, 1985), pp. 41–43.

EXHIBIT 38-1

Convertible Value Diagram



premium = 25%, and therefore conversion price = 20 × 1.25 = $25, a conversion ratio = 1,000 / 25 = 40 shares per note. If, in response to the share price increasing by 15% to $23, the convert price moves to $1100, with the bond floor, say, at $865, then

$$\text{Conversion premium} = [(\text{Convert price} / \text{Parity}) - 1] \times 100 \quad (38\text{-}4)$$
$$= [(1{,}100 / (23 \times 40)) - 1] \times 100 = 19.57\%$$

$$\text{Points premium} = (\text{Convert price} - \text{Parity}) / 10 \quad (38\text{-}5)$$
$$= [1{,}100 - (23 \times 40)] / 10 = 18.00 \text{ bond points}$$

$$\text{Investment premium} = [(\text{Covert price} / \text{Investment value}) - 1] \quad (38\text{-}6)$$
$$\times 100 = [(1{,}100 / 865.00) - 1] \times 100 = 27.17\%$$

In this numerical illustration, in response to the common stock experiencing a 15% gain (from $20 to $23), the convert note price increases only by 11% (from $1,000 to $1,100), reflecting a decline in the conversion premium from 25% to 19.57%. If, on the other hand, the stock price were to decline by 15%, the convert price would decline by less than 15%, and the conversion premium would expand to be higher than 25%. This is due to the positive convexity of the embedded long conversion option of the convert.

Note, therefore, that the valuation curve, ACVS, is convex in the segment CVS and concave in segment CA, with C being the point of inflection. Under distress conditions, with parity trending to (precipitously) lower levels beyond point C, the bond value of the convert declines in an accelerated manner and does not continue along the dotted line to the *y*-axis. In fact, even at some stock price levels not far from zero, there exists the distinct possibility of default by the issuer. Hence the valuation curve for the convertible in this region is not easily determined, or at least not a continuous curve as it then depends on multiple default-related factors including seniority of the convertible in the capital structure defining its claim priority and the recovery rate in the event of default. The value diagram schematic in Exhibit 38-1 shows an extreme, though unlikely, case of the convert value being only equal to its bond value beyond point C, with no remaining time value.[13]

The delta or neutral hedge ratio applicable to a convert is analogous to that of an equity call option and is the ratio of the change in the price of the convert to an infinitesimal change in its parity, and ranges from 0 to 1. At zero delta the convertible behaves like straight debt, and as equity when the delta is 1.0. At a delta of, say, 46.65%, for a conversion ratio of 40 shares per bond, to achieve a delta neutral position would need a short position of

$$\text{Conversion ratio} \times \text{delta} = 40 \times 0.4665 = 18.66 \text{ shares per bond}$$

The neutral hedge ratio is the tangent to, and the slope of, the convertible bond valuation curve at a given stock price level. For infinitesimal moves up or down in the stock price from this initial level, a hedged portfolio consisting of long the convert and short the appropriate number of shares, as illustrated above, will experience neither a loss nor gain as a result. For noninfinitesimal stock price change upward, the gain arising from the long position in the convert will be lesser than the loss incurred due to the short position in the shares as the conversion premium declines, as seen in the illustrative numerical example. In the event of a large move up, the ex ante neutral hedged position turns out to be ex post underhedged, and hence the long convert leg does not gain as much as the parity gain. The reverse is true in a large down move in share price. In this case, the ex ante neutral hedge position turns out to be overhedged and, therefore, the decline in the convert price, all else being the same, will be lower than the gain on the short position in parity, resulting in the conversion premium increasing. These scenarios exhibit the positive convexity, also called the positive gamma,[14] property of a long equity call option position with respect to the underlying stock, and hence with respect to parity for a long position in the convertible. On the other hand, if the convertible

13. The value of a convertible in a two-factor valuation model would be represented by a three-dimensional surface with the third dimension representing the interest rate plus credit spread on the *z*-axis. The simpler two-dimensional representation above is, therefore, a section of the pricing surface parallel to the *x*,*y*-plane, at a given level of interest rate plus credit spread, assuming a constant volatility level. On the other hand, the volatility surface of a convertible can be graphically represented if the interest rate plus credit spread were to be held constant, while volatility, represented on the *z*-axis, is assumed to change with changing stock price levels.

14. Gamma, as in equity options, is second derivative of the price change in the derivative with respect to the price change in the underlying. It measures the rate of change of the delta with respect to the underlying.

is callable prior to maturity, like all callable fixed income instruments, it also will have negatively convex attributes with respect to interest rates.[15]

The stages of a convertible and their attributes are discussed next as impacted by changes in two of its principal variables, namely, the price of the underlying equity and interest rates.[16]

STAGES OF A CONVERTIBLE NOTE

There are four stages of a convertible note approximately depicted in the value diagram in Exhibit 38-1. We describe each below.

Balanced Converts

Convertibles with conversion premium of 15–40%, and investment premium of 15–25%, respond materially to changes in both the underlying equity and interest rate. The deltas of such convertibles range from roughly 55–75%. Hence converts with these attributes, either upon issuance or as a result of subsequent stock price movements, are called *balanced convertibles*. Their upside/downside participation and risk/return trade-off characteristics appeal to outright convertible funds and equity funds seeking a lower risk alternative or add-on position to common stock from an issuer with attractive equity fundamentals.

Equity Substitute Converts

When the conversion premium is about 15% or less, its investment premium is usually higher than 40%, and equity delta is above 80–85%, it is viewed as being equity-like or as an *equity substitute.* At this stage, the investor put option to exchange the convert for its redemption price is deep-out-of-the-money. While share price is the prime determinant of the value of a convert in this stage, it cannot be emphasized enough that other factors, such as remaining call protection and stock price volatility, also materially affect its value. The shorter (longer) the remaining call protection, the lower (higher) the conversion premium an investor would be willing to pay reflecting the remaining time value of the security. Outright convert funds tend to sell the security at this stage in favor of other balanced converts, while equity income funds tend to buy in this stage. With the positive convexity feature of the convertible being very prominent at this stage, portfolio leverage and small net capital requirement due to the shorting at the high delta level, this stage of the convertible constitutes a potentially lucrative trading opportunity for hedge funds.

15. If a bond features an early redemption, or callability, the bond value will be negatively convex to interest-rate changes as the early redemption feature is in effect an embedded short put position from the holder's perspective. And all short option positions are negatively convex.

16. Interest rate as discussion here includes the applicable benchmark interest rate as well the credit spread.

Busted Converts

When the underlying share price declines to where the conversion option is deep out-of-the-money, the conversion premium increases while parity is still in the convex region, CVS, in the diagram. Conversion premium in this stage is usually greater than 50%, and sometimes significantly higher. The investment premium in this stage may be 15%, or lower, as the note's value approaches the bond floor due to the holder option to put the note to the issuer at par on settlement date and its value approximates as determined by its yield to maturity, which unless otherwise, is the settlement date.[17] Outright buyers tend to exit busted converts and are replaced by fixed income funds seeking equity exposure while receiving bond-like yields. Credit analysis expertise, understandably, is of importance. Hedging at this stage against further decline in the underlying shares can be achieved via overhedge through shorting more shares than suggested by the neutral hedge, However, the overhedge strategy bears the risk of substantial loss should the stock happen to bounce back. Instead, a long position in equity put or credit hedge, if available at reasonable prices, would be better alternatives.[18]

Distressed Converts

Convertible notes in this stage may be considered a subset of busted converts with the distinction that with the underlying share price so low as to materially increase the probability of default. Implied here is that credit spread widens out rapidly with declining levels of the underlying stock, very unlike in the other stages where the bond floor holds up reasonably well. In this stage, both the conversion premium and investment premium are quite small. This is the concave region of the valuation curve. This is where *distress funds* with expertise in bankruptcy proceedings, asset recovery in default, and post-bankruptcy reorganization tend to be the principal holders. Interestingly, the equity gamma is even higher than in the busted phase, and small changes in the underlying stock may change the delta significantly.

Before leaving this section, it is useful to point out that while conversion premium is commonly used to label the stage in which a convertible note belongs, a more reliable measure is the investment premium. For example, an in-the-money convertible note with an extended remaining period of call protection, on a high volatility stock that pays low or no dividend, can trade at a very substantial

---

17. Unlike straight bonds, convertibles generally do not have any significant operating or financial covenants. Currently, they rarely include an unconditional investor put option but may have an event-triggered put such as a poison put triggered by an acquisition of the underlying stock. In such a case, the convert note will be valued as the higher of the conversion value or the note's bond value based on the yield to maturity or yield to put.

18. Some funds, though, may choose to retain the exposure in the busted convertible note if they deem it worthwhile if the risk/return trade-off is compelling based on their credit analysis and valuation models. The yield forgone in exchange for the deep out-of-the-money call may be relatively minor or even negative, the latter due to possible pricing inefficiencies in this region.

conversion premium. However, the higher (lower) the investment premium, the unambiguously more (less) in-the-money is the convertible note.

INVESTING IN CONVERTIBLE SECURITIES

A common and oversimplified categorization of investors in convertibles as an asset class is that some are long-term holders and, by inference, the others are not. The former category includes dedicated convertible funds and others with asset allocations to convertibles such as equity income funds, insurance companies, many fixed income funds, and in-house managed pension funds as well as family offices. An aspect of the charter of dedicated convertible funds as well as of fixed income funds and others may not allow them to hold common shares, effect hedging by shorting securities, nor engage in option transactions, but convertibles with their embedded derivatives are permitted. The common investment objective of the outright investors is to obtain equity exposure with portfolio volatility lower than that of common stocks. To that end, inclusion of convertible securities, with their lower risk and equity upside potential of convertibles, as an asset class is attractive for active money managers as they are often measured by holding period returns compared to benchmark indices—such as the S&P 500 Index or the Russell 2000 Index of small stocks—on a risk-adjusted basis. In that context, the Sharpe ratio is an often-used measure of risk efficiency to evaluate a portfolio manager's performance.[19]

The second category of investors in convertibles are hedge funds. Security shorting and option trades to effect hedges for arbitrage purposes are their distinguishing characteristics. Hedge funds engaging in convertible arbitrage include those dedicated exclusively to the asset class, as well as multi-strategy hedge funds. The latter may participate selectively, from time to time and allocating capital accordingly, based on their assessment of the attractiveness of a specific convertible security or the asset class as a whole. A third group consists of the convertible and/or equity trading desks of investment banks engaged in underwriting and market-making of the securities. However, there has been a substantial reduction in their role as market-makers and liquidity providers due to the attendant capital requirements per banking regulations. Hedge funds are, therefore, viewed as liquidity providers—for a price—to some extent whose trades help toward price discovery

Outright investors will seldom buy a convert unless they like the fundamentals, or the *equity story,* of the underlying stock. Ideal attributes of an issuer, from the perspective of outright investors, include:

19. The Sharpe ratio is defined as the excess return of the portfolio divided by the risk of the portfolio as measured by the standard deviation of its returns. Portfolio excess return is the realized return of the portfolio minus the return from the riskless asset. It attempts to measure the excess return per unit of risk undertaken by the portfolio manager. The measure can be applied to portfolios or to asset classes. The higher the Sharpe ratio, the better the performance of the portfolio manager or the asset class.

- A strong management team with a well-articulated business model
- Presence in a growing sector of the economy
- The firm being in the growth phase of its business cycle
- Strong or improving credit with the ability to undertake the fixed liability without jeopardizing its credit rating
- An attractive yield advantage of the convertible over that of the underlying common share
- High volatility and hence the propensity of the underlying stock to exceed the conversion price threshold

Hedge funds, essentially being relative value traders, are more concerned with the relative cheapness of a convertible and hence arbitrage possibilities. Therefore, additional valuation inputs considered include:

- Liquidity of the convertible and that of its underlying stock
- Cost of stock borrow
- Credit spread for an otherwise identical straight debt, or a credit default swap for the issuer, if it exists, or an estimate thereof
- Hedging instruments available, their efficacy, and remaining basis risk[20]

Since a convertible note spans the space from straight debt at one extreme and pure equity on the other, it affords the investor spectrum to choose among these and the intervening stages that suit their investment objectives and mandates. A convertible note with low conversion premium will have higher delta with respect to the underlying equity and hence tend toward a common stock as the conversion premium decreases and the delta increases along with corresponding increase in the investment premium. In such situations, the convertible's sensitivity to downward moves in the stock is high because at the then high equity levels, the downside protection afforded by the bond floor more is distant. At low investment premium levels, conversely, the conversion premium is high and the delta with respect to the underlying equity is low. Hence the convert, now tending toward a bond, will be more sensitive to interest-rate changes.

Given the changing attributes of the convertible notes, successful investing in them requires a combination of tools in the areas of equity fundamentals, fixed income valuation, and valuing derivatives. The next section discusses the variables that, in conjunction with the descriptors, help determine their theoretical values and provides an overview of valuation modeling.

20. For example, given the thin, or in some cases nonexistent, market for credit default swaps on individual issuers, index swaps may be used as proxy. The offsetting effect of the latter not being the same introduces a correlation element and a residual risk, called the basis risk.

CONVERTIBLE NOTE VALUATION FRAMEWORK

If, in addition to the usual terms of the coupon rate, conversion ratio, and maturity date, the convertible note specifically neither permitted early conversion by the holder nor redemption by the issuer, then its value at any time would equal the present value of the scheduled and contingent cash flows from the valuation date forward until the maturity date, provided that the terminal stock price and the discount rate to calculate the present value were known. The above statement implicitly ignores the possibility of default by the issuer.

An earlier-generation measure to assess the relative attractiveness of a convertible note relied on this simplicity in calculating the *payback period.* Essentially, it is the time required, in years, over which the holder would recover the price of the convertible note, as opposed to acquiring the number of the underlying shares, and being compensated through the positive differential between the coupon payment of the note and the expected dividend payment from the underlying shares.[21] The shorter the payback period, the more attractive the convertible note, and particularly so if the payback period is inside the call protection period. Note that this metric also ignores the present value concept.

All current valuation models for convertible securities follow the arbitrage-free framework for contingent claims pioneered by Black and Scholes[22] and Merton[23] and are based on participants optimally acting in their best interest. That is, at all times, given the several interacting embedded options then available, the convertible note holder would choose the most likely value-maximizing choices whereas the issuer would correspondingly pursue optimal value-minimizing actions for the note, with the aim of preserving the residual value benefit for issuer's current common shareholders. Thus, there are game-theoretic aspects of the actions taken by the two parties. As a result, even for the so-called traditional convertible note, a closed-form solution to value it is not possible.

Further complexities are introduced when the conversion right, conversion ratio, call price, and put price features, if present, vary over time and could be specified as European, Bermudan, or American options, thereby requiring appropriate valuation boundary conditions. Other variations include mandatory conversion and whether accrued coupon is to be paid or not upon redemption, conversion, or put exercise.[24] Also to be considered are the cash payments, in part

21. Defined in years, at time = t, it is the ratio of (a) \$ price of the convertible note less its parity value, and (b) the annual cash flow from the convertible note coupon payments minus (the conversion ratio multiplied by annual dollar dividend of the underlying common stock).

22. F. Black and M. Scholes, "The Pricing of Options and Corporate Liabilities," *Journal of Political Economy*, May–June 1973, pp. 637–659.

23. R. Merton, "Theory of Rational Option Pricing," *Bell Journal of Economics and Management Science*, Spring 1973, pp. 141–183.

24. A convert note offering specifying that holders would not be eligible to receive the accrued interest pursuant to a redemption or call or put exercise is not looked upon favorably by holders. Therefore, they require cheaper terms at issue for convertible notes with such a clause—derogatively called *screw clause*—except where otherwise would involve "double dipping" payment to the holder. Use of the screw clause is not common now.

or whole, to satisfy the conversion option, changes in dividend payment, as well as whether there is a repo spread for the short equity position in the underlying stock by a hedge fund.[25]

Exercising the Embedded Options

The discussion that follows assumes the most general case, wherein the convertible note has a freely redeemable period and/or a conditional redeemable period, American-style conversion option, and also a put schedule of the Bermudan[26] type. Note that the prototype TSLA 2's of 24 is more restrictive and does not have these embedded options.

Issuer's Options

- *Conversion forcing redemption*: For a freely redeemable note, the benefits to shareholders from forcing conversion include saving the interest expense, lower leverage, and increased debt capacity value due to the additional equity in the balance sheet. However, the issuer may choose to defer redeeming the note if the after-tax cost of the coupon is lower than that of the dividend yield, or in the case of accreting converts, if the after-tax cash flows are positive to the issuer. While theoretically the issuer should redeem the freely callable note as soon as the parity value equal the redemption price, holders need to be provided a written notice of redemption of usually 15 to 30 days. However, with a view toward a higher probability of conversion, the issuer may delay issuing the redemption notice until the parity value exceeds the redemption level by a margin that reduces the likelihood of parity falling below the redemption price and, consequently, the holder opting to receive redemption price in cash instead. This *call delay*[27] becomes moot if the issuer is indifferent between issuance of shares upon conversion or cash. And particularly so if the issuer has already hedged the equity exposure at

25. The repo spread depends on how easily the underlying stock can be borrowed. The more difficult to borrow, the lower is the rebate for the cash collateral credited to the borrower while the lender uses the cash collateral to invest in (usually short-term) Treasury securities.
26. As opposed to a European option exercisable by the holder only at maturity, or an American option that is exercisable by the holder at any time during the life of the option, a Bermudan option can only be exercised on distinctly specified intermediate days prior to expiration.
27. It is equal to $\sigma\sqrt{t}$, where σ is the stock's volatility estimate for the period and t is the length in years of the redemption notice period. As a numerical illustration, if t is one month, the short-term volatility estimate is 0.30 per annum, and, absent any jumps, the stock is expected to move $0.30 \times \sqrt{(1/12)} = 0.866$, that is, ±8.66% in one month with a probability of 68%. The two-standard deviation, or equivalently, a 95% confidence interval, implies a call delay of $2 \times 8.66 = 17.32\%$ above the effective conversion price, assuming a log-normal return distribution for the stock price.

the time of issue through a derivative transaction, as has been done by the issuer pertaining to the TSLA 2's of 24.[28]

- *Debt refinancing redemption:* If the issuer does not want conversion to occur, then during a free-redemption period, the logic of call delay also applies here, except now the parity value needs to be below the redemption price so as to provide the desired cushion. The issuer's reasons for calling the debt may include elimination of the potential equity dilution, refinancing at a lower rate and/or extending maturity. The cost of debt of matching seniority and maturity is the appropriate benchmark from a cost of capital perspective.
- *Put extension sweetener*: If the convertible note feature includes a put or multiple puts scheduled prior to maturity, and in situations where it is optimal for the holder to exercise the immediately next put while the issuer does not wish that the put be exercised, put extension sweeteners may be used by inserting an additional put at a next suitable proximate date and/or a knock-in payment to the holder may be used as enticements to the holder to defer exercise of the put.

Holder's Options

- *Conversion option*: American options have an intrinsic value component plus a nonnegative time value component, the latter for the possibility of the underlying to go further in the direction that increases the value of the option. Voluntary exercise eliminates the time value and is the right decision only when the benefits of early exercise outweigh the time value component. In the context of the embedded long call option, unless forced to do so as a result of a redemption notice, voluntarily conversion by the holder is optimal only when the present value of parity plus the related dividend stream to the maturity date plus any other benefits of owning the common shares exceeds the present value of the price of the convertible note and its coupon stream. This is rarely ever the case in normal conditions and even redeemed convertibles are therefore optimally tendered for conversion on the last possible date prior to the expiration of the conversion option. With features such as dividend protection, dilution, and value preservation adjustments (described in Appendix 38A), as well as conversion ratio changes in the event of corporate actions (described in Appendix 38B), premature conversion is even less likely. Despite this, valuation models need to feature premature exercise option as an investor choice.
- *Put option*: If the convertible note features a put option, its exercise is rational if the estimated value of the note immediately following the

28. B. Grundy and P. Verwijmeren, "Disappearing Call Delay and Dividend-Protected Convertible Bonds," *Journal of Finance*, 2016, pp. 195–224.

earliest next put date is lower than the put price. Hence, the aforementioned put sweetener if enacted by the issuer to prevent early exercise will need to be similarly assessed. The same logic applies to the conditional poison put taking into consideration the make whole clause that would also likely be triggered.

For the most general case of currently redeemable by the issuer, and convertible by the holder, the above leads to the boundary condition for convertible bond value at any grid point in time and underlying stock price combination level, as

$$\max(\min(CB_1, CB_2), CB_3)$$

where CB_1 is the note price if the note is neither redeemed nor converted at that point in time, CB_2 is the note's redemption price, and CB_3 is its conversion value. If not redeemable, then $CB_2 = \infty$; and if not convertible, then $CB_3 = 0$; for conditionally redeemable and conditionally convertible, those respective levels apply.

Analytical Valuation Models and Factor Choices[29]

Convertible bond valuation models differ from each other in the number of *stochastic variables* or *factors* used in their construction.[30] The simpler one-factor model assumes the stock return as the underlying stochastic variable. All other items that impact the value of a convertible are descriptors and nonstochastic (i.e., deterministic) variables. A more complex multifactor models may, in addition, include interest rates, credit spreads, and exchange rates, the latter in the case of multicurrency securities. Based on the stochastic process assumed to generate the return process for the underlying asset, a partial differential Equation (PDE) that applies to corporate securities is developed. Boundary conditions relevant to the particular corporate security being valued, in this case, the convertible, are applied when solving the PDE using numerical methods.

Candidate stochastic variables used to model the value of a convert include:

- *Stock returns:* Single-factor model assumes stock returns to be the sole stochastic variable and posits a Weiner process for the evolution of stock return distribution, with specification for its first two moments. Simpler versions use a flat volatility as an input for all time and stock price levels. The more sophisticated ones may specify a time-dependent

29. Space limitations do not permit a thorough development of the valuation analytics. Hence only an overview is presented here.

30. A variable whose value changes over time in a nondeterministic manner is said to follow a stochastic process. Simply stated, a stochastic process describes the probabilistic evolution or behavior of a variable whose future value is uncertain and leads to different outputs even when provided the same input parameters and initial conditions. Or more formally, a stochastic process is a system that evolves in time while undergoing chance fluctuations. See R. Coleman, "What is a Stochastic Process," in *Stochastic Process, Problem Solvers,* vol. 14 (Dordrecht: Springer, 1974).

volatility structure, and yet others may also incorporate *option volatility skew,* wherein the volatility estimate depends on the extent the option is away from the at-the-money strike price.

Estimating the volatility of the underlying stock likely to be realized over the life of the convertible is of primary importance as it, in conjunction with the risk-free interest rate, most prominently affects the equity optionalities embedded in the convertible security. Implied volatilities from short-dated liquid options on the stock are used for near-term volatility estimates, while realized historical volatilities estimates for the stock return are inferred for longer maturities. Estimates of very high volatility stocks are generally priced at lower volatilities in the market due to the expectation of some degree of mean reversion of volatility over time. Additionally, the ex ante implied volatilities generally tend to be higher than the ex post realized volatility, except when the reverse occurs with uncertain frequency and duration. Thus, although statistical methods are available to estimate the evolution of volatility and its terms structure, it is still considered an art rather than a science in trading circles.

- *Interest rates:* The benchmark interest rate, usually the applicable U.S. Treasury rate, together with the credit spread applicable to the issue, helps estimate the value of the bond floor of a convert by discounting the convert's cash flows. An increase (decrease) in the interest rate increases (decreases) the value of the conversion option, and the reverse for the option to put the convert, if there exists an investor prematurity put feature.[31]

  Valuation models for bonds and bond options have interest rates as the main stochastic variable. Since the price dynamics of a convertible are also influenced to a considerable degree by the straight bond component and its convexities, it stands to reason that two-factor convertible models include interest rates as the second factor. However, fixed income valuation models themselves can be posited as multifactor models. Examples include the two-factor model of Longstaff and Schwartz with the factors being the short-term interest rate and the yield volatility.[32] In addition, a third factor, the long-term interest rate has also been posited for modeling the term structure. Based on their empirical research on U.S. Treasury bond returns, Litterman and Scheinkman label the three explanatory factors as representing the general interest

31. The issuer's interest being exactly contrary to that of the holder, the effect of changes in the interest rates are also exactly offsetting with respect to the issuer's propensity to redeem the convertible security. However, the issue becomes moot if the issuer has already entered into dilution-hedging contracts with underwriters and/or other derivative third parties, assuming nondefault by these counterparties.

32. F. Longstaff and E. Schwartz, "Interest Rate Volatility and the Term Structure of Interest Rates: A Two-Factor General Equilibrium Model," *Journal of Finance*, 1992, pp. 1259–1282.

rate, its slope, and its curvature.[33] However, opting for simplicity, Barone-Adesi, Bermudez, and Hatgioannides posit a two-factor model to value convertibles wherein the second factor is the a modification of the Hull and White dynamic for the stochastic interest rate.[34,35]

Under the latter version of the two-factor model, the term structure of interest rates is inferred from Eurodollar futures for short tenors and from swap rates for longer maturities, both of which sources are liquid. In addition, the correlation between the stock return process and the interest-rate process has to be estimated as also the market price of risk as interest rate is not a traded security.

- *Credit spread:* The higher the assessed probability of default by the issuer, the lower the credit rating of the issue and correspondingly the higher the credit spread. Credit risk is increasingly viewed as a stochastic variable in its own right due to the volatility of the credit-spread of non-investment-grade or unrated issues, which constitute the majority of the securities in this asset class. So, while stock returns, interest rates, and credit risk are three natural factors to drive their valuation, there is general disfavor for three-factor models. Additionally, Grimwood and Hodges suggest that the impact of interest rates is of the second order importance when valuing convertible securities.[36] An example of a two-factor model with the more important credit risk as the second factor is per Xiao.[37]

  Estimating the credit curve for a convert requires inferring the option-adjusted spread from currently traded straight bonds of similar seniority and tenor from the issuer or obtaining the credit default spread (CDS) estimate applicable for the issuer. However, due to market illiquidity in these products, such estimates are rarely available. The closest liquidly traded proxies are the CDS Indices for investment grade (CDX.NA.IG) and non-investment grade issues (CDX.NA.HY), and for some industry sub-sectors thereof. Using these estimates for a given convertible introduces the aforementioned basis risk. In addition, the correlation between the equity return factor and the credit risk factor needs to be posited.

- *Exchange rates:* Consider a U.S. dollar-denominated bond—both par and coupon are US$ denominated—exchangeable into shares of a UK pound (GBP) denominated underlying stock. In addition to the equity risk associated with the investor's conversion option into the underlying ordinary shares, a U.S.-based investor is also exposed to exchange rate risk. Since exchange rates are stochastic, they could potentially be an additional factor in the valuation of such converts. Volatilities for the underlying equity in GBP and the GBP/USD exchange rate evolution processes would have to be estimated as well as the correlation between them to value this composite option.

To summarize, the more the number of factors, the higher the modeling complexity in the number of partial differential equations to describe the process and also the cross-correlation between the stochastic processes. These, in turn, imply more parameter estimation as inputs and longer computation time. In each case, traders need to periodically calibrate the model to market prices.

Continuous time *partial differential equations* (PDE) are developed corresponding to the specific factor or factors selected to model the price evolution of the convertible. The system of PDEs is then solved by employing numerical methods that approximate them by *discrete difference equations*. These equations are then solved iteratively subject to applicable boundary conditions. The most frequently employed are (a) Explicit Finite Difference method, which is a forward difference approximation; (b) Implicit Finite Difference method, which is a backward difference method; and (c) Crank-Nicholson method, which is an average of the Implicit and Explicit Finite Difference methods. The explicit finite difference method, commonly used in the Binomial tree approach to value equity options, has the advantage of being computationally fast in convergence while the computationally slower implicit method has better convergence and stability properties. The Crank-Nicholson has the advantage of faster convergence than either of the other two.

Since no model perfectly describes the market valuation curve and model outputs depend on the estimated input parameters and variables, it is common practice to opt for the simpler models and making trading adjustments based on the historical observed bias of the model used. Furthermore, all models take the stand-alone security valuation approach and not the value of the security in the context of totality of all securities of the firm. They also take an atomistic approach and do not account for liquidity or size of the proposed trade, nor of the incremental risk approach of the particular trade on the desk's portfolio. It is commonly argued that most often, these trading judgment-based pricing adjustments and parameter estimation errors swamp the accuracy that might be derived from a theoretically more consistent and robust multi-factor model.

Along this line of logic is the Tsiveriotis-Fernandes single-factor model that employs a flat interest rate and solves the PDE solved using the explicit finite difference method.[38] It discounts the convert cash flows at the risky rate of

38. K. Tsiveriotis and C. Fernades, "Valuing Convertible Bonds with Credit Risk," *Journal of Fixed Income* 8(2), 2008, pp. 95–102.

the interest rate plus the credit spread, and the equity option at the risk-free rate. The logic being that should the holder opt for conversion, the issuer's liability can be defrayed by issuance of common shares and thus involves no credit risk. The model has been critiqued for inconsistency as it does not take into account theof probability of default by the issuer as the stock price declines to the concave region of the value diagram in Exhibit 38-1. Others have addressed this—while retaining the simplicity of a single-factor model by positing a heuristic or deterministic structure of the credit spread, specifically ever-widening as the stock level falls in the concave region even before the stock price reaches zero. In addition, some models may also provide estimates of recovery value in the event of default. One such is the off-the-shelf model, along with the applicable descriptor database and market prices of relevant securities, is from KYNEX, Inc,. and its front page is displayed in Exhibit 38-2.[39]

MODEL OUTPUTS: IMPLIEDS AND GREEKS

Given the requisite inputs, the most common application of the valuation models is to estimate the theoretical value of a convertible security on a stand-alone basis. If the theoretical value is, say, 102.5, and the security is trading at par, it is said to be 2.5% cheap theoretically. In addition, the models provide risk sensitivity attributes of the security, that is, the *greeks,* that help toward deeper evaluation of the security's risk/reward aspects. They are the partial derivatives of the security's change in value in response to an incremental change in the value of an underlying variable when viewed *ceteris paribus*.

Market-Implied Metrics

Equivalent to calculating the theoretical cheapness instead, with the market price of the convertible as an input, these models can be used to iteratively solve for the value of the selected variable that equates the model value to the market price, once again with all other inputs being the same. These are called the *market-implied partial* derivative metrics and include:

- *Implied volatility*: The higher (lower) the implied volatility, the richer (cheaper) the security.
- *Implied credit spread*: The higher (lower) the credit spread, the higher (lower) the market's assessment of the default probability of the security and hence lower (higher) the price of the security.

39. Note that there are several other commercial "off-the-shelf" models available in the market, and others available as a subscription service, such as from Bloomberg, and still others available free from investment banks and brokerage firms with the expectation of trade executions through them. Not surprisingly, therefore, most trading desks subscribe to one or more of these models and focus their attention on estimating the inputs to these models. There is the unstated assumption that the construction technology among the various vendors of the models results in valuation outcomes within acceptable bounds of each other, given the same set of inputs.

Tesla Inc (TSLA)

2.000% Convertible Bonds due May 15, 2024

COMPANY DESCRIPTION

Tesla Motors goal is to accelerate the world's transition to electric mobility with a full range of increasingly affordable electric cars. California-based Tesla designs and manufactures EVs, as well as EV powertrain components for partners such as Toyota and Daimler. Tesla has delivered almost 10,000 electric vehicles to customers in 31 countries. www.teslamotors.com

CUSTOM NOTES

Insert Indication

While the implied metrics are useful in assessing the user's *a priori* estimates and possibly generate trade ideas, caution is in order regarding their interpretations. First, the estimated "implieds" are conditioned on the estimation accuracies pertaining to all the other inputs into the model as well as the market price replication accuracy of model itself. Second, it is well known that the value of a convertible is most sensitive to volatility when the convert is near-the-money, and to credit-spread when deep out-of-the-money; it is less sensitive to either when deep-in-the-money. Misleading implications may be drawn if unmindful of the context, the skews, and maturities of the embedded options.

Partial Derivatives

The greeks commonly used in monitoring equity and bond derivative risk/reward profiles are also applicable in convertible portfolio management. The principal ones, in addition to the neutral hedge ratio or delta, include:

- *Gamma:* This measure of convexity, the rate of change of delta, is a very closely monitored second derivative and constitutes a prominent trading strategy by hedge funds. A long position in the convertible in the nondistressed stage—segment CS in the Exhibit 38-1—is positively convex due the holder being long the call and put options embedded in the convert. Shorting the underlying common stock against a long position in the convertible, usually in a delta-neutral position, unless deliberately retaining directionality exposure, increases the leverage in the portfolio not available to outright investors. In the concave segment of the convertible value diagram—segment CA in Exhibit 38-1—downside hedging by holders through buying equity put and/or credit protection, if available, is advisable. A negative gamma position resulting from short option positions such as writing a put or writing a call, or shorting a convertible with a view to harvest high implied volatility of the individual convertible or the portfolio, can quickly cause significant losses in the event of large up moves in the underlying. Typically, though, hedge funds buy additional convexity exposure by *"paying theta."* This gamma trading also affects the other greek metrics of the portfolio and, therefore, will need to be adjusted to obtain the desired levels of exposures to them.
- *Rho:* As in the case of straight bonds, this measures the change in the value of the convertible bond to a small change in the interest rate and is the bond's *duration*. The higher the volatility of interest rates or *yield volatility*, the higher the risk in the convertible due to its sensitivity to duration risk and the negative convexity embedded in the convertible. Common hedging trades for interest-rate risk are through shorting Eurodollar and/or U.S. Treasury futures and/or options on them.
- *Credit-spread delta,* or simply*, credit delta,* is used to monitor and separate the interest-rate risk from the credit risk of the position. A long convertible bond, unless credit hedged, is short credit convexity as the investor is also exposed to the credit risk of the bond. A credit default swap with a bond of the issuer of the convertible as the reference security, if available and liquid, would be the ideal credit hedge instrument. However, these being rarely available for the typically noninvestment-grade-rated or unrated issuers of convertibles, a short position in the appropriate CDX index is generally used as a proxy, at a portfolio level with the attendant credit basis risk introduced. For a portfolio with credit hedge instituted, increase (decrease) in the credit spread leads to higher (lower) portfolio P&L level due to the credit move. Further, as interest

rates and credit spread are generally correlated, hedging one also affects the measure of the other. Hence traders also use judgment in apportioning resources between hedging interest-rate and credit-spread risks. Asset swap for a convertible, if available, would hedge both interest-rate and credit-spread risks. The asset swap counterparty, in such a transaction, assumes both these risks and being compensated by cash flows from the convertible while the convertible holder retains the equity exposure.

- *Theta:* Measures the rate of time decay in the value of the options embedded in the convertible, with its decay rate increasing with declining time to maturity or the stipulated or conditional terminal date of the option. As in all options, the decay rate is highest closest to maturity or alternate early-termination events; the latter include mandatory conversion date and the convertible note *redemption notice period.* As theta is a drag on the portfolio's performance, its cost/benefit is intensely monitored.
- *Vega:* Measures the change in value of the convertible to a small change in volatility of the underlying stock. High volatility underlying shares, such as those in the Internet, media, technology, and telecommunication sectors, carry the risk of volatility collapse, more specifically, collapse of the implied volatility. Illiquidity-driven implied volatility collapse devastates the value of convertibles. This has occurred episodically in the past and includes the global recession that started in 2007–2008.[40] Note that volatility can have a perverse impact in close to event dates such as maturity date or redemption date with little or no remaining call protection remaining for the convert. In such situations, increase (decrease) in the volatility level can lower (increase) the value of the convertible though mitigated to some extent if the terminal price of the stock is an average price on the event date is computed over a stipulated averaging period. The role of vega, in addition to in the gamma trading context, is also crucial in variance and volatility swaps trades that aim to hedge or profit from the estimated volatility of the portfolio.
- *Second derivatives:* The most important of these are the gamma for equity options and its analog for interest rates, convexity. Another is *volga*, the rate of change in vega for a small change in volatility.
- *Cross partials:* These are second-order, although important, risk elements. Examples include the evolution of credit spread with the change in the price of the underlying stock and, similarly, for change in volatility with change in the underlying stock price.

---

40. Note that equity volatility may continue to be high for highly volatile stocks during periods of high stress in the market, as happened in the 2008 recession. However, investor withdrawals from the markets resulted in "fire sale" liquidation of securities in most asset classes and even more so in lower-rated securities. The convertible bond pricing curve experienced a significant dislocation, further accentuated by illiquidity. Therefore, although vega and illiquidity are distinctly different, holders are mindful of high-vega stocks in this context.

Collectively, these metrics help guide the investor toward a desired risk exposure and corresponding expected return from the perspective of a single security holding perspective. Additionally, the specific relative attractiveness compared with other available opportunities, its risk/expected return profile, and its contribution to the portfolio as a whole also need to be considered. The trading task is made easier when the model also provides scenario analyses—for varying input parameters of holding period horizon, rates, spread, volatility, changing richness/cheapness from current situations—and also built-in portfolio management, risk analytics, and trade execution systems. Most analytical trading models provide for these features.

Second in issuance only to convertible notes, though a distant second, is the structure colloquially called "mandatories," discussed next.

MANDATORILY CONVERTIBLE SECURITIES

In its earliest iteration, in the early 1990s, the current version of the mandatorily convertible security, or simply known as a *mandatory,* started out as a convertible preferred share maturing in three years, with an out-of-the-money conversion option benefiting the holder, as in a standard convertible debt security, but without the holder's option to receive par in the event of the parity value being less than par at maturity and instead was replaced with the holder mandatorily obligated to receive parity value delivered in shares at settlement. Thus, holders have no downside protection other than the higher preferred dividend yield of the mandatory that exceeded the dividend yield on the underlying common stock.

Therefore, it can be viewed as share-settled convertible, into the underlying shares, with the additional feature of an at-the-money put that the issuer is long and the holder is short, compensated for by the issuer paying a higher preferred dividend rate.[41] Equivalently, a mandatory with the underlying asset being one share of the common, can be viewed as a combination of (a) long one share of the underlying common stock at the reference price, plus (b) a *ratio call spread* comprising (i) a long position in less than one unit of a call at a higher strike price and lower conversion ratio, and (ii) a short position in one unit of an at-the-money call at the lower strike price and higher conversion ratio.

To illustrate, if the mandatory is sold at a 20% premium over the reference price of \$40, its conversion price—$40 \times 1.20 = \$48$—is the *higher strike price*. Its corresponding initial conversion ratio—$\$40 / \$48 = 0.8333$ shares—is also known as the *lower conversion ratio*, or the *upside conversion ratio*. The at-the-money short call position has a strike price of \$40 and a conversion ratio of 1 share. They are known, respectively, as the *lower strike price* and the *higher conversion ratio*.[42] In this context, the higher yield of a mandatory when compared to an

41. Or a higher coupon rate, if structured as a mandatory note.

42. If the mandatory is issued with a redemption value equal to \$50 or \$100, as is now commonly done, the underlying shares and strike prices are scaled accordingly. For example, in the case illustrated above, if the mandatory issue price were \$50 for a \$50 redemption price each, the upside conversion ratio would be $= \$50 / \$48 = 1.0417$.

otherwise identical traditional convertible security is to compensate for the short at-the-money leg in the ratio call spread. Its payoff diagram approximates that of a *prepaid forward share agreement*.[43]

The convertible mandatory product was developed in response to issuers' intent to lower the debt-to-equity ratio on their balance sheets, a factor considered by rating agencies in assessing the issuing corporate's credit worthiness and assigning debt rating accordingly. Its popularity with issuers stems from the possibility of selling common equity at a premium, thereby effecting a lower dilution rather than selling common shares at the then spot price. As it results in issuance of additional shares under any outcome, issuance of a mandatory receives the same 100% equity credit from the rating agency, S&P, as if the issuer had issued common shares.

In the equity-linked terminal payoff diagram in Exhibit 38-3, the 45-degree line GAE represents the common stock, and OABC the traditional convertible debt security; GABC represents the mandatory security.[44]

This basic structure has evolved, such as into mandatory convertible notes structure in Europe, and changes in the U.S. mandatories to address accounting and tax concerns of issuer and holders.[45,46] However, despite the structural differences, the descriptors and underlying variables applicable to the valuation of a mandatory are essentially the same as applicable to convertible notes. Additional features, analogous to convertible notes, now include conversion ratio adjustments (as in Appendix 38A), equity-dilution-reducing transactions by the issuer (as in Appendix 38C), as well as make-whole adjustments to conversion

---

43. Not surprisingly, therefore, that a suggestive marketing name for this structure from an underwriter investment bank was "YES," the acronym for Yield Enhanced Stock.

44. As an aside, from the mandatory securities' evolutionary perspective, the earliest mandatorily convertible security was of the capped common variety represented by GADF in the schematic of Exhibit 38-3. Within six months of its design, in 1991, by the investment bank Morgan Stanley, and called Preferred Equity Redemption Cumulative Stock ("PERC"), it was used to raise $4 billion by several then-well-known and desirable issuers such as General Motors, K-Mart, and Texas Instruments. It attracted yield-oriented investors due to its higher yield than that of the underlying common share, which was to compensate the investor for the short out-of-the-money call in the structure that benefited the issuer. PERCS soon lost popularity with investors due to its upside cap on the gains of the underlying and so reflected in the financial press. See, for example, L. Light, "'PERCS' You May Be Better Without," *Bloomberg News*, April 19, 1992.

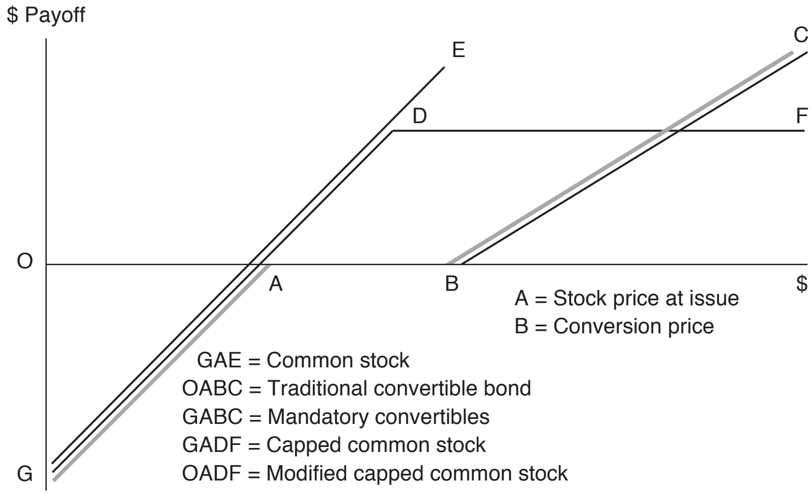
Another structure of the capped common—this one with downside protection of a bond—was issued by Microsoft Corp. in December 1996. Despite its payoff schematic as OADF, it was eagerly received by dedicated convertible investors as the only manner of obtaining exposure to a very popular growth stock whose common stock paid no dividends. These capped common structures are no longer issued in public markets.

45. The tax, accounting, and legal details are the realm of professionals in those fields and hence passing mention only here.

46. An overly simplified rationale for the current structure of U.S. mandatories is due to the earlier convertible preferred share structure resulting in dividend withholding from non-U.S. domiciled investors not otherwise subject to U.S. taxes. In addition, in the United States the structures have evolved to address the tax deductibility of the periodic distributions made to service the mandatory convertible security.

EXHIBIT 38-3

Equity-Linked Payoff Diagram



ratio upon fundamental change (as in Appendix 38B) and incrementally elaborated below.

Valuation

The most logical approach to valuing a mandatory in its current structural iteration is to value its constituent components, namely, the prepaid forward share agreement plus the ratio call spread, as proposed by Arzaq[47] and modified by Amman and Seiz.[48] The price of the mandatory at time t, P_t, is given by

P_t = Present value of the par amount discounted at the risk-free rate

+ Present value of the fixed coupon payment to maturity discounted at the credit curve for the issuer

+ Value of the long conversion option at the upper strike × the number of calls at the upper strike price

– Value of the short call at the lower strike × the number of calls at the lower strike price

47. E. Arzac, "PERCS, DECS, and Other Mandatory Convertibles," *Journal of Applied Corporate Finance*, Spring 1997, pp. 54–63.
48. J. Amman and R. Seiz, "Pricing and Hedging Mandatory Convertible Bonds," *Journal of Derivatives* 13(3), 2006, pp 30–46.

While the valuation of the options is straightforward using standard option valuation formulae, it is argued that because the par value can be settled in stock and hence the possibility of default is eliminated, its discounting should be at the risk-free rate. On the other hand, the cash coupons should be discounted at the risk-free rate plus the credit spread applicable to the payment date considering the possibility of default by the issuer. However, this differential discounting rate does not handle the case if, as seen in the Stanley Black & Decker mandatory (below), the periodic payments that proxy the coupons can be deferred without causing default and can also be paid in cash or shares or combination.

Sample Mandatory Convertible

A very recent mandatory issued in the United States exemplifies current evolution of the terms of the mandatory product.

Off of the closing price of the day for its common stock on November 7, 2019, Stanley Black & Decker raised a gross amount of $675 million through the sale of its "Equity Notes" via a group of underwriters. Effective for trade at the start of the next day, November 8, and trade settle date of November 13, 2019, and maturity date of November 15, 2022, this structure that was effectively a three-year mandatorily convertible security, convertible into its own stock (Ticker = "SWK") was priced at a 20% conversion premium, paying 5.25% per annum, to be paid quarterly, in arrears. Sold at 100% of its redemption value, also colloquially called par value, of $100, it is nonconvertible prior to maturity, other than in exceptional conditions specified. In addition, it includes standard features such as conversion ratio adjustments for corporate actions, make-whole upon fundamental change, and the issuer's choice to settle upon conversion by issuance of shares or cash or combination thereof. Further, SWK also has the option to pay the periodic payments, here termed as the "Contract Adjustment Payments," in cash, shares, or combination; these payments are deferrable but cumulative.[49]

Terms:	
Reference price:	Closing price on November 7, 2019 = $159.45
Initial conversion premium:	20%
Initial conversion price:	$159.45 × 1.20 = $191. 34
Initial upside conversion ratio:	$100.00 / $191.34 = 0.5226 common shares
Maximum settlement rate:	$100.00 / $159.45 = 0.6272 common shares

49. The preceding summary is abstracted from the detailed definition and language of the Offering Prospectus documents, and Supplements thereto, from the perspective of a holder of the security. It does not purport to be fully reflective of the tax, accounting, and legal aspects of the offering documents.

Further, if at settlement, the share price is lower than the conversion price but higher than the reference price, then conversion shall be into a variable number of the underlying common shares whose value equals \$100. For example, if the share price at settlement, as defined, were to be \$175, the number of shares due to the holder, assuming no prior conversion ratio adjustments, would be \$100.00 / \$175.00 = 0.5714 common shares.

The terms describing the structural aspects from which the above summary is extracted bears some mention. Labeled as Stanley Black & Decker "Equity Units," the security is issued as a "Corporate Unit" and offered at a price of 100% of each Equity Unit's "stated amount" of \$100, together with a contractual obligation for the holder to purchase and the issuer to sell a 10% interest in the issuer's 0% Perpetual Convertible Preferred Stock with a liquidation preference of \$1,000. The "Contract Adjustment Payments" shall be at the annual rate of 5.25% (payable as elaborated above). Only the 0% Perpetual Convertible Preferred has the conversion option and separated from it, the equity units do not. Further, if the event that the remarketing of the 0% Perpetual Convertible Preferred, which shall occur in 2022, a new, presumably higher, preferred dividend rate may apply to this remarketed convertible preferred and the conversion option continues with it. Typically, such remarketing efforts being rarely successful, the equity units shall obligatorily acquire the proportionate interest in the 0% perpetual convertible preferred and immediate conversion thereupon into the number of shares per the terms established.[50]

The make-whole matrix for fundamental change for a mandatory, while based on the same principles as that for a convertible note, reflects its aforementioned embedded ratio call spread and the present value of the projected cash flows to the maturity date.

For the Stanley Black & Decker 5.25% mandatory, in the make-whole matrix (see Exhibit 38-4), all cells under the column \$159.45 are set to zero, and holders will receive the Maximum Conversion Rate since that equates the holder's \$100 investment. Also, the last row representing the settlement or maturity date, has all cells at zero since at maturity both options in the embedded call spread have zero time value remaining. For all other cells, the adjustment reflects the time value of the call spread for each share price level and effective date. As usual, share adjustments shall be per linear interpolation for share price levels and effective dates not represented in the matrix, with the caveat that in no event shall the number of shares at settlement exceed twice the Maximum Settlement Rate of 0.6272.

Note that compared to the make-whole matrix for the Tesla 2's of 24, where with the exception of the zero filler cells and left-most column of the common share price at issue, all other cell entries are monotonically decreasing from left to right columns and from top to bottom rows. Not so in the case of the make-whole for the mandatory due to the two present value components and the two parts of the ratio call spread that define a mandatory.

---

50. From a holder perspective, abstracted from the above legal language is message that the periodic payments are tax deductible for the issuer with applicable resulting impact for the holder.

TRADING CONVERTIBLE PORTFOLIOS

The convertible asset class has evolved in response to changes in macro factors in the global economy. Prominent among the latter are the extended period of low interest rates, and low volatility levels accompanied by inexorably rising equity prices, though with some periodic correction blips. Both the supply side as well as the demand side for convertibles have significantly impacted their issuance volumes, structure, and portfolio trading.

On the supply side, trends include:

- Lower net issuance, defined as new issuance dollar amounts less matured, redeemed, or converted amounts. The upsurge in straight debt issuance at attractively low rates has reduced the need for issuance of convertibles with its attendant potential equity dilution.
- Issuer recognition that equity volatility, which is a by-product of its inherent business operations, is an asset that can also be monetized. This is manifested in ever tightening competitive terms offered to the issuer by competing investment banks in selling to the convertible asset class investors.
- Structural rationalizations, such as the dilution protection and value conservation clauses, contribute toward reducing pricing inefficiencies in the asset class.
- Reduced liquidity provision by investment banks in response to increased regulatory capital requirements has negatively affected secondary market trading.

The corresponding demand side trends include:

- Surge in passive trading and indexation and the proliferation of exchange-traded funds (ETF) has created considerable fee pressures for both the convertible long-only funds as well as the convertible arbitrage funds.[51]
- Reduced demand for downside protection, as offered by convertibles, in a generally rising equity unhedged exposure.

As a result, convertible portfolio management requires deliberate decisions on retained risk exposures. The tools available to the outright manager in that context are:

- Security selection: participating or not in any individual convertible security available based on the fundamental analysis of the underlying equity, its expected volatility, the issuer credit, and potential liquidity.
- Concentration and diversification aspects from issuer, industry sector, ratings, maturity tenor, and geographical/political risks.

51. Only a few dedicated convertible ETFs exist currently.

- Allocation of exposure to the asset class: specifically, this implies cash retention level in the case for dedicated convertible funds, despite the cash drag involved. For nondedicated, opportunistic long-investment investors into the asset class, it implies how much and when to invest. Thus, exposure timing is an important risk retention decision.

  While the principal sources of portfolio gains for outright funds are through valuation gains on the underlying stocks, and yield advantage of the convertibles, availability of analytical valuation models help inform their portfolio buy/sell/hold decisions, despite their not being permitted to engage in hedging trades. In addition to the fundamental research on equities and credit as done by the outright funds, convertible arbitrage incorporate the hedging analysis provided by the analytical valuation models in expressing their trades. Several dedicated convertible hedge funds have, as an upshot, evolved into trading in relative value credit arbitrage and capital structure arbitrage. That said, delta and gamma trading still remain a dominant focus area for convertible arbitrage funds and are operated with a leverage. While in the pre-2008 period portfolio leverage of 6× or higher was not uncommon, the current level is estimated to be in the 2–2.5× range.

  It is interesting, therefore, to study the P&L realization of a single convertible note through delta trading during what has been termed a "once-in-a-lifetime" period of rapid volatility evolution. This follows next.

DELTA TRADING P&L: A HIGH VOLATILITY SCENARIO EXAMPLE

Due to the exogenous event of the Coronavirus occurrence in the United States, security markets globally experienced valuation shocks. This has been intense in severity in the short period of time involved. In the United States, for example, the S&P 500 Index dropped 29.18% in one month, from February 19, 2020, to March 18, 2020. The TSLA common stock underlying the TSLA 2% of 24 convertible note, chosen by happenstance as the prototype security for this chapter, dropped from \$917.42 to \$361.22, a drop of 60.53%.[52]

Appendix 38D shows the daily changes in the convertible's value, its delta, gamma, and daily P&L for eight consecutive trading days, ending on March 18, 2020. It also shows the corresponding daily changes in the S&P Index, TSLA stock price, VIX Index levels, and the yield on Treasury five-year notes. The P&L reported is on an unlevered basis.

52. As of this writing, the S&P Index and TSLA stock have both recovered to reach new record levels. TSLA stock, in addition, has split 5:1 as of August 31, 2020. With the conversion ratio thus changed taken into consideration, the rest of the convertible valuation analytics remains unaffected.

KEY POINTS

- Structural evolutions in the convertible asset class products, in response to market macro factors and greater analytical sophisticated, on the part of issuers and investors, have contributed further toward convertibles being viewed as a fair and viable asset class for both issuers and investors.
- Convertible securities continue to be a small, though meaningful, source of investor capital for corporate issuers who, largely due to rating pressures, are generally unable or unwilling to access loan or senior unsubordinated debt markets.
- However, with dilution-neutralizing hedging being available to issuers, with TSLA 2% of 24 as an example, the average issuer profile is evolving toward larger size transactions and more liquidity.
- While yield advantage and positive convexity continue to be the principal return drivers, fundamental research, analytics, and risk measures are of ever-increasing importance as convertibles are now far evolved from when they were perceived—in some circles—as a small and hence inefficiently priced asset class.
- This trend toward pricing efficiency will be further enhanced when additional tools, such as single-name credit default swaps, become liquidly available to refine risk exposure types and levels that a holder chooses to retain in a convertible portfolio.

APPENDIX 38A

Conversion Ratio Adjustments to Corporate Actions

Objective: To preserve the conversion value of the conversion option embedded in the convertible security that might otherwise be adversely impacted by corporate actions or transactions while the convertible security is still outstanding.

Caveat: The adjustments, usually an increase in the applicable conversion ratio, will not be made if the convertible already participates concurrently with the common shares in proportion to the applicable conversion ratio as a result of the corporate actions described below. Exceptions to this caveat pertain to stock splits or reverse splits of the underlying common share, which will occur simultaneously.

Adjustment formulae for the typical cases, subject to a deferral option (see below) are:

1. *Anti-dilution adjustment*: For common share issuance pursuant to stock dividend, distribution of shares, stock split, or reverse split, the formula is

$$CR_{post} = CR_{pre} \times OS_{post} / OS_{pre} \tag{A38-1}$$

where CR = applicable conversion ratio, OS = shares outstanding, and the subscripts "pre" and "post" dates as defined for the above corporate event event.

2. *Discounted share sale adjustment*: This pertains to the case where through an offer of rights, warrants, or options, the underlying shares are offered for sale at a discounted price from the then-current stock price defined, say, as the average of the closing price of 10 consecutive days immediately preceding the offer announcement date. Such offers have an ex-date for the warrant or option exercise, and the formula is

$$CR_{post} = CR_{pre} \times (OS_{pre} + N_{addl}) / (OS_{pre} + N_{disc}) \tag{A38-2}$$

where N_{addl} = additional shares issued and N_{disc} = aggregate realized proceeds from the sale of the additional shares divided by the undiscounted average closing price, as defined.

Numerical example: OS_{pre} = 1,000,000 shares; distribution = one warrant per share outstanding; number of warrants to acquire an additional share = 2; average price of the share over the 10-day prior to the announcement date = \$40 per share; discounted price = 80% of the average price of \$40 = \$32 per share.

a. If all the warrants are exercised, then total issuable new shares = 500,000, then

$$CR_{post} = CR_{pre} \times (1{,}000{,}000 + 500{,}000) / (1{,}000{,}000 + (500{,}000 \times \$32 / \$40)) = CR_{pre} \times (1{,}500{,}000 / 1{,}400{,}000) = 1.0714$$

b. If only 700,000 warrants are exercised, total issuable new shares = 350,000, then

$$CR_{post} = CR_{pre} \times (1{,}000{,}000 + 350{,}000\ ) / (1{,}000{,}000 + (350{,}000 \times \$32 / \$40)) = CR_{pre} \times (1{,}350{,}000 / 1{,}280{,}000) = 1.0547$$

In the event that consideration for purchase of these warrants, rights, or options involves noncash consideration to any extent, the fair market value of such assets shall be determined by the board of directors of the issuer.

3. *Cash distributions and increase or decrease in dividends*: For the event date being the ex-dividend date, S as the stock price on the date immediately preceding the ex-dividend date, T as the threshold for the regular dividend then in effect preceding the ex-dividend date, and D as the distribution, the most frequently used formula is

$$CR_{post} = CR_{pre} \times S / (S - (D - T)) \tag{A38-3}$$

Note that the threshold dividend level is $T = 0$ in the case where the underlying stock did not pay regular periodic dividends at the time of issuance of the convertible, as in the case of the prototype Tesla convertible discussed. The logic for this adjustment is that in the case of the distribution D, the ex-dividend price of the underlying is expected to decline by an incremental amount over the usual decline to the extent that D exceeds T.

T = 0 also if this current distribution is a special or nonregularly scheduled distribution.

A less frequent alternate adjustment in the above cases is

$$CR_{post} = CR_{pre} \times (S - T) / (S - D) \tag{A38-4}$$

The adjustment in Equation A38-4 takes into consideration the ratio of the expected decline in the stock price, S, due to the regularly scheduled dividend threshold, T, to that expected to result from the increased or special dividend, D. This is perhaps a less defensible argument than that resulting in Equation A38-3.

Further, for every $D > T$, Equation A38-3 results in a larger conversion ratio adjustment. The opposite is the case where $D < T$, that is, in the event a cut in regular dividend should it occur.

In all events, T is adjusted in inverse proportion to the conversion ratio adjustment.

4. *In-kind distribution*: This case involves distribution in proportion to the underlying shareholding, and hence also proportional to the then-effective conversion ratio of the convertible. Further, in the usual non-readily-available traded prices of such assets—that may include debt assets, property, rights, warrants, options, unlisted shares—a fair market value estimate, F, is established by the board of directors, or their designees. A valuation period preceding the effective ex-distribution date and corresponding valuation methodology for pricing data available is also usually specified.

Conversion ratio adjustment in this case is identical to Equation A38-3, with $T = 0$ and F in place of D.

$$CR_{post} = CR_{pre} \times S / (S - F) \tag{A38-5}$$

5. *Spin-off of listed asset:* This case occurs when the common stock underlying the convertible effects a distribution of an exchange-listed equity or units in which it holds an interest. The event date is the spin-off effective date, the spin-off period is usually 10 days immediately preceding the spin-off date. The calculated fair market value, F, is the to-be-distributed equity's share price average of the reported closing prices for the spin-off period multiplied by the number of shares of the spin-off equity to be distributed per share of the underlying stock. S is the reported closing price of the underlying stock immediately preceding the ex-dividend date. In this case, the conversion ratio adjustment is

$$CR_{post} = CR_{pre} \times (P + F) / P \qquad \text{(A38-6)}$$

6. *Self-tender offer*: With a view to reducing the number of shares outstanding, if the issuer of the convertible security engages in share buybacks in the open market, there shall be no change in the conversion ratio of the convertible as the share price itself will reflect the effect of the share buyback, thereby benefiting all remaining equity interests, including the convertible holder. On the other hand, if effected through a self-tender or exchange offer to substantially all equity interests and not to the convertible holder, the convertible ratio will be adjusted upward to reflect the consideration paid out in the self-tender that results in the value of the underlying stock. The event date here is the expiration date of the tender offer and the conversion ratio adjustment is

$$CR_{post} = CR_{pre} \times (C_{tender} + (S_{tender} \times OS_{post})) / (S_{tender} \times OS_{pre}) \qquad \text{(A38-6)}$$

where

C_{tender} = the aggregate consideration received in cash and/or kind whose fair market value is established by the issuer's board of directors or their nominees

S_{tender} = usually the average of the reported closing price of the immediately 10 days starting with, and including, the trading day immediately following the tender offer expiration date

Note that OS_{post} excludes all shares accepted for purchase through this tender or exchange offer, while OS_{pre} does include such shares.

Deferral of conversion ratio adjustments: The above adjustments are made on the ex-date of the corporate event unless the change results in less than a typical threshold of 1% of the conversion ratio then in effect. In such cases, the ratio change is instituted at the earlier of when they cumulatively exceed the threshold level change or upon conversion.

APPENDIX 38B

Fundamental Change Make-Whole Adjustment to Conversion Ratio at Conversion

Motivation: Consider the case of an acquisition transaction where the common stock underlying the convertible is acquired in exchange for consideration comprising of a combination of:

- **a.** 0% to 100% of the acquiror's common shares
- **b.** 0% to 100% in cash
- **c.** Some illiquid or difficult to value in-kind asset(s)

Case (a): If 90%, or greater, of the consideration value is in the form of the acquiror's common shares, as agreed to by the acquiree's board of directors and so communicated to the Trustees for the issue, the time value of conversion option will be deemed to be unaltered. Consequently, there shall be no make-whole adjustment to the conversion ratio of the convertible. Going forward, post the effective date of the acquisition, the convertible security will continue into shares of the acquiror as determined in the acquisition share exchange ratio. Further, while the coupon rate and the maturity date remain unchanged, all other parameters including the dividend threshold, the value retention adjustments to the conversion ratio, will be correspondingly adjusted to conform to the terms of the convertible specified at issue. Despite these adjustments, the conversion value option may differ from before the event date due to the variables of the new underlying stock being different, particularly its volatility; its borrow cost, which, in turn, is a function of its liquidity; and the credit spread of the acquiror.

Case (b): An entirely cash takeout of the underlying common would retain zero residual time value of the holders' conversion option and would cause the holder to exercise conversion. The value erosion due to an in-kind component would be total.

Case (c): Subject to the conversion ratio adjustment, discussed in Appendix 38A, being in effect, some value erosion is likely, though not a total loss of value.

The *make-whole fundamental change matrix* specifies the temporary adjustment to the conversion ratio upon conversion, in the event of a fundamental corporate change. This matrix, left blank in a preliminary ("red") offering prospectus, is set forth in a supplement to the offering prospectus following the pricing of the convertible and prior to the commencement of its public trading on the relevant exchange on the next trading day.

The intent for this make whole fundamental change matrix is to mitigate the impact of value erosion through cases b and c above and also if redeemed by the issuer during a nonredemption period In effect for reasons permitted as described in the prospectus. Further, as an offset to provisional redemption terms or a freely redemption period, which would normally “cost” the issuer in a lower initial conversion premium or higher coupon, this make-whole may also be included in the defining terms of the convertible at issue.

As can be seen in Exhibit 38B-1, the matrix for the prototype Tesla 2’s of 24 share price scenarios for the underlying common are on the X-axis and Effective Dates for redemption or conversion on the Y-axis

The cells specify the number of additional shares, if any, to be added to the then effective conversion ratio to compensate for the erosion of the time value of the conversion option.

Typically, the *x*-axis scenarios extend to triple or even 5× times the price of the underlying at issue; going beyond 10×, as in the situation below, is highly unusual. For intermediate dates and stock price levels not represented in the matrix, a linear interpolation between the two adjustment ratios will be made for time difference based on a 365-day year. The matrix also specifies the maximum and minimum adjustment ratios. For example, for TSLA price at or above $2500 per share there shall be no additional share adjustment.

Calculation of the make-whole matrix cells: Recall the initial terms of the issue. They were as follows:

Issue pricing date:	Close of trading on May 2, 2019
Trade settle date:	May 7, 2019
Maturity date:	May 15, 2024
Par value of note:	$1,000.00
Price of note at issue:	$1,000.00
Reference price of the underlying:	$243.00 per share
Initial conversion premium:	27.5%
Initial conversion price:	$243 × 1.275 = $309.83
Initial conversion ratio:	$1,000 / $309.83 = 3.2276 shares per note
Redemption:	Nonredeemable for life

EXHIBIT 38B-1

Computation methodology for the cells in the matrix: Let S denote the stock price scenario under consideration, CRA denote the conversion ratio adjustment, ICR = 3.2276, as the initial conversion ratio. Then:

- For all rows under the column under S = \$243—which is the stock price on date of issue—and the last row pertaining to the maturity date, May 24, 2024, with the increasing stock price scenarios pertaining to that row, the CRA is calculated as follows:

  a. For $S \times \text{ICR} \geq \text{Par}$, CRA = 0;

  b. For $S \times \text{ICR} < \text{Par}$, CRA = $((\text{Par} - (S \times \text{ICR})) / S) - \text{ICR}$

  Numerical examples:

  1. For $S = 243$, $S \times \text{ICR} = 243 \times 3.2276 = 784.31$. Therefore, condition b applies. Hence,

  $$((1000 - 784.31) / 243) - 3.2276 = 0.8876$$

  Comment: 3.2276 + 0.8876 = 4.1152 shares is the upper limit and 3.2276 is the minimum number of shares specified for the Tesla convertible note. Similar limits pertaining to the make-whole adjustment matrix are common for new issue convertibles.

  2. For S = \$280 at maturity date, $S \times \text{ICR} = 280 \times 3.2276 = \$962.72$; condition b applies. Hence,

  $$((1{,}000 - 962.72) / 280) - 3.2276 = 0.3438$$

  3. For S = \$309.83, the initial conversion price, $S \times \text{ICR} = 309.83 \times 3.2276 = \$1{,}000$, and condition b applies. Hence adjustment ratio is zero. And so also for all other higher share price scenarios in that row.

- For S = \$2,500 or higher, there is zero conversion ratio adjustment specified regardless of the date of the option value erosion occurrence consequent to the fundamental corporate change event.
- For all other cells, a theoretical value— based on the then spot stock price, and the remaining time to maturity commencing from the event date—is computed with input variables as obtaining on the date of pricing the note. The adjustment ratio is then calculated as

  $$\text{Conversion ratio adjustment} = (\text{Theoretical value} - \text{ICR} \times S) / S$$

  Numerical example: For S = \$400, for date May 15, 2021, since the exact convertible valuation model is proprietary to the underwriter and hence not publicly available, the computed theoretical model value can be solved for and works out to be

  $$0.2509 = (1391.40 - 1{,}291.04) / 400$$

Note that here 1,291.40 is the conversion value at S= 400 and \$100.36 is the remaining time value computed using the convertible valuation model employed with values of variables—such as volatility, yield curve, credit spreads, stock borrow—as obtaining on the date of issue of the note. Hence the incremental adjustment of 0.2509 shares valued at S = 400 equals the remaining time value.

While the make-whole matrix does go a substantial way toward compensating the holder for the erosion of the time value of the conversion option, it is not perfect. The shortfall may come from the values of the estimated variables employed in the valuation model being different than those as of the event date, setting aside the idiosyncrasies of the valuation model and its sophistication.

- In the hypothetical case that the Tesla 2 of 24 had a provisional call at 130% after year 3—which it does not—the provisional conversion price would have been = \$309.83×1.30 = \$402.78. Then subject to the test that this provisional call price threshold was equaled or exceeded by TSLA closing price on 20 out of 30 trading days, the conversion ratio adjustment cells—for the column for \$402.78 or higher stock prices, for rows May 15, 2022, and May 15, 2023—would have been zeros.

APPENDIX 38C

Equity Dilution-Reducing Transactions by the Issuer

Equity dilution concern: Any financing undertaken by a corporate issuer is always analyzed for its eventual impacts on the cash flows and earnings per share that affect all holders of the issuer's securities. In the case of equity and equity-linked issues, this attention is further accentuated since equities, as the junior-most in the payoff hierarchy, are viewed as residual claimants to the assets of the firm. Black and Scholes, following their derivations to price options on an underlying stock, have also shown how a common share may be priced as call option based on the value of the underlying firm. Taking this concept a step further, Geske shows how an option on the underlying stock is thus a compound option on the value of the firm, and thus is even more sensitive with respect to the underlying firm value.[53]

53. Robert Geske, "The Valuation of Compound Options," *Journal of Financial Economics,* 1979, pp 63–81.

It is no surprise, therefore, that an issuer of a convertible security, with its embedded equity-linked options, be concerned with the dilution impact on the underlying shares should the conversion option be exercised thereby necessitating settlement by issuance of the stipulated shares or their cash value or in a combination thereof.[54,55] The direct effect of dilution is due to the reporting requirement that the issuer declare financial results, periodically, based on current shares outstanding as well as in the fully diluted form. The latter takes into account the potential incremental share issuances due to all then still outstanding equity-linked liabilities.

Additionally, the issuer is usually concerned by the signaling inferred by the market to the issuer's specific choice of the instrument, its size, pricing, use of proceeds, efficacy, and its eventual impact to equity valuation metrics. Finally, as it pertains to any equity-linked security, and particularly here applicable to convertible securities, is the impact of shorting of the underlying stock that is employed by hedge fund participants to hedge the convertible's embedded equity exposure to desired levels.[56]

Dilution reduction approaches: There are several methods available to either reduce or eliminate the dilution impact. In addition to open-market purchase of the underlying shares by the issuer, they include repurchase through a *forward contract*, a *pre-paid forward,* or a *collar contract* pertaining to the underlying common transacted, most commonly, with the derivatives desk of an investment bank as the counterparty, or even a *self-tender offer*. Each of these have their own advantages/drawbacks relating to the certainty of execution and net cost.

The most frequently used methods employed, as executed concurrently by TSLA at the time of issuance of the prototype "Tesla 2's of 24" convertible note, are:

- *"Happy meal" repurchase of shares*: Under this method of share buyback, the issuer enters into a derivative contract with the underwriter(s), or their affiliate(s), as counterparty, to offload the liability of the shares expected to be delivered, or their cash equivalent, or combination, upon conversion should it occur. This transaction is for the notional number of shares, underlying the aggregate note issue, occurs at an agreed upon delta hedge ratio, with the derivative contract maturity mirroring that of the convertible note. In turn, now with short equity exposure,

54. Ignoring the accounting and tax aspects, the in-cash settlement, in lieu of the physical settlement in shares, may be viewed as the issuer acquiring the applicable number of shares in the market and delivering equivalent value for them to the holder.
55. *A Roadmap to the Issuer's Accounting for Convertible Debt*, Deloitte, 2019, pp 1–260, provides details.
56. Holdings by hedge fund participants cannot be avoided even if the convertible new issue is initially fully subscribed for by, and fully allocated to, outright investors and zero allocations to hedge funds. Even in this case, hedge fund participants will establish positions via secondary market purchases.

the counterparty reduces some of it by buying back shares from hedge funds to whom a subset of the new notes is allocated. This benefits the hedge funds too as they seek to establish a short position against their newly acquired convertible note position. The price per share of the short exactly equals the reference price of the convertible. Because it provides the definitive price and assured short sale, with the exact settlement date as the new convertible note being allocated to them, the hedge funds are relived of the market exposure that they would have faced otherwise in sourcing and selling shares short in the open market to establish the hedge position at just the right starting neutral hedge ratio. This "packaged" bond allocation along with the requisite short equity trade in the underlying is, therefore, called a "happy meal" in the convertible vernacular.[57]

Numerical example: Consider a hypothetical convertible note of issue size \$100 million, issued at par = \$1000, priced off of a reference price of \$40 per share as of the close of trading on the date of issue, conversion premium = 25%. Hence conversion price = \$50 per share, and initially convertible into 20 shares per note, with aggregate number of underlying shares = 2 million, and suppose that the initial delta is 42% and allocation to hedge funds = \$35 million of notes, with the balance \$65 million to outright investors.

> Equity component of the short position with hedge funds in a happy meal transaction = 35,000 note × 20 shares per note × 0.42 hedge ratio = 294,000 shares
>
> Short sale proceeds = 294,000 shares at the reference price of \$40 per share = 294,000 × 40 = \$11.76 million
>
> Hedge funds net outlay = \$35 million allocation less \$ 11.76 short sale proceeds = \$23.24 million

To address the remaining initial short in the counterparty's position—to the tune of 546,000 shares, in this example—the counterparty will engage in actual or synthetically equivalent share purchases to start, and dynamically hedge the exposure to the expiration date.

- *Bond hedge overlay*: The purpose here is to synthetically raise the effective conversion price for some, or all, of the shares as stipulated in the overlay transaction. This bond hedge overlay consists of two parts, both subject to holders exercising conversion of the convertible security. The first involves the purchase of the hedge by the issuer from the counterparty, as described above, for the latter to deliver to the issuer the number of underlying shares agreed to, or their value in cash, or

57. The cost the happy meal is defrayed by the issuer from the proceeds of the note issue and usually ranges around 15% of the net fund raise.

combination thereof. The second is a warrant sold by the issuer to the counterparty at a higher conversion price—commonly 30% above the initial conversion price in the case of convertible notes, and 10–15% higher in the case of mandatorily convertible preferred shares—for the same number of underlying common shares as agreed to in the first part, or their cash value, or combination. For tax reasons, the warrant is issued separately and expires a few days beyond the maturity of the convertible.[58]

Equivalently, in lieu of the warrant, the same result can be attained by the issuer selling to the counterparty calls capped at the higher exercise price for the same number of shares as stipulated and with maturity date as in the convertible note. In this version, the two legs of the transaction are included in the same document.

ADDITIONAL COMMENTS

- Note that the conversion ratio adjustments made for the note per dilution protection and value preservation, described in Appendix 38A also carry through for the derivative contracts described here.
- Incremental to the direct upward pressure on the underlying stock caused by share purchases by the hedge counterparty as it sets up its own off-setting position, the inferred message of these dilution-reducing transactions is also beneficial to the underlying stock price.

58. For details, see the Deloitte note cited in footnote 55.

Source: US Treasury.gov; Yahoo! Finance; Kynex, Inc.

Issue Descriptors: Coupon Rate: 2.00%, Maturity Date: 5/15/2024; Par: $1,000; Underlying Common: TSLA; Reference Price: $243.00 as of 5/2/2020; Initial Conversion Premium: 27.5%; Conversion Price: $309.83; Conversion Ratio: 3.2276 shares per note; Non-redeemable.

Assumptions: Ignoring transaction costs and bid/ask spread; delta hedges and stock trades assumed executed at the levels indicated. Ignoring any inherent model error for the single-factor convertible bond model from KYNEX INC.; Default inputs used for equity volatility, interest rates, credit spreads per the model vendor.

Sample calculation: Portfolio profit/loss =gain (or loss) from the stock short position minus loss (or gain) in the note price
i.e. = ((703.48 – 608.00) × 0.9621 × 3.2276) – ((240.60 – 212.28) × 10) = $13.29 per bond

Comments:

1. The specific week chosen represents what has been termed "once in a generation" volatility in the markets with the S&P 500 Index dropping 29.18% in a month from its high on 2020.02.19 to 2020.03.18, and the VIX Volatility Index jumping from a modest 14.38 to its highest ever level of 82.69 points. Columns 1 through 8 indicate the level of market turbulence.
2. During the same period, TSLA declined by 36.73%. As expected, the convertible note starting so deep-in-the-money, with a high delta and low gamma, portrayed equity-like behavior as expected.
3. Delta trade P&L profile, in (column 13, demonstrates the inherent attributes of the convertible product of "upside participation with downside protection".
4. On 2020.03.17, while the S&P 500 Index gained 6%, TSLA stock declined by 3.34% yet the conversion premium also declined. This suggests a downward shift of the valuation curve due to the widening of its credit spread and/or the bid-offer.
5. The continuing high delta is due to the still remaining long non-call period and TSLA stock's high volatility.

Matthew Hyatt, Ph.D.
Quantitative Researcher
FactSet Research Systems

Tom P. Davis, CFA, Ph.D.
Director, Fixed Income and Derivative Analytics
FactSet Research Systems

The aim of any convertible bond (CB) model should be to capture the price action present in both the equity and fixed income markets. Early approaches by Goldman Sachs[1] employed a binomial lattice to this end. An often-cited model is that of Tsiveriotis and Fernandes,[2] which split the CB into cash and equity components with only the former being subject to credit risk. The inability of the equity to default is the common criticism of all these early models. Takahashi, Kobayashi, and Nakagawa[3] made progress in addressing this by introducing a reduced form model for a default adjusted discount rate. The model linked the credit to the equity through the functional choice of the intensity. Ayache, Forsyth, and Vetzal[4] extended the approach of Takahashi, Kobayashi, and Nakagawa by assuming a fractional loss of the predefault value of the equity. Andersen and Buffum[5] went a step further—they model the possibility of default as the first hitting time of a Cox process, where the default intensity links the credit to the equity movements.

5. Leif Andersen and Dan Buffum "Calibration and Implementation of Convertible Bond Models", *Journal of Computational Finance* (2004), pp. 1–34.

In all studies, the models are calibrated to traded nonconvertible (vanilla) bonds and equity options. Recently, Xiao[6] was able to obtain theoretical prices using this approach that only differed from observed CB prices by 1–2 points. Arguably, the prices are in close agreement, albeit still in error. The fact that the theoretical prices don't agree with observed prices shouldn't be surprising—even though corporate debt and CDS will trade to maturities of similar tenor to CBs, vanilla equity volatility markets rarely trade out beyond one to two years. With no meaningful volatility market, the ability to calibrate to the term of a convertible bond is limited—hence the inaccuracy.

As of mid-2019, there are more than 1800 daily closing CB prices from 1135 individual issuers as detailed in Exhibit 39-1. Across a five-year time horizon, that number of bonds with observable prices grows to more than 4000 individual securities.[7] Likewise, almost half the CB issuers have either an explicitly traded CDS or some other vanilla bonds in the market with observable prices. Rather than derive a theoretical price, the credit risk can be marked to term and the volatility can be implied from the market, thereby providing a full risk-neutral calibration. In this chapter, a model is outlined that explicitly captures default risk, based on the model by Andersen and Buffum, where the necessary modifications to calibrate to market prices, and the implied volatility, are detailed. The default characteristics of the model are also discussed by investigating five specific securities that represent a broad cross section of the CB universe by both tenor and credit spread. This leads to a specification of the intensity process that explicitly links the performance of the equity and credit by matching the model parameters to defaulted bond prices. Furthermore, a methodology for marking the credit risk for both traded and nontraded credits is presented, which is shown to capture the expected price action across the various asset classes.

The chapter concludes with a study of the implied volatility and sensitivities of the five CBs, where the links between the CB volatility and the equity volatility are investigated. The volatilities broadly agree across both markets with the longer-dated CB volatilities consistently trading at lower levels than the shorter-dated vanilla equity volatilities. This finding confirms the premise that marking to exchange-traded volatilities cannot provide an accurate valuation. Finally, links to convertible bond arbitrage are discussed before a summary of key points is given.

THE MODEL

The accepted theory for the valuation of convertible bonds is due to the early research notes published by Goldman Sachs and Tsiveriotis and Fernandes at Morgan Stanley. However, as previously noted, while these models contain the credit of the issuer, the credit is static and does not alter the bond characteristics

if the issuer is distressed. Therefore, Andersen and Buffum introduced credit dynamics by modelling default with a Cox process[8] (sometimes referred to as a doubly stochastic Poisson process). The process models the issuers' credit dynamics via an intensity process, which is linked to the equity price. As the equity price decreases, the "first hitting time" of the Cox process—representing the default of the CB issuer—becomes more likely. The addition of this jump-to-default process requires a modification of the drift of the equity to maintain arbitrage freedom—that is, all forward contracts are correctly priced. Since $E\left[dN\right]=\lambda\left(S,t\right)dt$ (where $\lambda\left(S,t\right)$ is the default intensity, S is the stock price, and E denotes risk-neutral expectation) the resulting stochastic differential equation has the risk-neutral drift of the equity modified by the default intensity

$$\frac{dS_t}{S_{t-}}=\left(r_t-q+\lambda\left(S,t\right)\right)dt+\sigma dW_t-dN_t \tag{39-1}$$

where r_t is the risk-free interest rate, q is the instantaneous dividend yield, σ is the equity volatility, and W_t is a Brownian motion. That the first hitting time represents a default is guaranteed by the last term in Equation (39-1): the change in the underlying equity is the entire value and the equity price is driven to zero (assuming that equity holders do not recover any value in default).

The addition of this jump to default process gives rise to a modified Black-Scholes partial differential equation,

$$\frac{\partial V}{\partial t}+\left(r_t-q+\lambda\left(S,t\right)\right)S\frac{\partial V}{\partial S}+\frac{1}{2}\sigma_{t,S}^2S^2\frac{\partial^2 V}{\partial S^2}+f\left(V,S,t\right)=\left(r_t+\lambda\left(S,t\right)\right)V-\lambda\left(S,t\right)R \tag{39-2}$$

where V is the value of the convertible bond with recovery rate R and the function $f\left(V,S,t\right)$ represents external cashflows such as coupon payments. Standard finite difference techniques can be used to solve this equation numerically[9] with the appropriate boundary conditions, including call and put features.

The bond coupons c can be represented as an additional term that needs to be inserted on the correct node of the finite difference grid when solving Equation (39-2),

$$f\left(V,S,t\right)=\sum_i c_i\delta\left(t-t_i\right) \tag{39-3}$$

On dates where the holder can convert the bond to shares, the boundary condition is

$$V_t\geq L_tS_t \tag{39-4}$$

for a conversion ratio L_t, which can be implemented in the finite difference grid as

$$V_{t-}=\max\left(V_{t+},L_tS_t\right) \tag{39-5}$$

9. Leif Andersen and Vladmir Piterbarg, *Interest Rate Modeling*, Volumes 1–3. (Atlantic Financial Press, 2010).

In addition to provisions that freely allow the holder to convert on certain dates, many convertible bonds also contain provisions that allow the holder to convert only if certain conditions are met, i.e., triggered conversion. Triggered conversion provisions that depend on S_t and V_t can often be included when solving Equation (39-2) via finite difference techniques. If the issuer can call the bond at some price H_t, then

$$V_t \leq \max\left(H_t, L_t S_t\right) \tag{39-6}$$

assuming the holder has the option to convert rather than to receive the call price H_t. Alternatively, the bondholder may own a put. This produces the free boundary condition

$$V_t \geq P_t \tag{39-7}$$

for a prespecified amount P_t. Other nonnumerical triggers do exist as there can be an announced redemption, a fundamental change to the company structure may occur that requires the bond to be redeemed, a distribution of entitlements or a rating condition may be attached to the bond. Mergers, asset transfers, corporate splits, or a change in the holding company may also be specified as redemption events. From a modelling perspective, these triggers are ignored.

The default intensity $\lambda\left(S,t\right)$ should be downward sloping (i.e., $\frac{\partial \lambda}{\partial S} < 0$) since as equity prices increase, credit generally tightens. Likewise, a distressed company corresponds to lower market capitalization and wider credit spreads. Several functional forms have been suggested in the literature; however, the particular functional form does not have a large impact on the results. The most popular and intuitive form is a power law, first introduced by Muromachi when studying Japanese convertible bonds[10]:

$$\lambda\left(S,t\right) = a\left(t\right)\left(\frac{S\left(0\right)}{S\left(t\right)}\right)^p \tag{39-8}$$

for an initial stock price, S(0). The determination of the function $a\left(t\right)$ and parameter p will be addressed by looking at the vanilla bond issuance and CDS quotes for the issuer.

THE DEFAULT INTENSITY

Given the parameterization in Equation (39-8), the exponent p must be determined. When fitting to Japanese corporate bonds, Muromachi found that $1.0 < p < 2.0$. This choice of p is illustrated in panel a of Exhibit 39-2, where equity price versus five-year CDS is plotted for Dish Network Corporation (DISH-US) from 2014 to 2019. This is known as a "hockey stick" graph, due to the shape of the scatter

10. Yukio Muromachi, "The Growing Recognition of Credit Risk in the Corporate and Financial Bond Markets," *NLI Research Institute* (January 1999), pp. 3–11.

plot. Following Muromachi, a log-log regression produces a parameter value of 1.0, and there is good overall agreement between the realized price movement and the calibrated intensity. However, the bounds defined by Muromachi do not persist in all markets over long time spans. As shown in panel b of Exhibit 39-2, the same calibration for Total SA (FP-FR) produces a best-fit of $p = 5.0$ to capture the desired price action. Olsen, Decker, Rustau, and Ho[11] find that calibrating the intensity to realized data is most effective for high yield credits, since such issuers generally display a comprehensive range of equity and CDS price action leading to superior statistical analyses of Equation (39-8). Nevertheless, calibration can still prove difficult for high yield credits. For instance, panel c of Exhibit 39-2 shows extreme CDS movements corresponding large decreases in the equity price of Chesapeake Energy Corp. (CHK-US) that cannot be captured.

Finally, for high-grade credits such as Commonwealth Bank of Australia (CBA-AU), shown in panel d of Exhibit 39-2, there is no history of distressed equity pricing, thereby making it impossible to calibrate to realized data. That same high-grade argument can also be applied to Dish and Total, since the range of realized equity price movement in panels a and b of Exhibit 39-2 do not decrease below USD 25 and EUR 35, respectively—there is no stressed market scenario present in the historic data. In contrast, the equity time series for Chesapeake covers USD 2–25.

In short, calibrating to realized price action is effective for specific issuers, but it is not applicable across the asset class, in fact credits that appear to calibrate well may not capture the desired stock–credit spread relationship if the history does not cover distressed regimes.

Now consider the effect of p on the valuation of convertible bonds[12]—accomplished by solving Equation (39-2). Exhibit 39-3 represents CB price versus stock price for a range of p values. These securities represent a broad spectrum of maturities from one to seven years. Likewise, they capture tight credit spreads (BioMarin), typical high-yield credit risk (Dish and Tesla), and distressed credit spreads (Chesapeake). When $p = 0$ (which amounts to ignoring the relationship between equity and credit) and the equity price tends to zero, the limiting value of the CB reduces to the bond floor, defined as the price of a hypothetical bond with identical terms and conditions as the convertible but ignoring the embedded equity option. The limitations of the models proposed by Goldman Sachs, Tsiveriotis and Fernandes, and Xiao are now evident. As there is no relationship between the credit risk and equity performance, the bond floor is fixed in those models regardless of the market perceived default probability. When $p > 0$, a "soft" bond floor is introduced in that the bond floor decreases when the stock price falls, signaling a distressed equity. As p is progressively increased, the value

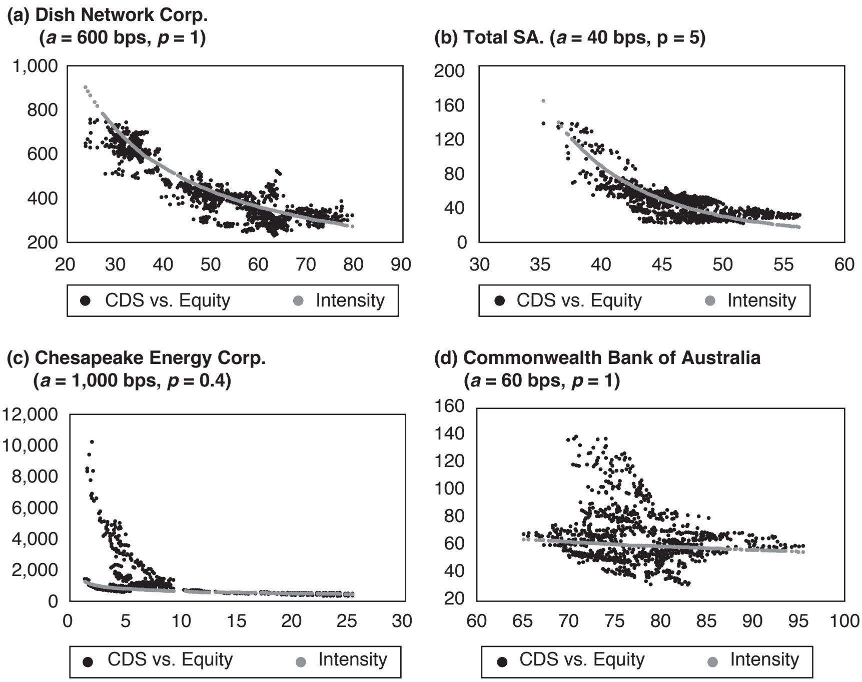
12. The CBs in question are BioMarin Pharmaceutical Inc. 1.5% 2020 (US09061GAF81), Tesla Inc 2.375% 2022 (US88160RAD35), Dish Network Corp. 1.5% 2024 (US25470MAD11), and Chesapeake Energy Corp 5.5% 2026 (US165167CY16).

EXHIBIT 39-2

Five-Year CDS vs. Equity and Calibrated Intensity



of the bond floor decreases to reflect the increased credit risk. Furthermore, as the tenor of the CB increases, the impact of p is magnified as credit risk typically increases with tenor. The soft bond floor was first reported by Takahashi et al.

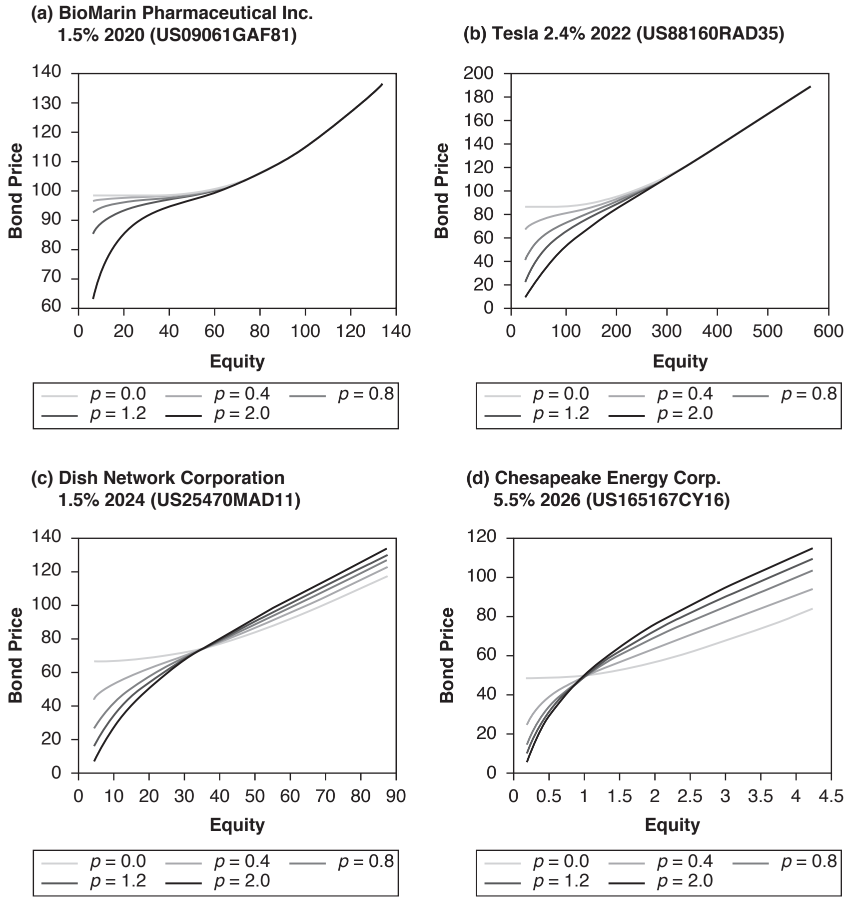
The static bond floor is certainly not borne out in financial data. In Exhibit 39-4, the closing bond prices for companies seeking bankruptcy protection are plotted for the day that the company filed for that protection. This is a snapshot of prices taken on that day and does not represent final recovery values, however, it does represent exactly the type of risk that Equation (39-8) aims to capture. There are 1134 distinct defaulted bonds[13] in Exhibit 39-4. There are several immediate takeaways:

- The average bond price was 37.
- Two-thirds of defaulted bonds had prices of 40 or less at default.

13. Data maintained by FactSet Research Systems Inc.

EXHIBIT 39-3

Bond Price vs. Equity



Note: From (1), $R = 0$ in this exhibit.

- The remaining third defaulted with higher prices–including a small fraction above par.
- The average price agrees closely with the standard ISDA CDS assumption that loss given default, LGD, is 60% for senior unsecured securities.

The choice of the Andersen and Buffum model is further motivated by the price action of the issuers of the bonds trading above par. Exhibit 39-5 represents the equity time series of four of these issuers.[14] A jump-to-default event

14. They are Residual Debt Services Ltd. (AXL-ZA), Lehman Brothers Holdings Inc. (LEHMQ-US), OFCB Capital PLC (OFCB-RU), and Transasia Airways Corporation (6702-TW).

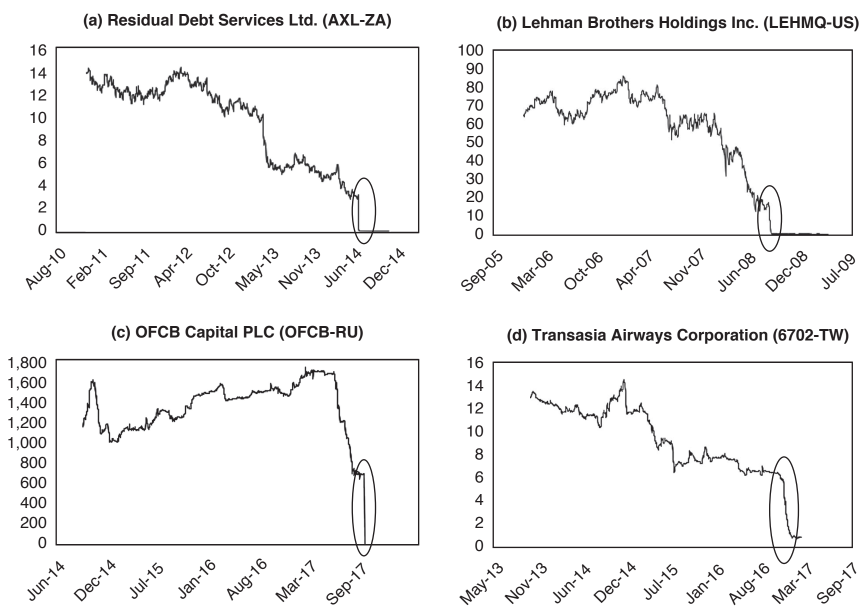
EXHIBIT 39-5

Equity Time Series Leading Up to Default



is observed for each company as the bankruptcy is announced. The addition of the Cox process, $N(t)$ in Equation (39-1), is therefore a necessary mechanism to capture this price movement.

Within the defaulted bond universe, 136 bonds were convertible. In Exhibit 39-6, the realized bond price versus equity performance of eight bonds is plotted. The bonds are chosen to be representative of results seen for issues with deeper data. In all cases, the realized performance agrees with Exhibit 39-3: as the equity drops significantly, the bond sells off markedly toward default, with a variety of recoveries observed from zero to 20% to 40%. Likewise, this is in line with the cross section observed in Exhibit 39-3. Furthermore, the selloff accelerates as the equity becomes distressed. We also note that prior to entering the distressed state, the bond price varies quite linearly versus the equity price. Hence convertible bonds display little positive gamma, but significant negative gamma, when the equity decreases sufficiently.

Translating this to Equation (39-8), bond prices where default typically occurs are not easily reachable unless p is sufficiently large. Rather than calibrating p at an issuer level to historic data, we can instead seek a value for p that is applicable across the asset class. Taking $p = 2$ produces model outcomes that match the default price distribution, as well as produces defaulted bond prices that are consistent with the distribution of defaulted bonds across all maturities. It also allows the debt–equity price action to be standardized across all issuers. Further refinement by tenor is also possible; likewise, calibrating to specific default values, such as LGD = 60%. On average, higher values of p increase credit risk, lower the bond floor, and translate to higher implied volatilities. For this chapter, $p = 2$ is applied across all issuers.

SPECIFYING THE CREDIT SPREAD

Following Andersen and Buffum, the function $a(t)$ in the default intensity from Equation (39-8) can be determined by a calibration to risky zero-coupon bond prices by solving for the equity price density, which satisfies the forward Kolmogorov Equation (the adjoint of Equation (39-2)), thereby incorporating the credit spread of each issuer. There are three possible situations one needs to account for in order to specify the credit spread.

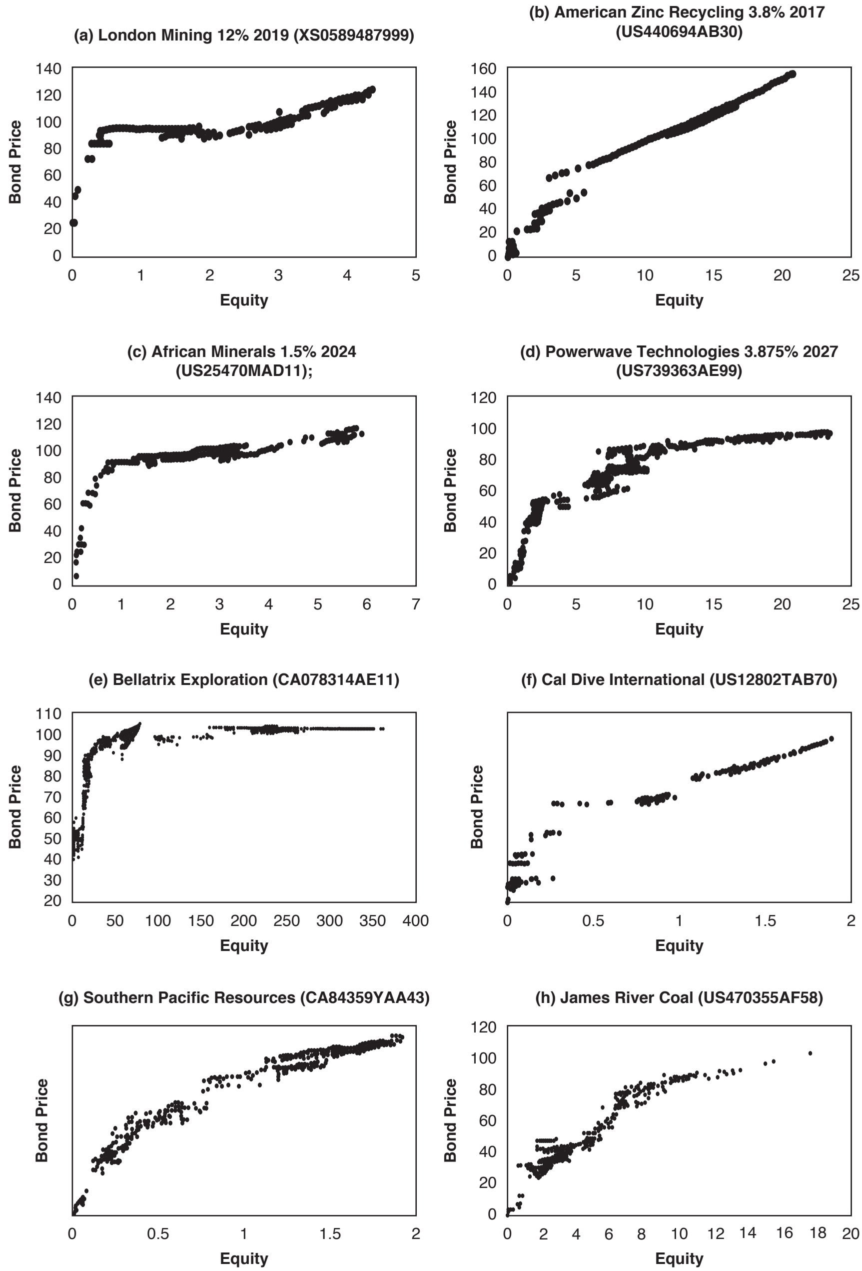
1. Traded CDS exists on the issuer

   The CDS represents the spot price of the credit risk. From Exhibit 39-1, the CDS is explicitly observed in the market for 327 CBs. For those bonds, the CDS should be used directly in Equation (39-8), after adjusting for seniority.
2. Issuer has traded vanilla bonds

   Across the 1135 CB issuers, 526 have vanilla bonds with closing prices in the market. For these counterparties, the asset swap spread from the bonds is adjusted for synthetic versus physical basis and seniority to mark the CDS.

EXHIBIT 39-6

Realized Bond Price vs. Equity for the Defaulted Convertible Bonds



Source: FactSet

3. Issuer has no vanilla bonds
   The remaining CBs are then mapped to either a traded index proxy, or by industry geography and rating to specific traded issuers.

With the credit risk marked to term, the volatility, σ, is implied from Equation (39-2) to match the market price,

$$V(S,t,\sigma) = B_t \tag{39-9}$$

where B_t, is the closing bond price for day t. To illustrate the methodology, return to the four bonds from Exhibit 39-3, with the addition of one further security, namely, the Oasis Petroleum Inc 2.625% 2023 bond (US674215AJ77).

In terms of the credit mark-to-market, we then have:

- Traded CDS: Dish Network Corp., Chesapeake Energy Corp. (DISH-US, CHK-US)
- Outstanding vanilla bonds: Oasis Petroleum Inc. (OAS-US)
- Index map: BioMarin Pharmaceutical Inc. (BMRN-US)
- Hybrid index map and traded CDS: Tesla Inc (TSLA-US)

These five bonds will form the remainder of this chapter. The results for CHK-US are represented in Exhibit 39-7, where several observations are apparent. Firstly, the bond price tracks the performance of the equity closely. Secondly, the volatility and the bond price are negatively correlated; that is, on average, the volatility decreases (increases) when the forward increases (decreases). This is the price action contained in the SABR model by Hagan et al.[15] More formally, Hagan et al. propose a stochastic volatility model where asset prices are correlated to volatilities that correctly reproduces the dynamics of the volatility skew. The correlation, borne out by calibration to a specific market, is typically negative. For our purposes, we shall term the negative correlation between volatility and bond prices as "SABR-like."

As the equity increases, the equity volatility decreases and the CDS tightens, leading to an overall risk reduction. Likewise, decreases in the equity price correspond to CDS widening and equity volatility increasing. A quick calculation shows that $\rho = -0.77$ between the stock and CDS, where ρ is the Pearson correlation coefficient. These observations further motivate the functional choice of the intensity process Equation (39-8) since the power law induces CDS spread widening as the equity price decreases, and vice versa. Running the same calculation on the implied volatility and the bond price produces $\rho = -0.58$. As desired, the price action is SABR-like.

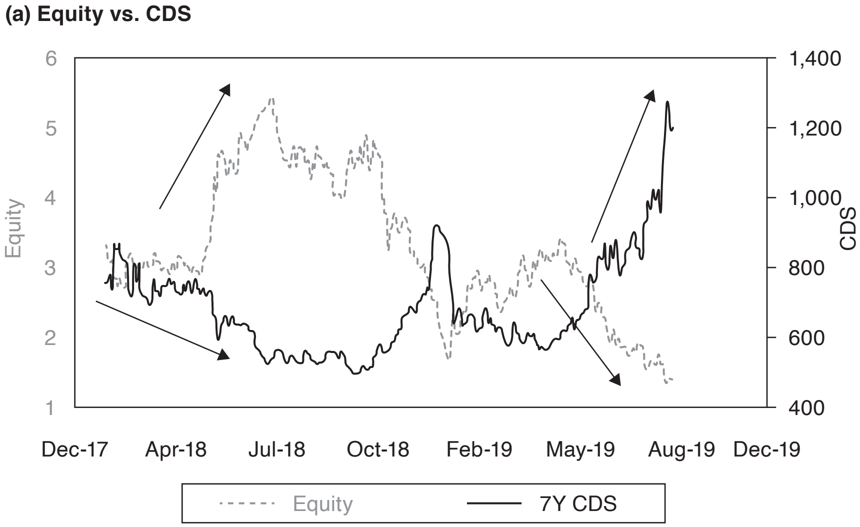
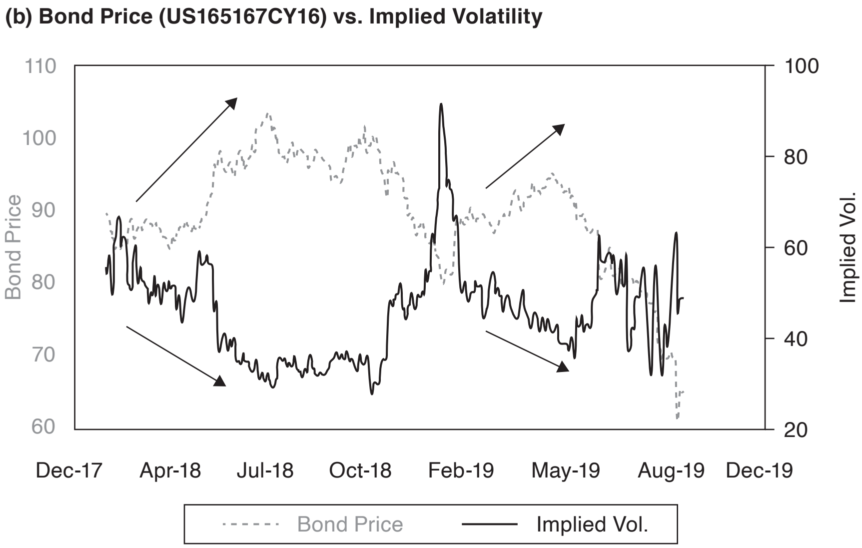
EXHIBIT 39-7

CHK-US





Note: The axis matches the time series.

Similar price action is observed in Exhibit 39-8 for DISH-US. Again, the bond price tracks the performance of the underlying equity and the implied volatility is negatively correlated to the performance of the security itself, with $\rho = -0.73$. As required, spread tightening corresponds, on average, to increases in market capitalization. Weakening credit quality equates to CDS widening and $\rho = -0.94$ between the CDS and stock price; the price action is again SABR-like.

No traded CDS exists for OAS-US. However, nonconvertible bonds have been issued by this company. With the CB time series available from late 2016, there are four separate vanilla bonds with daily closing prices. The available bonds are the Oasis 7.25% February 2019 issue (US674215AD08), the Oasis 6.5% November 2021 security (US674215AD08), and the Oasis 6.875% January 2023 issue (US674215AE80). Furthermore, in mid-2018 the Oasis 6.25% May 2026 bond (USU65204AC06) was issued. From the 2016 snapshot, these securities translate to tenors from three to eight years. Although the CDS is absent, the bonds' z-spreads can be employed to infer a synthetic CDS; in this case with term structure.

Theoretically, the credit risk from a bond and the CDS are equivalent—for a given maturity, the z-spread from a bond should equal the spread payable on a CDS contract of the same tenor. In practice, the markets trade separately and a bond-CDS basis exists. Tracking that basis allows a bond z-spread to be adjusted to produce a synthetic CDS. Returning to Exhibit 39-1, across the 1135 CB issuers, 526 have vanilla bonds with closing prices in the market. For these counterparties, if the CDS does not trade explicitly, the credit spread from the bonds can be adjusted for the synthetic versus physical basis and seniority to mark a "synthetic CDS." In panel a in Exhibit 39-9, the convertible bond credit spread, interpolated to a five-year tenor, for the 526 issuers is plotted versus the traded index CDX.NA.HY.5Y. The basis itself is represented in panel b in Exhibit 39-9. Although the basis varies significantly, it has been almost universally positive through time. Moreover, the outright spread levels of the CB issuers are commensurate with CDX.NA.HY, thereby indicating that CB issues can typically be regarded as high-yield bonds. On average, any synthetic CDS should therefore be marked wider if inferred from vanilla bonds. Typically, post-2008, CDS trades wider than bonds due to protection buying pressure, in contrast to pre-2008 when CDS traded tighter due to the structured credit bid.

The z-spread for three of the Oasis nonconvertible bonds are plotted in Exhibit 39-10. Initially, from September 2016 to early 2018, two bonds traded. Their maturities translate to tenors of approximately five and eight years. During this period, the term structure between those points is flat, which is not unexpected, since beyond five years, credit risk premiums generically only increase marginally. From April 2018, the credit spread for the November 2021 bond tightens. In effect, it is rolling down the curve toward a three-year tenor and subsequently to even more short-dated maturities. At the same time, the May 2026 bond was issued. This provided a new eight-year point. Combining and interpolating the z-spreads to fixed tenor produces an initial estimate for the five-year

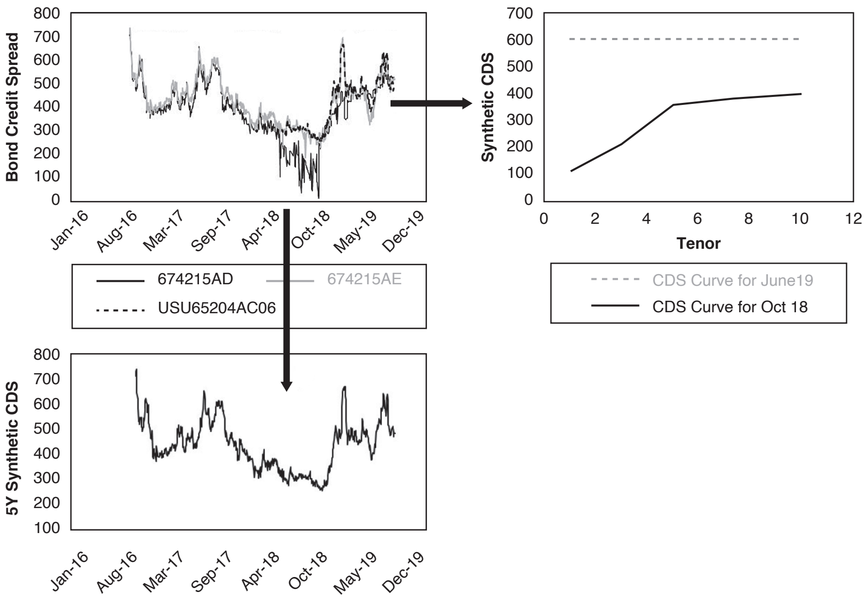
EXHIBIT 39-10

OAS-US Nonconvertible Bond Z-Spread Mapped to the Five-Year Synthetic CDS and CDS Term Structure



synthetic CDS. Here, set the bond-CDS basis at 50 bps, which aligns with panel b in Exhibit 39-9 for mid-2016. Adjusting the spread wider for the bond-CDS basis produces the final synthetic CDS plotted in Exhibit 39-10.

One further observation is that the spread tightening for the bond maturing in November 2021 fails to hold after October 2018. Essentially the credit spread widens out to comparable levels to the five- to eight-year tenor bonds. This is a curve flattening effect—a bearish indicator, as it corresponds to a market perception of immediate corporate headwinds. The result is protection buying in the front end of the curve; that is, if default is imminent, then long-dated protection is not warranted. In Exhibit 39-10, the curve flattening is shown in the shape of the CDS curves that are plotted for October 2018 and then for June 2019. The one-year point widens from 100 bps to 600 bps, equivalent to the five-year spread.

The equity and synthetic CDS for Oasis Petroleum are plotted in panel a in Exhibit 39-11. A quick calculation between the synthetic CDS and the stock price produces $\rho = -0.39$, a weaker correlation, but still exhibiting the relationship contained in Equation (39-8). Once the synthetic CDS time series is constructed, Equation (39-9) can be solved, leading to the observation that the bond price again tracks the equity. The resulting implied volatility time series is represented in panel b in Exhibit 39-11, where it is plotted against the CB price. The SABR-like price action continues with the implied volatility showing high negative correlation to the bond price, with $\rho = -0.72$. Although qualitative, the high correlation indicates that the synthetic CDS is capturing the idiosyncratic risk associated with OAS-US. Looking across both panels a and b in Exhibit 39-11, the CB price continues to track the underlying equity.

Marking BMRN-US is more problematic, since there are neither traded CDS nor any outstanding vanilla bonds. Instead, an index proxy can be sought. The advantage of this approach is that systemic risk is automatically captured, as any macro event that moves the market will be represented through the mark-to-market of the index. The knock-on effect is that any equivalent price movement in the CB will mirror the index proxy. Conversely, the limitation is that any idiosyncratic spread risk cannot be represented. Generically, CB issuers are cash-poor, low-credit-quality counterparties. On that basis, the obvious candidate for marking BMRN-US is the high-yield index CDX.NA.HY. The geographies match: the index represents a broad cross section of North American high-yield issuers. CDX.NA.HY is also liquid, with daily trading volumes exceeding USD 10 BN.[16] CDX.NA.HY trades as a bond price that can then be converted to a CDS spread. There are maturities from three to seven years, with five years representing the main tenor for on-the-run trading. This forms the starting point for building a synthetic CDS. An individual credit is then marked as a spread to that curve, either tighter or wider. In Exhibit 39-12, that mark for BMRN-US is shown.[17] The maturity on the bond is October 2020. CB data exists from July 2014. Hence, by 2018, the tenor has migrated from six years to two years. Initially, as the tenor was six years, the synthetic CDS was marked 100 bps wider than CDX.NA.HY. This agrees with the bond-CDS basis from panel b in Exhibit 39-9. BMRN-US is not rated by any agency.

An alternative to an index adjusted mark is to map BMRN-US to a spread representative of the industry. As a biotechnology firm, that industry is broadly "Health Technology." A comparison to other convertible bond issuers in that industry from mid-2014 places that mark in the high-yield single-B to CCC rating band, as shown in panel b in Exhibit 39-12. The 100bp differential varies through time. However, as the bond matures, the synthetic CDS in panel a of Exhibit 39-12 has been interpolated to roll down the curve and reflect the shortening maturity. As desired, the synthetic CDS captures the spread widening in late 2015 and early 2019, thereby capturing systemic risk.

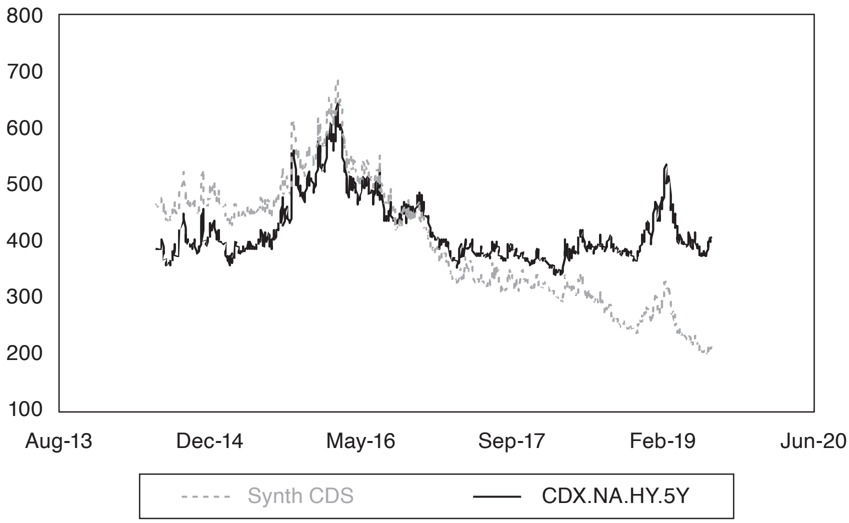
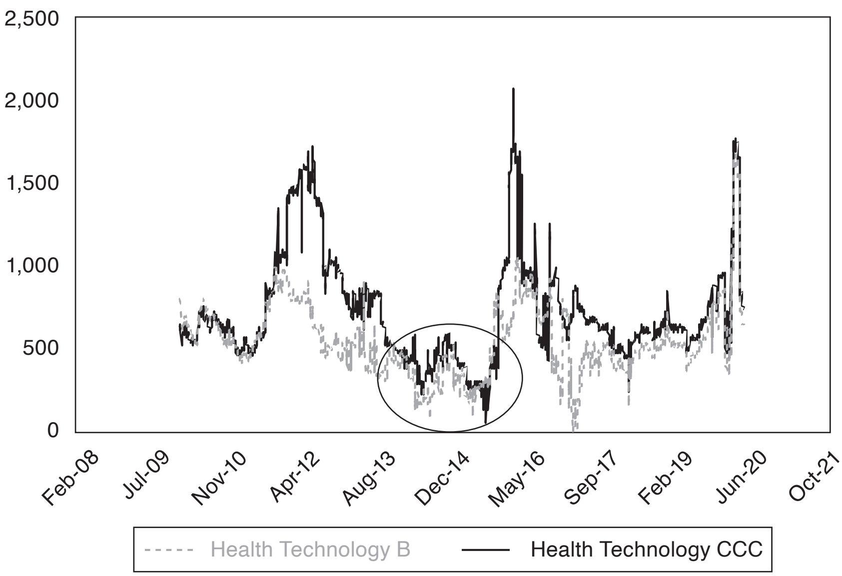
EXHIBIT 39-12

BMRN-US Synthetic CDS

(a) Marked to Maturity from CDX.NA.HY



(b) Compared to Convertible Bond Issuer CCC and B Health Technology Sector Indices



Source: FactSet

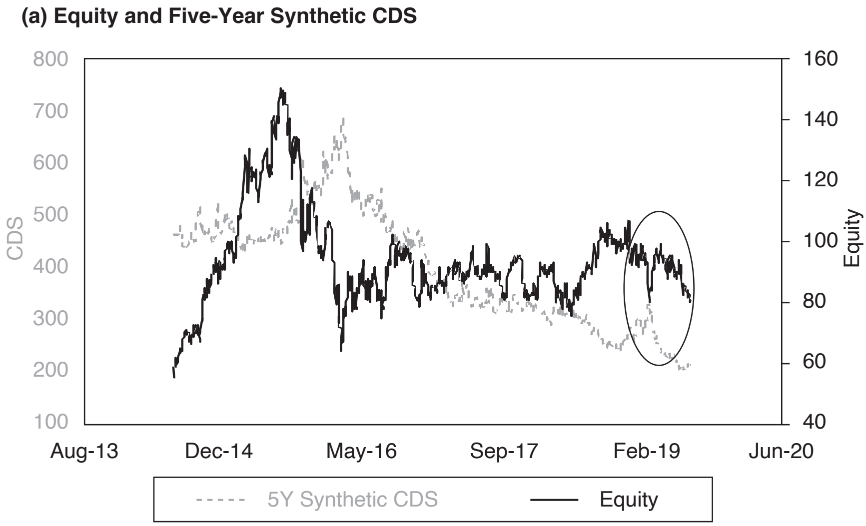
In Exhibit 39-13a, the stock price is plotted against the five-year synthetic CDS for BMRN-US. A quick calculation produces $\rho = -0.05$. The CB price is plotted against the implied volatility in panel b in Exhibit 39-13. Again, the correlation is lower with $\rho = -0.24$. This is not surprising as idiosyncratic risk cannot be captured from the index map. However, both panels a and b in Exhibit 39-13 continue to display SABR-like price movement. On average, CDS widening corresponds to decreases in market capitalization and spread tightening equates to increases in the equity price. Furthermore, the market shock from February 2019 is captured. Likewise, large market moves/trends in the CB price and the implied volatilities continue to follow the expected market movement.

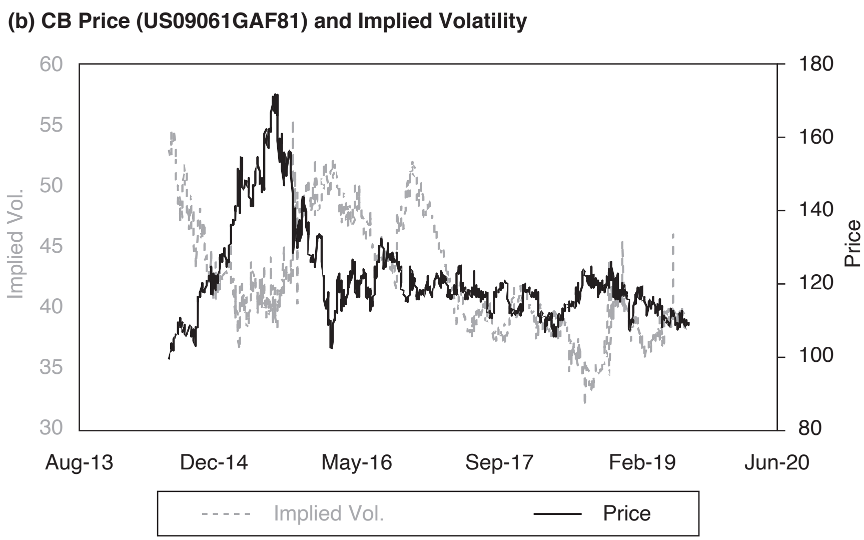
The final bond under consideration is the Tesla Corp. 2.2% 2022 bond. Approximately 18 months after issuance, Tesla CDS began trading in the market, therefore the effectiveness of the synthetic CDS can be tested, as this bond requires marking the synthetic CDS before transferring to the traded contract. Analogously to BMRN-US, the synthetic CDS is derived as a spread to CDX.NA.HY as the same credit quality arguments hold. Tesla is involved in a cycle of research and development on several fronts. This equates to a cash-intensive phase of the business with limited income. The long-term viability of the resulting products is also uncertain. Tesla is a high-yield issuer with an immature business model versus the majority of issuers in CDX.NA.HY. As such, Tesla should be marked wider than the index. Bond price data are available from March 2017. At that time CDX.NA.HY.5Y closed at 354 bps. Therefore, mark the five-year CDS for Tesla at 600 bps. Maintaining that spread to the index across tenors produces a CDS term structure. The actual Tesla CDS began trading in June 2018. The initial closing price was 515 bps. The corresponding synthetic mark was 600 bps. As shown in panel a of Exhibit 39-14, Tesla CDS immediately underwent spread widening. Intuitively this makes sense. Investors are, on average, long the credit. The market appetite will be for credit risk mitigation, that is, buying protection. After a wide close at 717bp, the CDS stabilized at 560bp in late July—in line with the last synthetic CDS close. Tesla CDS has subsequently traded as tight as 450 bps and as wide as 710 bps. This reflects the uncertainty in the market surrounding this credit.

The time series produced from calculating the implied volatility is graphed in panel b in Exhibit 39-14. Tesla Inc. is a credit subject to significant idiosyncratic risk. Hence, the efficacy of the index mark is diluted. From March 2017, the synthetic CDS tightens from 600 bps to 550 bps whereas the stock and CB price oscillates across a \$200 range. The CB price varies from 100 to 130 in the same period. Nevertheless, the Tesla bond is included to show that despite the idiosyncratic limitations, the CB can still be successfully marked. The level of uncertainty in this credit results in little meaningful SABR-like market movement. Just taking the region where the CDS trades, a quick calculation between the price and the implied volatility yields $\rho = -0.001$, whereas for the equity and the CDS, $\rho = -0.22$. There are areas where the price action matches expectations—for example, September 2017 and August 2018. But in general, there is

EXHIBIT 39-13

BMRN-US

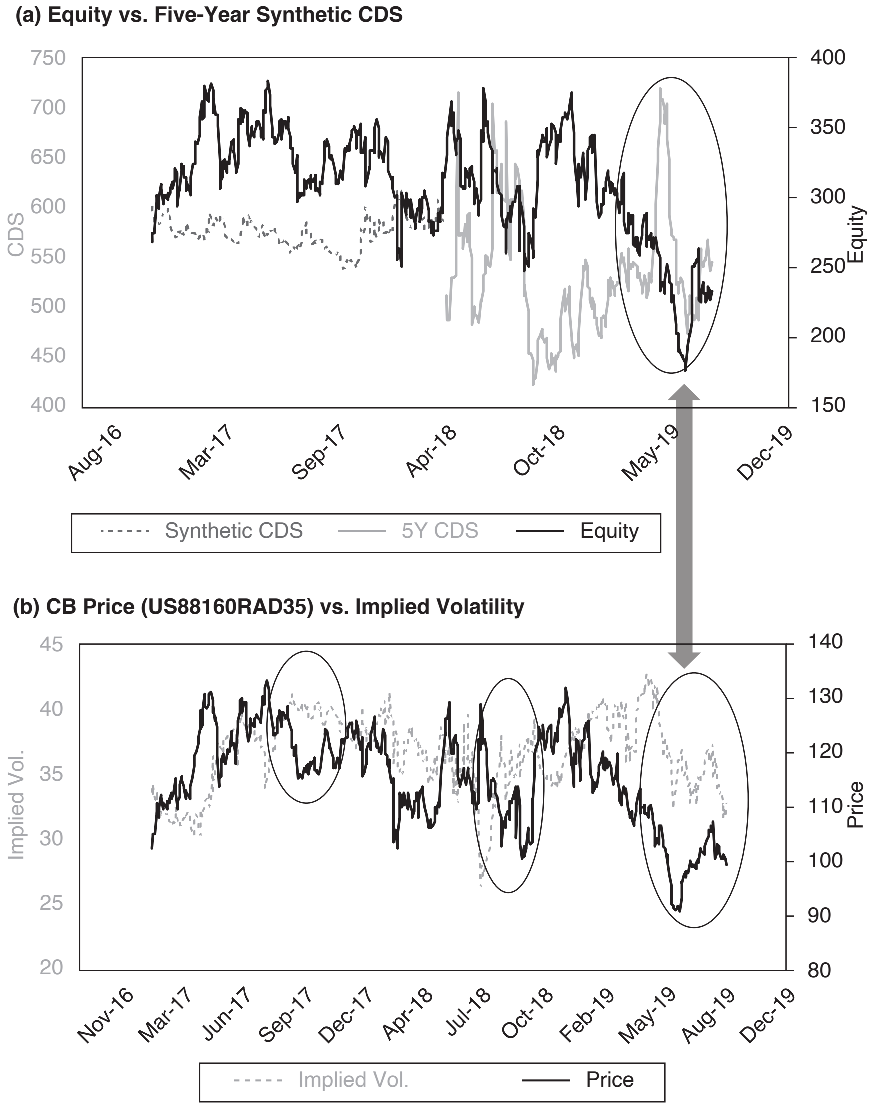




Note: Axis color corresponds to the color of the time series.

EXHIBIT 39-14

TSLA-US



Note: Axis color corresponds to the respective time series.

significant market uncertainty. Consider the time series from April to June 2019. Despite the CDS widening from 500 bps to 725 bps, the decrease in bond price equates to a decrease in implied volatility. This is counterintuitive and does not agree with the SABR price action expected from Hagan et al. What it suggests is that the CDS is too tight; that is, a wider CDS would have lowered the bond floor. If the CDS is sufficiently wide, marking the bond would require an increase in the implied volatility—not a decrease. The fact that falling prices and decreasing volatilities occur for extended periods suggests sustained mispricing.

SENSITIVITIES

The impact of the dynamic credit component from Equation (39-8) is not limited to the soft bond floor. The impact is also apparent in the sensitivities of the CBs. Define the unscaled delta as

$$\Delta = \frac{\partial V}{\partial S} \tag{39-10}$$

where V is the present value of the bond. Note that the unscaled delta can be greater than 1 because the bond represents more than one share of the underlying equity; that is, the unscaled delta is a function of the conversion ratio. If the conversion ratio is greater than 1, the delta can also exceed 1.

Similarly, the sensitivity to the volatility is

$$\nu = \frac{\partial V}{\partial \sigma} \tag{39-11}$$

and the sensitivity to interest rates is

$$\rho = \frac{\partial V}{\partial r} \tag{39-12}$$

where ∂r is a parallel perturbation to the infinitesimal short rate, which translates into a parallel shift of the yield curve. Following the notation of Calamos,[18] the credit delta, or sensitivity to the credit curve (omicron), is defined as

$$o = \frac{\partial V}{\partial CDS} \tag{39-13}$$

and ∂CDS represents a shock to the traded, or synthetic, CDS. Time decay is defined as

$$\theta = \frac{\partial V}{\partial t} \tag{39-14}$$

where θ is estimated using a one-calendar-day shift.

18. Nick P. Calamos, *Convertible Arbitrage* (New Jersey: Wiley, 2003).

The effect of the intensity process leads to seemingly counterintuitive analytics. The credit spread dynamics can produce deltas greater than the conversion ratio for sufficiently low stock prices. The vega can also be negative, given the downward concavity of bond value in the region where stock prices are low. The rho is typically negligible, demonstrating the validity of the statement in Andersen and Buffum that using deterministic rates is justified. This point is also made more compellingly by Grimwood and Hodges[19] who investigate convertible bonds using a stochastic interest rate. Their conclusion is that "the stochastic modeling of the spot interest rate appears the least important model feature."

To illustrate this, the deltas from Equation (39-10) of the four bonds from Exhibit 39-3 are plotted in Exhibit 39-15. When the credit dynamics are ignored ($p = 0$) the delta versus stock chart looks intuitive, being bounded between zero and the conversion ratio (mimicking a vanilla equity option). However, when the dynamics are included, delta can exceed the conversion ratio. The higher delta is capturing default risk—when the company is stressed, small increases in the equity price equate to a significant reduction in credit risk and a corresponding increase to the soft bond floor. Likewise, a decrease in the stock price under this scenario significantly decreases the bond floor. This is the main limitation of the early models from Goldman Sachs, Tsiveriotis and Fernandes, and Xiao: the downside value of the CB is limited to the bond floor, greatly underestimating the risk to the bondholder.

The four bonds in Exhibit 39-15 represent a cross section of maturities from one to seven years. For all maturities, the delta shows the behavior described above, with higher p values increasing delta. For CBs that are strongly in-the-money, the delta becomes independent of p. Hence, the choice $p = 2$ captures the downside risk and produces consistent price action across maturities. This behavior of delta was first reported by Olsen et al. and Ayache et al. Define the gamma as

$$\Gamma = \frac{\partial \Delta}{\partial S} \tag{39-15}$$

All four cases shown in Exhibit 39-15 show negative gamma with an inflection point where gamma becomes weakly positive, with longer-date securities showing a more pronounced effect. Significant positive gamma is only observed for short-dated bonds issued by well-capitalized issuers. The only exception is when $p = 0$, which consistently yields positive gamma. Xiao[6] found that positive gamma is a nontrivial contributor to the value of a CB, but this is only true when $p = 0$ and the credit risk is independent of equity movements.

CB prices are only monotonically increasing with volatility when $p = 0$, as shown in Exhibit 39-16. As the bond's maturity is increased, the bond price can actually decrease with volatility for nonzero p, with the effect being magnified as

19. Russell Grimwood and Stewart Hodges, "The Valuation of Convertible Bonds: A Study of Alternative Pricing Models," Working Paper, *University of Warwick* (2002).

p increases. Note, this is an added subtlety from our earlier assertion of SABR-like price action. In isolation, the implied volatility increases the value of the equity option. However, along with the equity upside comes heightened jump-to-default risk as a higher volatility translates to uncertainty and therefore credit deterioration. In certain circumstances, there is an upper limit to the CB price. For example, in panel b in Exhibit 39-16, the valuation of the TSLA CB cannot exceed 130 when $p = 2$. Furthermore, a volatility higher than 60% will reduce the valuation of the bond, which contradicts the classical hedging strategy that seeks to profit from higher volatility through delta hedging. That is only the case when $p = 0$, when the credit spreads are dynamically linked to credit there are scenarios where investors benefit from falling volatilities.

EXHIBIT 39-15

Unscaled Equity Delta

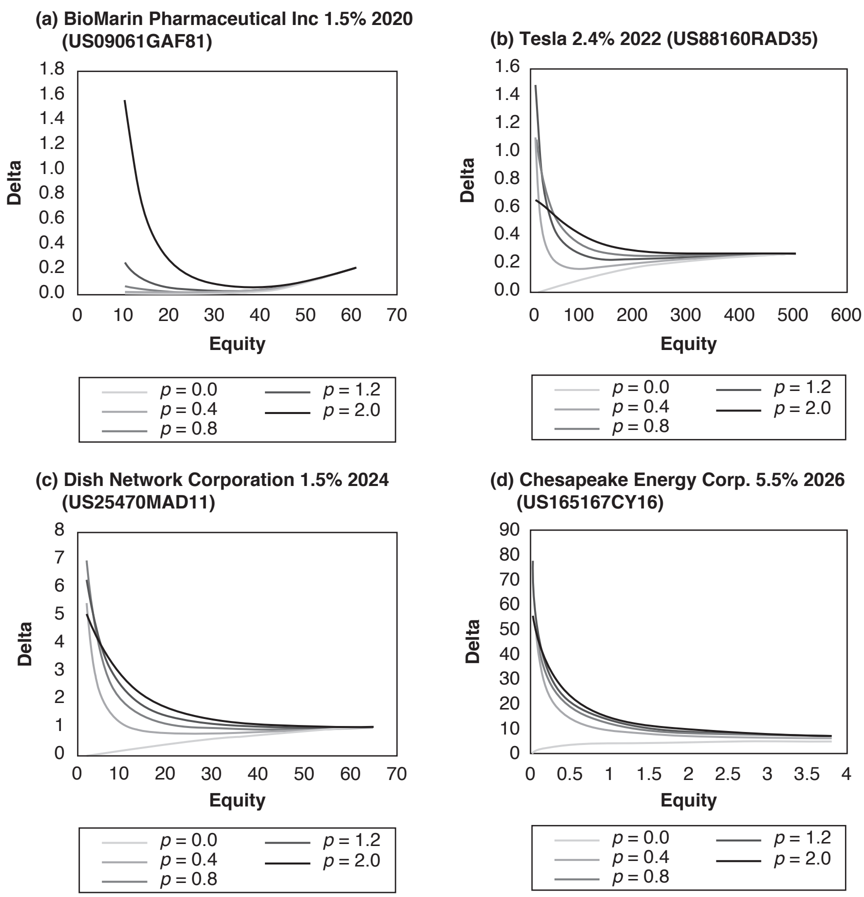


EXHIBIT 39-16

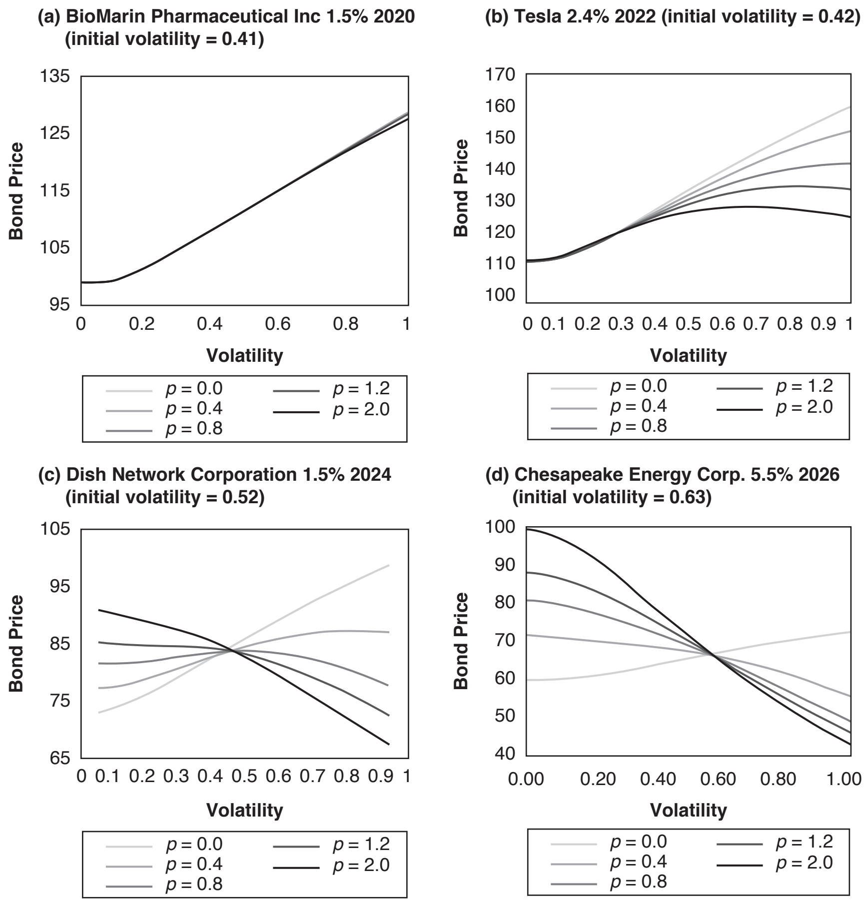
Bond Price vs. Volatility



The volatilities implied from CBs are typically long dated. Here, four of the five bonds under consideration have maturities greater than three years, which are well in excess of exchange-traded equity option markets. Typically, implied volatilities decrease with tenor, as per Hagan et al. The results from Exhibit 39-16 suggest that there may in fact be an upper limit to CB volatilities. At the very least, the valuation of CBs penalizes high-volatility stocks thereby moving volatilities naturally lower. This begs the question whether these two market implied volatilities are consistent.

Implied Volatilities

To connect the CB and exchange-traded option markets, the 80% moneyness implied volatilities for one-month to two-year equity options are plotted in Exhibit 39-17, along with the volatilities implied from the CB prices. The choice of 80% moneyness is designed to match the initial low-delta CB prices. Subsequent adjustments for moneyness to more accurately map the volatilities could be undertaken, but that is beyond the scope here. Across all five securities, the CB implied volatilities trade consistently lower than the exchange-traded volatilities. For BMRN-US, OAS-US, and CHK-US, the CB time series tracks the exchange traded data closely. DISH-US displays similar correlation in panel d of Exhibit 39-17, but with periods where the relationship breaks down. For example, in mid-2018, the CB volatilities are consistently higher than their equity-implied counterparts. The CB volatilities do subsequently trade back down. This is an indication of mispricing or an arbitrage opportunity. The CB volatilities for TSLA-US in panel b in Exhibit 39-17 are consistent from the synthetic CDS to the actual traded CDS contract. The Tesla CB volatilities trade consistently lower than equity option implied volatilities. Recall from earlier arguments that marking to exchange traded volatilities cannot match CB prices. These results confirm the premise from the introduction. Attempting to mark CBs from exchange-traded options will always result in error. With long-dated CB volatilities trading consistently at lower levels than short-dated exchange-traded volatilities, marking to the exchange-traded volatilities will either overvalue the option or undervalue the bond due to negative vega. Failing to mark to term will result in mismarking the bond.

The relationship between the exchange-traded volatilities and the CB-implied volatilities suggests a methodology to mark nontraded credit spreads. As shown previously for BMRN-US, marking to a traded index is useful in capturing systemic risk. However, there is a subjective element of where the specific credit should be marked versus the index—that is, wider or tighter. To examine this, fix the CB price and assume positive vega as shown for Biomarin in panel a in Exhibit 39-16. As credit spreads widen (tighten), the bond floor decreases (increases). The CB implied volatility must therefore increase (decrease) to match the CB price. It is now possible to adjust the index mark to solve for an implied volatility that is lower than, or at least in line with the longer maturity, equity-option-implied volatilities. Returning to BMRN-US, the choice of marking the credit wider than CDX.NA.HY was in part due to a view on the maturity of the business, the bond–CDS basis, but also to ensure the relationship between the CB and equity volatilities held. Nevertheless, the initial CB vol marks for BioMarin in panel a in Exhibit 39-17 were higher than the shorter-dated exchange-traded volatilities. This suggests that the CDS mark may be too wide. However, the general agreement of the volatility term structure across the time series points to an alternative explanation. The initial high-implied-volatility marks indicate that the bond initially traded at a premium. This may have been a supply issue with open interest in the bond forcing prices higher. Over time that demand–supply

imbalance then corrected itself as the bond seasoned, as demonstrated by the decrease in CB-implied volatility versus the listed options.

Marking Tesla wider than CDX.NA.HY was related to the ongoing research-dependent nature of the enterprise and the associated cash burn. The overall viability of the business model is uncertain. The resulting agreement of the term structure of the implied volatilities confirms the choice. The outright magnitudes of the volatilities also support the view that the Tesla CDS trades too tightly. From panel b in Exhibit 39-16, Tesla displays positive vega for volatilities under 60%. The CB-implied volatilities have consistently traded between 25% and 40% with the exchange-traded volatilities at similar magnitudes only in mid-2017. Exchange-traded volatilities have increased in magnitude since early 2018, with prints more than 20 volatility points higher than those seen in 2017. However, the CB volatilities remain range bound despite the tenors between the asset classes progressively converging. The capital structure appears misaligned and the CB volatility is too cheap. This view is most easily expressed by buying Tesla protection; that is, the portfolio manager is expecting the CDS to widen thereby lowering the bond floor and increasing the volatilities.

Going a step further, the implied volatility term structure is also consistent across the CBs themselves. In addition to the Dish 2.375% 2024 bond, there is another security: Dish 3.375% 2026 (US25470MAB54). Likewise, Tesla has issued a second CB: Tesla 1.25% 2021 (US88160RAG65). The implied volatilities for these four bonds are shown in Exhibit 39-18. The implied volatilities for Dish are consistent, with the longer maturities trading at lower levels than the shorter-dated bond across the entire time series, as shown in panel a in Exhibit 39-18. Furthermore, the elevated volatilities observed in mid-2018 in panel d in Exhibit 39-17 are consistent across both bonds. The implied volatilities are also highly correlated with $\rho = 0.93$. This suggests that there was an asset class–wide misalignment across the capital structure of DISH-US. The Tesla bonds displayed the same price action across tenors from June 2018 to June 2019 ($\rho = 0.83$). Again, as the maturity increases the implied volatilities decrease. However, from May to early September 2019, the 2021 volatilities traded down below the 2022 volatilities. Recall from panel b in Exhibit 39-14 that there were price dislocations for the Tesla 2022 bond, with decreasing prices corresponding to decreasing implied volatilities during this same period. The short-dated volatilities trading at lower levels to the 2022 maturity indicate that the 2021 bond is oversold and reinforces the view that the Tesla CDS is trading too tightly. That misalignment was corrected in late September with the 2021 volatilities returning to higher outright magnitudes versus the 2022 implied volatilities.

Linking exchange-traded and CB-implied volatilities is new. Likewise, the agreement between the term structure of the implied volatilities of the different asset classes has not previously been reported. The internal consistency of the term structure within the convertible bonds themselves is also new. In effect, combining the asset classes provides a consistent view of implied volatility for a given stock out to maturities that are not accessible from exchange-traded markets.

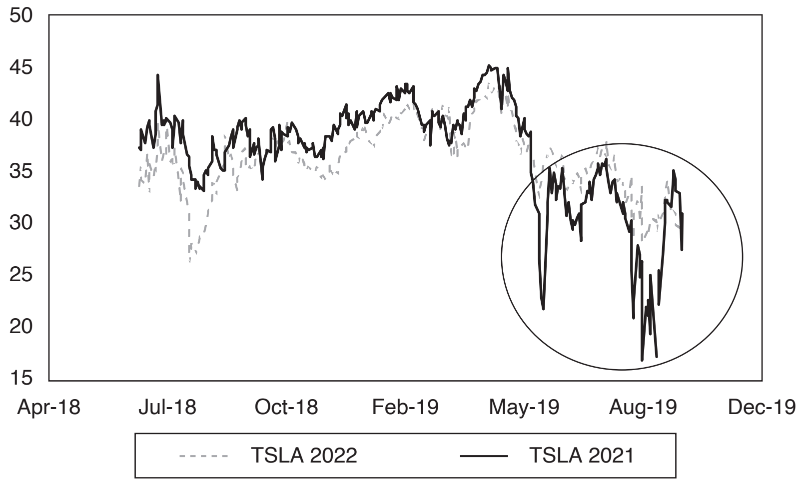
(a) DISH 2.375% 2024 (US25470MAD11) and DISH 3.375% 2026 (US25470MAB54)

(b) CB Implied Volatilities for Tesla 1.25% 2021 (US88160RAG65) and Tesla 2.375% 2022 (US88160RAD35)



Sensitivity Time Series

Recall that the value of $p = 2$ was chosen to ensure agreement between the realized distribution of defaulted bond prices and the soft bond floor. This can result in negative vega and outsized delta, as seen in Exhibit 39-15 and Exhibit 39-16. In Exhibit 39-19 the time series for delta, vega, and rho are represented for all five bonds. In all cases, rho is negligible, as generally credit derivatives do not display large exposures to interest rates, giving further evidence for the conclusion above that the interest rate is the least important aspect of a convertible bond model.

Tesla displays a consistently positive vega, whereas the vega for the other four bonds moves between positive and negative values based on the equity performance, as outlined in Exhibit 39-16. The most notable delta is that for Chesapeake. In late 2018, the delta spiked as the equity decreased from USD 5 to USD 1. For sufficiently low equity prices, the delta increases markedly in response to the default risk that a low market capitalization represents (shown in Exhibit 39-15). For all five bonds, the sensitivities are stable, thereby producing meaningful risk. The difficulty for any portfolio manager hedging these securities arises from the inflection points in the risk—for example, where vega switches from positive to negative for $S \gg 0$, or the delta spikes as $S \rightarrow 0$.

In Exhibit 39-20, the gamma theta and omicron are plotted for the five bonds studied. Most noteworthy is the Chesapeake 5.5% bond, where not only is the gamma consistently negative but it decreases from values close negligible to values with a magnitude of nearly 12 times the stock price. Recall from Exhibit 39-15 that for sufficiently low values of S, $\Delta \gg 1$. Alternatively, from a low stock valuation, small increases in the stock price correspond to dramatic decreases in the value of the bond, which was certainly the case in 2019 with the uncertainty surrounding Chesapeake's viability.[20] For the other bonds, the key takeaway is that the gamma has negligible magnitude. It can oscillate from weakly positive to weakly negative, as for Dish in panel d in Exhibit 39-20, but its overall importance to the bond valuation is less than omicron. The time series agree with Exhibit 39-6. CBs display weak positive gamma when $S \gg 0$ and outsized negative gamma as $S \rightarrow 0$. Another observation is that $|\theta| \approx \Gamma$ when Γ is positive. Also note that from comparing Exhibit 39-19 to Exhibit 39-20, $|o| \approx |\rho|$.

20. Chesapeake filed for bankruptcy in June of 2020.

CONVERTIBLE BOND ARBITRAGE

The most commonly known trading strategy, associated with the idea of "arbitraging" a convertible bond, is where the bondholder shorts the underlying equity against the bond itself; essentially this is a pairs trade. The exact size of the short position is usually defined by Δ, but other ratios have been studied. This is in fact a relative value trade, not a true arbitrage, in the econometric sense. Following the literature,[21] what the arbitrageur seeks are "undervalued" or "mispriced" bonds at

Lewis, and Patrick Verwijmeren,"Convertibles and Hedge Funds as Distributors of Equity Exposure," *Review of Financial Studies* (2012), pp. 3077–3112.

issuance. When an appropriate initial offer is identified, the arbitrageur places the order and shorts the stock into the street. The pricing function employed in these studies is Tsiveriotis and Fernandes, without exception. The model is calibrated to historic equity volatilities calculated from 150 to 250 trading days of closing prices, prior to valuation. Where the model price is higher than the traded price, the bond is deemed to be undervalued.

The profitability of this position has been associated with gamma trading the delta hedged bond.[22] As the stock price fluctuates, the arbitrageur adjusts the delta hedge and takes profit, thereby monetizing the position. This type of trading requires positive gamma. Holding rates and credit constant, a delta-hedged positive gamma position is shown in Exhibit 39-21, where the profit and loss (P&L) profile for a long-dated, at-the-money, delta-hedged TSLA-US option is represented. The option strike is the conversion price of the Tesla 2.4% 2022 bond, that is, \$327. The option is marked at 40% volatility, which is comparable to panel b in Exhibit 39-17. Essentially, this is equivalent to assuming $p = 0$ in Equation (39-2), coupled with a short equity position. From the shape of the resulting profit and loss (P&L) profile, this is also known as positive convexity; that is, as the stock price fluctuates, the arbitrageur always takes profit. The more volatile the stock, the more re-hedging of the stock position and the more profitable the position. Hence, if the bond is mispriced, it is trading at a lower volatility than the arbitrageur's anticipated market volatility, and the position may be profitable.

It is difficult to support the gamma trading theory based on the results presented in this chapter. Firstly, the gamma, when positive, is too weak to monetize for long dated positions. In Exhibit 39-20 gamma is of similar magnitude to theta. Even if the gamma is fully monetized, it will struggle to outperform the time decay. It would require extreme moves in the stock price to return even modest P&L. Calamos[23] does state that the trader must identify a "convertible with high gamma." However, Calamos does not explain how to make that identification. Moreover, the gamma switches from positive to negative. Under this scenario, the arbitrageur is under hedged and rebalancing the short position from movement in the underlying equity locks in a loss. Secondly, applying any model without dynamic credit (equivalent to $p = 0$ in Equation (39-8)) will misspecify the risk profile as there is no negative gamma, nor will the model display negative vega. As the stock price falls sufficiently, the expected P&L gains will not be realized and the anticipated P&L gains from a $p = 0$ model will not result.

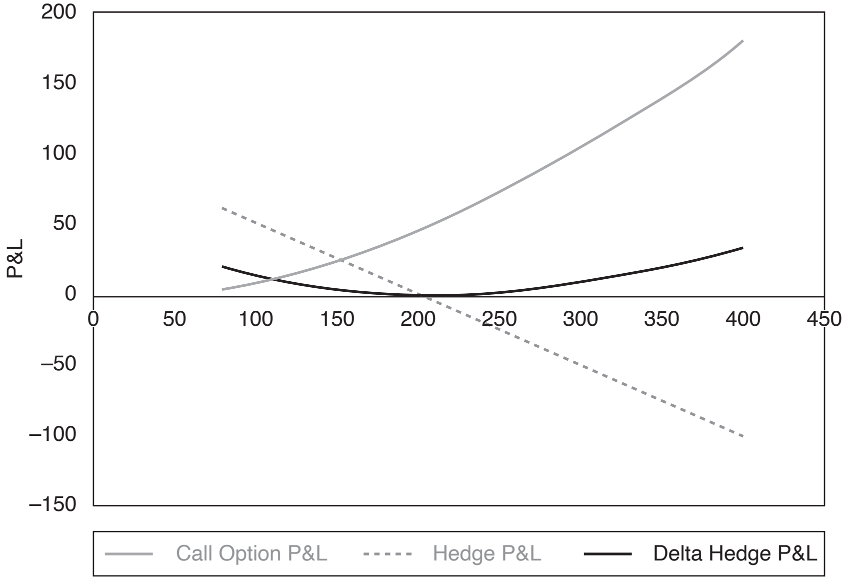
EXHIBIT 39-21

At-the-Money TSLA-US Delta-Hedged Option Position (Strike = 327) for a Five-Year Maturity



The limitations of historic volatility are well documented. Implied volatilities are forward looking whereas historic volatilities can only offer a measure of realized volatility—if a convertible bond is undervalued, it must be quantified in terms of expected, not realized market performance. Convertible bonds may be priced attractively at issuance, as the low credit quality and size of many CB issuers will restrict the pool of eligible investors. Couple that with thinner liquidity and higher bid-offer spreads and the appetite from investors will be even lower. However, it is not mispriced, nor underpriced—it is the market price subject to these frictions.

There are other reasons to execute the delta-hedged convertible bond position.[24] If the yield on the bond is higher than the borrowing/funding cost, the arbitrageur has a positive carry. If the underlying credit is distressed and the equity has sold off, the bond is deemed to be busted. The option is essentially worthless, but an underlying credit position remains. Delta hedging the bond will isolate the credit risk. If the arbitrageur anticipates that the credit spread will tighten, the soft bond floor will increase, and the arbitrageur will book a profit.

24. See for example, John Crosby, "Convertible Bond Arbitrage," *Grizzly Bear Capital,* http://www.john-crosby.co.uk/pdfs/ConvBondArb_PDF.pdf.

One key differentiator from the gamma position is that despite a small sensitivity to credit, the potential spread moves may be several hundred to several thousand basis points. The arbitrageur may seek to exploit the outright volatility position. Holding interest rate and credit spread constant, the delta-hedged position is now long vega. If the bond has positive vega and volatilities rise, the arbitrageur will see mark-to-market gains. Similarly, these strategies can be combined. For example, the equity and the credit could be hedged together. The delta hedge then acts as downside protection. Finally, as the bond seasons, and the embedded option loses value, the gamma trading strategy can be effective. Calamos outlines several gamma capture strategies, namely, with Bull and Bear hedges. These approaches either under hedge versus the model delta, or they are over weight versus the delta, based on the directional view of the market. The ability to realize P&L through re-hedging can then outperform the cost of holding the option itself. However, this is only effective for short-dated positions where the gamma can outperform the theta.

KEY POINTS

- Calibrating to bond price produced meaningful implied CB volatilities. Across a variety of maturities and credit spreads, extended time series were obtained, not just for volatilities, but for sensitivities as well.
- The observed price action replicates the negative correlation observed in the market, that is, as bond prices decline, implied volatilities increase, and vice versa. High correlations between these risk factors were also observed.
- The term structure of the CB-implied volatilities agreed with exchange traded implied volatilities for each issuer. As maturities increased, the outright volatility levels declined with the CB-implied volatilities lower than shorter dated exchanged traded volatilities. Furthermore, the CB volatilities were consistent within the asset class; that is, longer-dated volatilities trade at lower outright levels than shorter-dated contracts.
- The choice of the intensity to capture the process between credit and equity allowed calibration to defaulted bond prices via a "soft bond floor." This also translated to increased deltas for sufficiently low equity prices. Likewise, negative vega was observed for higher market capitalizations.
- Negative gamma was also observed for low stock prices. This result questions the established understanding of convertible bond arbitrage as a gamma trading strategy.

CHAPTER
FORTY

CREDIT ANALYSIS FOR CORPORATE BONDS

Martin Fridson, CFA

Frank J. Fabozzi, Ph.D., CFA, CPA
Professor of Finance
EDHEC Business School

Adam B. Cohen, J.D.

The purpose of this chapter is to provide a framework for the credit analysis of corporate bonds. Although there are numerous types of corporate bonds outstanding, three major issuing segments can be differentiated: industrials, utilities, and finance companies. This chapter will deal primarily with industrials in its general description of bond analysis and then discuss utility and finance issues. Special factors that must be considered in the credit analysis of high-yield corporate issues are addressed. At the end of this chapter, credit scoring models for identifying potential issuers that may default are described.

APPROACHES TO CREDIT ANALYSIS

Traditionally, credit analysis for corporate bonds has focused almost exclusively on the default risk of the bond—the chance that the bondholder will not receive the scheduled interest payments or principal at maturity. This one-dimensional analysis concerned itself primarily with the calculation of a series of ratios historically associated with fixed income investment. These ratios typically would include fixed charge coverage, leverage, and funds flow/total debt. Such an approach was deemed appropriate when interest rates were stable and investors purchased bonds with the purpose of holding them to maturity. Under those conditions, fluctuations in the market value of the bonds owing to interest rate changes were minimal, and fluctuations owing to credit changes of the bond issuer were mitigated by the fact that the investor had no intention of selling the

Parts of this chapter are based on the chapter by Jane Tripp Howe that appeared in previous editions of this handbook.

bond before maturity. During the past four decades, however, the purpose of buying bonds has changed dramatically. Investors still purchase bonds for security and thereby forgo the higher expected return of other assets such as common stock. Increasingly, however, investors buy bonds to trade them actively with the purpose of making a profit on changes in interest rates or in absolute or relative credit quality. The second dimension of corporate bond credit analysis addresses the latter purpose of buying a bond. What is the likelihood of a change in credit quality that will affect the price of the bond? This second dimension deals primarily with ratios and profitability trends, such as return on equity, operating margins, and asset turnover, generally associated with common stock analysis. Both dimensions should be applied in corporate bond analysis because they address the same issue—default or credit risk—from complementary perspectives. Only by using both dimensions of credit analysis will the analyst address the dual purpose of bondholding: security of interest and principal payments and stability or reduction in credit risk during the life of the bond.

Another outgrowth of the shift from buy-and-hold strategies to active bond management is a premium on prompt responses to news that affects a company's ability to generate cash flow to cover its interest charges. A sudden leap or plunge in stock price may reflect significant new information about a company's future profitability that the bond market does not yet reflect. By taking a clue from the equity market, an astute investor may get a jump on competitors in catching an upswing or avoiding a downswing in the issuer's bonds.

Beyond this sort of reactive approach, bond investors can use equity-based information to conduct systematic and potentially profitable analysis. The idea that stock analysis and bond analysis are intertwined has been advanced by the development of options analysis.[1] Underlying this line of reasoning is the basic insight that all of a company's liabilities derive their value from the same set of cash flows. This suggests that the intrinsic value of the equity must be consistent with the intrinsic value of the debt. (Note that the equity value referred to here is economic value, rather than the accounting value represented on the balance sheet by shareholders' equity.)

The ability to derive analytical benefits from these insights springs from the expectation that the company's owners will cease paying interest, that is, default on their debt, if the value of their equity drops to zero. This rational response is analogous to homeowners whose mortgages exceed the value of their houses "mailing the keys to the bank" instead of continuing to make interest payments. It follows that the bigger the equity cushion beneath bondholders, the more remote is the probability of default.

More generally, the probability of default is a function not only of the equity cushion's size, but also its volatility. A company with a comparatively small

1. Credit risk models, discussed in Chapter 42, are referred to as "structural models," "asset-value models," and "firm-value models."

equity cushion may receive a fairly high rating if its stock price is exceptionally stable. An extremely steady share price makes the company's equity value very unlikely to fall to zero and trigger a default.

A final caveat on the interpretation of equity valuations in the context of credit analysis is that under certain circumstances an increase in the equity cushion can indicate *increased* risk of default. The ultimate effect of a leveraged buyout (LBO) is that a substantial portion of the equity in the company's capital structure is replaced by debt, resulting in substantially heightened credit risk. To effect the transaction, however, the LBO sponsor must pay a premium to prevailing market value to acquire the stock from the existing shareholders. Sometimes, word of the pending LBO leaks into the market before the deal is announced, pushing the share price higher. That results in a short-run increase in the equity cushion, but analysts who leap to the conclusion that credit risk is declining will receive a rude surprise when the true cause of the price appreciation comes to light.

INDUSTRY CONSIDERATIONS

The first step in analyzing a bond is to gain some familiarity with the industry. Only within the context of an industry is a company analysis valid. For example, a company growing at 15% annually may appear attractive. However, if the industry is growing at 50% annually, the company is competitively weak. Industry considerations can be numerous. An understanding of the nine variables discussed in this section, however, should give the general fixed income analyst a sufficient framework for properly interpreting a company's prospects:

- Economic cyclicality
- Growth prospects
- Research and development expenses
- Competition
- Sources of supply
- Degree of regulation
- Labor
- Accounting
- Event risk

In some industries, for instance, an analysis of labor costs must consider technological advances that have made it feasible to outsource certain functions to lower-wage countries. Examples include handling of customer inquiries, analysis of diagnostic results, and financial statement analysis. Also, cross-border differences in accounting standards complicate credit quality comparisons of industry peers domiciled in different countries.

Economic Cyclicality

Does the industry closely follow gross domestic product (GDP) growth, as does the retailing industry, or is it recession-resistant but slow-growing, like the regulated electric utility industry? The growth in earnings per share (EPS) of a company should be measured against the growth trend of its industry. Major deviations from the industry trend should be the focus of further analysis. Some industries may be somewhat dependent on general economic growth but be more sensitive to demographic changes. For example, the aging of the U.S. population should cause demand for health care to grow faster than the economy as a whole. Analysts must bear in mind, however, that efforts by government and employers to control health care costs may limit revenue growth. Other industries, such as banking, are sensitive to interest rates. When interest rates are rising, the earnings of banks with a high federal funds exposure underperform the market because their loan rates lag behind increases in the cost of money. Conversely, as interest rates fall, banking earnings outperform the market because the lag in interest change works in the banks' favor.

In general, however, the earnings of few industries correlate perfectly with one economic statistic. Not only are industries sensitive to many economic variables, but often various segments within a company or an industry move countercyclically or at least with different lags in relation to the general economy. For example, the housing industry can be divided between new construction and remodeling and repair. New construction historically has led GDP growth, but repair and remodeling have exhibited less sensitivity to general trends. Therefore, in analyzing a company in the construction industry, the performance of each of its segments must be compared with the performance of the subindustry.

Growth Prospects

A second industry variable related to economic cyclicality is the growth prospects for an industry. Is the growth of the industry projected to increase and be maintained at a high level, such as in the nursing home industry, or is growth expected to decline, as in the defense industry? Each growth scenario has implications for a company. In the case of a fast-growth industry, how much capacity is needed to meet demand, and how will this capacity be financed? In the case of slow-growth industries, is there a movement toward diversification or a consolidation within the industry, such as in the railroad industry? A company operating within a fast-growing industry often has a better potential for credit improvement than does a company whose industry's growth prospects are below average. However, barriers to entry and the sustainability of growth must be considered along with growth prospects for an industry. If an industry is growing rapidly, many new participants may enter the business, causing oversupply of product, declining margins, and possible bankruptcies.

The growth prospects of an industry also should be considered in a global context, particularly if a company has international exposure. Frequently, the growth prospects of an industry vary by country. For example, the soft drinks industry is declining in the United States but continues to achieve high growth in many emerging market countries.

Research and Development Expenses

The broad assessment of growth prospects is tempered by the third variable—the research and development (R&D) expenditures required to maintain or expand market position. Products with high-tech components can become dated and obsolete quickly. Therefore, although a company may be well situated in an industry, if it does not have the financial resources to maintain a technological lead or at least expend a sufficient amount of money to keep technologically current, its position is likely to deteriorate in the long run. In the short run, however, a company with R&D expenditures consistently below industry averages may produce above-average results because of expanded margins.

Evaluation of research and development is further complicated by the direction of technology. Successful companies not only must spend an adequate amount of resources on development, but they also must be correct in their assessment of the direction of the industry. Deployment of significant amounts of capital may not prevent a decline in credit quality if the capital is misdirected. For example, computer companies that persisted in devoting a high percentage of their capital expenditures to the mainframe component of their business suffered declines in credit quality as the mainframe business declined. In industries such as software and telecommunications, new technologies emerge frequently, and not all achieve market viability. A company that ties its product plans to the wrong technology loses competitive ground in addition to being unable to recover a substantial investment in R&D.

Competition

Competition is based on a variety of factors, with their relative importance varying by industry. Price is almost always a major competitive consideration, but product quality also affects the customers' decisions. For many consumer products it is difficult to measure product quality by objective standards. Brand name recognition and celebrity endorsements consequently shape perceptions of product quality. Companies also compete by striving to achieve advantages in distribution and by cultivating long-term relationships with customers.

Some companies are able to maintain strong competitive positions over extended periods through patents and trademarks. The flip side is that the expiration of a patent can lead to a major revenue loss. This is particularly pertinent for a pharmaceutical maker that will have to begin competing with generic drug producers once patent protection expires on a highly successful product. Another danger signal is heavy concentration of revenues at a small number of customers. In such a situation, a decision by a major customer to switch to another provider could deal a severe blow.

Increasingly, all forms of competition are waged on an international basis and are affected by fluctuations in relative currency values. Companies that fare well are those that compete successfully on a global basis and concentrate on the regions with the highest potential for growth. Consumers are largely indifferent to the country of origin of a product as long as the product is of high quality and reasonably priced. This fact is exemplified by the significant increase in the manufacture of automobiles and automobile parts in Mexico that are shipped to the United States.

Competition within an industry relates directly to the market structure of an industry and has implications for pricing flexibility. An unregulated monopoly is in an enviable position in that it can price its goods at a level that will maximize profits. Most industries encounter some free-market forces and must price their goods in relation to supply and demand, as well as the price charged for similar goods. In an oligopoly, a pricing leader is not uncommon. A concern arises when a small company is in an industry that is moving toward oligopoly. In this environment, the small company's costs of production may be higher than those of the industry leaders, and yet it may have to conform to the pricing of the industry leaders. In the extreme, a price war could force the smaller companies out of business. This situation has occurred in the automobile industry over many decades, first on a national and later on a global basis. Many U.S. producers either failed or merged with larger competitors as the field narrowed to the Big Three—General Motors, Ford Motor Company, and Chrysler. In addition to getting squeezed on costs and pricing, smaller automakers faced a disadvantage in producing fewer models, making them more sensitive to changes in consumer tastes than the industry leaders. Similarly, concentration in one region of the world became a handicap as the industry globalized. Recessions usually vary in severity from country to country, so global producers could reduce their vulnerability to economic downturns by spreading their sales across continents.

A concern also arises when there is overcapacity in the industry. Often overcapacity is accompanied by price wars. Generally, price wars result in an industry-wide financial deterioration as battles for market share are accompanied by declining profits or losses.

Sources of Supply

The market structure of an industry and its competitive forces have a direct impact on the fifth industry variable—sources of supply of major production components. A company that is not self-sufficient in its factors of production but is sufficiently powerful in its industry to pass along increased costs is in an enviable position.

Degree of Regulation

In a regulated monopoly such as electric power generation, pricing is determined by a government body. The intention is to prevent companies from extracting excess profits, yet to provide a fair rate of return on capital. That policy tends to promote stable earnings regardless of economic conditions. State regulatory commissions vary, however, in their responsiveness to requests for rate relief to offset increased costs.

Non-monopoly industries face regulation in such areas as labor practices, financial reporting, product safety, and environmental impact. The costs of complying with these regulations are often substantial and the ability to pass the costs on to customers varies by industry. Compliance with regulations that are stricter than in other countries may disadvantage companies relative to foreign-based competitors. Violating regulations can result in costly fines as well as reputational damage that may result in lost business.

Labor

The seventh industry factor requiring analysis is the labor situation. Is the industry heavily unionized? If so, what has been the historical incidence of strikes? What level of flexibility does management have to reduce the labor force? When do the current contracts expire, and what is the likelihood of timely settlements? The labor situation is also important in nonunionized companies, particularly those whose labor situation is tight. What has been the turnover of professionals and management in the firm? What is the probability of a firm's employees, such as highly skilled engineers, being hired by competing firms? What is the likelihood of union activity in nonunionized companies? Are the states in which unionization is a possibility right-to-work states and therefore more difficult to unionize? How much of a cost advantage do the nonunionized companies have over the unionized companies?

The more labor-intensive an industry, the more significance the labor situation assumes. This fact is evidenced by the domestic automobile industry, in which overcapacity and high unionization have contributed to high fixed costs and cyclic record operating losses.

Occasionally, analysts concentrate on the per-hour wages of the labor force. Such an emphasis is misleading. An evaluation of the labor force should concentrate on work rules because work rules are more important in the overall efficiency of an organization than the wage rates. This is an important factor in the profitability of some automobile supply companies.

Accounting

One more industry factor to be considered is accounting. Does the industry have special accounting practices, such as those in the insurance industry or the electric utility industry? If so, an analyst should become familiar with industry practices before proceeding with a company analysis. Also important is whether a company is liberal or conservative in applying accounting rules. The norm of an industry should be ascertained and the analyst should analyze comparable figures.

Particular attention should be paid to companies that use an accounting system other than U.S. generally accepted accounting principles (GAAP). Reported results should be reconciled with those that would have been reported under U.S. GAAP. In addition, changes in GAAP should be scrutinized.

Care also should be taken when dealing with historical data. Frequently, companies adjust prior years' results to accommodate discontinued operations and changes in accounting. These adjustments can mask unfavorable trends. For example, companies that regularly dispose of underperforming segments and then highlight the more profitable continuing operations may be trying to hide poor management. To appreciate all trends fully, both the unadjusted and the adjusted results should be analyzed.

Accounting practices also demand attention when mergers and acquisitions occur. How much of pro forma synergies are attributable to savings that are not yet realized but are allowed in pro forma results? How much goodwill is generated by the combination? Are any contracts written up because the acquiring company believes that it can improve the historical performance of the company it acquired? A conscientious analyst will be aware of these accounting entries and determine whether they reflect a pro forma reality or a too-optimistic assessment of future performance.

Event Risk

The final industry factor to consider is event risk. This term refers to a major discontinuity in a company's financial performance. It includes transactions that radically alter a company's capital structure, such as leveraged buyouts and takeovers that are heavily financed with debt. Event risk also comprises shocks such as natural disasters, environmental catastrophes, nationalizations, terrorist attacks, and revelations of accounting fraud.

Shocks can have severe credit impact, up to and including bankruptcy. As an example, on April 6, 2020, Standard & Poor's downgraded Envision Healthcare all the way from B to CC in the wake of the COVID-19 pandemic. In just two weeks, business plunged by 65% to 75% at the ambulatory surgical center operator. In their determination to avoid contracting the new coronavirus, even people with mandatory care needs stayed away from doctors' offices. Shocks are unforeseeable by their nature, but in some instances it is possible to assess a company's risk of experiencing a shock such as an environmental calamity or a costly product liability problem.

FINANCIAL ANALYSIS

Having achieved an understanding of an industry, the analyst is ready to proceed with a financial analysis. The financial analysis should be conducted in three phases. The first phase consists of traditional ratio analysis for bonds. The second phase, generally associated with common stock research, consists of analyzing the components of a company's return on equity. The final phase considers such nonfinancial factors as management and foreign exposure and includes an analysis of the indenture.

Traditional Ratio Analysis

There are numerous ratios that can be calculated in applying traditional ratio analysis to bonds. Of these, the following eight will be discussed in this section:

- Pretax interest coverage
- Leverage
- Cash flow
- Net assets
- Intangibles
- Unfunded pension liabilities
- Age and condition of plant
- Working capital

These selected ratios are the ones with the widest degree of applicability. In analyzing a particular industry, however, other ratios assume significance and should be considered.

Pretax Interest Coverage

Generally, the first ratio calculated in credit analysis is pretax interest coverage. This ratio measures the number of times interest charges are covered on a pretax basis. Pretax interest coverage is calculated by dividing pretax income plus interest charges by total interest charges. The higher the coverage figure, the safer is the credit. If interest coverage is less than 1×, the company must borrow or use cash flow or proceeds from the sale of assets to meet its interest payments.

Generally, published coverage figures are pretax as opposed to after-tax because interest payments are a pretax expense. Although the pretax interest coverage ratio is useful, its utility is a function of the company's other fixed obligations. For example, if a company has other significant fixed obligations, such as rents or leases, a more appropriate coverage figure would include these other fixed obligations. An example of this is the retail industry, in which companies typically have significant lease obligations. A calculation of simple pretax interest coverage would be misleading in this case because fixed obligations other than interest are significant.

The analyst also should be aware of any contingent liabilities such as a company's guaranteeing another company's debt. Although the company being analyzed may never have to pay interest or principal on the guaranteed debt, the existence of the guarantee diminishes the quality of the pretax coverage. In addition, the quality of the guaranteed debt must be considered.

Once pretax interest coverage and fixed-charge coverage are calculated, it is necessary to analyze the ratios' absolute levels and the numbers relative to those of the industry. For example, pretax interest coverage for an electric utility of 3.0× is consistent with an A rating, whereas the same coverage for a drug company would indicate a lower rating.

Exhibit 40-1 shows the various key pretax interest coverage ratios reported by Standard & Poor's and how they are computed by that rating agency. The exhibit defines each measure used in a ratio and the formula.

Leverage

A second important ratio is leverage, which can be defined in several ways. The most common definition of *leverage* is long-term debt as a percent of total capitalization. The higher the level of debt, the higher is the percentage of operating income that must be used to meet fixed obligations. If a company is highly leveraged, the analyst also should look at its margin of safety. The *margin of safety* is defined as the percentage by which operating income could decline and still be sufficient to allow the company to meet its fixed obligations.

The traditional method of calculating leverage uses the company's capital structure as stated in the most recent balance sheet. A helpful supplement to the traditional ratio is the *market-adjusted debt ratio*. It uses debt as reported, but substitutes for stated shareholders' equity the market value of all outstanding shares.

One drawback to the traditional, book-value-based leverage ratio is that the accounting rules generally require physical assets to be recorded at historical cost. They may be written down to reflect impairment, but not written up to reflect increases in their economic value, unless they become involved in an acquisition. Furthermore, the accounting rules require immediate expensing, rather than capitalizing, of many outlays that create substantial long-run value. Examples include research and development, the creation of brand names, and the buildup of an effective sales organization. Consequently, the traditional ratio may overstate leverage by understating the economic value of the company's equity.

The market-adjusted version is a useful corrective, because under normal conditions, the stock market will reflect a disparity—whether positive or negative—between the book value and economic value of a company's assets. Analysts should bear in mind, however, that share prices can be highly volatile. As gauged by the company's stock market value, leverage may look considerably higher a month from now than today, with the change mainly reflecting a general drop in share prices rather than a fundamental decline in the company's earnings prospects.

EXHIBIT 40-1

S&P Glossary of Terms and Formulas for Key Ratios

Glossary

Pretax income from continuing operations: Net income from continuing operations before (1) special items, (2) minority interest, (3) gains or reacquisition of debt, plus income taxes.

Eight times rents: Gross rents paid multiplied by capitalization factor of eight.

Equity: Shareholders' equity (including preferred stock) plus minority interest.

Free operating cash flow: Funds from operations minus capital expenditures and minus (plus) the increase (decrease) in working capital (excluding changes in cash, marketable securities, and short-term debt).

Funds from operations (or funds flow): Net income from continuing operations plus depreciation, amortization, deferred income taxes, and other noncash items.

Gross interest: Gross interest incurred before subtracting (1) capitalized interest, (2) interest income.

Gross rents: Gross operating rents paid before sublease income.

Interest expense: Interest incurred minus capitalized interest.

Long-term debt: As reported, including capitalized lease obligations on the balance sheet.

Operating income: Sales minus cost of goods manufactured (before depreciation and amortization), selling, general and administrative, and research and development costs.

Total debt: Long-term debt plus current maturities, commercial paper, and other short-term borrowings.

Formulas for Key Ratios

Pretax interest coverage

$$= \frac{\text{Pretax income from continuing operations} + \text{Interest expense}}{\text{Gross interest (before subtracting capitalized interest and interest income)}}$$

Pretax interest coverage including rents

$$= \frac{\text{Pretax income from continuing operations} + \text{Interest expense} + \text{Gross rents}}{\text{Gross interest} + \text{Gross rents}}$$

EBITDA interest coverage

$$= \frac{\text{Pretax income from continuing operations} + \text{Interest expense} + \text{Depreciation and amortization}}{\text{Gross interest}}$$

Funds from operations (or funds flow) as a % of total debt

$$= \frac{\text{Funds from operations}}{\text{Total debt}} \times 100$$

$$\text{Free operating cash flow as a \% of total debt} = \frac{\text{Free operating cash flow}}{\text{Total debt}} \times 100$$

(Continued)

EXHIBIT 40-1

S&P Glossary of Terms and Formulas for Key Ratios (*Continued*)

Pretax return on permanent capital

$$= \frac{\text{Pretax income from continuing operations} + \text{Interest expense}}{\begin{array}{c}\text{Sum of (1) the average of the beginning of year and end of} \\ \text{year current maturities, long-term debt, noncurrent deferred} \\ \text{taxes, minority interest, and shareholders' equity and} \\ \text{(2) average short-term borrowings during year per footnotes} \\ \text{to financial statements}\end{array}} \times 100$$

$$\text{Operating income as a \% of sales} = \frac{\text{Operating income}}{\text{Sales}} \times 100$$

$$\text{Long-term debt as a \% of capitalization} = \frac{\text{Long-term debt}}{\text{Long-term debt} + \text{Equity}} \times 100$$

$$\text{Total debt as a \% of capitalization} + \text{short-term debt} = \frac{\text{Total debt}}{\text{Total debt} + \text{Equity}} \times 100$$

Total debt + 8 times rents as a % of capitalization + short-term debt + 8 times rents

$$= \frac{\text{Total debt} + 8 \text{ times gross rentals paid}}{\text{Total debt} + \text{Equity} + 8 \text{ times gross rentals paid}} \times 100$$

Source: "Adjusted Key U.S. Industrial Financial Ratios," *Standard & Poor's Credit Week*, September 20, 2000, pp. 39–44.

Finance companies traditionally have been among the most highly leveraged companies. Debt-to-equity ratios of 10:1 are not unusual for *captive finance companies* that finance the sales of, and have debt guarantees from, parent companies engaged in manufacturing or retailing. For noncaptive companies, ratios of 5:1 to 7:1 are typical nowadays. Investors tolerate finance companies' high leverage because of the generally liquid nature of their assets. Loans, receivables, and other financial instruments ordinarily can be sold without substantial loss of face value if necessary to repay maturing debt. In contrast, industrial companies typically include large amounts of plant and equipment that cannot be disposed of so quickly. Therefore, book-value-based leverage of 5:1 or more would cause an industrial company to be viewed as highly speculative.

In addition to considering the absolute and relative levels of leverage of a company, the analyst should evaluate the debt itself. How much of the debt has a fixed-rate, and how much has a floating rate? A company with a high component of debt tied to the prime rate may find its margins being squeezed as interest rates rise if there is no compensating increase in the price of the firm's goods. Such a debt structure may be beneficial during certain phases of the interest rate cycle, but it precludes a precise estimate of what interest charges for the year will be. In general, a company with a small percentage of floating-rate debt is preferable to a similarly leveraged company with a high percentage of floating-rate debt.

The maturity structure of the debt also should be evaluated. What is the percentage of debt that is coming due within the next five years? As this debt is refinanced, how will the company's embedded cost of debt be changed?

The existence of material operating leases can understate the leverage of a firm. Operating leases should be capitalized to give a true measure of leverage.

A company's bank lines often constitute a significant portion of its total debt. These lines should be analyzed closely in order to determine the flexibility afforded to the company. The lines should be evaluated in terms of undrawn capacity as well as security interests granted. In addition, the analyst should determine whether the line contains a "material adverse change" (MAC) clause under which the line could be withdrawn. For example, a company that has drawn down its bank lines completely and is in jeopardy of activating its MAC clause may have trouble refinancing any debt. In a similar manner, undrawn lines should be evaluated in terms of their capacity to replace commercial paper, if needed. In the event that a company's commercial paper rating is downgraded, the company's access to the commercial paper market may evaporate quickly. In this scenario, the company may be forced to draw on its bank lines to replace its maturing commercial paper. A company whose commercial paper is fully backed by bank lines is in a stronger position than one whose bank lines do not cover its outstanding commercial paper.

Exhibit 40-1 shows the key leverage ratios used by Standard & Poor's and the formula for calculating each ratio.

Cash Flow

A third important ratio is cash flow as a percent of total debt. *Cash flow* is often defined as net income from continuing operations plus depreciation, depletion, amortization, and deferred taxes. In calculating cash flow for credit analysis, the analyst also should subtract noncash contributions from subsidiaries. In essence, the analyst should be concerned with cash from operations. Any extraordinary sources or uses of funds should be excluded when determining the overall trend of cash-flow coverage. Cash dividends from subsidiaries also should be questioned in terms of their appropriateness (too high or too low relative to the subsidiary's earnings) and also in terms of the parent's control over the upstreaming of dividends. Is there a legal limit to the upstreamed dividends? If so, how close is the current level of dividends to the limit?

Net Assets

A fourth significant ratio is net assets to total debt, which gauges a company's ability to repay debt by liquidating assets to generate cash. This is not something companies do under normal circumstances; their ordinary practice is to refinance debt as it comes due or repay it from operating cash flow. Asset liquidation for debt repayment is most apt to occur when a company is under financial strain, when asset values are likely to be depressed. Therefore, analysts must be mindful that at the point at which liquidation value becomes relevant, it may differ significantly from the value currently reflected on the balance sheet and also from the present market value.

Discrepancies between book value and liquidation value arise from the inherently illiquid nature of many fixed assets. Consider a specialized piece of heavy equipment in a mine in a remote area. The balance sheet value associated with this asset is its purchase price less depreciation charges recorded since the equipment was acquired. Not reflected in that valuation are the costs of transporting the equipment to a buyer. Moreover, the depreciation charges, which were set at the time of the machinery's purchase, may not take into account the possibility of subsequent introduction of a competing, more cost-effective model, which would reduce the value of earlier-generation equipment.

To identify gaps between book value and liquidation value, analysts can obtain information on sales of comparable assets. In the energy sector, for example, widely reported sales of oil reserves provide dollars-per-barrel benchmarks. Acquisitions of retailing chains and restaurants similarly furnish useful estimates of current market value of comparable properties.

Even when such market-based data can be found, however, debt holders must be cautious about concluding that their principal will be fully covered in liquidation. For example, suppose that during a period of airline industry prosperity an airline sells bonds collateralized by planes. The prices then being paid for used aircraft may imply that the collateral's asset value comfortably exceeds the face amount of the bonds. The bonds may come due, however, when the notoriously cyclical airline business is in a downturn, making it difficult for the borrower to refinance the debt. Demand for used aircraft is likely to be minimal at that point, reducing the liquidation value of the collateral to much less than the bonds' face amount.

Takeovers, recapitalizations, and other restructurings increase the importance of asset coverage protection. Unfortunately for some bondholders, mergers or takeovers may decimate their asset coverage by adding layers of debt to the corporate structure that is senior to their holdings. While the analyst may find it difficult to predict takeovers, it is crucial to evaluate the degree of protection from takeovers and other restructurings that the bond indenture offers.

In extreme cases, the analyst must consider asset coverage in the case of bankruptcy. This is particularly important in the case of lease obligations because the debtor has the ability to reject leases in bankruptcy. In the case of lease rejections, the resulting asset protection may depend on a legal determination of whether the underlying lease is a true lease or a financing arrangement. Even if the lease if determined to be a true lease, the determination of asset protection is further complicated by a determination of whether the lease relates to nonresidential real property or to personal property. The difference in security (i.e., recovery in a bankruptcy) is significant. Damages under a lease of nonresidential real property are limited to three years of lease payments. Damages under a lease of personal property are typically based on all amounts still due under the lease.

In addition to the major variables just discussed, the analyst also should consider several other financial variables, including intangibles, unfunded pension liabilities, the age and condition of the plant, and working capital adequacy.

Intangibles

Intangibles often represent a small portion of the asset side of a balance sheet. Occasionally, particularly with companies that have or have had an active acquisition program, intangibles can represent a significant portion of assets. In this case, the analyst should estimate the actual value of the intangibles and determine whether this value is in concert with a market valuation. A carrying value significantly higher than market value indicates a potential for a write-down of assets. The actual write-down may not occur until the company actually sells a subsidiary with which the intangibles are identified. However, the analyst should recognize the potential and adjust capitalization ratios accordingly.

Unfunded Pension Liabilities

Unfunded pension liabilities also can affect a credit decision. Although a fully funded pension is not necessary for a high credit assessment, a large unfunded pension liability that is 10% or more of net worth can be a negative. Of concern is the company with unfunded pension liabilities high enough to interfere with corporate planning. For example, in the late 1980s, a steel company with high unfunded pension liabilities might have delayed or decided against closing an unprofitable plant because of the pension costs involved. The analyst also should be aware of a company's assumed rate of return on its pension funds and salary-increase assumptions. The higher the assumed rate of return, the lower the contribution a company must make to its pension fund, given a set of actuarial assumptions. Occasionally, a company having difficulty with its earnings will raise its actuarial assumption and thereby lower its pension contribution and increase earnings. The impact on earnings can be dramatic. In other cases, companies have attempted to "raid" the excess funds in an overfunded retirement plan to enhance earnings.

In periods of declining interest rates, the analyst also must consider the discount rate companies use to discount their future obligations. Companies generally use the yield of AA corporate bonds as a discount factor, a benchmark that has been criticized by market analysts.

Age and Condition of Plant

The age of a company's plant also should be estimated, if only to the extent that it differs dramatically from industry standards. A heavy industrial company with an average plant age well above that of its competitors is probably already paying for its aged plant through operating inefficiencies. In the longer term, however, the age of the plant is an indication of future capital expenditures for a more modern plant. In addition, underdepreciation of the plant significantly increases reported earnings.

The availability of information regarding the average age and condition of plants varies among companies. On the one hand, airline carriers readily provide the average age of their fleet and the money they will save as they replace older aircraft with more fuel-efficient aircraft that require fewer people in the cockpit. On the other hand, the average age of a plant compared with the industry average is not always available for some companies such as paper producers. Furthermore, companies with older plants generally emphasize the capital improvements that have been made to them over the years, which distort direct comparisons. In this case, it is helpful to read closely several years of management's explanation of operating results in the annual reports. Often this section will include mentions of above-average maintenance expense and machines that were out of service for a period of time for maintenance. Such comments indicate that the plants and machines may not be as efficient as portrayed initially.

Working Capital

A final variable in assessing a company's financial strength concerns the strength and liquidity of its working capital. *Working capital* is defined as current assets less current liabilities. Working capital is considered a primary measure of a company's financial flexibility. Other such measures include the current ratio (current assets divided by current liabilities) and the acid test (cash, marketable securities, and receivables divided by current liabilities). The stronger the company's liquidity measures, the better it can weather a downturn in business and cash flow.

In assessing this variable, the analyst should consider the normal working capital requirements of a company and industry. The components of working capital also should be analyzed. Although accounts receivable are considered to be liquid, an increase in the average days a receivable is outstanding may be an indication that a higher level of working capital is needed for the efficient running of the operation. Furthermore, companies frequently have accounts receivable financing, some with recourse provisions. In this scenario, comparisons among companies in the same industry may be distorted.

The state of contraction or expansion also should be considered in evaluating working capital needs. Automobile manufacturers typically need increased working capital in years when automobile sales increase.

Analysis of the Components of Return on Equity

Once the preceding financial analysis is complete, the bond analyst traditionally examines the earnings progression of the company and its historical return on equity (ROE). This section of analysis often receives less emphasis than the traditional ratio analysis. It is equally important, however, and demands equivalent emphasis. An analysis of earnings growth and ROE is vital in determining credit quality because it gives the analyst necessary insights into the components of ROE and indications of the sources of future growth. Equity analysts devote a major portion of their time to examining the components of ROE, and their work should be recognized as valuable resource material.

A basic approach to examining the components of ROE breaks down return on equity into four principal components: pretax margins, asset turnover, leverage, and one minus the tax rate. These four variables multiplied together equal net income/stockholders' equity, or return on equity, as shown below:

$$\text{Net income/equity} = (\text{net pretax income/sales} + \text{operating pretax income/sales}) \times (\text{sales/assets}) \times (\text{assets/equity}) \times (1 - \text{tax rate})$$

The analyst should examine the progression of these four components of ROE for a minimum of five years and through at least one business cycle. The progression of each variable should be compared with the progression of the same variables for the industry, and deviations from industry standards should be further analyzed. For example, perhaps two companies have similar ROEs, but one company is employing a higher level of leverage to achieve its results, whereas the other company has a higher asset-turnover rate. Since the degree of leverage is largely a management decision, the analyst should focus on asset turnover. Why have sales for the former company turned down? Is this downturn a result of a general slowdown in the industry, or is it that assets have been expanded rapidly, and the company is in the process of absorbing these new assets? Conversely, a relatively high rise in asset-turnover rate may indicate a need for more capital. If this is the case, how will the company finance this growth, and what effect will the financing have on the firm's embedded cost of capital?

The analyst should not expect similar components of ROE for all companies in a particular industry. Deviations from industry norms are often indications of management philosophy. For example, one company may emphasize asset turnover, and another company in the same industry may emphasize profit margin. As in any financial analysis, the trend of the components is as important as the absolute levels.

Nonfinancial Factors

After the traditional bond analysis is completed, the analyst should consider some nonfinancial factors that might modify the evaluation of the company. Among these factors are the degree of foreign exposure, the quality of management, and ownership. The amount of foreign exposure should be ascertainable from the annual report. Sometimes, however, specific country exposure is less clear because the annual report often lists foreign exposure by broad geographic divisions. If there is concern that a major portion of revenue and income is derived from potentially unstable areas, the analyst should carefully consider the total revenue and income derived from the area and the assets committed. Further consideration should be given to available corporate alternatives should nationalization of assets occur. Additionally, the degree of currency exposure should be determined. If currency fluctuations are significant, has management hedged its exposure?

The internationalization of the bond markets and the ability of countries to issue debt in other countries highlight the importance of understanding the effect of currency risks. For example, many Mexican companies issued U.S. dollar–denominated debt in the early 1990s. This issuance had a positive impact on the financials of these Mexican companies because of the generally lower interest rates available in the United States relative to Mexico. However, when the peso was devalued significantly in December 1994, the ability of some of these companies to meet their U.S. dollar–denominated obligations was questioned. Of particular concern were the companies whose revenues were largely denominated in pesos but whose interest expense was denominated in U.S. dollars.

The quality and depth of management are more difficult to evaluate. The best way to evaluate management is to spend time with management, if possible. Earnings progress at the firm is a good indication of the quality of management. Negative aspects would include a firm founded and headed by one person who is approaching retirement and has made no plan for succession. Equally negative is the firm that has had numerous changes of management and philosophy. On the other hand, excessive stability is not always desirable. In discussing the factors it considers in assigning a credit rating, Moody's Investors Service notes the following regarding the quality of management:

> Although difficult to quantify, management quality is one of the most important factors supporting an issuer's credit strength. When the unexpected occurs, it is a management's ability to react appropriately that will sustain the company's performance.[2]

In assessing management quality, the analysts at Moody's, for example, try to understand the business strategies and policies formulated by management. Following are factors that are considered: (1) strategic direction, (2) financial philosophy, (3) conservatism, (4) track record, (5) succession planning, and (6) control systems.

In recent years, focus has been on the corporate governance of the firm and the role of the board of directors. The bylaws are the rules of governance for the corporation. The bylaws define the rights and obligations of officers, members of the board of directors, and shareholders. Several firms have developed services that assess corporate governance. One type of service provides confidential assessment of the relative strength of a firm's corporate governance practices. The customer for this service is a corporation seeking external evaluations of its current practice. The second is a service that rates (or scores) the corporate governance mechanisms of companies. Generally, these ratings are made public at the option of the company requesting an evaluation.

Analysts should also consider the ownership of a company. If a single family or small group of investors holds a controlling interest, the company may tend to be overly conservative in its response to changes in its markets. Owners also

2. "Industrial Company Rating Methodology," *Moody's Investors Services: Global Credit Research*, July 1998, p. 6.

should be judged in terms of whether they are strategic or financial. Often financial buyers invest for the short to intermediate term, hoping to sell their positions (or the entire company) at a profit. If such a sale involves a leveraged buyout, the credit quality of the bonds is lowered, sometimes dramatically.

COMBINING FINANCIAL AND NONFINANCIAL ANALYSIS

The ultimate credit judgment on a company must consider both its financial risk profile and its business risk profile. Strength in one aspect of credit quality may be offset by weakness in the other. Exhibit 40-2 illustrates one approach to integrating the two modes of analysis.

Standard & Poor's employs a matrix of six levels of business risk, from "excellent" to "vulnerable," and six levels of financial risk, from "minimal" to "highly leveraged." The table shows the midpoint of the range of ratings that may be assigned to a company within a given cell. The actual rating ordinarily will be within one notch of that rating. For example, in most cases a company with a "satisfactory" business risk profile and an "intermediate" financial risk profile will be rated in the range of BBB+ to BBB–.

Certain cells, such as "excellent" business risk profile/"highly leveraged" financial risk profile, are blank. This is because such combinations are extremely improbable. For some companies, overarching risks such as major litigation and balance-sheet-straining acquisitions fall outside the matrix. Finally, the matrix excludes ratings lower than CCC+ because by definition, companies in those categories reflect an acute vulnerability or impending crisis.

Specific obligations may be rated higher than the company rating, based on security, or lower than the company rating, based on subordination within

EXHIBIT 40-2

Business and Financial Risk Profile Matrix

Business Risk Profile	*Financial Risk Profile*					
	Minimal	**Modest**	**Intermediate**	**Significant**	**Aggressive**	**Highly Leveraged**
Excellent	AAA	AA	A	A–	BBB	—
Strong	AA	A	A–	BBB	BB	BB–
Satisfactory	A–	BBB+	BBB	BB+	BB-	B+
Fair	—	BBB–	BB+	BB	BB–	B
Weak	—	—	BB	BB–	B+	B–
Vulnerable	—	—	—	B+	B	CCC+

These rating outcomes are shown for guidance purposes only. Actual rating should be within one notch of indicated rating outcomes.

EXHIBIT 40-3

Financial Risk Indicative Ratios (Corporate)

	FFO/Debt (%)	Debt/EBITDA (x)	Debt/Capital (%)
Minimal	Greater than 60	Less than 1.5	Less than 25
Modest	45–60	1.5–2	25–35
Intermediate	30–45	2–3	35–45
Significant	20–30	3–4	45–50
Aggressive	12–20	4–5	50–60
Highly Leveraged	Less than 12	Greater than 5	Greater than 60

the capital structure. Subordination includes *structural subordination*, whereby servicing of a holding company's debt depends on receiving dividends from subsidiaries. By law, dividends can be paid only after the subsidiaries' own debt has been serviced.

Exhibit 40-3 provides a key to the classifications of companies within the six financial risk profile categories. For example, a company with funds flow from operations to debt of 45% to 60%, debt/earnings before interest, taxes, depreciation, and amortization (EBITDA) of 1.5 to 2×, and debt/capital of 25% to 35% is deemed to have "modest" financial risk. S&P characterizes these benchmark ratios as guidelines rather than absolute rules. For instance, a company with very stable financial ratios may qualify for a particular financial risk category despite a somewhat lower FFO/debt percentage or a higher debt/capital percentage than shown in the exhibit. Electric utilities benefit from this leeway because of their demonstrated superiority in access to capital, their liquidity, and their effective management of capital programs and maturity schedules.

INDENTURE PROVISIONS

An *indenture* is a contract that defines the legal rights and obligations of the issuer and the bondholders, represented through the trustee, with respect to a bond issue. The indenture establishes fundamental rules for three primary investor concerns: (1) payments by the issuer to bondholders, (2) limits on the kinds of issuer behavior that may harm bondholders' prospects for repayment, and (3) the enforcement mechanisms available to bondholders if issuers do not fulfill their obligations.

First, the indenture and the related note that represents the debt enshrine a bondholder's individual right to the timely payment of principal and interest. The bond may also be subject to special pricing and redemption provisions, such as a ratings-based coupon step-up, a call schedule, a make-whole redemption, a sinking fund, or a maintenance and replacement fund. These payment provisions are discussed in Chapter 10.

Second, the indenture will contain provisions called *covenants* that attempt to limit some issuer behavior that could increase credit risk. For example, if an issuer doubles its amount of outstanding debt in order to pay dividends to shareholders while neglecting reinvestment in its business, then bondholders will face a greater risk of a payment default on their bonds. A strong Debt covenant or Restricted Payments covenant could limit this kind of recapitalization event. Indenture analysis is principally focused on restrictive covenants not only to help evaluate contractual protections against risky behavior by issuers but also to consider the upside possibility of a consent solicitation or a premium tender for their bonds if the issuer wants to take actions that otherwise would be restricted by the bond covenants. Covenant protections can have important market pricing implications, especially in the leveraged-buyout (LBO) context. When the Texas power company TXU Corp. was acquired in 2007, it had significant bonds outstanding at three different legal entities. The TXU holding company bonds had very weak covenant protections and remained outstanding and traded well below par for years after the LBO, while the TXU Energy subsidiary bonds had stronger covenant protections that would have impeded the optimal LBO financing, and so they were redeemed at a premium. The value of a third set of bonds was relatively protected because they had been issued by a different, state-regulated subsidiary with limits on its ability to borrow.

Covenant protections can vary enormously even among bonds of the same issuer, but they can generally be described as being investment-grade or high-yield type covenants. Some industry groups such as real estate investment trusts (REITs) and finance companies have special covenant features, as explained below. Bear in mind that covenants vary over time as investors become more or less sensitive to event risk and the view of what is "market" practice changes. For example, Change of Control puts and secured debt restrictions became very important for investment-grade bond investors following the 1988 LBO of RJR Nabisco, but then generally waned over the next two decades. Then the buyout boom of the mid-2000s and resulting bondholder losses resurrected these kinds of protections, so that since 2010 the inclusion of a Change of Control covenant has again become standard for both high-yield and investment-grade nonfinancial bonds.

Enforcement is the third primary concern. If there is a *default* under the indenture, then the enforcement of bondholder rights is handled according to detailed rules that are generally similar among all corporate indentures.

Generally, if there is *payment default* because a principal or interest payment is not made on time, then the trustee may act on its own to sue for payment, although an individual bondholder can also sue for payment. If there is a *covenant default,* such as selling an asset in violation of an Asset Sales covenant, then enforcement could occur in several ways. The issuer might realize its mistake and attempt to *cure,* or remedy, the breach if possible. The issuer might ask bondholders for permission in a *consent solicitation* for a *waiver* from having to comply with the indenture provision or for an *amendment* to the indenture so that the covenant is changed. Bondholders or the trustee might become aware of a default and formally give notice of a default to try to *accelerate* the bonds for early payment. Sometimes, the issuer, trustee, and bondholders might disagree about the meaning of an indenture covenant and litigate the matter. For example, when Tyco International split its businesses into three separate, publicly traded companies, bondholders sued to stop the transaction based on a violation of the Mergers covenant, and Tyco paid to settle the litigation. Typically, either the trustee or 25% of bondholders must act in order to declare a default and attempt to accelerate the bonds.

Until the early 2000s, issuers could often obtain a consent solicitation for a negotiated price commonly ranging from 50 to 500 basis points, based upon the perceived need of the issuer and the reasonably likely credit harm to the investor. Indenture litigation was relatively rare. But now, the strength of hedge funds in the bond market has created a transactional mindset that has swept away the old relationship model, where the issuer and investors wanted to be reasonable with each other on the expectation of future bond issuances. Instead, the common response to a consent solicitation is that holders want a costly make-whole redemption instead. Many issuers actively seek to exploit clever loopholes in their indentures that undermine the spirit if not the letter of the deal, while many investors scour the contract to find technical violations on which to threaten a lawsuit if their bonds are not redeemed. Today's more adversarial bond world can see a dozen indenture lawsuits threatened or commenced in a typical year, and there are some hedge fund managers who have made their fortunes and reputations largely on litigating debt contracts. These active credit funds have become the primary guardians of the covenants, who then enlist the trustees to fight alongside them.

Bond indentures should be considered in light of the covenants in bank credit agreements. Historically, loan covenants would be more restrictive than bond covenants. In particular, credit agreements can contain *maintenance covenants* that require the borrower to maintain a certain level of consolidated net worth, a ratio of total debt to cash flow, or some other financial metrics that serve as a proxy for the creditworthiness of the borrower. If a maintenance covenant is breached, then the lenders can seek to accelerate. Bondholders sometimes hope that the more restrictive bank credit agreements will provide some aura of protection to bondholders, but investors should be cautious about this idea. Borrowers often ask lenders for waivers and amendments, and there were numerous examples in which some market participants took credit views based on expected covenant breaches that turned out to be incorrect, such as when MGM Mirage (Resorts) obtained a series of amendments from its lenders in 2009 that involved pledging additional collateral. However, a dramatic and counterintuitive shift has occurred since the 2008 credit crisis: despite the experienced losses from weak covenants in the buyouts and subsequent debt exchanges of 2006–2010, bank and bond covenants became progressively weaker with new issues in the 2010s. This acceptance of worse terms was driven by the decline of relationship banking, the growth of rules-based CLOs, and falling interest rates leading to a reach for yield, such that contractual covenant risk was given little weight amidst a feeding frenzy for higher-yielding credit. In fact, by 2020, over 80% of all large corporate loans in the United States and Europe were being issued with no maintenance covenants at all. These loans are referred to as *covenant lite,* and now sometimes an issuer's loans have even less protective covenants than the bonds!

Note that the prospectus or offering memorandum for a bond will contain a description of the covenants, but it is the indenture that controls as the legally binding contract, and so the indenture should be used for covenant analysis. The indenture of a U.S. issuer usually can be obtained from the SEC's EDGAR website if the issuer is a public company or otherwise files with the SEC. Alternately, the indenture may be obtained from the trustee who is listed in the prospectus or sometimes directly from the issuer.

Outlined below are the most common indenture covenants, and how they vary for investment-grade versus high-yield bonds. Following that is an explanation of some special industry and bond types. Bear in mind that covenants work together as a kind of "system" where one corporate action can implicate multiple indenture provisions.

Typical Bond Covenants

Guarantees/Future Guarantors Covenant

A bond is primarily the obligation of the issuer. Often the issuer is a holding company that relies on its own subsidiaries to upstream cash for the issuer to make payments to bondholders. If the issuer fails to make a payment, then bondholders may want to make a claim for payment against the subsidiaries that hold the operating assets. This is possible if there are *subsidiary guarantees* by which the issuer's subsidiaries promise to pay interest and principal if the issuer does not. A bond may have subsidiary guarantees when it is issued, or a *Future Guarantors covenant* may require subsidiaries to provide guarantees in the future. Guarantees are an important determinant of recoveries in bankruptcy, especially when there may be significant debt, trade claims, or other liabilities against subsidiaries.

A guarantee can put the bondholders' claims on an equal footing with other claims against subsidiaries.

Investment-grade bonds usually do not have subsidiary guarantees, while high-yield bonds typically are offered with these guarantees. Note this seeming paradox that will repeat across covenants and has endured for decades: while the investment-grade investors have relatively the most to lose in seeing their issuers falling from investment-grade to high-yield status in the case of dividends, LBOs, and other dramatic events, it is the investment-grade investors that have the least covenant protections from these kinds of bad actions.

Debt Covenant

The *Debt covenant* limits the amount of additional borrowings by the issuer. A Debt covenant has become rare among investment-grade bonds but is customary for high-yield issues. The typical version says that the issuer and its subsidiaries generally cannot incur debt unless a *Ratio test* is met, which typically requires meeting a pro forma 2X EBIDTA:interest expense coverage ratio or a maximum debt:EBITDA leverage ratio. However, even when the Ratio test cannot be met, certain types of *Permitted Debt* are allowed. Permitted Debt includes specific carveouts such as for a set amount of credit facilities, project and acquisition financing, and a general-purpose debt basket. Generally, a Debt covenant is designed to allow an issuer to borrow more money when its EBITDA and total asset base are increasing. The risk to bondholders is that the new debt remains even if financial results decline because the Debt covenant is not a maintenance covenant.

Importantly, for the Debt covenant and other restrictive covenants, investors must confirm which entities in the capital structure must obey the covenants. Ideally, the issuer and all its subsidiaries would be subject to the covenants, but many indentures exempt so-called unrestricted subsidiaries.

Subsidiary Debt Covenant

Investment-grade bonds occasionally have a *Subsidiary Debt covenant* that is intended to limit the amount of money that can be borrowed by subsidiaries, and therefore, reduce the risk of structural subordination.

Negative Pledge/Liens Covenant

Bondholders generally do not want other debt to be secured ahead of or alongside their bonds because secured debt will recover ahead of unsecured debt in bankruptcy. This concern is addressed by one of two similar provisions that have an important substantive difference. A *Negative Pledge covenant* is used for almost all unsecured bonds and generally requires that if some other debt becomes secured, then the bonds must be equally and ratably secured. The Negative Pledge for an investment-grade bond will typically only restrict pledging some subset of the issuer's total assets (for example, manufacturing plants), allow exceptions to finance capital expenditures and asset acquisitions, and have a *general secured debt carveout* equal to 10% to 15% of a balance sheet metric such as consolidated net tangible assets or stockholders' equity. For a high-yield bond, the covenant will typically apply to all of the issuer's assets, but a lengthy list of *Permitted Liens* will have carveouts matched to particular items of Permitted Debt and other exceptions.

In comparison, a secured bond should have a true *Liens covenant,* which restricts securing other debt and does not give the issuer the option to secure new debt by ratably securing the existing bonds, but would still allow some Permitted Liens. For investors, seeing new secured debt issued can have an immediate negative impact on their existing bond values and reduce their recoveries in bankruptcy. From an issuer perspective, the ability to issue secured debt can allow a financing lifeline when there is a sudden, unexpected event. For example, cruise ship operator Carnival Corp. was a longtime issuer of unsecured bonds with investment-grade ratings, but when the Covid-19 virus froze its revenues in 2020, it found flexibility in its existing Liens covenants to issue $4 billion of new three-year bonds secured by ships and intellectual property to keep the company afloat until sailings could resume.

Sale/Leaseback Covenant

A *Sale/Leaseback covenant* is standard for investment-grade bonds and is especially important when there is significant credit support from owned manufacturing facilities or high-value real estate, such as department stores with owned locations. If a company sells real estate and then takes back a lease on that property, the bondholder is harmed twice: first, because there would be fewer assets to recover against in bankruptcy, and second, because the issuer will have committed itself to future lease payments. Therefore, the covenant usually blocks a sale/leaseback transaction unless it is used to finance a new location or the proceeds of the sale are used to repay long-term debt or acquire new assets. This covenant had been common for high-yield bonds from the late 1980s through the early 2000s, but has largely faded away for that market, in part because the sale would be addressed by the Asset Sales covenant of a high-yield bond, while aspects of the lease would be addressed by the Debt and Liens covenants.

Restricted Payments Covenant

A *Restricted Payments covenant* primarily limits the amount of dividends that can be paid to stockholders. While these dividend restrictions might occasionally appear in investment-grade bond issues, they are now generally restricted to high-yield bonds. Typically, 50% of the issuer's net income can be paid to stockholders, on the theory that the other half of profits should be reinvested in the business or used to pay down debt. Paying dividends based on net income is also usually conditioned upon meeting the pro forma Ratio test of the Debt covenant. This same Restricted Payments covenant will also generally limit stock purchases, repaying subordinated debt before its maturity, and making so-called restricted investments in entities such as joint ventures that might not be obligated to obey the indenture covenants.

Asset Sales Covenant

The Asset Sales covenant is rare for investment-grade bonds but standard for high-yield bonds. The covenant does not prevent asset sales, but generally requires that the proceeds of a sale be used to acquire new assets or repay debt that is secured or otherwise effectively senior to the bonds. If that is not done, then the issuer usually must offer to buy back the bonds at par within a year.

Mergers Covenant

The *Mergers covenant,* also known as the successor obligor provision, is designed to ensure a degree of continuity between the bond debt and the issuer's assets that support the debt. If the issuer merges with another company or transfers "substantially all" of its assets to another company, then the bond obligation must remain with the merged company or bulk of the assets. Otherwise, investment-grade bondholders could be left holding bonds of a mere shell company that has sold off its assets because an investment-grade bond usually does not have an Asset Sales covenant.

High-yield bonds have a similar Mergers covenant, but their version would generally require meeting the Debt covenant's Ratio test as a condition to the merger or asset transfer.

Change of Control Covenant

The *Change of Control covenant* is nearly universal for high-yield bonds and allows bondholders to put bonds back to the issuer at 101% upon a defined Change of Control. This covenant also appears in the majority of nonfinancial investment-grade bonds issued since 2010, but with the additional requirement that the bonds become rated below investment grade. The Change of Control definition may include one or more triggers, such as (1) a sale of substantially all assets, (2) the acquisition of more than half of the issuer's voting stock by a third party, (3) a merger with another company, (4) a liquidation of the company, and (5) a hostile change in the board of directors. The Change of Control put can be blunt protection against the risk of credit-damaging leverage in an LBO, a chance to assess the new ownership of the issuer, or a simple 101% put opportunity for a bond trading below par.

Special Covenants and Situations

Some industries and special situations have bond covenants that vary from the common pattern and we outline these below.

Real Estate Investment Trusts

REITs are almost always investment-grade issuers, and their covenants have a great degree of similarity to each other. The REIT indenture usually has one or more maintenance covenants based on levels of secured debt, unsecured debt, and interest coverage.

Utilities

Utilities tend to be investment-grade issuers yet have traditionally issued secured debt, often under the title of First Mortgage Bonds with indentures that have been used for decades, and sometimes feature maintenance and replacement funds and sinking funds. These secured bonds may limit the amount of additional debt that may be issued under the mortgage to a certain percentage of net property. Today, many utilities issue bonds with limited covenants that look like those of other investment-grade issuers, with only a standard make-whole redemption option. However, investors have some comfort that state utility regulations may effectively limit the leverage of these companies.

Finance Companies

Finance companies are usually investment-grade issuers and have less complex covenants than in the past. A negative pledge type Liens covenant is common, and if the issuer is a finance subsidiary of an operating company, such as how John Deere Capital Corp. is a business of the farm vehicle manufacturer Deere & Company, then the parent may have a support guarantee in which the parent promises to invest in or manage the finance subsidiary for it to maintain a certain net worth or other credit metric.

Banks and Insurance Companies

The holding companies for banks and insurance companies are typically rated investment grade and their bonds will have a limited Liens covenant that restricts pledging shares of major subsidiaries and perhaps a limited kind of Asset Sales covenant that restricts selling significant minority stakes in major subsidiaries. The regulated subsidiaries may issue their own, higher-rated debt, in which the covenants are often less important because state and federal laws practically limit borrowing by regulated subsidiaries.

Split-Rated Issuers

Bonds issued with one investment-grade rating and one high-yield rating often have investment-grade covenants, but perhaps with the addition of a strong Future Guarantors covenant or a limited Restricted Payments covenant that controls dividend payments.

Secured High-Yield Bonds

Traditionally, bank loans were secured and bonds were not. This began to change significantly in the 2000s as bank lenders became comfortable with the idea of allowing bonds to be sold with second liens that would recover behind the bank loans. These bonds are often subject to an *intercreditor agreement* that affirms the primacy of the lenders' liens and limits somewhat the arguments that bondholders can make in bankruptcy.

By 2010 over one-fourth of U.S. high-yield bonds were sold with some collateral protection, and since then, in a typical quarter, somewhere between 20% and 30% of new issues are secured. Not only are first and second liens now routine, but there has also been a proliferation of slices of secured bonds sandwiched in between levels over time, such as the EP Energy 8% 1.25 Lien Notes due 2024, Hovnanian Enterprises 10% 1.75 Lien Notes due 2025, and Halcón Resources 13% Senior Secured Third Lien Notes due 2022. These odd pockets of secured debt are created to take advantage of loopholes in the Liens covenant, to the delight of issuers that want to find incremental financing and for investors who want to make relative-value trades among varying levels of collateral priority. Further, an issuer may have secured bonds that have greater rights than some of its secured loan tranches! There have now been numerous companies with 10 or more different tranches of debt with different recovery rights, such as

Altice, Caesars Entertainment, and Intelsat. This phenomenon has dramatically reshaped the old rules of thumb that "secured" lenders usually recover 80% to 100% of their debt in bankruptcy and that unsecured bondholders get something of a 50% to 80% recovery. In this new era, "it depends on the covenants" more than ever, and positioning and litigating over the fulcrum security has become the key battleground.

Private Bonds

So-called private bonds are usually small offerings that are sold to just a handful of institutions, tend not to trade frequently, and are generally not covered by research or media outlets. These bonds can often be more heavily negotiated and include loan-like maintenance covenants.

UTILITIES

Historically, utilities have been regulated monopolies. These companies generally operate with a high degree of financial leverage and low fixed-charge coverage (relative to industrial companies). These financial parameters have been accepted historically by investors owing to the regulation of the industry and the belief that there is minimal, if any, bankruptcy risk in those securities because of the essential services they provide.

The changing structure of the electric utility industry brought about by significant investment in nuclear generating units and their inherent risk, as well as the transition to deregulation, has changed this belief. Initially, the faltering financial position of General Public Utilities precipitated by the Three Mile Island nuclear accident and the regulatory delays in making a decision regarding the units highlighted the default risk that exists in the industry. Subsequently, the defaults of several Washington Public Power Supply System issues, the restructuring of Tucson Electric Company, and the bankruptcies of Public Service Company of New Hampshire and El Paso Electric Company and the transition to deregulation reemphasized the default risk. In addition, the industry is faced with the acid rain issue and increased uncertainty in construction costs and growth rates.

Segments Within the Utility Industry

There are three major segments within the utility industry: electric companies, gas companies, and telephone companies. This chapter will deal primarily with electric utilities. Many companies are involved in both electric and gas service, so analysis requires a working knowledge of both businesses. A working knowledge of the different facets of the electric utility industry is also required as traditional electric utilities diverge in their strategies, with some companies emphasizing transmission and distribution exclusively while other companies emphasize generation.

Nonfinancial Factors

Although financial factors are important in analyzing any company, nonfinancial factors are particularly important in the electric utility industry and may alter a credit assessment. The following nonfinancial factors are of particular importance to the utility industry: (1) regulation, (2) source of the company's energy, (3) growth and stability of the company's territory, (4) capital structure, (5) degree of activity in international and nonutility investments, and (6) competitive position.

To reflect the importance of nonfinancial factors, S&P utilizes a 10-point business risk assessment. In June 2004 S&P assigned new business profile scores to refine its assessment of relative risk among the utility and power companies. At that point the rating agency also divided the group into subsectors to allow more in-depth statistical analysis of the distribution of its ratings and its rating changes. The subsectors are Transmission and Distribution—Water, Gas, and Electric; Transmission Only—Electric, Gas, and Other; Integrated Electric, Gas, and Combination Utilities; Diversified Energy and Diversified Non-Energy; and Energy Merchant/Developers/Trading and Marketing.

Regulation

The utility industry includes both regulated and unregulated entities. In some cases, the two types coexist as subsidiaries within a single corporate structure. Power generation has been deregulated in some states, with merchant power companies selling electricity at competitive rates, but remains regulated in others. The transmission segment remains highly regulated. Retail distribution is deregulated, with consumers free to choose their providers based on such factors as price and quality of service.

For regulated entities, regulation is perhaps the most important credit analysis variable. Regulators, operating mainly at the state level, largely determine how much profit these businesses earn and retain. If a company has regulated operations in more than one state, the analyst should weight the evaluation of the regulatory environment by the revenues generated in each state.

The evaluation of regulatory commissions is a dynamic process. The composition of commissions changes because of retirements, appointments, and elections. The implications of personnel changes are not clear until decisions are made. For example, it is not always the case that elected commissioners are pro-consumer and appointments by a conservative governor are pro-business. Several brokerage firms can assist in evaluations of commissions.

In addition, the Federal Energy Regulatory Commission (FERC) regulates interstate operations and the sale of wholesale power. Currently, FERC regulation is considered to be somewhat more favorable than that of the average state regulatory commission.

Utilities that are constructing or operating nuclear reactors are also subject to the regulation of the Nuclear Regulatory Commission (NRC). The NRC has broad regulatory and supervisory jurisdiction over the construction and operation of nuclear reactors. Importantly, the NRC approves licensing of nuclear reactors, as well as the transfer of licenses.

Regulation is best quantified by recent rate decisions and the trend of these decisions. Although a company being analyzed may not have had a recent rate case, the commission's decisions for other companies operating within the state may be used as a proxy. Regulatory commissions are either appointed or elected. In either case, the political atmosphere can have a dramatic effect on the trend of decisions.

The regulators determine innumerable issues in a rate decision, although analysts often mistakenly focus only on the allowed rate of return on equity or the percentage of request granted. For example, a commission might rule that an electric utility must reduce rates by 10%. However, if the commission allows the utility to accelerate its depreciation, the negative effect on the cash flow of the company from the rate reduction may be largely offset, particularly if the company had been or was expected to exceed its allowed ROE. The commissions also determine how much of construction work in progress (CWIP) is allowed into the rate base. A company may appear to have a favorable allowed ROE but be hurt by the fact that only a small portion of the company's capital is permitted to earn that return, and the CWIP earns nothing. Allowance of CWIP in the rate base was of critical importance during the 1980s because of the high construction budgets for nuclear generating plants and the length of time these plants were under construction. Some companies have had more than half their capital in CWIP that was not permitted to earn a return.

The importance of whether CWIP is allowed in the rate base is highlighted by the financial distress and January 1988 bankruptcy filing of Public Service Company of New Hampshire (PSNH). PSNH's Seabrook Nuclear Unit I was virtually complete in 1986. However, licensing delays and New Hampshire's statutory prohibition of CWIP in the rate base were major contributing factors in the bankruptcy filing.

In addition, regulators have a high degree of control over the cash flow of a company through the allowance or disallowance of accounting practices and the speed with which decisions are made on cases.

Source of the Company's Energy

The source of the company's energy is a second important variable, with the impact on fuel cost being especially important for merchant generators. Each fuel must be evaluated in the context of the overall cost of operating a plant. For many years, nuclear generation was out of favor because of extensive licensing requirements, high capital costs, and heavy decommissioning expenses. Companies with large dependence on nuclear power were viewed less favorably than those with natural gas or coal units. More recently, nuclear-based generation companies have gained popularity among investors as they have written down their capital costs, while coal has suffered from escalating pollution concerns and the cost of oil and natural gas has risen. Additionally, in the mid 2000s, a number of nuclear-powered utilities were successful in their requests for 20-year license renewals.

Growth and Stability of the Company's Territory

The energy-source variable relates to a third variable—the growth and stability of the company's territory. Although above-average growth is viewed positively in an industrial company, above-average growth gets mixed reviews with respect to an electric utility. An electric utility with above-average growth may face construction earlier than its competitors depending on the supply/demand balance and regulation in its service territory.

Slow growth is not necessarily positive if it places a utility in a position of excess capacity. The increase in cogeneration and the mergers executed in order to better match supply and demand can place a utility at risk. This can result if utility A is selling power to utility B. If the expiration of the contract coincides with utility B's ability to purchase power for less and results in utility B's nonrenewal of the contract, utility A may be negatively affected unless it can sell the power to a third utility. The issue of growth has been complicated by deregulation and the requirement in many states for disaggregation of generation from transmission and distribution, as well as the requirement that customers be allowed to choose their supplier. In this new era, utilities engaged in generation must be able to match supply and demand for power.

Corporate Structure

A fourth variable, whether or not a company is a subsidiary of a holding company, also should be considered. Holding-company status permits nonutility subsidiaries, but these subsidiaries (even if successful) will not necessarily improve the overall credit quality of the company. This depends on the regulatory atmosphere. Furthermore, when there are several electric utility subsidiaries, the parent is more likely to give relatively large equity infusions to the relatively weak subsidiaries. The stronger subsidiary may have to support the other subsidiaries. Finally, holding companies should be analyzed in terms of consolidated debt. Although a particular subsidiary may have relatively strong financial parameters, off-balance-sheet financing may lower the overall assessment.

Competitive Position

A final nonfinancial factor is the competitive position of a utility. An electric utility with a comparatively low rate structure is generally in a stronger position politically to request rate increases or to request a rate freeze than one with rates higher than national averages and particularly one with rates higher than regional averages.

The competitive position of an electric utility is increasingly important as customer choice increases. Companies with high overall rates, and particularly those with high commercial rates, may find themselves losing customers as access to transmission and distribution lines increases.

Financial Analysis

The changing competitive nature of the electric industry resulting from deregulation requires that the traditional evaluation of an electric utility be modified. Although historic ratio analysis still should be conducted, an electric company also should be evaluated in the context of its new competitive situation. Is new generation being constructed in its territory that produces energy at a lower cost than the established generation? How does the company plan to expend its excess cash flow? In an era of consolidation, will the company be acquired or be an acquirer? Will the company remain in generation or sell its generation and deal solely with transmission and distribution? Location is also important. Some merchant power plants have been constructed too far from the power grid to succeed.

The following major financial ratios should be considered in analyzing an electric utility: (1) leverage, (2) pretax interest coverage, (3) cash-flow/capital expenditures, and (4) cash flow/capital.

Leverage

In calculating the debt leverage of an electric utility, long-term debt/capitalization is standard. However, the amount of short-term debt also should be considered because this is generally variable-rate debt. A high proportion of short-term debt also may indicate the possibility of the near-term issuance of long-term bonds. In addition, several companies guarantee the debt of subsidiaries (regulated or nonregulated). The extent of these guarantees should be considered in calculating leverage.

Fixed-charge coverage for the electric utilities is low relative to coverage for industrial companies. This is accepted by investors because of the stability of the industry. However, emphasis should be placed not only on the exact coverage figures but also on the trend and quality of the coverage.

A third important ratio is net cash-flow/capital expendures. This ratio should be approximated for three years (the typical electric company's construction forecast). The absolute level, as well as the trend of this ratio, gives important insights into the trend of other financial parameters. An improving trend indicates that construction spending probably is moderating, whereas a low net cash-flow/spending ratio may indicate inadequate rates being approved by the commissions and a heavy construction budget. Estimates for construction spending are published in the company's annual reports. Although these are subject to revision, the time involved in building generation makes these forecasts reasonably reliable. In calculating cash flow, the standard definition outlined earlier should be followed. However, allowance for funds used during construction (AFUDC) also should be subtracted.

FINANCE COMPANIES

Finance companies are essentially financial intermediaries. Their function is to purchase funds from public and private sources and to lend them to consumers and other borrowers of funds. Finance companies earn income by maintaining a positive spread between what the funds cost and the interest rate charged to customers. The finance industry is highly fragmented in terms of type of lending and type of ownership. This section will briefly outline the major sectors in the industry and then discuss the principal ratios and other key variables used in the analysis of finance companies.

Segments Within the Finance Industry

The finance industry can be segmented by type of business and ownership. Finance companies lend in numerous ways in order to accommodate the diverse financial needs of the economy. Five of the major lending categories are (1) sales finance, (2) commercial lending, (3) wholesale or dealer finance, (4) consumer lending, and (5) leasing. Most often companies are engaged in several of these lines rather than one line exclusively. Sales finance is the purchase of third-party contracts that cover goods or services sold on a credit basis. In most cases, the sales finance company receives an interest in the goods or services sold. Commercial finance is also generally on a secured basis. However, in this type of financing, the security is most often the borrower's accounts receivable. In factoring, another type of commercial lending, the finance company actually purchases the receivables of the company and assumes the credit risk of the receivables.

Dealer or wholesaler finance is the lending of funds to finance inventory. This type of financing is secured by the financed inventory and is short term in nature. Leasing, on the other hand, is intermediate- to long-term lending—the lessor owns the equipment, finances the lessee's use of it, and generally retains the tax benefits related to the ownership.

Consumer lending historically has involved short-term, unsecured loans of relatively small amounts to individual borrowers. In part because of the more lenient bankruptcy rules and higher default rates on consumer loans, consumer finance companies have dramatically expanded the percentage of their loans for second mortgages. The lower rate charged to individuals for this type of loan is offset by the security and lower default risk of the loan.

There are numerous other types of lending in addition to those just described. Among these are real estate lending and export/import financing.

The ownership of a finance company can significantly affect evaluation of the company. In some instances, ownership is the most important variable in the analysis. There are three major types of ownership of finance companies: (1) captives, (2) wholly owned, and (3) independents.

Captive finance companies, such as Ford Motor Credit, are owned by the parent corporation and are engaged solely or primarily in the financing of the parent's goods or services. Generally, maintenance agreements exist between the parent and the captive finance company under which the parent agrees to maintain one or more of the finance company's financial parameters, such as fixed-charge coverage, at a minimum level. Because of the overriding relationship between a parent and a captive finance subsidiary, the financial strength of the parent is an important variable in the analysis of the finance company. However, captive finance companies can have ratings either above or below those of the parent.

A wholly owned finance company differs from a captive in two ways. First, it primarily finances the goods and services of companies other than the parent. Second, maintenance agreements between the parent and the subsidiary generally are not as formal. Frequently, there are indenture provisions that address the degree to which a parent can upstream dividends from a finance subsidiary. The purpose of these provisions is to prevent a relatively weak parent from draining a healthy finance subsidiary to the detriment of the subsidiary's bondholders.

Independent finance companies are either publicly owned or closely held. Because these entities have no parent, the analysis of this finance sector is strictly a function of the strengths of the company.

Financial Analysis

In analyzing finance companies, several groups of ratios and other variables should be considered. There is more of an interrelationship between these ratios and variables than for any other type of company. For example, a finance company with a high degree of leverage and low liquidity may be considered to be of high investment quality if it has a strong parent and maintenance agreements. Variables should be viewed not in isolation but rather within the context of the whole finance company–parent company relationship.

Asset Quality

The most important variable in analyzing a finance company is asset quality. Unfortunately, there is no definitive way to measure asset quality. However, there are several variables that in the aggregate present a good indication of asset quality.

Diversification is one measure of portfolio quality. Is the portfolio diversified across different types of loans? If the company is concentrated in or deals exclusively in one lending type, is there geographic diversification? A company that deals exclusively in consumer loans in the economically sensitive Detroit area would not be viewed as favorably as a company with broad geographic diversification. Accounting quality is also an important factor in assessing portfolio quality. The security for the loans is also an important variable in portfolio quality. The stronger the underlying security, the higher is the loan quality. Analysts should be concerned primarily with the level of loans compared with levels of similar companies and the risk involved in the type of lending. For example, the expected loan loss from direct unsecured consumer loans is higher than for consumer loans secured by second mortgages. However, the higher fees charged for the former type of loan should compensate the company for the higher risk.

Numerous ratios of asset quality such as loss reserves/net charge-offs, net losses/average receivables, and nonperforming loans/average receivables give good indications of asset quality. However, finance companies have a high level of discretion in terms of what they consider and report to be nonperforming loans and what loans they charge off. Therefore, unadjusted ratios are not comparable among companies. In addition, companies periodically change their charge-off policies.

Despite the drawbacks of the asset-quality ratios, they are useful in indicating trends in quality and profitability. Of these ratios, loss reserves/net charge-offs is perhaps the most important ratio in that it indicates how much cushion a company has. A declining ratio indicates that the company may not be adding sufficient reserves to cover future charge-offs. Such a trend may lead to a future significant increase in the reserves and therefore a decrease in earnings as the increase is expensed. Net losses/average receivables and nonperforming loans/average receivables are other indicators of asset quality. An increasing ratio indicates a deterioration in quality. Declines may be exacerbated by an overall contraction or slow growth in the receivables. On the other hand, because of different accounting treatments, a stable net losses/average receivables ratio under deteriorating economic conditions may indicate a delay in loss recognition. Consideration also should be given to the age of receivables. In recent years, some finance companies have increased their lending dramatically over a short period of time and reported material improvement in their overall financial parameters. These results have been misleading in some cases where the dramatic improvement has been driven by inadequate reserves. Often the dramatic improvement has been followed by increased losses as the portfolio ages.

The long-term history of a company is also an indicator of credit quality. Does management have a history of managing risk conservatively? How long has management been in place? Is there pressure on management to accelerate growth? Has management responded to this type of pressure by expanding into more risky businesses either through acquisition or internal expansion?

Leverage

Leverage is a second important ratio used in finance company analysis. By the nature of the business, finance companies typically and acceptably are more highly leveraged than industrial companies. The leverage is necessary to earn a sufficient return on capital. However, the acceptable range of leverage depends on other factors, such as parental support, portfolio quality, and type of business. The principal ratio to determine leverage is total debt to equity, although such variations as total liabilities to equity also may be used. In a diversified company with high portfolio quality, a leverage ratio of 5 to 1 is acceptable. On the other hand, a ratio as high as 7 to 1 is acceptable for a captive with a strong parent and maintenance agreements. The analyst always should view the leverage of a finance company in comparison with similar companies.

Liquidity

The third important variable in finance company analysis is liquidity. Because of the capital structure of finance companies, the primary cause of bankruptcies in this industry is illiquidity. If for some reason a finance company is unable to raise funds in the public or private market, failure can follow quickly. This inability to raise funds could result from internal factors, such as a deterioration in earnings, or from external factors, such as a major disruption in the credit markets. Whatever the cause, a company should have some liquidity cushion. The ultimate fallback, a sale of assets, is only a last resort because the sales could have long-term detrimental effects on earnings. The traditional liquidity ratio is cash, cash equivalents, and receivables due within one year divided by short-term liabilities. The higher this ratio, the higher is the margin of safety. Also to be considered are the liquidity of the receivables themselves and the existence of bank lines of credit to provide a company with short-term liquidity during a financial crisis. Liquidity calculations also should consider contractual obligations to fund loans. In general, the smaller and weaker companies should have a higher liquidity cushion than companies with strong parental backing that can rely on interest-free loans from their parents in times of market stress. Finally, analysts should take into account a company's ability to raise secured funding, either from banks or private investors or through asset-backed securities facilities.

Asset Coverage

A fourth important variable in the analysis of finance companies that is related to the three variables just discussed is the asset coverage afforded the bondholder. In assessing asset protection, the analyst should consider the liquidation value of the loan portfolio.

A definitive assessment of the value of assets is difficult because of the flexibility finance companies have in valuing assets. For example, a finance company that plans to liquidate its commercial real estate portfolio over 12 months in a depressed real estate environment will value its assets much lower than if it planned to sell the same assets systematically over a three- to five-year period. The value of interest-only securities (IOs) created from a finance company's asset securitizations is also subjective and depends on future credit experience and prepayments. Is management conservative or aggressive in valuing these instruments? How has management valued the residuals of automobile leases? Are there periodic write-offs or gains on these loans?

Earnings Record

The fifth variable to be considered is the finance company's earnings record. The industry is fairly mature and is somewhat cyclical. The higher the annual EPS growth, the better. However, some cyclicality should be expected. In addition, the analyst should be aware of management's response to major changes in the business environment. The easing of personal bankruptcy rules over the years and the fact that personal bankruptcy is becoming more socially acceptable have produced significantly higher loan losses in direct, unsecured consumer loans. Many companies have responded to this change by contracting their unsecured personal loans and expanding their portfolios invested in personal loans secured by second mortgages.

Management

The sixth variable to be considered is the finance company's management. This variable is difficult to assess. However, a company visit combined with an evaluation of business strategies and credit scoring methodologies (analysis used for assessing loan applicants) will provide some insight into this variable.

Size

A final factor related to the finance company or subsidiary is size. In general, larger companies are viewed more positively than smaller companies. Size has important implications for market recognition in terms of selling securities and of diversification. A larger company can more easily diversify the types and geographical location of its loans, thereby lessening the risk of its portfolio, than a smaller company can.

In addition to an analysis of the financial strength of the company according to the preceding variables, the analyst must incorporate the net effect of any affiliation the finance company has with a parent. If this affiliation is strong, it may be the primary variable in the credit assessment. The affiliation between a parent company and a finance subsidiary is straightforward; it is captive, wholly owned, or independent. However, the degree to which a parent will support a finance subsidiary is not as straightforward. Traditionally, the integral relationship between a parent and a captive finance subsidiary has indicated the highest level of potential support. However, it is becoming increasingly clear that a wholly owned finance subsidiary can have just as strong an affiliation. For example, General Electric Capital finances few or no products manufactured by its parent, General Electric Company (GE). GE, however, receives substantial tax benefits from its consolidation of its tax return with GE Capital. Additionally, GE has a sizable investment in the finance subsidiary. In this case, the parent also has a formal agreement with GE Capital by which it is committed to infuse capital if fixed charge coverage of 1.1 × is not maintained. Even aside from that mechanism, there is a strong presumption that GE would protect its investment in GE Capital if the finance subsidiary were to need assistance. In other cases, the benefit of a strong affiliation and maintenance agreement may be offset by weakness in the parent company's financial position.

In addition to affiliation, affiliate profitability, and maintenance agreements, the analyst also should examine any miscellaneous factors that could affect the credit standing of the finance company. For example, new legislation could produce significant changes in the finance industry's structure or profitability. Cases in point of recent years include the Bankruptcy Abuse Prevention and Consumer

Protection Act of 2005 and the Dodd-Frank Wall Street Reform and Consumer Protection Act of 2010.

THE ANALYSIS OF HIGH-YIELD CORPORATE BONDS

High-yield bonds, sometimes disparagingly referred to as "junk bonds," are corporate issues rated speculative grade (below Baa/BBB–). Like all corporate bonds, they combine interest rate risk with credit risk, but unlike investment-grade issues, credit risk dominates their price movements. The high-yield universe is split between fallen angels, which are bonds rated investment-grade at issuance and subsequently downgraded to speculative grade, and original issue high-yield bonds that were rated speculative grade at issuance. Fallen angels have the disadvantage of the looser covenants associated with their original ratings. In many cases, however, they are run by managers who are strongly motivated to recapture their investment-grade ratings through prudent financial policies that can lead to upgrading. Original issue high-yield bonds offer the advantage of stronger covenants and in some cases, the possibility that as comparatively new issuers that are not yet widely known, they are underrated by the rating agencies and undervalued by bond investors.

Many of the tools employed in evaluating investment-grade bonds can also be applied to high-yield issues, but the emphasis of the analysis is different. In contrast to the investment-grade universe, where it is extremely rare for a company to go directly to default, an average of more than 4% of speculative grade issuers default each year.[3] As a consequence, high-yield analysts must focus intensely on the downside in a company's operations, its sources of liquidity, and the salvage value of its assets in the event of default.

The price of a company's high-yield bonds, like its stock price, can be highly sensitive to minor changes in the earnings outlook. High-yield analysts therefore operate much as equity analysts do in participating in companies' earnings calls and tracking industry data that may shed light on future profits. They go beyond their equity counterparts in studying the details of the issuers' funding capability and covenant provisions, which become highly pertinent under conditions of financial stress.

The following sections address aspects of credit analysis that require expanded attention in the analysis of high-yield corporate bonds.

Competition

In the popular mind, high-yield companies are small players in their markets, yet over the years there have been many exceptions to this stereotype. Examples

3. Source: Moody's Investors Service.

include the three largest U.S. automakers (General Motors, Ford Motor Company, and Chrysler), the world's largest operator of health care facilities (HCA), and the world's largest casino operator (Caesars Entertainment). Size does not automatically confer a competitive advantage, nor do smaller companies invariably report inferior profit margins due to a lack of scale economies. Instead of participating in all market segments, including mature and highly competitive ones, some small companies manage to carve out highly profitable niches. They do not strive to minimize unit costs by maximizing volume, but instead obtain premium prices by offering superior selection or convenience.

By the same token, analysts should not accept at face value the glib assertions of high-yield market promoters that the rating agencies arbitrarily and mistakenly penalize companies for being small. The agencies do not rate companies speculative grade because they are small, but rather because of certain consequences of their smallness.

Some small companies lack geographical diversification and are therefore highly vulnerable to a regional economic downturn. Others have no credible succession plans in place because domination by strong-willed founders makes it difficult for them to attract and retain capable candidates at the next level of management. Neither should analysts assume, as private equity firms probably would like them to, that a high level of equity ownership by key employees is so powerful a motivator that corporate failure is inconceivable.

Cash Flow

One of the most important elements in analyzing a high-yield security is cash flow. In recent years, analysts have concentrated increasingly on *free cash flow* (FCF), defined as cash flow from operations minus capital expenditures. FCF can be calculated as follows:

EBIT × (1 − Tax Rate)

\+ Depreciation and Amortization

− Changes in Working Capital

− Capital Expenditures

= Free Cash Flow

A company that generates free cash flow is not dependent on external financing and therefore should not be stymied by a temporary unavailability of credit. In addition, FCF generators are best positioned to refinance maturing debt during periods when capital markets are open, but only to the strongest high-yield borrowers. For a company in this select group, investors theoretically need concern themselves only with the risk that positive FCF generation will prove unsustainable.

The rise in popularity of free cash flow is partly a reaction to abuse of a popular cash-flow proxy of earlier decades, EBITDA. In the 1990s, competition for deals pushed the debt loads on leveraged buyouts (LBOs) to an extreme that made issuers look very weak by standard financial ratios such as EBITDA/Interest Expense. Underwriters responded by promoting "adjusted EBITDA." The newfangled ratio conveniently eliminated the impact of operating losses that were deemed to reflect "restructurings," which was too often a euphemism for failed investments. Even before this distortion of reality became common, EBITDA had serious shortcomings as a cash-flow measure by virtue of ignoring capital expenditures and working capital requirements. These are essential cash uses that a company may have difficulty funding in a period of tight credit.

For all its faults, EBITDA remains the high-yield market's standard for calculating leverage. Analysts view a company's total debt outstanding as some number of "turns" of EBITDA. Suppose, for instance, that a company's debt is equivalent to four × its EBITDA at a time when corporate buyers and LBO sponsors are paying six × EBITDA to acquire comparable companies. Bondholders will feel comfortable that in the event of default they will fully recover their principal from the proceeds of a sale of the company in bankruptcy. As with free cash flow, the key assumption is that the level of cash generation will not fall. Proceeds equivalent to six × a greatly reduced EBITDA will not be as great as the company's debt load.

Net Assets

In analyzing a bond, the analyst must ascertain or at least approximate the liquidation value of the assets. Are these assets valued properly on the balance sheet? Of particular interest may be real estate holdings. For example, in analyzing the gaming companies, a market assessment of land holdings should be included. On the other hand, one also should consider the likelihood of those assets being available for liquidation, if necessary. To whom do they belong? Are they mortgaged or being used as collateral? Assets are occasionally spun off to the equity owners of the company. In such a circumstance, the bondholders may experience a sudden and dramatic deterioration of credit quality. Other bondholders are secured by specific assets such as railroad cars or a nuclear power station. In these circumstances, the value and marketability of the collateral must be ascertained. Collateral, by definition, must be specific, and so must be the analysis. Ten railroad engines may appear to provide adequate collateral until it is discovered that the engines are not only obsolete but have not been maintained for a number of years. Five aircraft may appear to be adequate collateral until it is discovered that the engines were financed separately and do not constitute collateral.

Particular attention must be paid to the asset protection in a takeover situation. In this instance, assets that originally provided protection for an investor's holdings could be used to secure new debt senior to the investor's position.

The analyst also must focus on the location of the assets. If the assets are in a foreign country, the analyst should be familiar with that country's laws regarding expatriation of funds. In the extreme case, the analyst should be familiar with that country's laws regarding bankruptcy proceedings. Notwithstanding high-yield investors' traditional claim that they focus on the verifiable values of hard assets, it is in fact common to attribute substantial value to certain items that do not even qualify as assets under generally accepted accounting principles. For example, media and telecommunications companies are often evaluated by attributing a dollar amount to each customer or potential customer. Current valuations may be justified by the prices being paid for comparable properties in mergers and acquisitions transactions. In the future, however, the value of these unofficial assets may evaporate as new technologies emerge to provide communications services more cheaply or more effectively. There is also a risk that if a company becomes financially distressed its existing customers (particularly business customers) may switch to other providers.

Management

Management is a critical element in the assessment of any company. Given enough time, poor management can bankrupt the most prosperous enterprise. Conversely, good management is essential to the long-run survival of all firms.

Many successful firms are launched by the top engineers or salespeople at industry-leading firms. They may bring strong talent and motivation, but analysts must evaluate the entire team to ensure that all key functions are in capable hands. Does the company have a strong financial manager? Are proper controls in place? Incentives can also play a significant role in determining a company's long-run success. Ownership of a significant portion of the company by management is generally a positive, if not necessarily a panacea.

There are two principal ways to evaluate management. The first is to judge the team by its results. This is accomplished through financial analysis. The second way is to meet with senior managers to judge first-hand their vision for the firm as well as their understanding of the business. This is achieved by attending new-financing road shows, as well as arranging one-on-one meetings where possible, and participating in companies' quarterly earnings calls.

An analyst must be well-prepared for meetings with management. Lack of preparation creates the risk of being swayed by a slick presentation that lacks true substance. In one presentation to potential bond investors, the senior management of a company that manufactured gas pump nozzles stated that European operations would generate major growth because of increased environmental requirements to reduce gasoline fumes at service stations. In an effort to estimate the potential for this new revenue opportunity, an analyst asked management to discuss the state of European environmental laws and how they differed from laws in the United States. Management was unable to answer the question. The company subsequently filed for bankruptcy.

Leverage

Companies that issue high-yield bonds generally are highly leveraged. Leverage per se is not harmful and in many circumstances is beneficial to growth. However, the degree of leverage should be evaluated in terms of its effect on the financial flexibility of the firm. As pointed out earlier, leverage should be calculated on absolute and market-adjusted bases. The most common approach to market adjustment is to calculate a market value for the equity of the firm. To the extent that the common stock is selling below book value, leverage will be understated by a traditional approach. Some firms also adjust the market value of debt in calculating leverage. This approach is interesting, but a consistent approach must be employed when convertibles are considered in the equity equation. The benefit of adjusting the equity side of the leverage equation is clear. As the market values a company's equity upward, the market is indicating a willingness to support more leverage. A similar increase in the market adjustment of a firm's debt may indicate an upward appraisal of creditworthiness or an overall lowering of interest rates. In either case, the company probably would have the opportunity to refinance at a lower cost and thereby increase profitability.

Care also should be taken to evaluate sources of leverage that are not stated clearly on the balance sheet. These sources arise from the use of complicated financings.[4] For example, consider deferred-coupon bonds that are commonly used by high-yield issuers. Deferred-coupon bonds permit the issuer to postpone interest payment to some future year. As a result, the interest burden is placed on future cash flow to meet the interest obligations. Because of this burden, the presence of deferred-coupon bonds may impair the ability of the issuer to improve its credit quality in future periods. Moreover, if senior bonds have deferred-coupon payments, the subordinated bonds will be adversely affected as the amount of senior bonds increases over time relative to the amount of subordinated bonds. For example, one type of deferred-coupon bond that has been widely used in some years is the payment-in-kind (PIK) bond. With this bond structure, a high-yield issuer has the option either to pay interest in cash or pay the equivalent of interest with another bond with the same coupon rate. If the issuer does not have the ability to pay the interest in cash, payment with another bond will increase future interest expense and thereby adversely affect the issuer's future cash flow. If the PIK bonds are senior bonds, subordinated bonds are adversely affected over time as more senior bonds are added to the capital structure and future interest expense is increased further.

4. William A. Cornish, "Unique Factors in the Credit Analysis of High-Yield Bonds," in Frank K. Reilly (ed.), *High-Yield Bonds: Analysis and Risk Assessment* (Charlottesville, VA: Association for Investment Management and Research, 1990).

Corporate Structure

High-yield issuers usually have a holding-company structure. The assets to pay creditors of the holding company will come from the operating subsidiaries. It is therefore critical to analyze the corporate structure. Specifically, the analyst must understand how cash will be passed between subsidiaries and the parent company and among the subsidiaries. The corporate structure may be so complex that the payment structure becomes confusing.

For example, in the mid 2000s Charter Communications created a dizzyingly complex corporate structure. The cable television systems operator capitalized on its rapidly growing EBITDA to create and further leverage a succession of new intermediate holding companies. Eventually, the operating subsidiaries stood beneath a parent operating company and eight layers of holding companies with names such as Charter Communications Holding Company, LLC, Charter Communications Holdings, LLC, and CCH I Holdings, LLC.

Simply calculating financial ratios for the consolidated company did not produce an accurate picture of Charter's debt-servicing capability. Each holding company's ability to make interest payments depended on dividends from the companies positioned below it on the corporate totem pole. Those companies could not lawfully pay dividends before meeting their own debt service requirements and they were further constrained by restrictions, tied to leverage covenants, on upstreaming of dividends. This was an especially acute concern for holders of a convertible bond of the ultimate holding company, Charter Communications, Inc. (CCI).

Charter kept its highly leveraged web of companies solvent by frequently tapping the capital markets to retire maturing debt. Extensive intercompany loans further complicated the picture. The game ended when a financial crisis shut the markets down. Charter filed for bankruptcy in 2009 and the importance of mastering the intricacies of high-yield analysis once again became apparent. Senior secured lenders at the parent operating company and at the holding companies just above it, who were closest to the assets, recovered 100% of their principal. In contrast, note holders at some of the more remote holding companies recovered negligible amounts. Somewhat anomalously, convertible bondholders at CCI, who were furthest of all from the assets, enjoyed a higher percentage recovery than creditors of some intermediate holding companies. This was achieved partly with cash proceeds of the sale of the convertible issue, which had been retained at CCI to cover interest payments.

Covenants

While an analyst should consider covenants when evaluating any bond issue (investment-grade or high-yield), it is particularly important for the analysis of high-yield issuers. The importance of understanding covenants was summarized by one high-yield portfolio manager as follows:

> Covenants provide insight into a company's strategy. As part of the credit process, one must read covenants within the context of the corporate strategy. It is not sufficient to hire a lawyer to review the covenants because a lawyer might miss the critical factors necessary to make the appropriate decision. Also, loopholes in covenants often provide clues about the intentions of management teams.[5]

Note, however, that some specialized consulting firms offer assistance in interpreting covenants, combining financial sophistication with legal expertise.

Definitions

Great care must be paid to definitions. As discussed earlier with respect to cash flow, definitions can materially skew cash-flow projections. When asked to define certain terms, management often will state that its definitions are "standard." There is no standard definition.

Definitions also should be evaluated in covenants. For example, a "change of control" typically triggers a 101% put option for the bondholder, but the term does not necessarily refer to all changes in controlling interest in the company. A change of control may be defined to include an acquisition of the company but not a merger (in which the company's separate corporate structure disappears). In some cases, acquisition by a major existing shareholder is excluded from the definition.

CREDIT SCORING MODELS

To this point in the chapter, the focus has been on traditional ratios and other measures that credit analysts use in assessing default risk. Several researchers have used these measures as input to assess the default risk of issuers using the statistical technique of multiple discriminant analysis (MDA). This tool is primarily a classification technique that is helpful in distinguishing between or among groups of objects and in identifying the characteristics of objects responsible for their inclusion in one or another group. One of the chief advantages of MDA is that it permits a simultaneous consideration of a large number of characteristics and does not restrict the investigator to a sequential evaluation of each individual attribute. For example, MDA permits a credit analyst studying ratings of corporate bonds to examine, at one time, the total and joint impact on ratings of multiple financial ratios, financial measures, and qualitative factors. The analyst is thereby freed from the cumbersome and

---

5. Robert Levine, "Unique Factors in Managing High-Yield Bond Portfolios," in *High-Yield Bonds: Analysis and Risk Assessment*. p. 35.

possibly misleading task of looking at each characteristic in isolation from the others. MDA seeks to form groups that are internally as similar as possible but that are as different from one another as possible.

From the preceding description of MDA it can be seen why it has been applied to problems of why bonds get the ratings they do and what variables seem best able to account for a bond's rating. Moreover, MDA has been used as a predictor of bankruptcy. While the steps involved in MDA for predicting bond ratings and corporate bankruptcies are a specialist topic, the following discussion addresses the results of the work of Edward Altman, the primary innovator of MDA for predicting corporate bankruptcy.[6] The models of Altman and others involved in this area are updated periodically. Here the purpose is only to provide an illustration of how MDA models work.

In one of Altman's earlier models, referred to as the "*Z*-score model," he found that the following MDA could be used to predict corporate bankruptcy.[7]

$$Z = 1.2X_1 + 1.4X_2 + 3.3X_3 + 0.6X_4 + 1.0X_5$$

where

X_1 = working capital/total assets (in decimal)
X_2 = retained earnings/total assets (in decimal)
X_3 = earnings before interest and taxes/total assets (in decimal)
X_4 = market value of equity/total liabilities (in decimal)
X_5 = sales/total assets (number of times)
Z = Z-score

Given the value of the five variables for a given firm, a *Z*-score is computed. The *Z*-score is used to classify firms with respect to whether or not there is potentially a serious credit problem that would lead to bankruptcy. Specifically, Altman found that *Z*-scores of less than 1.81 indicated a firm with serious credit problems, whereas a *Z*-score in excess of 3.0 indicated a healthy firm.

Subsequently, Altman and his colleagues revised the *Z*-score model based on more recent data. The resulting model, referred to as the "zeta model" found that the following seven variables were important in predicting corporate bankruptcies and were highly correlated with bond rating:[8]

- Earnings before interest and taxes (EBIT)/total assets
- Standard error of estimate of EBIT/total assets (normalized) for 10 years

6. See Chapters 8 and 9 in Edward I. Altman, *Corporate Financial Distress and Bankruptcy: A Complete Guide to Predicting and Avoiding Distress and Profiting from Bankruptcy*, 2d ed. (Hoboken, NJ: Wiley, 1993).
7. Edward I. Altman, "Financial Bankruptcies, Discriminant Analysis and the Prediction of Corporate Bankruptcy," *Journal of Finance* (September 1968), pp. 589–609.
8. Edward I. Altman, Robert G. Haldeman, and Paul Narayann, "Zeta Analysis: A New Model to Identify Bankruptcy Risk of Corporations," *Journal of Banking and Finance* (June 1977), pp. 29–54.

- EBIT/interest charges
- Retained earnings/total assets
- Current assets/current liabilities
- Five-year average market value of equity/total capitalization
- Total tangible assets, normalized

While credit scoring models have been found to be helpful to analysts and bond portfolio managers, they do have limitations as a replacement for human judgment in credit analysis. Quantitative models are effective in identifying companies that share certain characteristics with defaulting companies, but many of the companies identified by the models do not default. One thing a statistical model cannot readily spot is the possibility of bringing in new management that will turn the company around and prevent a default. Therefore, an investor who is faced with a potentially large loss on a distressed company may benefit from assessing a company's prospects for redirecting itself, rather than selling based solely on a quantitative score. In practice, professional high-yield bond and distressed-debt managers do not rely entirely on models such as the Z-score, but at most use them to supplement their own hands-on analysis.

KEY POINTS

- Credit analysis has evolved from exclusive focus on default risk in a buy-and-hold strategy to playing a role in active management of corporate bond portfolios.
- Equity-related information can help to create a systematic analysis, but it is important also to consider other determinants of credit risk.
- Key areas of a credit assessment include industry analysis, financial analysis, and indenture provisions.
- Analysis of high-yield, or speculative-grade, corporate bonds requires particular focus on the downside in a company's operations, its cash flow, and the quality of its management.
- Quantitative credit scoring models cannot replace hands-on credit analysis, but can usefully supplement it.

CHAPTER
FORTY-ONE

THE CREDIT ANALYSIS OF MUNICIPAL GENERAL OBLIGATION AND REVENUE BONDS

Sylvan G. Feldstein, Ph.D.
Industry Consultant

Douglas Gaylor
Industry Consultant

David Ratner, CFA
Industry Consultant

The degree of safety of investing in municipal bonds has been considered second only to that of U.S. Treasury bonds, but beginning in the fourth quarter of the last century, ongoing concerns developed among many investors and underwriters about the potential default risks of municipal bonds.

One concern resulted from the well-publicized billion-dollar general obligation note defaults in 1975 of New York City. Not only did specific investors face the loss of their principal, but the defaults sent a loud and clear warning to municipal bond investors in general. The warning was that regardless of the supposedly ironclad legal protections for the bondholder, when issuers have severe budget-balancing difficulties, the political hues, cries, and financial interests of public employee unions, vendors, and community groups may be dominant forces in the initial decision-making process.

This reality was further reinforced by the federal bankruptcy law that took effect on October 1, 1979, which makes it easier for municipal bond issuers to seek protection from bondholders by filing for bankruptcy. One by-product of the increased investor concern is that since 1975, the official statement, which is the counterpart to a prospectus in an equity or corporate bond offering and is to contain a summary of the key legal and financial security features, has become more comprehensive. As an example, before 1975 it was common for a city of New York official statement for a general obligation bond sale to be only six pages long, whereas for a bond sale in February 2020 the preliminary official statement was 106 pages long.

More recently, highly visible defaults in 2013 and 2014 of $9.5 billion of Detroit's municipal bonds, followed by the defaults in 2014, 2015, and 2016 of $57.2 billion of Puerto Rico municipal bonds, drew increased attention to the reliability of credit ratings on municipal bonds.

The second reason for the increased interest in credit analysis was derived from the changing nature of the municipal bond market. It is now characterized by strong buying patterns by private investors and institutions. The patterns were caused in part by high federal, state, and local income tax rates. Tax-exempt bonds increasingly have become an important and convenient way to shelter income. One corollary of the strong buyers' demand for tax exemption has been an erosion of the traditional security provisions and bondholder safeguards that had grown out of the default experiences of the 1930s. General obligation bond issuers with high tax and debt burdens, declining local economies, and chronic budget-balancing problems had little difficulty finding willing buyers. Also, revenue bonds increasingly were rushed to market with legally untested security provisions, modest rate covenants, reduced debt reserves, and weak additional-bond tests. Because of this widespread weakening of security provisions, it has become more important than ever before that the prudent investor carefully evaluate the creditworthiness of a municipal bond before making a purchase.

This concern has been increased when the rating agencies in 2009 recalibrated their ratings upward on many general obligation and essential service revenue bonds. They argued that municipal bond issues probably should have slightly better ratings relative to corporate bonds in the context of both historical default rates and recovery levels following default. This resulted in higher ratings on many municipal bonds.

In analyzing the creditworthiness of a general obligation, tax-backed, or pure revenue bond, the investor should cover five categories of inquiry: (1) legal documents and opinions, (2) politics/management, (3) underwriter/financial advisor, (4) general credit indicators and economics, and (5) red flags, or danger signals.

The purpose of this chapter is to set forth the general guidelines that the investor should rely upon in asking questions about specific bonds.

THE LEGAL OPINION

Popular opinion holds that much of the legal work done in a bond issue is boilerplate in nature, but from the bondholder's point of view the legal opinions and document reviews should be the ultimate security provisions because, if all else fails, the bondholder may have to go to court to enforce his or her security rights. Therefore, the integrity and competency of the lawyers who review the documents and write the legal opinions that usually are summarized in the official statements are very important.

The relationship of the legal opinion to the analysis of municipal bonds for both general obligation and revenue bonds is threefold. First, the lawyer should check to determine whether the issuer is indeed legally able to issue the bonds. Second, the lawyer is to see that the issuer has properly prepared for the bond sale by enacting the various required ordinances, resolutions, and trust indentures and without violating any other laws and regulations. This preparation is particularly important in the highly technical areas of determining whether the bond issue is qualified for tax exemption under federal law and whether the issue has been structured in such a way as to not violate federal arbitrage regulations. Third, the lawyer is to certify that the security safeguards and remedies provided for the bondholders and pledged by either the bond issuer or third parties (such as banks with letter-of-credit agreements) are actually supported by federal, state, and local government laws and regulations.

General Obligation Bonds

General obligation bonds are debt instruments issued by states, counties, towns, cities, and school districts. They are secured by the issuers' general taxing powers. The investor should review the legal documents and opinion as summarized in the official statement to determine what specific *unlimited* taxing powers, such as those on real estate and personal property, corporate and individual income taxes, and sales taxes, are legally available to the issuer, if necessary, to pay the bondholders. Usually for smaller governmental jurisdictions, such as school districts and towns, the only available unlimited taxing power is on property. If there are statutory or constitutional taxing power limitations, the legal documents and opinion should clearly describe how they affect the security of the bonds.

For larger general obligation bond issuers, such as states and big cities that have diverse revenue and tax sources, the legal opinion should indicate the claim of the general obligation bondholder on the issuer's general fund. Does the bondholder have a legal claim, if necessary, to the first revenues coming into the general fund? This is the case with bondholders of state of New York general obligation bonds. Does the bondholder stand second in line? This is the case with bondholders of state of California general obligation bonds. Or are the laws silent on the question altogether? This is the case for most other state and local governments.

Additionally, certain general obligation bonds, such as those for water and sewer purposes, are secured in the first instance by user charges and then by the general obligation pledge. (Such bonds are popularly known as being "double barreled.") If so, the legal documents and opinion should state how the bonds are secured by revenues and funds outside the issuer's general taxing powers and general fund.

Revenue Bonds

Revenue bonds are issued for project or enterprise financings that are secured by the revenues generated by the completed projects themselves, or for general public-purpose financings in which the issuers pledge to the bondholders tax and revenue resources that were previously part of the general fund. This latter type of revenue bond, sometimes known as a "dedicated tax bond," is usually created to allow issuers to raise debt outside general obligation debt limits, issuance without voter approvals and to get higher credit ratings. The trust indenture and legal opinion for both types of revenue bonds should provide the investor with legal comfort in six bond-security areas:

- The limits of the basic security
- The flow-of-funds structure
- The rate, user-charge, or dedicated revenue and tax covenants
- The priority of pledged revenue claims
- The additional-bonds test
- Other relevant covenants and issues

The Limits of the Basic Security

The legal documents should explain what the pledged revenues for the bonds are and how they may be limited by federal, state, and local laws. The importance of this is that although most revenue bonds are structured and appear to be supported by identifiable revenue streams, those revenues sometimes can be negatively affected directly by other levels of government. For example, the state of Wyoming in the early 1980s issued Mineral Royalties Revenue Bonds. On the surface, the bond issue had all the attributes of a revenue bond. The bonds had a first lien on the pledged revenues, and additional bonds could only be issued if a coverage test of 125% was met. Yet the revenues to pay bondholders were to be received by the state from the federal government as royalty payments for mineral production on federal lands. The U.S. Congress was under no legal obligation to continue this aid program. Therefore, the investor must read carefully the legal documents to learn if there are shortcomings of the bond security.

The Flow-of-Funds Structure

The legal documents should explain what the bond issuer has promised to do concerning the pledged revenues received. What is the order of the revenue flows through the various accounting funds of the issuer to pay for the operating expenses of the facility, payments to the bondholders, maintenance and special capital improvements, and debt service reserves? This sometimes is referred to as the "waterfall." Additionally, the legal documents should indicate what happens to excess revenues after they pass through the waterfall. Do they go to the issuer's general fund or do they stay within the indenture to be used to call bonds or make capital repairs?

The flow of funds of many revenue bonds is structured as *net revenues* (i.e., debt service is paid to the bondholders immediately after revenues are paid to the basic operating and maintenance funds, but before paying all other expenses). A *gross revenues* flow-of-funds structure is one in which the bondholders are paid even before the operating expenses of the facility are paid. Examples of gross revenue bonds are those issued by the New York Metropolitan Transportation Authority. However, although it is true that these bonds legally have a claim to the fare-box revenues before all other claimants, it is doubtful that the system could function if the operational expenses, such as wages and electricity bills, were not paid first.

The Rate, User-Charge, or Dedicated Revenue and Tax Covenants

The legal documents should indicate what the issuer has legally committed itself to do to safeguard the bondholders. If user rates are involved do they only have to be sufficient to meet expenses, including debt service, known as one times debt service coverage? Is the one-time coverage test calculated for the *average annual debt* service requirement or for the higher *maximum annual debt service* one? Additionally, is the coverage requirement for higher amounts such as 1.1 times or 1.25 times so as to provide for reserves? The legal documents should indicate whether or not the issuer has the legal power to increase rates or charges of users without having to obtain prior approvals by other governmental units.

The Priority of Pledged Revenue Claims

The legal documents should state whether or not other levels of government or claimants can legally tap the revenues of the issuer even before they start passing through the issuer's flow-of-funds structure. An example would be the highway revenue bonds issued by the Puerto Rico Highway and Transportation Authority. These bonds are secured in part by the revenues from the Commonwealth of Puerto Rico gasoline tax. Yet, if in a worst-case scenario no other funds are available to pay their debt service, under the Commonwealth's constitution the moneys are first to be applied to the Commonwealth's own general obligation bonds. This feature was reinforced in 2019 when the U.S. Appeals Court upheld the right of the Commonwealth in bankruptcy to withhold revenues.

The Additional-Bonds Test

The legal documents should indicate under what circumstances the issuer can issue additional bonds that share equal claims to the issuer's revenues. Usually, the legal requirement is that the maximum annual debt service on the new bonds as well as on the old bonds be covered by the projected net revenues by a specified minimum amount. This can be as low as one times coverage. Some revenue bonds have stronger additional-bonds tests to protect the bondholders. Also, how the historical revenues are calculated is important. Can the issuer select specific prior months to be used such as 12 out of the last 15 months? Who determines the projection numbers for the future revenues? Is it an independent consultant with expertise in the area? How conservative are the projections and how are they certified? Additionally, the definition of revenues is important. Does it include revenues generated by the enterprise, or could it also include special supplemental payments? These are all questions that have to be addressed by the analyst in reviewing the additional bonds test formula.

Other Relevant Covenants and Issues

Lastly, the legal documents should indicate whether there are other relevant covenants for the bondholder's protection. These usually include pledges by the issuer of the bonds to insure the project (if it is a project-financing revenue bond), to have the accounting records of the issuer annually audited by an outside certified public accountant and provide timely reports to investors, and to employ independent engineers to annually review the capital plant and make mandatory recommendations to keep the facility operating for the life of the bonds.

In addition to the above aspects of the specific revenue structures of general obligation and revenue bonds, two other developments over the recent past make it more important than ever for the investor to carefully review the legal documents and opinions summarized in the official statements. The first development involves the mushrooming of new financing techniques that may rest on legally untested security structures. The second development is the increased use of legal opinions provided by local attorneys who may have little prior municipal bond experience. (Legal opinions traditionally have been written by experienced municipal bond attorneys.)

Legally Untested Security Structures and New Financing Techniques

In addition to the more traditional general obligation bonds and toll road, bridge, and tunnel revenue bonds, there are now more non-voter-approved, innovative, and legally untested security mechanisms. These innovative financing mechanisms include lease-rental bonds, moral obligation housing bonds, "dedicated tax-backed" and structured "asset-backed" bonds, take-and-pay power bonds with step-up provisions requiring the participants to increase payments to make up for those that may default, commercial bank-backed letter-of-credit "put" bonds, and tax-exempt commercial paper. What distinguishes these newer bonds from the more traditional general obligation and revenue bonds is that they have little history of court decisions and other case law to firmly protect the rights of the bondholders. For the newer financing mechanisms, the legal opinion should include an assessment of the probable outcome if the bond security were challenged in court. Note, however, that most official statements do not provide this to the investor.

The Need for Reliable Legal Opinions

For many years, concern over the reliability of the legal opinion was not as important as it is now. As a result of the numerous bond defaults and related shoddy legal opinions in the nineteenth century, the investment community demanded that legal documents and opinions be written by recognized municipal bond attorneys. As a consequence, over the years, a small group of primarily Wall Street-based law firms and certain recognized firms in other financial centers dominated the industry and developed high standards of professionalism.

Now, however, more and more issuers have their legal work done by local law firms, a few of whom may have little experience in municipal bond work. This development, along with the introduction of more innovative and legally untested financing mechanisms, has created a greater need for reliable legal opinions. An example of a specific concern involves the documents the issuers' lawyers must complete so as to avoid arbitrage problems with the Internal Revenue Service.

By 2020, there were thousands of attorneys located throughout the country who were listed in the *Bond Buyers' "Red Book"* or Municipal Marketplace online. They presented themselves as being experts in municipal finance law and provided various security structure and tax opinions. Sorting out quality distinctions in their work and who is well grounded in the law, and who is not, is challenging.

On negotiated bond issues, one remedy has been for the underwriters to have their own counsels review the documents and to provide separate legal opinions.

THE NEED TO KNOW WHO REALLY IS THE ISSUER

Still another general question to ask before purchasing a municipal bond is just what kind of people are the issuers? Are they conscientious public servants with clearly defined public goals? Do they have histories of successful management of public institutions? Have they demonstrated commitments to professional and fiscally stringent operations? Additionally, issuers in highly charged and partisan environments in which conflicts chronically occur between political parties or among political factions or personalities are clearly bond issuers to scrutinize closely and possibly to avoid. Such issuers should be scrutinized regardless of the strength of the surrounding economic environment.

For General Obligation and Tax-Backed Bonds

For general obligation bond issuers, focus on the political relationships that exist among chief executives such as mayors, county executives, and governors, and among their legislative counterparts. Issuers with unstable political elites are of particular concern. Of course, rivalry among politicians is not necessarily bad. What is undesirable is competition so bitter and personal that real cooperation among the warring public officials in addressing future budgetary problems may be precluded. An example of an issuer that was avoided because of such dissension *was* the city of Cleveland. The political problems of the city in 1978 and the bitter conflicts between Mayor Kucinich and the city council resulted in a general obligation note default in December of that year.

For Revenue Bonds

When investigating revenue bond issuers, it is important to determine not only the degree of political conflict, if any, that exists among the members of the bond-issuing body but also the relationships and conflicts among those who make the appointments to the body. Additionally, the investor should determine whether the issuer of the revenue bond has to seek prior approval from another governmental jurisdiction before the user fees or other charges can be levied. If this is the case, then the stability of the political relationships between the two units of government must be determined.

An important example involves the creditworthiness of the water and electric revenue bonds and notes issued by Kansas City, Kansas. Although the revenue bonds and notes were issued by city hall, it was the six-member board of public utilities, a separately elected body, that had the power to set the water and electricity rates. In the spring of 1981, because of a political struggle between a faction on the board of public utilities and the city commissioners (including the city's finance commissioner), the board refused to raise utility rates as required by the covenant. The situation came under control only when a new election changed the makeup of the board in favor of those supported by city hall.

In addition to the preceding institutional and political concerns, for revenue bond issuers in particular, the technical and managerial abilities of the staff should be assessed. The professional competency of the staff is a more critical factor in revenue bond analysis than it is in the analysis of general obligation bonds. The reason is that unlike general obligation bonds, which are secured in the final instance by the full faith and credit and unlimited taxing powers of the issuers, many revenue bonds are secured by the ability of the revenue projects to be operational and financially self-supporting.

The professional staffs of authorities that issue revenue bonds for the construction of nuclear and other public power-generating facilities, apartment complexes, hospitals, water and sewer systems, and other large public works projects, such as convention centers and sports arenas, should be reviewed carefully. Issuers who have histories of high management turnovers, project cost overruns, or little experience should be avoided by the conservative investor or at least considered higher risks than their assigned commercial credit ratings may indicate. Additionally, it is helpful for revenue bond issuers to have their accounting records annually audited by outside certified public accountants so as to provide the investor with a more accurate picture of the issuer's financial health.

ON THE FINANCIAL ADVISOR AND UNDERWRITER

Shorthand indications of the quality of the investment are (1) who the issuer selected as its financial advisor, if any; (2) its principal underwriter if the bond sale was negotiated; and (3) its financial advisor if the bond issue came to market competitively. Additionally, many prudent underwriters will not participate if there are significant credit-quality concerns. Therefore, it is also useful to learn who was the underwriter for the bond sales as well.

Identifying the financial advisors and underwriters is important for two reasons.

The Need for Complete, Not Just Adequate, Investment Risk Disclosures

The first reason relates to the quality and thoroughness of information provided to the investor by the issuer. The official statement, or private-placement papers if the issue is placed privately, is usually prepared with the assistance of lawyers and a financial advisor or by the principal underwriter. There are industry-wide disclosure guidelines that generally are adhered to, but not all official statements provide the investor with complete discussions of the risk potentials that may result from either the specific economics of the project or the community settings and the operational details of the security provisions. It is usually the author of this document who decides what to emphasize or downplay in the official statement. The more professional and established the author is in providing unbiased and complete information about the issuer, the more comfortable the investor can be with information provided by the issuer and in arriving at a credit-quality conclusion.

The Importance of Firm Reputation for Thoroughness and Integrity

By itself, the reputation of the issuer's financial advisor and/or underwriter should not be the determinant credit-quality factor, but it is a fact the investor should consider, particularly in the case of marginally feasible bond issues that have complex flow-of-funds and security structures. The securities industry is different from other industries, such as real estate, in that trading and investment commitments are usually made over the phone or electronically with a formal documented trail following. Many institutional investors, such as banks, bond funds, and insurance companies, have learned to judge issuers by the company they keep. Institutions tend to be conservative, and they are more comfortable with financial information provided by established financial advisors and underwriters who have recognized reputations for honesty. Individual investors and analysts would do well to adopt this approach.

GENERAL CREDIT INDICATORS AND ECONOMIC FACTORS IN THE CREDIT ANALYSIS

The last analytical factor is the economic health or viability of the bond issuer or specific project financed by the bond proceeds. The economic factors cover a variety of concerns. When analyzing general obligation bond issuers, one should look at the specific budgetary and debt characteristics of the issuer, as well as the general economic environment. For project-financing, or enterprise, revenue bonds, the economics are limited primarily to the ability of the project to generate sufficient charges from the users to pay the bondholders. These are known as *pure revenue bonds*.

For revenue bonds that rely not on user charges and fees but instead on general purpose taxes and revenues, the analysis should take basically the same approach as for the general obligation bonds. For these bonds, the taxes and revenues diverted to the bondholders would otherwise go to the state's or city's general fund.

As an example, the bonds of the New York State Municipal Assistance Corporation for the City of New York Bonds (MAC), secured by general New York City sales taxes and annual state-aid appropriations, were structured to appear as pure revenue bonds, but in essence they were not. They incorporated a bond structure created to bail out New York City from severe budget deficits. The creditworthiness of the bond was tied to that of the underlying jurisdiction, which has had portions of its taxing powers and general fund revenues diverted to secure this new revenue-type bailout bond. Besides looking at the revenue features, the investor therefore must look at the underlying jurisdiction. These MACs were first issued in 1975 and refunded through the years. It should be noted that in 2004, the MACs were refunded, now with "Sales Tax *Asset* Receivable Corporation" bonds and stretched out to 2033 for paying off operating deficits of the 1960s.

For General Obligation Bonds

For general obligation bonds, the economic concerns include questions in four specific areas: debt burden, budget soundness, tax burden, and the overall economy.

Debt Burden

In relation to the debt burden of the general obligation bond issuer, some of the more important concerns include the determination of the total amount of debt outstanding and to be issued that is supported by the general taxing powers of the issuer as well as by earmarked revenues.

For example, general obligation bonds issued by school districts in New York State are general obligations of the issuer and are also secured by state-aid payments due the issuer. If the issuer defaults, the bondholder can go to the state comptroller and be paid from the next state-aid payment due the local issuer.

Key debt ratios that reveal the burden on local taxpayers include determining the per capita amount of general obligation debt as well as the per capita debt of the overlapping or underlying general obligation bond issuers. Other key measures of debt burden include determining the amounts and percentages of the outstanding general obligation bonds as well as the outstanding general obligation bonds of the overlapping or underlying jurisdictions to real estate valuations. These numbers and percentages can be compared with most recent year medians, as well as with the past history of the issuer, to determine whether the debt burden is increasing, declining, or remaining relatively stable.

In addition to the general obligation bonds outstanding, the debt of the general obligation bond issuer could include leases, certificates of participation (COPs), appropriation, and "moral obligation" bonds.

Additionally, the amount of the unfunded pension liabilities should be determined. What is the difference between the expected assets of the public employee system at current annual contribution rates, the future benefits to be paid out, and if the issuer has a reasonable plan to eliminate the unfunded liability? Can pension benefits unilaterally be reduced by the local governments? Such steps are allowed in some jurisdictions, but not in others. An example of the latter is New York State, where the state constitution prevents the reduction of pension benefits once they are granted. Therefore, the unfunded pension liabilities of local governments in New York must be taken much more seriously than in states where such guarantees do not exist.

Still another special debt figure that came into the forefront in the first decade of the twenty-first century involves the actuarially determined costs of providing health care for retirees. These are postemployment benefits. In many jurisdictions they are not legally mandatory and are paid on a pay-as-you-go basis. There are usually strong political groups such as unions and the retirees themselves that support these benefits. In some jurisdictions the potential size of this liability is greater than the outstanding general obligation bonds.

For purposes of determining the special debt figure—which represents the potential liability in a worst-case environment—the COPs, appropriation and lease obligations, the moral obligations, the unfunded pension liabilities, and the retiree health care costs should be shown and broken out.

Budgetary Soundness

Concerning the budgetary operations and budgetary soundness of the general obligation bond issuer, some of the more important questions include how well the issuer over at least the previous five years has been able to maintain balanced budgets and fund reserves. How dependent is the issuer on short-term debt to finance annual budgetary operations? How have increased demands by residents for costly social services been handled? That is, how frugal is the issuer? How well have the public-employee unions been handled? They usually lobby for higher salaries, liberal pensions, and other costly fringe benefits. Clearly, it is undesirable for the pattern of dealing with the constituent when demands and public-employee unions results in raising taxes and drawing down nonrecurring budget reserves. Last, another general concern in the budgetary area is the reliability of the budget and accounting records of the issuer. Are interfund borrowings reported? Who audits the books?

It should be noted that by 2020, e-commerce and Internet usage were steadily growing among American consumers. Many states, counties, and city governments over the past 50 years have derived substantial revenues from sales taxes that are not always applied to Internet sales. In some jurisdictions, over 20% of an issuer's revenues may come from local sales taxes. How the growth of the Internet affects this revenue source is uncertain at this time, but at some future date could be a significant negative for the budgets of at least some issuers as well as for their bonds secured by these taxes.

Tax Burden

Concerning the tax burden, it is important to learn two things initially. First, what are the primary sources of revenue in the issuer's general fund? Second, how dependent is the issuer on any one revenue source? If the general obligation bond issuer relies increasingly on a property tax, wage and income taxes, or sales tax to provide the major share of financing for annually increasing budget appropriations, taxes could quickly become so high as to drive businesses and people away. Many larger northern states and cities with their relatively high income, sales, and property taxes appear to be experiencing this phenomenon. Still another concern is the degree of dependency of the issuer on intergovernmental revenues, such as federal or state revenue sharing and grants-in-aid, to finance its annual budget appropriations. Political coalitions on the state and federal levels that support these financial transfer programs are not permanent and could undergo dramatic change very quickly. Therefore, a general obligation bond issuer that currently has a relatively low tax burden but receives substantial amounts of intergovernmental monies should be reviewed carefully by the investor. If it should occur that the aid monies are reduced, as has been occurring under many federal and state programs, certain issuers primarily may increase their taxes instead of reducing their expenditures to conform to the reduced federal grants-in-aid.

Overall Economy

The fourth and last area of general obligation bond analysis concerns the issuer's overall economy. For local governments, such as counties, cities, towns, and school districts, key items include learning the annual rate of growth of the full value of all taxable real estate for the previous 10 years and identifying the 10 largest taxable properties. What kinds of business or activity occur on the respective properties? What percentage of the total property tax base do the 10 largest properties represent? What has been the building permit trend for at least the previous five years? What percentage of all real estate is tax-exempt, and what is the distribution of the taxable ones by purpose (such as residential, commercial, industrial, and public utility)? Last, who are the five largest employers? Concerning the final item, communities that have one large employer are more susceptible to rapid adverse economic change than communities with more diversified employment and real estate bases. For additional information that reveals economic health or decline, one must determine whether the population of the community over the previous 10 years has been increasing or declining by age and income and how the monthly and yearly unemployment rates compare with the national averages, as well as with the previous history of the community.

For state governments that issue general obligation bonds, the economic analysis should include many of the same questions applied to local governments. In addition, the investor should determine on the state level the annual rates of growth for the previous five years of personal income and retail sales.

For Revenue Bonds

Airport Revenue Bonds

For airport revenue bonds, the economic questions vary according to the type of bond security involved. There are two basic security structures.

The first type of airport revenue bond is one based on traffic-generated revenues that result from the competitiveness and passenger demand of the airport. The financial data on the operations of the airport should come from audited financial statements going back at least three years. If a new facility is planned, a feasibility study prepared by a recognized consultant should be reviewed. The feasibility study should have two components: (1) a market and demand analysis to define the service area and examine demographic and airport use trends and (2) a financial analysis to examine project operating costs and revenues.

Revenues at an airport may come from landing fees paid by the airlines for their flights; passenger facility charges (PFCs); concession fees paid by restaurants, shops, newsstands, and parking facilities; and from airline apron and fueling fees.

Also, in determining the long-term economic viability of an airport, the investor should determine whether or not the wealth trends of the service area are upward, whether the airport is dependent on tourism or serves as a vital transfer point, whether passenger enplanements and air cargo handled over the previous five years have been growing, whether increased costs of jet fuel and airport safety would make other transportation such as trains and automobiles more attractive in that particular region, and whether the airport is a major domestic hub for an airline, which could make the airport particularly vulnerable to route changes caused by schedule revisions and changes in airline corporate management.

The second type of airport revenue bond is secured by a lease with one or more airlines for the use of a specific facility such as a terminal or hangar. The lease usually obligates them to make annual payments sufficient to pay the expenses and debt service for the facility. For many of these bonds, the analysis of the airline lease is based on the credit quality of the lessee airline. Whether or not the lease should extend as long as the bonds are outstanding depends on the specific airport and facility involved. For major hub airports, it may be better not to have long-term leases because without leases, fees and revenues can be increased as the traffic grows, regardless of which airline uses the specific facility. Of course, for regional or startup airports, long-term leases with trunk (i.e., major airline) carriers are preferred.

After 9/11, air travel suffered a unique temporary downturn. While air travel remains an essential service, after the terrorist attacks, the analysis of the credit quality of airports and airlines with related bankruptcy issues has undergone increased scrutiny.

Charter School Bonds

Charter school bonds are for publicly funded private schools that offer more institutional and academic flexibility than local public schools. State-aid funding usually follows the student who goes from a traditional public school to a charter school. Bond proceeds go for capital improvements.

Some important credit questions to ask include: (1) How long is the charter granted by the state or local school district, and is it renewable? (2) What is the charter school enrollment history—is it growing? (3) Does the school serve a specialty academic niche, or is it just relieving overcrowding at local public schools? (4) What is its reputation in the community? (5) Is there competition? (6) Is there a waiting list? (7) Is the school prudently run with cash reserves, i.e., how many days of cash are on hand? and (8) How reasonable are the operating and maintenance expenses in relationship to the revenues and debt service requirements?

Continuing Care Retirement Community Bonds

A continuing care retirement community (CCRC) provides housing accommodations and health-related services to elderly persons, typically for the duration of their lifetimes. These nonprofit organizations finance a portion of development and operating costs by issuing bonds secured by the entrance fees and monthly fees paid by their residents. The potential demand for a CCRC is largely affected by the number of elderly persons in the nearby area with qualifying assets and income, the presence and proximity of competitor facilities, and the strength of the local real estate market. Other important considerations include whether advance fee deposits are partially or fully refundable, the experience of the general contractor and management, the background of the sponsor, and the amount of cash reserves on hand. A careful analysis of the data and assumptions of any feasibility study formed is essential.

Dedicated Tax-Backed and Structured/Asset-Backed Bonds

More recently, states and local governments have issued increasing amounts of bonds where the debt service is to be paid from so-called dedicated revenues such as sales taxes, tobacco settlement payments, fees, and penalty payments. Many are structured to mimic the asset-backed bonds that are common in the taxable market. The "assets" providing the security for the municipal bonds are the "dedicated" or "special" revenues instead of credit card receivables, home equity loans, and auto loan repayments that are commonly used to secure the taxable asset-backed bonds.

Additionally, the municipal bonds may be subject to some form of annual legislative appropriation and result from statutes specially created to pledge the identified taxes and revenues and allow for the bond sales. In good economic times many investors as well as the rating agencies tend to blur the credit distinctions between these bonds and the issuer's own general obligation bonds. In fact, many such bonds carry higher credit ratings than the underlying general obligation bonds because the "coverage" on the former appears to be so high. In most instances, the general obligation bonds are legally backed by specific state constitutional provisions, whereas, the dedicated tax and structured/asset-backed bonds are recent legislative creations and have not been tested yet in stressful budgetary, economic, and political environments.

Higher Education Bonds

Debt is often issued by institutions of higher education to finance the costs of building/renovating facilities or purchasing land for expansion. These bonds are secured by revenues of the given project, student charges, and/or a general obligation of the college or university. An investor in higher education bonds should carefully consider the following: (1) Is student demand for the issuing institution strong and growing? (2) Does the school have flexibility to increase tuition or enrollment if needed? (3) How experienced are senior management and the board of trustees? (4) What are the school's various sources of funding? (5) What is the endowment level and how is it trending? (6) How well does the school manage expenses and repay its debts? (7) What is the physical condition of school facilities? and (8) Are there any construction or project-specific risks?

Highway Revenue Bonds

There are generally two types of highway revenue bonds. The bond proceeds of the first type are used to build specific revenue-producing facilities such as toll roads, bridges, and tunnels. For these pure enterprise revenue bonds, the bondholders have claims to the revenues collected through the tolls. The financial soundness of the bonds depends on the ability of the specific projects to be self-supporting. Proceeds from the second type of highway revenue bond generally are used for public highway improvements, and the bondholders are paid by earmarked revenues such as gasoline taxes, automobile registration payments, and driver's license fees.

Concerning the economic viability of a toll revenue bond, the investor should ask a number of questions.

1. What is the traffic history, and how inelastic is the demand? Toll roads, bridges, and tunnels that provide vital transportation links are clearly preferred to those that face competition from interstate highways, toll-free bridges, or mass transit.

2. How well is the facility maintained? Has the issuer established a maintenance reserve fund at a reasonable level to use for such repair work as road resurfacing and bridge painting?
3. Does the issuer have the ability to raise tolls to meet covenant and debt reserve requirements without seeking approvals from other governmental actors such as state legislatures and governors? In those few cases where such approvals are necessary, the question of how sympathetic these other power centers have been in the past in approving toll-increase requests should be asked.
4. What is the debt-to-equity ratio? Some toll authorities have received substantial nonreimbursable federal grants to help subsidize their costs of construction. This, of course, reduces the amount of debt that has to be issued.
5. What is the history of labor-management relations, and can public-employee strikes substantially reduce toll collections?
6. When was the facility constructed? Generally, toll roads financed and constructed in the 1960s tend to be in better financial condition because the cost of financing was much less.
7. If the facility is a bridge that could be damaged by a ship and made inoperable, does the issuer have adequate use-and-occupancy insurance?

Those few toll revenue bonds that have defaulted have done so because of either unexpected competition from toll-free highways and bridges, poor traffic projections, or substantially higher than projected construction costs. An example of one of the few defaulted bonds is the West Virginia Turnpike Commission's Turnpike Revenue Bonds, issued in 1952 and 1954 to finance the construction of an 88-mile expressway from Charleston to Princeton, West Virginia. The initial traffic-engineering estimates were overly optimistic, and the construction costs came in approximately \$37 million higher than the original budgeted amount of \$96 million. Because of insufficient traffic and toll collections, between 1956 and 1979 the bonds were in default. By the late 1970s with the completion of various connecting cross-country highways, the turnpike became a major link for interstate traffic. The bonds became self-supporting in terms of making interest coupon payments. It was not until 1989 that all the still-outstanding bonds were finally redeemed.

More recently, a new group of start-up toll roads has been financed with municipal bonds. The revenue projections for several roads turned out to be overly optimistic. Some have had to draw on the debt reserves. Others have had to be restructured and even defaulted. Examples include the Santa Rosa Bay Bridge Authority in Florida, the Southern Connector Toll Road in South Carolina, and the San Joaquin Toll Road in California.

Concerning the economics of highway revenue bonds that are not pure enterprise type but instead are secured by earmarked revenues, such as gasoline taxes, automobile registration payments, and driver's license fees, the investor should ask the following questions:

- Are the earmarked tax revenues based on state constitutional mandates, such as the state of Ohio's Highway Improvement Bonds, or are they derived from laws enacted by state legislatures, such as the state of Washington's Chapters 56, 121, and 167 Motor Vehicle Fuel Tax Bonds? A constitutional pledge is usually more permanent and reliable.
- What has been the coverage trend of the available revenues to debt service over the previous 10 years? Has the coverage been increasing, stable, or declining?
- If the earmarked revenue is a gasoline tax, is it based on a specific amount per gallon of gasoline sold or as a percentage of the price of each gallon sold? With greater conservation and more efficient cars, the latter tax structure is preferred because it is not as susceptible to declining sales of gasoline and because it benefits directly from any increased gasoline prices at the pumps.
- What has been the history of statewide gasoline consumption through recessions and oil shocks?

Hospital Revenue Bonds

Two unique features of hospitals make the analysis of their debt particularly complex and uncertain. The first concerns their sources of revenue, and the second concerns the basic structure of the institutions themselves.

During the past 45 years, the major sources of revenue for most hospitals have been (1) payments from the federal (Medicare) and combined federal-state (Medicaid) hospital reimbursement programs, and (2) payments from commercial insurers. How well the hospital management markets its service to attract more private-pay patients and commercial insurers, and how conservatively it budgets for the governmental reimbursement payments, which may not keep up with the annual rate of hospital expense increases, are key elements for distinguishing weak from strong hospital bonds.

Particularly for community-based hospitals (as opposed to teaching hospitals affiliated with medical schools), a unique feature of their financial structure is that their major financial beneficiaries, physicians, have no legal or financial liabilities if the institutions do not remain financially viable over the long term. An example of the problems that can be caused by this lack of liability is found in the story of the Sarpy County, Nebraska, Midlands Community Hospital Revenue Bonds. These bonds were issued to finance the construction of a hospital three miles south of Omaha, Nebraska, that was to replace an older one located in the downtown area. Physician questionnaires prepared for the feasibility study prior to the construction of the hospital indicated strong support for the replacement facility. Many doctors had used the older hospital in downtown Omaha as a backup facility for a larger nearby hospital. Unfortunately, once the new Sarpy hospital opened in 1976, many physicians found that the new hospital could not serve as a backup because it was 12 miles further away from the major hospital than the old hospital had been. Because these physicians were not referring their patients to the new Sarpy hospital, it was soon unable to make bond principal payments and was put under the jurisdiction of a court receiver.

The preceding factors raise long-term uncertainties about many community-based hospitals, but certain key areas of analysis and trends reveal the relative economic health of hospitals that already have revenue bonds outstanding. The first area is the liquidity of the hospital as measured by the ratio of dollars held in current assets to current liabilities. In general, a five-year trend of high values for the ratio is desirable because it implies an ability by the hospital to pay short-term obligations and thereby avoid budgetary problems. Days cash on hand is an important measure as well. The second indicator is the ratio of long-term debt to equity, as measured in the unrestricted end-of-year fund balance. In general, the lower the long-term debt to equity ratio, the stronger the finances of the hospital are. The third indicator is the actual debt service coverage of the previous five years, as well as the projected coverage. The fourth indicator is the annual bed-occupancy rates for the previous five years. The fifth is the percentage of physicians at the hospital who are professionally approved (board certified), their respective ages, and how many of them use the hospital as their primary institution.

For new or expanded hospitals, much of the preceding data are provided to the investor in the feasibility study. One item in particular that should be determined for a new hospital is whether the physicians who plan to use the hospital actually live in the area to be served by the hospital. Because of its importance in providing answers to these questions, the feasibility study must be prepared by reputable, experienced researchers.

Housing Revenue Bonds

For housing revenue bonds, the economic and financial questions vary according to the type of bond security involved. There are two basic types of housing revenue bonds, each with a different type of security structure. One is the housing revenue bond secured by *single-family* mortgages, and the other is the housing revenue bond secured by mortgages on *multifamily* housing projects.

Concerning single-family housing revenue bonds, the strongly secured bonds usually have five characteristics:

- The single-family home loan bonds are collateralized by GNMA, FNMA, or FHLMC securities; or the loans are insured by the Federal Housing Administration (FHA), Department of Veteran Affairs (VA), or an acceptable private mortgage insurer or its equivalent. If the individual home loans are not insured, then they should have a loan-to-value ratio of 80%

or less. Prior to 2007, many bonds had acceptable private mortgage insurance; it has not been used much in recent years due to the downgrading of insurers.

- If the conventional home loans have less than 100% primary mortgage insurance coverage, or are not backed by federal collateral, an additional 5% to 10% mortgage-pool insurance policy or its equivalent may be required. Like with primary PMI, this has not been used much in the last decade.
- In addition, there is over-collateralization of the bonds with mortgages or mortgage-backed securities, as well as investments. This is typical of State HFA indentures, which have open liens and regular new issues.
- The issuer of the single-family housing revenue bonds is in a region of the country that has stable or strong economic growth as indicated by increased real estate valuations, personal income, and retail sales, as well as low unemployment rates. This is more of a factor for prepayment speeds.
- State housing finance agency support explicit or implicit.

In the 1970s, state agency issuers of single-family housing revenue bonds assumed certain prepayment levels in structuring the bond maturities. In recent years, most issuers have abandoned this practice but investors should review the retirement schedule for the single-family mortgage revenue bonds to determine whether or not the issuer has assumed large, lump-sum mortgage prepayments in the early year cash-flow projections. If so, how conservative are the prepayment assumptions, and how dependent is the issuer on the prepayments to meet the annual debt service requirements? Of course, while the focus of this chapter is on credit analysis, the investor should be aware that extraordinary redemptions of these bonds can occur from prepayments on the mortgages. Lately only one state housing agency still does this.

It should be noted that since the mid-1990s, issuers have adopted structures similar to those in the taxable mortgage-backed securities market that incorporate prepayment assumptions. In tax-exempt single-family housing bonds, these are usually the planned amortization class (PAC) structures, as well as passthroughs.

State issuing agencies usually have professional in-house staffs that closely monitor the home mortgage portfolios, whereas the local issuers do not. Finally, many state issuing agencies have accumulated substantial surplus funds over the years that can be viewed as an additional source of bondholder protection.

For multifamily housing revenue bonds, there are four specific, although overlapping, security structures. The first type of multifamily housing revenue bond is one in which the bonds are secured by federally insured mortgages. In the past, the federal insurance covers all but the difference between the outstanding bond principal and collectible mortgage amount (usually 1%), and all but the *nonasset* bonds (i.e., bonds issued to cover issuance costs and capitalized interest). The FHA

Risk Sharing Program with State FHAs now cover 100% of the mortgages upfront. The attractiveness of the federal insurance is that it protects the investor against bond default within the limitations outlined. The insurance protects the bondholders regardless of whether the projects are fully occupied and generating rental payments.

The second type of multifamily housing revenue bond is one in which the federal government subsidizes, under the HUD Section 8 program, all annual costs (including debt service) of the project not covered by tenant rental payments. Under Section 8, the eligible low-income and elderly tenants pay up to 30% of their incomes for rent. Because the ultimate security comes from the Section 8 subsidies, which normally escalate annually with the increased cost of living in that particular geographic region, the bondholder's primary risks concern the developer's ability to complete the project, find tenants eligible under the federal guidelines to live in the project, and then maintain high occupancy rates for the life of the bonds. The investor should carefully review the location and construction standards used in building the project, as well as the competency of the project manager in selecting tenants who will take care of the building and pay their rents. In this regard, state agencies that issue Section 8 bonds usually have stronger in-house management experience and resources for dealing with problems than do the local development corporations that have issued Section 8 bonds. It should be noted that the federal government has eliminated appropriations for new Section 8 projects. Since 1995, the federal government has restricted automatic rent increases under the Section 8 program. This has introduced financial pressure.

The third type of multifamily housing revenue bond is one in which the ultimate security for the bondholder is the ability of the project to generate sufficient monthly rental payments from the tenants to meet the operating and debt service expenses. Some of these projects may receive governmental subsidies (such as interest-cost reductions under the federal Section 236 program and property tax abatements from local governments), but the ultimate security is the economic viability of the project. Key information includes the location of the project, its occupancy rate, whether large families or the elderly will primarily live in the project, whether or not the rents necessary to keep the project financially sound are competitive with others in the surrounding community, and whether or not the project manager has a proven record of maintaining good service and of establishing careful tenant selection standards. Many of these unenhanced programs are financed with Low Income Housing Tax Credits which provide significant equity for the projects. These have superior performance, as opposed to "affordable housing" projects of non-profit issuers.

A fourth type of multifamily housing revenue bond is one that includes some type of private credit enhancement to the underlying real estate. These credit enhancements can include guarantees or sureties of an insurance company, securitization by Fannie Mae (Federal National Mortgage Association or FNMA), or a bank letter-of-credit.

Another feature of many multifamily housing revenue bond programs, particularly those issued by state housing agencies, is the state moral obligation pledge or a State FHA general obligation pledge. Several state agencies have issued housing revenue bonds that carry a potential state liability for making up deficiencies in their one-year debt service reserve funds, should any occur. In most cases, if a drawdown of the debt reserve occurs, the state agency must report the amount used to its governor and state budget director. The state legislature, in turn, may appropriate the requested amount, although there is no legally enforceable obligation to do so. Bonds with this makeup provision are called *moral obligation bonds*.

The moral obligation provides a state legislature with permissive authority—*not mandatory authority*—to make an appropriation to the troubled state housing agency. Therefore, the analysis should determine (1) whether the state has the budgetary surpluses for subsidizing the housing agency's revenue bonds, and (2) whether there is a consensus within the executive and legislative branches of that particular state's government to use state general fund revenues for subsidizing multifamily housing projects.

Industrial Revenue Bonds

Generally, industrial revenue bonds are issued by state and local governments on behalf of individual corporations and businesses. The security for the bonds usually depends on the economic soundness of the particular corporation or business involved. If the bond issue is for a subsidiary of a larger corporation, one question to ask is whether or not the parent guarantees the bonds. Is it obligated only through a lease, or does it not have any obligation whatsoever for paying the bondholders? If the parent corporation has no responsibility for the bonds, then the investor must look very closely at the operations of the subsidiary in addition to those of the parent corporation.

For companies that have issued publicly traded common stock, operating data are readily available in the quarterly (10-Q) and annual (10-K) financial reports that must be filed with the Securities and Exchange Commission. For privately held companies, financial data are more difficult to obtain.

In assessing the economic risk of investing in an industrial revenue bond, another question to ask is whether the bondholder or the trustee holds the mortgage on the property. Although holding the mortgage is not usually an important economic factor in assessing either hospital or low-income multifamily housing bonds in which the properties have very limited commercial value, it can be an important strength for the holder of industrial development revenue bonds. If the bond is secured by a mortgage on a property of a major retailer, or an industrial facility such as a warehouse, the property location and resale value of the real estate may provide some protection to the bondholder, regardless of what happens to the company that issued the bonds. Of course, the investor always should avoid possible bankruptcy situations regardless of the economic attractiveness of the particular piece of real estate involved. The reason is that the bankruptcy process usually involves years of litigation and numerous court hearings, about which no investor should want to be concerned.

Land-Secured "Dirt" Bonds

Public infrastructure costs associated with new development projects on raw land are often financed by land-secured bonds, also known as "dirt" bonds. Revenue from the additional tax or assessment placed on the properties benefitting from these improvements is the primary security for the bondholders. Additional security is provided by the ability of the sponsoring governmental entity to commence foreclosure or tax sales if property owners are delinquent on their taxes or assessments. Important credit factors to consider include: (1) Is the development's location, demographics, and competitive position favorable? (2) Does the developer possess sufficient experience and financial resources? (3) Is there a debt service reserve and other funds, and how are they funded? (4) Is the lien created by the tax/assessment fixed or variable, and what is the resulting debt service coverage provided? (5) Is the value of the land relative to the outstanding liens sufficient to discourage property owners from walking away?

Lease-Rental Bonds

Lease-rental bonds usually are structured as revenue bonds, and annual payments, paid by a state or local government, cover all costs including operations, maintenance, and debt service. It should be noted that many Certificate of Participation Bonds, or COPs, are similar in security structure in that they too are dependent on the annual legislative appropriation process. The public purposes financed by these bond issues include public office buildings, fire houses, police stations, university buildings, mental health facilities, and highways, as well as office equipment and computers. In some instances, the payments may come from student tuition, patient fees, and earmarked tax revenues, and the state or local government is not legally obligated to make lease-rental payments beyond the amount of available earmarked revenues. However, for many lease-rental bonds, the underlying lessee state, county, or city is to make payment from its general fund subject to annual legislative appropriation. For example, the Albany County, New York, Lease Rental South Mall Bonds were issued to finance the construction of state office buildings. Although the bonds were technically general obligations of Albany County, the real security came from the annual lease payments made by the State of New York. These payments were appropriated annually. For such bonds, the basic economic and financial analysis should follow the same guidelines as for general obligation bonds.

Public Power Revenue Bonds

Public power revenue bonds are issued to finance the construction of electrical generating plants. An issuer of the bonds may construct and operate one power plant, buy electric power from a wholesaler and sell it retail, construct and operate several power plants, or join with other public and private utilities in jointly financing the construction of one or more power plants. This last arrangement is known as a joint-power financing structure may require the participating underlying municipal electric systems to pay the bondholders whether or not the plants are completed and operating, the focus here is how the investor determines which power projects will be financially self-supporting without the backup security feature.

There are at least five major questions to ask when evaluating the investment soundness of a public power revenue bond:

- Does the bond issuer have the authority to raise its electric rates in a timely fashion without going to any regulatory agencies? This is particularly important if substantial rate increases are necessary to pay for new construction or plant improvements.
- How diversified is the customer base among residential, commercial, and industrial users?
- Is the service area growing in terms of population, personal income, and commercial/industrial activity so as to warrant the electrical power generated by the existing or new facilities?
- Are rates competitive with neighboring IOUs?
- What are the projected and actual costs of power generated by the system, and how competitive are they with other regions of the country? Power rates are particularly important for determining the long-term economic attractiveness of the region for industries that are large energy users.
- How diversified is the fuel mix? Is the issuer dependent on one energy source such as hydro dams, oil, natural gas, coal, or nuclear fuel?

Concerning electrical generating plants fueled by nuclear power, the aftermath of the Three Mile Island nuclear accident in 1979 has resulted in greater construction and maintenance reviews and costly safety requirements prompted by the Federal Nuclear Regulatory Commission (NRC). The NRC oversees this industry. In the past, although nuclear power plants were expected to cost far more to build than other types of power plants, it also was believed that once the generating plants became operational, the relatively low fuel and maintenance costs would more than offset the initial capital outlays. However, with the increased concern about public safety brought about by the Three Mile Island accident, repairs and design modifications are now expected to be made even after plants begin to operate. Of course, this increases the ongoing costs of generating electricity and reduces the attractiveness of nuclear power as an alternative to the other fuels such as natural gas.

Public-Private Partnerships

Privatization is a form of municipal financing where a private company pays a large payment to operate, and often build or improve, a governmental asset (e.g., usually toll roads). The purchaser issues debt to help finance this large upfront cost, and the operating revenues are pledged to repay bondholders. The bonds issued are referred to as private-placement partnership bonds (PPP). Important questions to ask about these bonds are: (1) What is the length of the concession agreement? (2) How are prices or tolls set? (3) Does the governmental entity share in any revenue? (4) Are there any noncompete provisions? (5) What levels of maintenance, capital expenditures, and service are required? (6) What are the conditions and repercussions for nonperformance? (7) What are the assumptions and conclusions of any feasibility study performed? and (8) What is the experience and financial resources of the contractor/operator?

Tobacco Revenue Bonds

Some tobacco bonds are solely secured by revenues in the Master Settlement Agreement (MSA) annually paid to states by cigarette companies. Important credit issues include: (1) the credit quality of the cigarette companies making the annual payments; (2) the consumption assumptions used in sizing the original bond issue, i.e., the degree of leveraging used; (3) current consumption trends and their impacts on cash flows and debt coverage; and (4) the status of the various court cases.

Tribal Casino Bonds

Native American governments in general finance the construction of their casino gaming facilities by issuing debt. Tribal casino bonds derive their revenues from the gaming operations of these facilities. Given the limited diversity of the revenue streams and the lack of hard collateral assets, evaluating the future viability and profitability of the new gaming facility is essential, including analysis of the relevant demographics, competitive factors, and quality of casino management. Buyers should also assess the financial strength, governance structure, and development project expertise of the issuing tribal entity. Other issues to consider include whether the cash trapping and debt service reserve fund features of the issued debt are sufficient, any gaming compact and revenue-sharing arrangements with state governments, and potential regulatory changes.

Water and Sewer Revenue Bonds

Water and sewer revenue bonds are issued to provide for a local community's basic needs and as such are not usually subject to general economic changes. Because of the vital utility services performed, their respective financial structures are usually designed to have the lowest possible user charges and still remain financially viable. Generally, rate covenants requiring that user charges cover operations, maintenance, and approximately 1.2 times annual debt service and reserve requirements are most desirable. On the one hand, a lower rate covenant provides a smaller margin for unanticipated slow collections or increased operating and plant maintenance costs caused by inflation. On the other hand, rates that generate revenues more than 1.2 times the annual debt service and reserve requirements could cause unnecessary financial burdens on the users of the water and sewer systems.

A useful indication of the soundness of an issuer's operations is to compare the water or sewer utility's average quarterly customer billings to those of other water or sewer systems. Assuming that good customer service is given, the water or sewer system that has a relatively low customer billing charge generally indicates an efficient operation and therefore strong bond-payment prospects.

Key questions for the investor to ask include the following:

- Has the bond issuer, through local ordinances, required mandatory water or sewer connections? Also, local board of health directives against well water contamination and septic tank usage can often accomplish the same objective as the mandatory hookups.
- Does the issuer have to comply with an EPA consent decree and thereby issue significant amounts of bonds?
- What is the physical condition of the facilities in terms of plant, lines, and meters, and what capital improvements are necessary for maintaining the utilities as well as for providing for anticipated community growth?
- For water systems in particular, it is important to determine if the system has water supplies in excess of current peak and projected demands. An operating system at less than full utilization is able to serve future customers and bring in revenues without having to issue additional bonds to enlarge its facilities.
- What is the operating record of the water or sewer utility for the previous five years?
- If the bond issuer does not have its own distribution system but instead uses other participating local governments that do, are the charges or fees based on the actual water flow drawn (for water revenue bonds) and sewage treated (for sewer revenue bonds) or on gallonage entitlements?
- For water revenue bonds issued for agricultural regions, what crop is grown? An acre of oranges or cherries in California will provide the grower with more income than will an acre of corn or wheat in Iowa.
- For expanding water and sewer systems, does the issuer have a record over the previous two years of achieving net income equal to or exceeding the rate covenants, and will the facilities to be constructed add to the issuer's net revenues?
- Has the issuer established and funded debt and maintenance reserves to deal with unexpected cash-flow problems or system repairs?
- Does the bond issuer have the power to place tax liens against the real estate of those who have not paid their water or sewer bills? Although the investor would not want to own a bond for which court actions of this nature would be necessary, the legal existence of this power usually provides an economic incentive for water and sewer bills to be paid promptly by the users.

Additional bonds should be issued only if the need, cost, and construction schedule of the facility have been certified by an independent consulting engineer and if the past and projected revenues are sufficient to pay operating expenses and debt service. Of course, for a new system that does not have an operating history, the quality of the consulting engineer's report is of the upper-most importance.

RED FLAGS FOR THE INVESTOR

In addition to the areas of analysis just described, certain red flags, or negative trends, suggest increased credit risks.

For General Obligation Bonds

For general obligation bonds, the signals that indicate a decline in the ability of a state, county, town, city, or school district to function within fiscally sound parameters include the following:

- Declining property values and increasing delinquent taxpayers
- An annually increasing tax burden relative to other regions
- An increasing property tax rate in conjunction with a declining population
- Declines in the number and value of issued permits for new building construction
- Actual general fund revenues consistently falling below budgeted amounts
- Increasing end-of-year general fund deficits
- Budget expenditures increasing annually in excess of the inflation rate
- The unfunded pension liabilities are increasing
- General obligation debt increasing while property values are stagnant
- Declining economy as measured by increased unemployment and declining personal income

For Revenue Bonds

For revenue bonds, the general signals that indicate a decline in credit quality include the following:

- Annually decreasing coverage of debt service by net revenues
- Use of debt reserve and other reserves by the issuer
- Growing financial dependence of the issuer on unpredictable federal and state-aid appropriations for meeting operating budget expenses
- Chronic lateness in supplying investors with annual audited financials
- Unanticipated cost overruns and schedule delays on capital construction projects
- Frequent or significant rate increases
- Deferring capital plant maintenance and improvements
- Excessive management turnovers
- Shrinking customer base
- New and unanticipated competition

INFORMATION SOURCES FOR THE ANALYST

The Official Statement

An official statement describing the issue and the issuer is prepared for new offerings. A preliminary official statement is issued prior to the final official statement. These statements are known as the OS and POS. These statements provide potential investors with a wealth of information. The statements contain basic information about the amount of bonds to be issued, maturity dates, coupons, the use of the bond proceeds, the credit ratings, a general statement about the issuer, and the name of the underwriter and members of the selling group. Much of this information can be found on the cover page or in the first few pages of the official statement. It also contains detailed information about the security and sources of payments for the bonds, sources and uses of funds, debt service requirements, relevant risk factors, issuer's financial statements, a summary of the bond indenture, relevant agreements, notice of any known existing or pending litigation, the bond insurance policy specimen (if insured), and the form of opinion of bond counsel. The official statement contains most of the information an investor will need to make an informed and educated investment decision.

Continuing Disclosure Under Rule 15c2-12

Rule 15c2-12, which took effect in 1995, required dealers to determine that issuers before issuing new municipal bonds made arrangements to disclose in the future financial information *at least* annually as well as notices of the occurrence of any of 11 "material event notices" as specified in the rule. By the beginning of 2020, the amended rule contained 16 material event notices. Also by 2020, the annual report and notices of material events are to be filed with the Municipal Securities Rulemaking Board (MSRB), in an electronic format as prescribed by the MSRB. The MSRB designated its Electronic Municipal Market Access system (EMMA), found at http://emma.msrb.org as the sole repository for such disclosure filings.

It should be noted that many issuers, such as hospitals, toll roads, and CCRCs provide unaudited interim information to bondholders on a quarterly and even a monthly basis.

The National Federation of Municipal Analysts

The National Federation of Municipal Analysts (NFMA) was established in 1983 and by 2020 had a membership of 1,000 municipal professionals, drawing in part from the institutional investors in municipal bonds who advocated increased and timely information for investors. By 2020, its committees have developed detailed disclosure guidelines and risk factors in municipal securities ranging from specific credit sectors to swap structures. They are recommended for municipal bond issuers to use in providing ongoing financial and operating information to investors and analysts. The web site is www.nfma.org.

The Governmental Standards Accounting Board

The Governmental Standards Accounting Board (GSAB) is a nonprofit organization that sets generally accepted accounting standards (GAAP) for state and local governments. Established in 1984 it provides detailed guidelines. For many years it has improved financial reporting standards in reports of state and local governments that are used by analysts, auditors, and other users. By improving the transparency of state and local government accounting, it helps prevent issuers from obfuscating budget deficits and long-term liabilities that in the past had resulted in budgetary disasters and bond defaults.[1]

KEY POINTS

- The five categories of inquiry when analyzing the creditworthiness of a general obligation, tax-backed, or pure revenue bond are (1) legal documents and opinions, (2) politics/management, (3) underwriter/financial advisor, (4) general credit indicators and economics, and (5) red flags, or danger signals.
- From the perspective of the bondholder, the legal opinions and document reviews should be the ultimate security provisions. The reason is that if all else fails, the bondholder may have to go to court to enforce his or her security rights. The relationship of the legal opinion to the analysis of municipal bonds for both general obligation and revenue bonds is the following: (1) the attorney should check to determine whether the issuer is indeed legally able to issue the bonds; (2) the attorney is to see that the issuer has properly prepared for the bond sale by enacting the various required ordinances, resolutions, and trust indentures and without violating any other laws and regulations; and (3) the attorney is to certify that the security safeguards and remedies provided for the bondholders and pledged by either the bond issuer or third parties are actually supported by federal, state, and local government laws and regulations.
- Before purchasing a municipal bond the investor should investigate whether the issuer's officials (1) are conscientious public servants with clearly defined public goals; (2) have a history of successful management of public institutions; and (3) have demonstrated commitments to professional and fiscally stringent operations. In addition, it is important to scrutinize closely (and possibly avoid) issuers in highly charged and partisan environments in which conflicts chronically occur between political parties or among political factions or personalities.

1. The website is www.gasb.org.

- Indicators of the quality of the investment are (1) who the issuer selected as its financial advisor, if any; (2) its principal underwriter if the bond sale was negotiated; and (3) its financial advisor if the bond issue came to market competitively. It is also useful to find out who was the underwriter for the issue.
- An analytical factor to consider in assessing the creditworthiness of an issue is the economic health or viability of the bond issuer or specific project financed by the bond proceeds. The economic factors cover a variety of concerns. When analyzing general obligation bond issuers, the specific budgetary and debt characteristics of the issuer, as well as the general economic environment should be investigated. For project-financing, or enterprise, revenue bonds, the economics are limited primarily to the ability of the project to generate sufficient charges from the users to pay the bondholders. In the case of revenue bonds that rely not on user charges and fees, but instead on general purpose taxes and revenues, the analysis should take basically the same approach as for the general obligation bonds. For these bonds, the taxes and revenues diverted to the bondholders would otherwise go to the state's or city's general fund.

CHAPTER

FORTY-TWO

CREDIT-RISK MODELING

Tim Backshall

Kay Giesecke, Ph.D.
Professor of Management Science and Engineering
Stanford University and
Founder and CEO
Intelligent Financial Machines

Lisa Goldberg, Ph.D.
Professor in the Practice of Statistics and Economics
University of California, Berkeley and
Director of Research
Aperio Group

Since the turn of the century, we have seen many theoretical developments in the field of credit-risk research. In view of the large-scale changes in market conditions, the entry of more sophisticated market participants, and the increase in complexity of investable assets, most of the research has focused on pricing of corporate debts. But many of these models have failed to describe real-world phenomena such as credit-spreads realistically. This practitioner-oriented chapter attempts to describe the history and future of modeling credit-risk and valuation of credit-risky assets.

Credit-risk is the distribution of financial losses owing to unexpected changes in the credit quality of the counterparty in a financial agreement. Examples range from agency downgrades to failure to service debt to liquidation. Credit-risk pervades virtually all financial transactions. The distribution of credit losses is complex. At its center is the probability of default, by which we mean any type of failure to honor a financial agreement. To estimate the probability of default, we need to specify

- A model of investor uncertainty
- A model of the available information and its evolution over time
- A model definition of the default event

However, default probabilities alone are not sufficient to price credit-sensitive securities. We need, in addition,

- A model for the risk-free interest rate
- A model of recovery on default
- A model of the premium investors require as compensation for bearing systematic credit-risk

The credit premium maps actual default probabilities to market-implied probabilities that are embedded in market prices. To price securities that are sensitive to the credit-risk of multiple issuers and to measure aggregated portfolio credit-risk, we also need to specify

- A model that links defaults of different entities

There are three main quantitative approaches to analyzing credit. In the *structural approach,* we make explicit assumptions about the dynamics of a firm's assets, its capital structure, and its debt and shareholders. A firm defaults if its assets are insufficient according to some measure. In this situation, a corporate liability can be characterized as an option on the firm's assets. The *reduced-form approach* is silent about why a firm defaults. Instead, the dynamics of default are given exogenously through a default rate, or intensity. In this approach, prices of credit-sensitive securities can be calculated as if they were default-free using an interest rate that is the risk-free rate adjusted by the intensity. The *incomplete-information approach* combines the structural and reduced-form models. While avoiding their difficulties, it picks the best features of both approaches: the economic and intuitive appeal of the structural approach and the tractability and empirical fit of the reduced-form approach.

In this chapter we review the three approaches in the context of the multiple facets of credit modeling that were just mentioned. Our goal is to provide a concise overview and a guide to the large and growing literature on credit-risk.[1]

STRUCTURAL CREDIT MODELS

The basis of the structural approach, which goes back to Black and Scholes[2] and Merton,[3] is that corporate liabilities are contingent claims on the assets of a firm. The market value of the firm is the fundamental source of uncertainty driving credit-risk.

Classical Approach

Consider a firm with market value V, which represents the expected discounted future cash flows of the firm. The firm is financed by equity and a zero-coupon bond with face value K and maturity date T. The firm's contractual obligation is to repay the amount K to the bond investors at time T. Debt covenants grant bond investors absolute priority: if the firm cannot fulfill its payment obligation, then bondholders immediately will take over the firm.

1. A more mathematical introduction can be found in Kay Giesecke, "Credit-Risk Modeling and Valuation: An Introduction," in David Shimko (ed.), *Credit-Risk: Models and Management,* Vol. 2 (London: Riskbooks, 2004).
2. Fischer Black and Myron Scholes, "The Pricing of Options and Corporate Liabilities," *Journal of Political Economy* 81 (1973), pp. 81–98.
3. Robert C. Merton, "On the Pricing of Corporate Debt: The Risk Structure of Interest Rates," *Journal of Finance* 29 (1974), pp. 449–470.

EXHIBIT 42-1

Default Interpretation in the Classical Approach

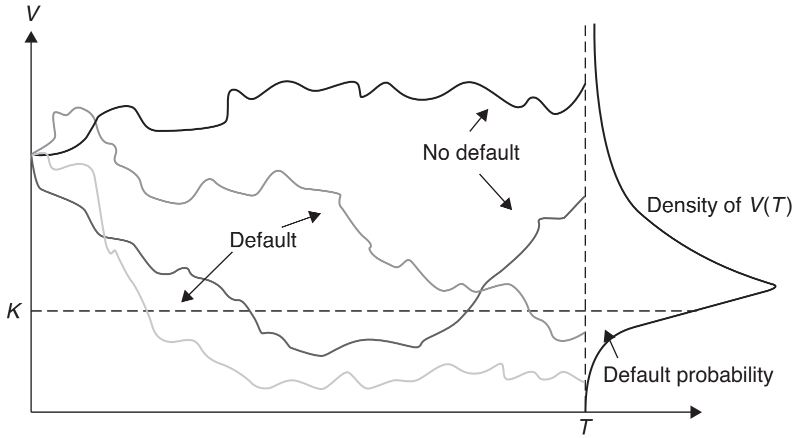

Exhibit 42-1 shows several possible paths of firm value. Default occurs if the firm value at maturity is less than the face value of the debt K. The particular path the firm value has taken does not matter here; only the firm value at T is important. The probability of default therefore is equal to the probability that firm value is below debt face value at maturity. To calculate this probability, we make assumptions about the distribution of firm value at debt maturity. The standard assumption is that firm value is log-normally distributed. The probability of default then is given as the area under the log-normal firm value density between 0 and face value, as shown in the graph. This probability can be calculated explicitly in terms of K, the current firm value $V(0)$, the volatility of firm value, the growth rate of firm value and T.

Assuming that the firm can neither repurchase shares nor issue new senior debt, the payoffs to the firm's liabilities at debt maturity T are as summarized in Exhibit 42-2. If the asset value $V(T)$ exceeds or equals the face value K of the bonds, the bondholders will receive their promised payment K, and the shareholders will get the remaining $V(T) - K$. However, if the value of assets $V(T)$ is

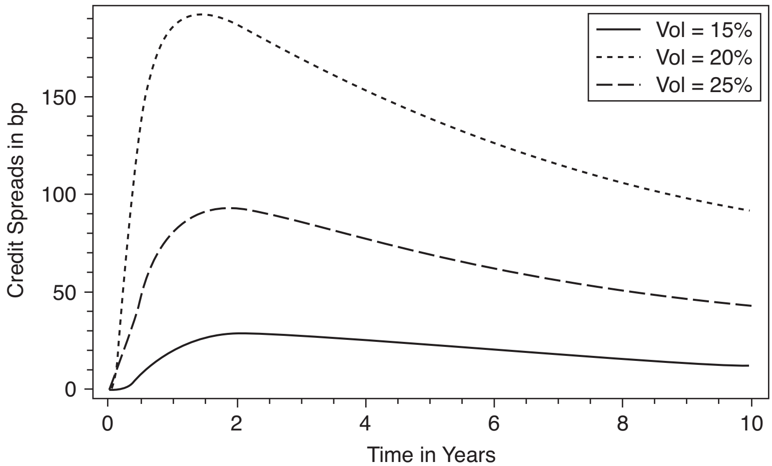
EXHIBIT 42-2

Payoffs at Maturity in the Classical Approach

Event Description	Assets	Debt	Equity
No default	$V(T) \geq K$	K	$V(T) - K$
Default	$V(T) < K$	$V(T)$	0

EXHIBIT 42-3

Term Structure of Credit-Spreads, Varying Asset Volatility, in the Classical Approach



less than K, the ownership of the firm will be transferred to the bondholders, who lose the amount $K - V(T)$. Equity is worthless because of limited liability.

Summarizing, the value of the bond is equivalent to that of a portfolio composed of a default-free loan with face value K maturing at time T and a short European put position on the assets of the firm with strike K and maturity T. The value of the equity is equivalent to the payoff of a European call option on the assets of the firm with strike K and maturity T. Pricing equity and credit-risky debt thus reduces to pricing European options.

The credit-spread is the difference between the yield on a defaultable bond and the yield on an otherwise equivalent default-free zero bond. It gives the excess return demanded by bond investors to bear the potential default losses. The credit-spread is a function of maturity T, asset volatility (the firm's business risk), the initial leverage ratio $K/V(0)$, and risk-free rates.

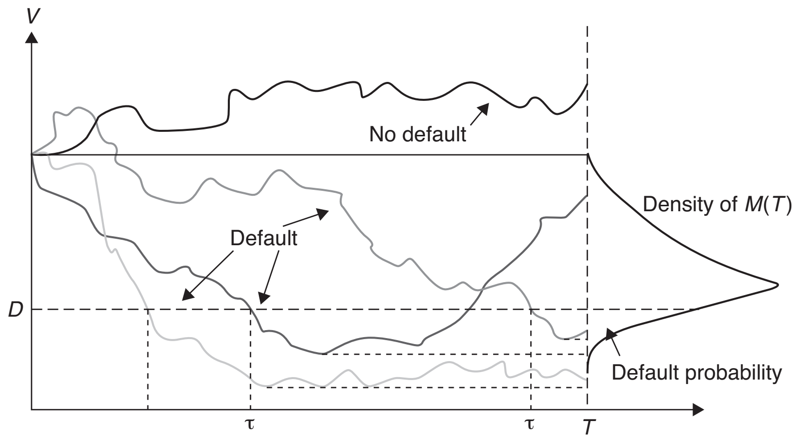
Letting initial leverage be 80% and risk-free rates be 6%, in Exhibit 42-3 we plot the model term structure of credit-spreads for varying asset volatilities. We see clearly that as asset volatility (business risk) rises, then so does the spread required by the market to compensate for the risk of default. Other noticeable traits of this graph are the rapid fall to zero spreads at short maturities and the more pronounced hump-shaped curve as volatility rises higher.

First-Passage Approach

In the classical approach, firm value can dwindle to almost nothing without triggering default. This is unfavorable to bondholders, as noted by Black and

EXHIBIT 42-4

Default in the First-Passage Approach



Cox.[4] Bond indenture provisions often include safety covenants that give bond investors the right to reorganize a firm if its value falls below a given barrier.

First-passage time models generalize the classical model such that a default can occur not only at maturity of the debt contract but also at any point of time. They assume that default happens if the firm value V hits a specified default barrier D. The default barrier in general can be a stochastic process, as is the firm value. For tractability reasons, however, one often works with a simple time-dependent, nonstochastic barrier specification, or just a constant barrier.

Suppose that the default barrier D is a constant between zero and the initial firm value—this is reasonable because we would expect liabilities to be nonnegative and less than current assets. Then the default time is more realistically defined as when the value of the firm crosses below the default barrier. In other words, firms can default at times other than debt maturity. This relaxation of the European nature of the default event in the classical approach provides some more realistic behavior.

Exhibit 42-4 shows several possible paths of firm value and a constant default barrier D. Suppose for the moment that D is equal to the face value of the firm's debt. Default occurs if the firm value falls, at any time before the horizon T, below the default barrier. As shown, different firm-value paths correspond to different default times. Unlike the classical model discussed earlier, here the entire path the firm value follows is relevant. Firm-value paths that imply survival in the classical approach can

4. Fischer Black and John C. Cox, "Valuing Corporate Securities: Some Effects of Bond Indenture Provisions," *Journal of Finance* 31 (1976), pp. 351–367.

imply default in the first-passage approach. Therefore, the first-passage approach implies higher probabilities of default than the classical approach.

The probability of default is given by the probability that the minimum firm value at the horizon $M(T)$ is lower than the barrier D. In order to calculate this probability, we make an assumption about the distribution of future firm values, as in the classical approach. This determines also the distribution of the minimum firm value at the horizon. With log-normal firm values, this distribution is inverse Gaussian. The default probability is given as the area under the inverse Gaussian density curve between 0 and the default barrier D.

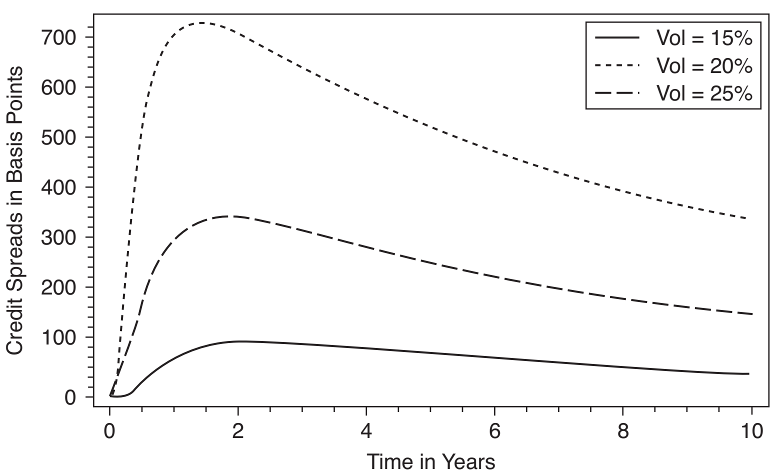
We consider the payoff to investors in the firm's liabilities. For simplicity, we assume that the default barrier is equal to the face value of firm debt. If the firm value never fell below the barrier over the term of the bond, then bond investors receive the bond's face value K and equity investors would receive the remaining $V(T) - K$. However, if the firm falls below the barrier at some point during the bond's term, then the firm defaults. In this case the firm stops operating, bond investors take over its remaining assets, and equity investors receive nothing.

Therefore, the equity position is equivalent to that of a down-and-out call on firm assets with strike equal to the face value of the debt, barrier level equal to the default barrier, and maturity equal to debt maturity. The value of the debt is given as the difference between firm value and equity value. Pricing equity and credit-risky debt thus reduces to pricing European barrier options.

We consider the credit-spread implied by a first-passage model in Exhibit 42-5. We assume that the default barrier is constant and equal to the face value of the bonds. We set leverage equal to 60% and risk-free rates to 6%,

EXHIBIT 42-5

Term Structure of Credit-Spreads, Varying Asset Volatility, in the First-Passage Model



as in Exhibit 42-3. We assume that in the event of default, bond investors recover a fraction of 50% of their initial investment.

With increasing maturity T, the spread asymptotically approaches zero. This is at odds with empirical observation; for many firms, spreads tend to increase with increasing maturity, reflecting the fact that uncertainty is greater in the distant future than in the near term. This discrepancy follows from two model properties: the firm value grows at a positive (risk-free) rate, and the capital structure is constant and assumed known with certainty. We can address this issue by assuming that the total debt grows at a positive rate or that firms maintain some target leverage ratio as in Collin-Dufresne and Goldstein.[5] A critical insight from this plot is that the level of spreads in the first-passage model is much higher and much more realistic than in the classical model. This is due to the fact that default probabilities are higher in the first-passage approach, as we discussed earlier.

Dependent Defaults

Credit-spreads of different issuers are correlated through time. Two patterns are found in time series of spreads. The first is that spreads vary smoothly with general macroeconomic factors in a correlated fashion. This means that firms share a common dependence on the economic environment, which results in cyclic correlation between defaults. The second relates to the jumps in spreads: we observe that these are often common to several firms or even entire markets. This suggests that the sudden large variation in the credit-risk of one issuer, which causes a spread jump in the first place, can propagate to other issuers as well. The rationale is that economic distress is contagious and propagates from firm to firm. A typical channel for these effects are borrowing and lending chains. Here the financial health of a firm also depends on the status of other firms as well.

We want to incorporate these two default correlation mechanisms into the structural approach to credit. To introduce cyclic correlation, it is natural to assume that firm values of several firms are correlated through time. This corresponds to common factors driving asset returns. We consider the simplest case with two firms whose firm values are log normal. Our definition of default follows the classical approach.

Exhibit 42-6 illustrates the situation. The axes show the marginal asset return distributions of the two firms. Individual asset returns are normally distributed, hence the bell shape. Individual returns are modeled through a linear factor model, which represents systematic and firm-specific risk. Systematic risk is modeled by a common latent factor X, which drives the systematic variation in the asset returns of both firms. The sensitivity of a firm's return to this common factor controls the asset correlation across firms. This asset correlation drives the default correlation between firms.

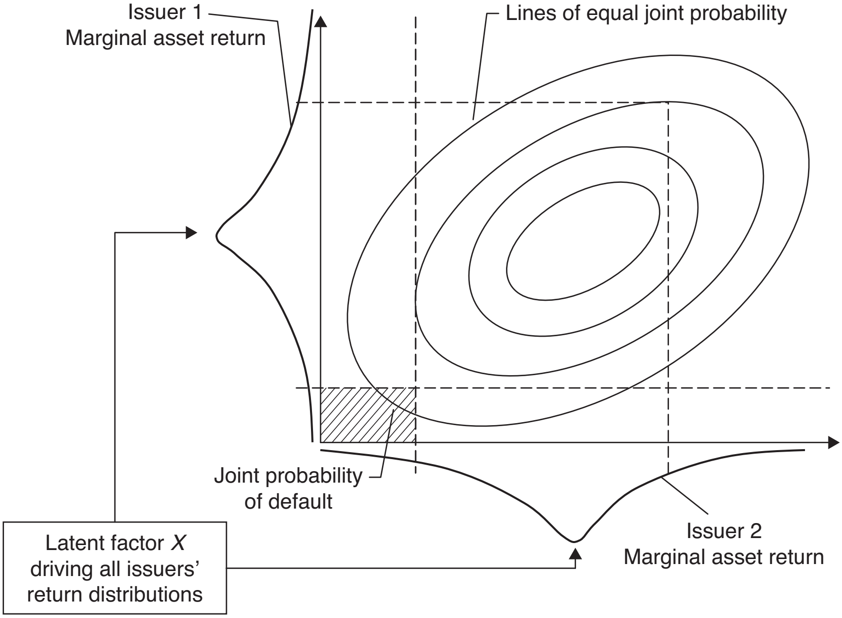
EXHIBIT 42-6

Illustrative Example of Structural-Based Joint Default Modeling



The elliptical shapes represent lines of equal joint asset value probability. The shaded area on the bottom left illustrates the joint default probability, as defined by the area under which issuer 1's asset value is below its default barrier and issuer 2's is below its default barrier.

Asset correlation captures the dependence of firms on common economic factors in a natural way. Modeling default contagion effects is much more difficult. A straightforward idea is to consider a jump-diffusion model for firm value. We would stipulate that a downward jump in the value of a given firm triggers subsequent jumps in the firm values of other firms with some probability. This would correspond to the propagation of economic distress. This approach is difficult, however, because of the lack of closed-form results on the joint distribution of firms' historical asset lows. This is what we need to calculate the probability of joint default.

A more successful attempt is to introduce interaction effects through the default barriers D_i. Suppose that the barrier is random and depends on the firm's liquidity state, which, in turn, depends on the default status of the firm's counterparties. If a firm's liquidity reserves are stressed owing to a payment default of a counterparty, it finances the loss by issuing more debt. This increases the default, barrier: the firm is now more likely to default, all else being equal. With no counterparty defaults the default barrier remains unaffected. This model allows a closed-form approximation of the credit portfolio loss distribution.

Credit Premium

Issuers of credit-sensitive securities share a common dependence on the economic environment. It follows that aggregated credit-risk cannot be diversified away. This undiversifiable or systematic risk commands a premium, which compensates risk-averse investors for assuming credit-risk.

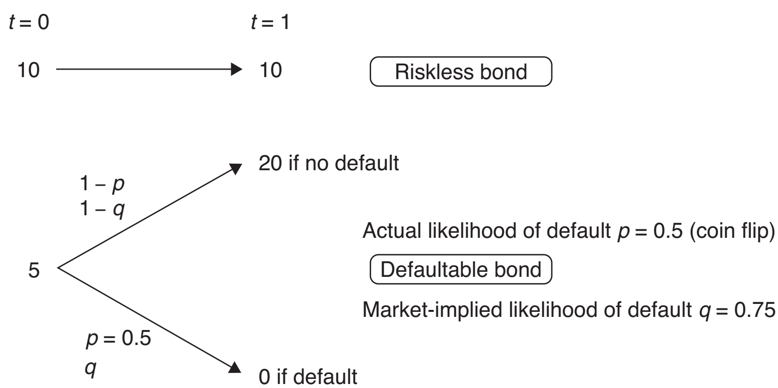
The credit premium is empirically well documented. Its importance relates to the uses of a quantitative credit model. As a default probability forecasting tool, a credit model must reflect the historical default experience. As a tool for pricing credit-sensitive securities, it must fit observed market prices. To make use of both market data and historical default data in the calibration and application of a credit model, we need to understand the relationship between actual defaults and defaultable security prices.

Here the risk premium comes into play: it maps the actual likelihood of default $p(T)$ into the market-implied likelihood of default $q(T)$ that is embedded in security prices.

We examine the difference between the two using a simple example in Exhibit 42-7. We consider a one-period market with two securities, a risk-free bond paying 10 and trading at 10 (risk-free rates are zero) and a defaultable bond trading at 5 that pays 20 in case of no default and zero in case the issuer defaults by the end of the trading period.

EXHIBIT 42-7

Real-World vs. Market-Implied Probability of Default



Suppose that the actual probability of default is $p = 0.5$ (50%, or a coin flip). This is, however, not the probability the market uses for pricing the bond: it would lead to a price of $p20 + (1 - p)0 = 10$, which is double the price at which the bonds are actually trading. At this price, risk-averse investors would rather put their money into the risk-free bond that costs 10 as well, unless they get a discount as compensation for the default risk. The market requires a discount of 5, and the corresponding price reflects the market-implied probability of default q, which satisfies $5 = (1 - q)20$. This yields $q = 0.75$ (75% probability of default), which is bigger than the actual probability of default $p = 0.5$.

To account for risk aversion in calculating the expected payoff of the defaultable bond, the market puts more weight on the unfavorable states of the world in which the firm defaults. In the structural credit models with firm value dynamics as described previously and constant risk-free rates, the situation is only a little more complicated.

In the absence of arbitrage opportunities, the credit-risk premium α is uniquely determined through market prices of credit-sensitive securities such as equity or debt and is measured as the excess return on firm assets over the risk-free return per unit of firm risk measured in terms of asset volatility. If the market is risk-averse, then α is positive: investors in credit-risky firm assets require a return that is higher than the risk-free return. The excess return on any credit-sensitive security is given by its volatility times α.

Calibration

The calibration of a quantitative credit model is closely related to its use. To price single-name credit-sensitive securities using a structural model, we need to calibrate the risk-free rate, the asset volatility, the asset value, the face value of the debt, the default barrier, and the maturity of the debt. The default barrier is relevant only in the first-passage approach. To use the model to forecast actual default probabilities, we need to calibrate additionally the growth rate of firm assets or, equivalently, the credit-risk premium α. In a multiple-firm setting we need to estimate asset correlations in addition to the single-name parameters.

Firm values are not observable. The goal is to estimate the parameters of the firm-value process based on equity prices, which can be observed for public firms. Risk-free interest rates can be estimated from default-free Treasury bond prices via standard procedures. We bypass estimation of face value and maturity of firm debt from balance-sheet data, which is nontrivial given the complex capital structure of firms. In practice, these parameters often are fixed ad hoc, as some average of short- and long-term debt, for example. We introduce a more reasonable solution to this problem later.

We consider the classical approach, as briefly discussed earlier. Given equity prices and equity volatilities, Jones, Mason, and Rosenfeld and many others suggest to back out asset values and asset volatilities by numerically solving a system of two equations.[6] The first equation relates the equity price to asset value, time, and asset volatility and follows from the Black-Scholes pricing function for a European call with strike *K* and maturity *T*. The second equation relates the equity price to asset and equity volatility, the delta of equity, and asset value. This relation is obtained from applying Ito's formula to the first equation.

We can use these two equations to "translate" a time series of equity values into a time series of asset values and volatilities. As for the equity volatility, we can use the empirical standard deviation of equity returns or a true forecasting model such as Barra Equity Risk models. Given a time series of asset returns, the empirical growth rate yields an estimate of the market price of credit-risk. The estimate of the firm growth rate, however, is very poor: it is based on two asset-return observations only.

Further, given the asset-return time series of several firms, asset correlation can be estimated. Alternatively, we can introduce a linear-factor model for normally distributed asset returns that expresses the idea that firms share a common dependence on general economic factors. This is similar to the idea we discussed earlier.

Can We Predict the Future?

To a certain extent, users of structural models implicitly assume that they can. In structural models, firm value is the single source of uncertainty that drives credit-risk. Investors observe the distance of default as it evolves over time. If the firm value has no jumps, this implies that the default event is not a total surprise. There are "predefault events" that announce the default of a firm. In the first-passage approach, we can think of a predefault event as the first time assets fall dangerously close to the default barrier (see Exhibit 42-8).

This has significant implications for the fitting of structural models to market prices. First, since default can be anticipated, the model price of a credit-sensitive security converges continuously to its recovery value. Second, the model credit-spread tends to zero with time to maturity going to zero.[7] Quite telling in this regard are the credit-spreads implied by the classical and first-passage approaches (see Exhibits 42-3 and 42-5). Both properties are at odds with intuition and market reality. Market prices do exhibit surprise downward jumps on default. Even for very short maturities in the range of weeks, market credit-spreads remain positive. This indicates that investors do have substantive short-term uncertainty about defaults, in contrast to the predictions of the structural models.

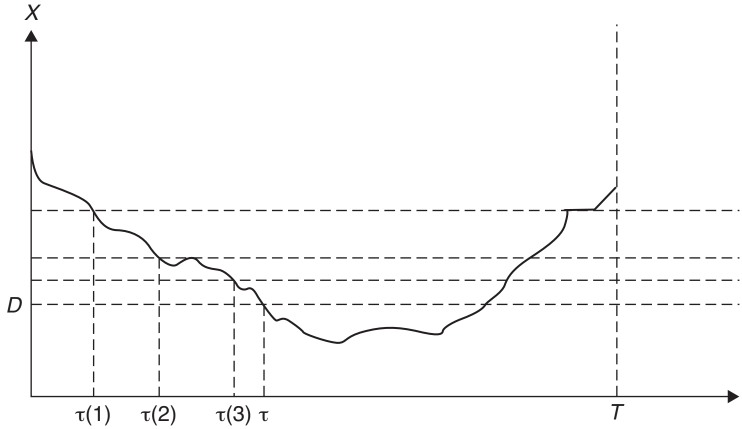
EXHIBIT 42-8

Announcing the Default Timing by a Sequence of "Predefault" Events in the First-Passage Approach



REDUCED-FORM CREDIT MODELS

Reduced-form models were developed in the 1990s.[8] Here we assume that default occurs without warning. This means that investors face short-term credit-risk, which is absent from the structural models discussed previously. This is a desirable model property because it allows us to fit the model to market credit-spreads.

Default Intensity

The rate at which default occurs is called the *default intensity,* and we denote it by λ. We can think of the *intensity* at time t as the conditional probability that default will happen immediately, given that the firm has escaped default by t. As such, it describes the short-term credit-risk investors face.

The intensity is the central ingredient of all reduced-form models. It is modeled as a (nonnegative) stochastic process under the market-implied probability. The time evolution of the intensity reflects changes in the instantaneous default probability of a firm. The intensity model is calibrated from market prices

8. See Philippe Artzner and Freddy Delbaen, "Default Risk Insurance and Incomplete Markets," *Mathematical Finance* 5 (1995), pp. 187–195; Robert A. Jarrow and Stuart M. Turnbul, "Pricing Derivatives on Financial Securities Subject to Credit-Risk," *Journal of Finance* 50 (1995), pp. 53–86; and Darrell Duffie and Kenneth J. Singleton, "Modeling Term Structures of Defaultable Bonds," *Review of Financial Studies* 12 (1999), pp. 687–720.

of credit-sensitive securities issued by the firm. There is a one-to-one relation between the intensity and the corresponding default probabilities.

We give two simple but useful specifications for the intensity and the corresponding default probabilities.

- *Example 1*. Suppose that λ is a constant. Then default is a Poisson arrival, and the default time is exponential with parameter λ. The default probability thus is given by $q(T) = 1 - \exp(-\lambda T)$.
- *Example 2*. Suppose that $\lambda = \lambda(t)$ is a deterministic function of time t. Then default is an inhomogeneous Poisson arrival. A simple but useful parameterization that is frequently used is the assumption that $\lambda(t)$ is stepwise defined over finite periods across the spread curve—these stepwise constants can be calibrated easily from market data.

These examples constitute only a small sample of possible parameterizations of the default intensity. There are many more choices, often borrowed from the classical term-structure models based on the short-term interest rate. This is motivated by the close analogy of defaultable term-structure models and classical, nondefaultable term-structure models to which we turn next.

Valuation

The description of the default dynamics through the market-implied default intensity λ leads to tractable valuation formulas. Below we describe several different specifications of these formulas corresponding to different units for the value recovered by investors at default.

We consider a zero-coupon bond paying 1 at maturity T if there is no default and a fraction $0 < R < 1$ of an equivalent (face value 1, maturity T) but default-free bond at default if default occurs before maturity T. This recovery specification is often called *equivalent recovery*. Given the market-implied probability of default $q(T)$, and assuming that R is a constant, the present value of the bond can be written as $\exp(-rT) - \exp(-rT)(1 - R)q(T)$. Here, r is the constant risk-free rate of interest. Thus the value of the bond is the value of an otherwise equivalent risk-free bond minus the present value of the default loss $(1 - R)$. If the intensity is constant (Example 1) and recovery is zero, we obtain for the bond price today $\exp[-(r + \lambda)T]$. This means that the value of the defaultable bond is calculated as if the bond were risk-free by using a default-adjusted discount rate. The new discount rate is the sum of the risk-free rate r and the intensity λ. This parallel between pricing formulas for defaultable bonds and otherwise equivalent default-free bonds is one of the best features of reduced-form models.

An alternative recovery model is called *fractional recovery of predefault market value*. Here it is assumed that the bond recovers a fraction $0 < R < 1$ of the market value of the bond just prior to default. If the recovery rate and the intensity are constant (Example 1 above), we obtain the following convenient formula for the bond price: $\exp\{-[r + \lambda(1 - R)]T\}$. This is the value of a zero-recovery defaultable bond when the issuer's default intensity is "thinned" to $\lambda(1 - R)$. The intuition behind this is as follows. Suppose that the bond defaults with intensity λ. At default, the bond becomes worthless with probability $(1 - R)$, and its value remains unchanged with probability R. Clearly, the predefault value of the bond is not changed by this way of looking at default. Consequently, for pricing, we can ignore the "harmless" default, which occurs with intensity λR. We then price the bond as if it had zero recovery and a default intensity of $\lambda(1 - R)$. The fractional-recovery pricing formula is then implied by the formula for equivalent recovery.

The results for the valuation of more complex credit-sensitive securities are analogous, and in the general case, a credit-sensitive security can be valued as if it were not sensitive to credit-risk by using an adjusted rate for discounting payoffs.

We take a closer look at the credit-spreads implied by reduced-form models. In the simple case where recovery is zero and some technical conditions are satisfied, we can show that short-term credit-spreads tend to λ and not zero. This should be contrasted with the structural models, where the spread goes to zero with time to maturity going to zero. In the reduced-form models, the default event is unpredictable; it comes without warning. There is always short-term uncertainty about the default event, for which investors demand a premium. This premium, expressed in terms of yield, is given by the intensity.

The unpredictability of default has another important consequence. In line with empirical observation, the model price of a credit-sensitive security will drop abruptly to its recovery value on default. This is in direct conflict with the structural models considered earlier, in which the price converges to its default contingent value and remains there as equity value drops to zero.

Default Correlation

In the reduced-form approach we can introduce cyclical default correlation by assuming that firms' default intensities are correlated through time. Similarly to the structural models of correlated default, we can introduce systematic and firm-specific factors that drive the intensities of firms. The sensitivity of a firm with respect to the systematic factors controls the intensity correlation across firms. This intensity correlation drives the dependence between firm defaults. Joint default probabilities can be calculated by observing that the intensity of the first default in a portfolio of names is the sum of the default intensities of the individual issuers in the portfolio.

Reduced-form models provide a flexible framework for modeling the dynamics of multiple-issuer credit-risk. However, calibration of the model to market variables is not trivial because of the scarcity of default data and the need to model a large number of parameters simultaneously. There are also studies that argue that the approach can be problematic for other reasons.

Taking account of contagious default correlation in the reduced-form approach is not an easy exercise. The idea is that there are correlated jumps in firms' default intensities corresponding to the correlated jumps we observe in credit-spreads. A variant of this assumes that there are marketwide events that can trigger joint defaults.[9] Another variant assumes that the default intensity of a firm depends explicitly on the default status of related counterparty firms in the market.[10] To avoid running into a circularity problem, one can suppose that only the default of designated "primary" firms has an effect on other "secondary" firms.

While Jarrow and Yu[11] focus on the pricing of credit-sensitive securities in the presence of contagion effects, it is difficult to calculate joint default probabilities and portfolio loss distributions within this approach. As Davis and Lo[12] and Giesecke and Weber[13] show, one can obtain tractable closed-form characterizations of loss distributions at the cost of more restricting assumptions that relate to the homogeneity of firms and the symmetry in their counterparty relations.

Calibration

Reduced-form models typically are formulated directly under the market-implied probability. This suggests that we calibrate directly from market prices of various credit-sensitive securities. One often uses liquid debt prices or credit default swap spreads, although Jarrow argues that equity is a good candidate as well.[14] Depending on the characteristics of the calibration security, it may be necessary to make parametric assumptions about the recovery process as well. With fractional recovery and zero bonds, for example, the problem is to choose the parameters of the adjusted short rate model $r + \lambda(1 - R)$ such that model bond prices best fit observed market prices.

Here one can either parameterize the adjusted short rate directly or specify the component processes separately. With a separate specification, identification problems may arise because only the product $\lambda(1 - R)$ enters the pricing formula just described. In general, in the estimation problem one can draw from the experience related to nondefaultable term-structure models given the close analogy to reduced-form defaultable models.[15]

INCOMPLETE-INFORMATION CREDIT MODELS

For the purpose of measuring default risk, neither the structural nor the reduced-form model explicitly accounts for the fact that investors rely on information that is imperfect. The framework described in this section addresses this issue directly by giving a common perspective on reduced-form and structural models. This perspective leads to previously unrecognized hybrid models that incorporate the best features of both traditional approaches while avoiding their shortcomings.

Incomplete-information credit models were introduced by several researchers.[16] Giesecke and Goldberg[17] describe a structural reduced-form hybrid default model based on incomplete information. This model, hereafter denoted I^2, is a first-passage time model: it assumes that a firm defaults when its value falls below a barrier. All first-passage time models require descriptions of both firm value and a default barrier. What distinguishes the I^2 model from traditional first-passage time models as we described them earlier is that it assumes that investors do not know the default barrier. The importance of modeling uncertainty about the default barrier is highlighted by high-profile scandals at firms such as Enron, Tyco, and WorldCom. In these cases, public information led to poor estimates of the default barrier.

Both the expected default barrier and the uncertainty around it can be calibrated to available information in the I^2 model. Imagine that a firm is believed to be in good financial health but that a particular analyst thinks otherwise. The analyst can increase the forecasts to line up with her views by raising the expected value of the barrier. She also can adjust the variance of the default barrier to the level of her confidence in reported levels of the firm's liability.

Other incomplete-information models can be envisioned. We can think of a situation where we cannot observe firm values or receive noisy or lagged firm-value information. Another situation is when we are uncertain about both firm values and the default barrier.

With incomplete information, default becomes a surprise event. It cannot be anticipated any more, as it can in the traditional first-passage models. It follows that investors face short-term credit-risk as in the reduced-form models. With short-term uncertainty, the model prices generated by the incomplete-information models provide an excellent fit to market prices. In particular, model prices are consistent with the jumps in prices observed around the default announcement. Model spreads are consistent with the nonzero short-term spreads observed in the credit markets. Exhibit 42-9 shows the term structure of credit-spreads implied by

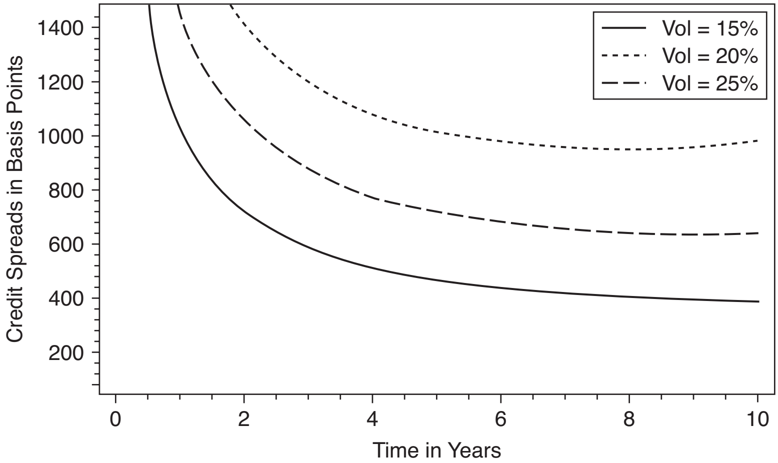
EXHIBIT 42-9

Term Structure of Credit-Spreads, Varying Asset Volatility, in the I^2 Model



the I^2 model, assuming risk-free rates of 6%. Strictly positive short spreads reflect the compensation for the short-term credit-risk that investors face.

Giesecke and Goldberg calibrate the I^2 model from market data and further analyze its empirical properties. In particular, the I^2 model output is compared empirically with a traditional first-passage model. Two main conclusions can be drawn. The I^2 model reacts more quickly because it takes direct account of the entire history of public information rather than just current values. Furthermore, the I^2 model predicts positive short spreads for firms in distress. The traditional first-passage model always predicts that short spreads are zero.

Dependent Defaults

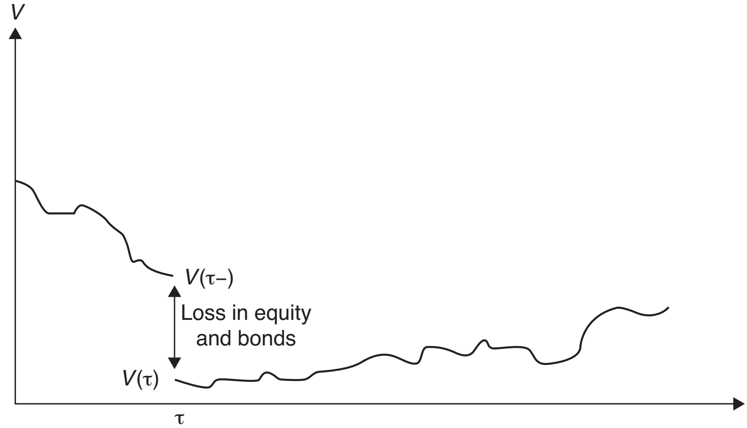
Since incomplete-information models are based on the structural approach, we can model cyclical default correlation through firm-value correlation.

Contagious default correlation arises very naturally with incomplete information. Consider the I^2 model. With defaults of firms arriving over time, we learn about the unobserved default barriers of the surviving firms.[18] This means that we update the distribution we put on a firm's default barrier with the information we extract from the unanticipated defaults of counterparty firms and reassess firms' default probabilities. The situation in which we do

18. This is discussed in detail in Kay Giesecke, "Correlated Default with Incomplete Information," *Journal of Banking and Finance* 28 (2004), pp. 1521–1545.

EXHIBIT 42-10

Firm Value in the Incomplete-Information Model



not directly observe firm values is very similar.[19] In both scenarios, the "contagious" jumps in credit-spreads we observe in credit markets are implied by informational asymmetries.

Credit Premium

The credit-risk premium is the mapping between the actual probability and the market-implied probability. To understand the structure of the premium, we examine the dynamics of firm value and corporate liabilities in the I^2 model. We argued earlier that thanks to the unpredictability of default, prices of credit-sensitive claims including firm equity and debt drop precipitously at default. Empirical observation shows that equity drops to near zero. This makes sense because equity holders have no stake in the firm after default. The value of the bonds is diminished by bankruptcy costs, which is described by some fractional recovery R.

Consequently, firm value, which is equal to the sum of equity and debt values, also drops at default. This is shown in Exhibit 42-10. Therefore, there are two sources of uncertainty related to firm value:

- The first is the diffusive uncertainty.
- The second is the uncertainty associated with the downward jump at default.

19. This is analyzed in Pierre Collin-Dufresne, Robert Goldstein, and Jean Helwege, "Are Jumps in Corporate Bond Yields Priced: Modeling Contagion via the Updating of Beliefs," working paper, Carnegie Mellon University, 2002.

Giesecke and Goldberg show that in the I^2 model the credit-risk premium can be decomposed into two components, which correspond to the two sources of uncertainty:[20]

- The diffusive risk premium α compensates investors for the diffusive uncertainty in firm value. As in the traditional structural models, it is realized as a change to the drift term in firm-value dynamics.
- The default event risk premium β is not present in the traditional structural models. It compensates investors for the jump uncertainty in firm value and is realized as a change to the default probability. Driessen[21] empirically confirms that this event risk premium is a significant factor in corporate bond returns.

Giesecke and Goldberg demonstrate that the assumption of no arbitrage is realized in the mathematical relationships among α, β, the recovery rate assumed by the market, and the coefficients of the price processes of traded securities. The price processes depend explicitly on the leverage ratio, so the premia α and β do as well. As Giesecke and Goldberg discuss,[22] this violates an important condition for the Modigliani and Miller theorem.[23] The I^2 model therefore is not consistent with the Modigliani-Miller theorem. It provides a new way to measure the deviation of real markets from the idealized markets in which the Modigliani-Miller theorem holds.

The structure of the incomplete-information risk premium is analogous to the risk premium in reduced-form models considered in El Karoui and Martellini[24] and Jarrow, Lando, and Yu.[25] The diffusive premium related to the firm-value process corresponds to a premium for diffusive risk in the default intensity process. The event risk premium is analogous to the default event risk premium in intensity-based models. However, in the incomplete-information setting it is defined in the general reduced-form context where an intensity need not exist.

Calibration

There is a lively debate in the literature concerning which data should be used to calibrate credit. Jarrow[26] points to a division between structural and reduced-form modelers on this issue. Traditionally, structural models are fit to equity markets and reduced-form models are fit to bond markets. Jarrow argues that the equity and bond data can be used in aggregate to calibrate a credit model, and he gives a recipe for doing this in a reduced-form setting.

Giesecke and Goldberg[27] apply reasoning similar to that of Jarrow to calibrate the I^2 model. The estimation procedure makes use of historical default rates in conjunction with data from equity, bond, and credit default swap markets. Huang and Huang[28] give empirical evidence that structural models yield more plausible results if calibrated to both kinds of data. Importantly, the physical and market-implied probabilities are fit simultaneously. The output of the calibration includes estimates of the risk premium, market-implied recovery, model security prices, and physical probabilities of default.

One issue addressed in Giesecke and Goldberg[29] is the relationship between model and actual capital structures. In the classical setting, equity is a European option, with strike price and date equal to the face value and maturity of a zero bond. This model fits market data only to the extent that firm debt can be represented adequately as a zero bond. Giesecke and Goldberg make use of the flexibility imparted by incomplete information to give a more realistic picture of equity. Specifically, equity is a down-and-out call with a stochastic strike price. This approach sidesteps the intractable problem of describing a complex capital structure in terms of a single face value and maturity date.

KEY POINTS

- Credit-risk is the distribution of financial losses owing to unexpected changes in the credit quality of the counterparty in a financial agreement.
- Estimating probability of default requires the specification of a (1) model of investor uncertainty, (2) model of the available information and its evolution over time, and (3) model definition of the default event.
- Because default probabilities alone are not sufficient to price credit-sensitive securities, it is necessary to have a (1) model for the risk-free

interest rate, (2) model of recovery on default, and (3) model of the premium investors require as compensation for bearing systematic credit-risk.

- The credit premium maps actual default probabilities to market-implied probabilities that are embedded in market prices.
- In order to price securities that are sensitive to the credit-risk of multiple issuers and measure aggregated portfolio credit-risk, a model that links defaults of different entities must be specified.
- The three main quantitative approaches to analyzing credit are the structural approach, the reduce-form approach, and the incomplete-information approach.
- The basis of the structural approach is the Black-Scholes-Merton framework, in which corporate liabilities are contingent claims on the assets of a firm. The market value of the firm is the fundamental source of uncertainty driving credit-risk. The structural approach makes explicit assumptions about the dynamics of a firm's assets, its capital structure, and its debt and shareholders. A firm defaults if its assets are insufficient according to some measure. In this situation, a corporate liability can be characterized as an option on the firm's assets.
- First-passage time structural models generalize the classical model such that a default can occur not only at maturity of the debt contract, but also at any point of time.
- Credit-spreads of different issuers are correlated through time and must be incorporated into a credit-risk model. Two patterns are found in time series of spreads: (1) spreads vary smoothly with general macroeconomic factors in a correlated fashion, and (2) there are jumps in spreads that are common to several firms or even entire markets.
- Reduced-form models assume that default occurs without warning. That is, this approach is silent about why a firm defaults. Instead, the dynamics of default are given exogenously through a default rate, or intensity. In this approach, prices of credit-sensitive securities can be calculated as if they were default-free using an interest rate that is the risk-free rate adjusted by the intensity. Default intensity is the rate at which defaults occur.
- The incomplete-information approach combines the best features of the structural and reduced-form models while at the same time avoiding the shortcomings of the two models. More specifically, it combines the economic and intuitive appeal of the structural approach and the tractability and empirical fit of the reduced-form approach.

PORTFOLIO MANAGEMENT AND STRATEGIES

This page intentionally left blank

CHAPTER
FORTY-THREE

INTRODUCTION TO BOND PORTFOLIO MANAGEMENT

Kenneth E. Volpert, CFA
Consultant

Traditional bond management can be likened to a sailing regatta. The index is the lead boat, since it doesn't have to contend with expenses and transaction costs, and all managers (including index fund managers) are the other boats, trying to make up the distance and pass the index boat—or at least keep pace with it. Strategies that may be used to make up the difference and pass the index lead boat comprise a wide spectrum of styles and approaches. Exhibit 43-1 displays the major elements of these approaches.

In this chapter, we'll examine this spectrum, investigating the pros and cons of matching—and mismatching—bond indexes, and comparing ways of constructing bond portfolios. We'll look closely at the factors to consider when matching a bond index's risk factors, as well as the methods that may provide an edge over an index.

OVERVIEW OF TRADITIONAL BOND MANAGEMENT

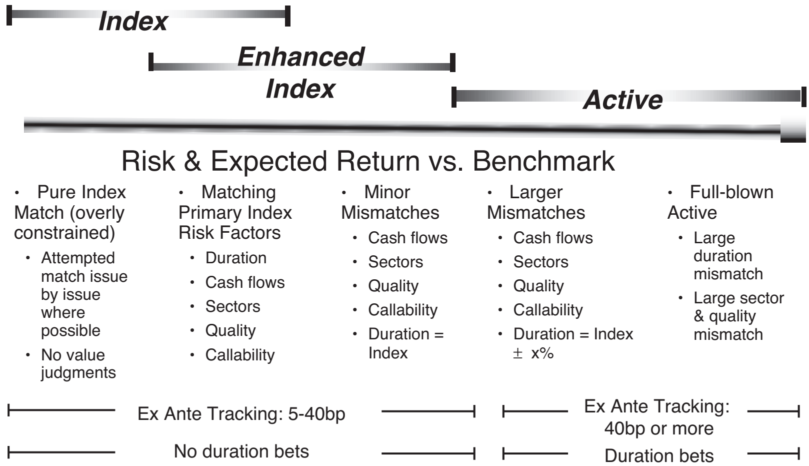
Although bond portfolio management can be complicated, choosing an investment approach starts with a fairly simple question: How much risk would you like to take?

Pure Bond Index Matching

Pure bond indexing offers the lowest risk (and lowest expected return) approach to bond management versus a specific benchmark. This approach essentially guarantees that returns will lag behind the index by the cost difference (expenses plus transaction costs). Pure bond index matching attempts to fully replicate the index by owning all of the bonds in the index in the same proportion as the index. In the bond market, however, this approach is difficult to accomplish and costly to implement. Many bonds in the index were issued years ago, and are illiquid. Also, many bonds were issued at a time when interest rates were significantly different from current rates. Today's bondholders may be unwilling to incur a gain or loss by selling their bonds to an index fund.

EXHIBIT 43-1

Traditional Bond Management Risk Sprectrum



On December 31, 2020, the Bloomberg Barclays US Aggregate Index contained more than approximately 12,000 different issues, including more than 260 Treasury bonds, over 600 federal agency issues, 7,500 credit (corporate and non-U.S. government) issues, 370 asset-backed issues, 3,000 commercial mortgage-backed securities, and 450 broadly categorized mortgage issues (essentially hundreds of thousands of mortgage pools). In the Treasury market, matching an index, security by security, is feasible, although not desirable (for reasons we'll cover later). However, full replication cannot be reasonably implemented in the agency, mortgage, or corporate bond markets. Thousands of agency and corporate issues are locked away in long-term bond portfolios and must be purchased from the investors who own them—often at a large premium. For this reason, full replication of a broad bond index is inefficient, if not impossible. And, as you'll see, it's also unnecessary.

Enhanced Indexing: Matching Primary Risk Factors

This approach involves investing in a large sample of bonds so that the portfolio's risk factors match the index's risk factors. The result is a portfolio that will have higher average monthly tracking differences (standard deviation of tracking differences) than the full-replication approach. But, it can be implemented and maintained at a much lower cost. This lower cost results in *net* investment performance that is much closer to the index. Returning to the regatta analogy, the portfolio boat stays on the same "tack" as the index boat, but "trims its sails" to run more efficiently. Staying on the same tack means that the sails are set to take the portfolio boat in the same direction as the index boat, and are exposed to the same winds and elements. By trimming the sails, the little details of the portfolio boat's sail position and shape result in better performance and more efficient execution than the index boat. The risk factors that need to be matched are duration, cash-flow distribution, sector, quality, and call exposure (more on this later). This approach is considered a form of enhanced indexing because the return is enhanced relative to the full replication indexing approach (more on this later as well).

Enhanced Indexing: Minor Risk Factor Mismatches

This approach allows for minor mismatches in the risk factors (except duration) to tilt the portfolio in favor of particular areas of relative value, such as certain sectors, credit ratings, term structure, call risk, or other factors. Because the mismatches (and impact on tracking) are very small, this is still considered enhanced indexing. These additional enhancements are essentially sail-trimming strategies.

Active Management: Larger Risk Factor Mismatches

This is a conservative approach to active management. The manager will make larger mismatches in the risk factors in an attempt to add greater value. This approach may also make small duration bets. In most cases, the management fee and transaction costs are significantly higher than for pure or enhanced indexing, yet the net investment return is usually lower. These additional costs are the reason a typical index portfolio often outperforms the average active manager in performance universes. Typically, the manager will moderately change tack to seek greater "winds" (for example, longer than benchmark duration to add value from expected lower interest rates) to overcome the strategy's higher cost. As a result, manager risk increases the likelihood that the portfolio will deviate from the market return and structure.

Active Management: Full-Blown Active

This is an aggressive active style in which large duration and sector bets are made, and significant variation from the index can occur. Above-average performance consistency is difficult to find among the managers that employ this approach. As a result, investors who choose this management style need to look deeper than recent performance to distinguish the good from the bad. This approach may involve a significant changing of course relative to the index boat, and may risk significant tracking and portfolio structure variations. Of course, the goal of this riskier strategy is to provide a return that is higher than that of the index.

OVERVIEW OF THE CORE/SATELLITE APPROACH

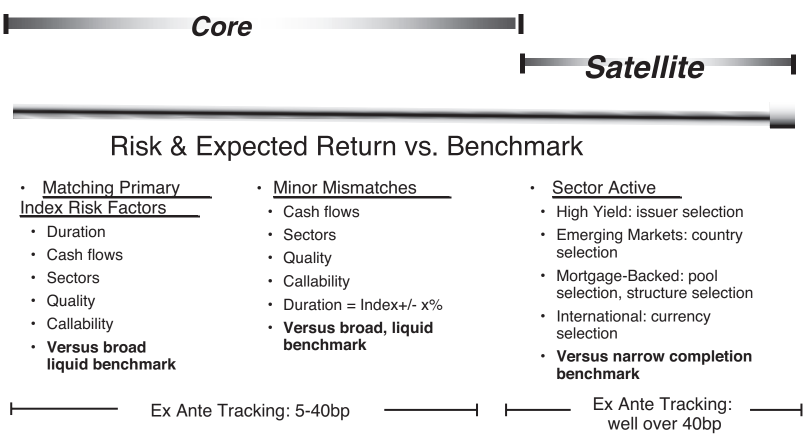
Although these traditional approaches are alive and well, many investment managers have moved a few steps beyond this conventional model and are building portfolios with a conservative, low-cost (often index-based) core, and satellites that may encompass a variety of active strategies. As shown in Exhibit 43-2, a core portfolio is typically managed against a broad, liquid benchmark within a tight risk budget, generally under 40 basis points ex-ante tracking standard deviation versus the benchmark. As we'll see, there are several ways to build the core and the satellite portions of such portfolios.

Risk-Factor Matching

In this strategy, the manager creates a broadly diversified portfolio that closely replicates primary index risk factors such as portfolio duration, key rate durations, sectors, quality, and callability. The ex-ante tracking error is expected to be below 20 basis points. Since this high-quality, liquid bond market is assumed to be efficiently priced, the expected opportunity to outperform the index is very limited. Therefore, the objective is to match and replicate the risks, and generate the returns, of the target benchmark at the lowest possible cost (management fee and transaction costs).

EXHIBIT 43-2

Core/Satellite Risk Spectrum



Minor Mismatching

Here, the manager is given a larger risk budget (20 to 40 basis points) to mismatch relative to a broad liquid benchmark's characteristics such as key rate durations, sector and quality weightings, and even overall portfolio duration, to a limited extent. The expectation is that the manager will add value relative to that broad benchmark. As a result of this expected added value, the manager would also have a higher fee structure.

The Satellite Investments

The satellite portion focuses on the less-liquid sectors that have lower correlations with the broad liquid core. This manager is given a smaller pool of assets and a much larger risk budget relative to the narrow benchmark. This bigger risk budget provides an opportunity for the manager to take meaningful selection, sector, and quality risk relative to the benchmark, with the expectation of adding considerable value.

Examples of such narrow, less-liquid markets include high-yield and emerging market bonds. In the high-yield market, issuer and sector selection are the primary determinants of added value versus the benchmark. Within the emerging bond market, country selection is a driving force in adding value. In many cases, the mortgage-backed market (agency and particularly nonagency) is viewed as a satellite market because of the many structural complexities based on interest-rate volatility risk and credit risk in the nonagency market. Securities exposed to non-U.S. currencies may be considered satellites, as could inflation-protected securities.

A key requirement of the satellite component is that it acts as a diversifier and that it has a higher expected return due to its illiquidity and lower credit quality.

WHY CHOOSE INDEXING?

As we've demonstrated, indexing plays a major role in bond management. Some managers may use indexing for part of a portfolio; for other managers, it may serve as the approach for an entire portfolio. So why is indexing an effective method of bond investing? Put simply, bond indexing, which has proven its mettle over the past two decades, offers broad diversification and low costs. Low costs are vital to bond indexing because lower costs mean tighter tracking of an index. This, in turn, means that an index portfolio will provide competitive performance that is consistent with the market—or market segment—that it tracks. And it means that nonindex (that is, higher-cost) portfolios will have difficulty beating the index portfolio. Finally, indexing provides a major psychological benefit: It allows investors to focus on asset allocation—or, in the case of the core/satellite approach, on selecting the best investment managers.

Broad Diversification

Broad bond index portfolios provide excellent diversification. The Bloomberg Barclays US Aggregate Bond Index, which is designed to capture the entire U.S. investment-grade bond market, had more than 8,200 issues and more than $15 trillion in market value as of early 2020. A large bond index portfolio designed to replicate this Index may have 1,000 to 3,000 or more issues, resulting in significant issuer diversification benefits. Most active portfolios have much heavier specific issuer concentrations, resulting in significant exposure to issuer event (credit) risk.

In addition, an index portfolio designed to match the Bloomberg Barclays US Aggregate Bond Index will have exposure to not only Treasury and agency sectors, but also to mortgages, industrials, electric and telephone utilities, finance, dollar-denominated non-U.S., and asset-backed sectors. Such a portfolio will also have broad exposure to the yield-curve with holdings from one year to more than 30 years to maturity. These sources of diversification result in a portfolio with lower risk for a given level of return than is available from less diversified portfolios.

Low Cost

As we've mentioned, the primary reason for an index fund's competitive performance is lower cost. This lower cost takes two forms: (1) lower management fees and (2) lower transaction costs associated with lower portfolio turnover rates. This lower cost advantage is durable and predictable—year after year.

Competitive Performance

Since index portfolios have lower management fees and lower transaction costs (resulting from significantly lower portfolio turnover), it's not surprising that they usually outperform the average active portfolio in most universes. After all, a broad index, by design, is a representation of the whole pie of investment alternatives. As a result, the sum of all active managers should equal the index in composition. Also, the sum of the investment performance of all active managers (grossed up for the higher management fees and transaction costs) should also equal the index in performance.

Market Performance Predictability

A properly managed broad bond index portfolio can be assured of performing in line with the market as a whole. Regardless of the market's direction, the investor can be assured the performance of a diversified broad bond index portfolio will follow along.

A Time-Tested Track Record

Bond index portfolios have been successfully managed (that is, close tracking to the benchmark) since the early 1980s—through rising and falling interest rate cycles, as well as periods when credit-spreads widened and narrowed. Through all these market changes, bond indexing has proven to provide a more-than-competitive return with low to moderate risk.

Perhaps the most significant benefit of indexing is that it enables investors to concentrate on more important decisions—namely, the proper allocation of assets. Often, time and effort are wasted in the hope of adding 20 to 40 basis points to the very efficiently priced bond portion of a portfolio, while existing misallocation of assets to stocks or international investments results in hundreds of basis points of underperformance for the entire portfolio. Indexing the core portion of the portfolio that represents the highly liquid markets helps facilitate more effective use of limited decision-making resources available to most investors. For those using a core/satellite approach, indexing provides an opportunity to focus on selecting the best managers for the satellites.

WHICH INDEX SHOULD BE USED?

Once you've decided on an indexing approach to bond management, you should focus on the next important question: Which index? A bond index is defined by a set of rules (that is, characteristics) that are then applied to all issues in the marketplace. The rules include maturity, size, sector, and quality characteristics. The issues that fit the rules are then combined, as if in a portfolio, with each issue's weight determined by its relative market value outstanding.

Generally, the broader the index, the better the benchmark. An index we've discussed, the Bloomberg Barclays US Aggregate Bond Index, is the broadest U.S. bond index. As we've mentioned, the Bloomberg Barclays US Aggregate Bond Index consisted of more than 8,200 issues, representing a market value of more than $15 trillion. The composition of the Index, illustrated in Exhibit 43-4, was 41% government (U.S. Treasury and agency) bonds, 23% credit-related (corporate and non-U.S. government) bonds, 3% asset-backed bonds and commercial mortgage-backed bonds, and 28% mortgage-backed securities. Sub-indices of the Bloomberg Barclays US Aggregate Bond Index can be created to capture that result in different risk/return profiles. For example, a credit index may appeal to those who seek higher yields from the spread sectors, or a 1-to-5-year government/credit index would better serve those who are seeking a short-duration portfolio.

An important part of choosing an index is understanding the risks that are involved in the bond market's various segments. Chief among these risks are market value risk and income risk, although the degree to which they apply to a given part of the bond market can vary widely.

Market Value Risk

Generally, the longer a bond portfolio's maturity, the higher is its yield. (This assumes a normally sloped yield-curve.) The total return of a bond is made up of the coupon (or income) component and the principal (or price change) component. Since the yield-curve, which impacts the principal component of total return, is likely to shift, the longer-term bond portfolio will not necessarily have a higher total return. As the maturity or duration of the portfolio lengthens, market value risk rises. In addition, the lower the interest-rate environment, the greater the market value risk, especially for the intermediate-term and long-term portfolios. This is the result of two factors: the portfolio's duration increases as interest rates decrease, and the portfolio's lower yield-to-maturity provides less of a cushion to offset principal losses. Therefore, for investors who are risk-averse in terms of their principal, the short-term or intermediate-term index may be more appropriate than the long-term index.

Income Risk

Many investors invest for income. They spend only the income that their investment distributes, and they avoid dipping into their principal. Foundations and retirees invest for a stable—and hopefully growing—income stream that they can depend on for current and future consumption. It's obvious that if stability and durability of income are the primary concerns, the long-term portfolio is the least risky, and the short-term portfolio the most risky.

Liability Framework Risk

Pension funds and financial institutions invest to finance future liabilities. Long-term liabilities require investments in long-term assets to minimize risk, resulting in both a portfolio and a liability stream that are equally sensitive to interest-rate changes. A portfolio that invests in short-term bonds may look less risky on an absolute-return basis, but it is actually much riskier when the portfolio market value is compared to the present value of the pension liability. (The difference is the surplus or deficit.) This is because of the short-term portfolio's mismatch with its long-term liabilities. The surplus risk will be minimized on a fully funded plan when the duration of the portfolio is matched (or immunized) to the duration of the liability.

Exhibit 43-3 contains a summary comparison showing that the investment with the lowest market value risk has the highest income or liability risk. Likewise, the investment with the highest market value risk has the lowest income or liability risk. Clearly, the risk framework chosen depends on whether the investment objective is principal preservation or income durability.

PRIMARY BOND INDEXING RISK FACTORS

As effective as indexing is as a bond management tool, it doesn't eliminate the risks of bond investing by any means. Successful indexing requires matching the primary risk factors of the benchmark index in a credit-diversified portfolio. This

EXHIBIT 43-3

Bond Market Risk Summary

NAV Type	Market-Value Risk	Income or Liability Risk	Average Maturity	Current Duration	Portfolios
Stable-dollar NAV	Lowest	Highest	30–90 Days	0.1	Money market portfolios
Variable NAV	Low	High	2–4 Years	2.5	Short-term portfolios
	Medium	Medium	7–10 Years	5.0	Intermediate-term portfolios
	High	Low	15–25 Years	10.0	Long-term portfolios

EXHIBIT 43-4

Primary Bond Index Matching Factors

	Government	Corporate	MBS
Modified adjusted duration	x	x	
Present value of cash flows	x	x	
Percent in sector and quality		x	
Duration contribution of sector		x	
Sector/coupon/maturity cell weights		x	x
Issuer exposure control		x	

doesn't mean an index manager must fully replicate an index. Rather, it means that the manager must understand the risk factors and how they're measured. Exhibit 43-4 lists the primary risk factors that apply to the government, corporate, and mortgage sectors; the following paragraphs explain each primary risk factor.

Portfolio Modified Adjusted Duration

The modified adjusted duration (or option-adjusted modified duration) is a simple, single measure of the portfolio's interest-rate risk. It's a great place to start, but is entirely too rough of a measure to adequately track an index. Duration is the average time to receipt of the present value of the bond cash flows. The portfolio duration will give the manager a rough approximation of the price change observed if interest rates rise or fall (in a parallel fashion) immediately by 1%. If rates rise by 1%, a five-year duration portfolio will experience a 5% decline in value [(+1% yield change) × (portfolio duration of 5 years) × (−1)]. If the yield-curve does not move in a parallel fashion, the duration is of limited value. For obvious reasons, it's important to match the duration of the portfolio to the duration of the benchmark index.

Key Rate Durations

A more accurate way to capture yield-curve risk is by matching the key rate durations (known as KRDs) of the index. Yield-curve changes are composed of parallel shifts, curve twists (for example, short rates down, intermediate rates unchanged, long rates up), and curve butterfly movements (for example, short and long rates down, intermediate rates up). By breaking down the index (and portfolio) into a stream of future payments and discounting each payment to the present value and summing these values, one calculates the index (and portfolio) market value. By matching the percent of the portfolio's present value that comes due at certain intervals in time (that is, KRDs) with that of the benchmark index, the portfolio will be largely protected from tracking errors (versus the benchmark) associated with yield-curve changes. Since the portfolio duration is equal to the benchmark index duration, this method will guard against parallel changes in yield. Since all points in time (KRDs) are closely matched in percent, any local term structure movements (non-parallel changes) will not affect tracking because these yield change risks are essentially immunized. For callable securities, the cash flows need to be distributed to the KRDs in accordance with the probability of call. A 10-year bond that is highly likely to be called in three years should have cash flows that are allocated primarily to the three-year KRD.

Percent in Sector and Quality

The yield of the index is largely replicated by matching the percentage weight in the various sectors and qualities, assuming that the replicating portfolio fully accounts for all maturity categories. Matching duration contribution of sectors and qualities, without matching the portfolio percentage weight exposed to the sectors and qualities, may expose the portfolio to significant tracking risk during periods of extreme duress. This is due to the default risk that can reduce the value of all of an issuer's bonds by a given magnitude, regardless of the maturity.

Duration Contribution of Sector

An effective way of protecting a portfolio from tracking differences associated with changes in sector spreads (industry risk) is to match the amount of the index duration that comes from the various sectors. (This can be done without excessively constraining the process, subject to managing the market weights, as we've described earlier.) If this can be accomplished, a given change in sector spreads will have an equal impact on the portfolio and the index.

Duration Contribution of Quality

Similarly, the most effective way to protect a portfolio from tracking differences related to changes in quality spreads (leverage/economic risk) is to match the amount of the index duration that comes from the various quality categories. This is particularly important in the lower-rated categories, which are characterized by larger spread changes.

Sector/Coupon/Maturity Cell Weights

The call exposure of an index is difficult to replicate. By itself, the convexity value (convexity measures how a bond's duration changes as yield levels change) is inadequate since it measures expected changes in duration over a small change in yield levels. In addition, the change in convexity can be very different as yield levels change. Managers who attempt to match only the index convexity value often find themselves having to buy or sell highly illiquid callable securities to stay matched and, in the process, generating excessive transaction costs. A better method of matching the call exposure is to match the sector, coupon, and maturity weights of the callable sectors. By matching these weights, the convexity of the index should be matched. In addition, as rates change, the changes in call exposure (convexity) of the portfolio will be matched to the index, requiring little or no rebalancing.

In the mortgage market, call (prepayment) risk is significant. Clearly, the greater the refinancing activity, the shorter the index duration due to the greater likelihood that the higher coupons (issues priced above par) will be refinanced with lower coupon securities. For this reason, matching the coupon distribution of the mortgage index is critical. The best risk management is accomplished by matching the index weights in a multidimensional matrix of the maturity (balloon, 15-year, 30-year), sector (FNMA, FHLMC, GNMA), coupon (0.5% increments), and seasoning (new, moderate, and seasoned). This level of detail is easily accomplished in a large portfolio (more than $1 billion in assets), but more difficult in smaller portfolios.

The FNMA and FHLMC's government-sponsored enterprises (GSE) disclosures of additional pool detail, such as FICO scores and average loan balances, result in further division of mortgage pricing of specified pools from "to be announced" (TBA) mortgage pricing.

Issuer Exposure

If the major risk factors described above are matched but with a limited number of issuers, one significant risk remains, but it can still be diversified away. Event risk—a risk widely watched during periods of significant corporate leveraging events (leveraged buyouts, LBOs) or during periods of significant economic stress—needs to be measured and controlled. Issuer exposure, like exposure to sector and quality, must first be measured in percentage terms versus the issuer weight in the index, because periods of serious economic distress can cause bond prices, regardless of maturity, to drop precipitously. However, setting market value limits without regard to issuer duration risk and issuer index weights is not adequate. Spreads widen immediately after a negative credit event. Therefore, an additional measure of the issuer event risk impact on a portfolio is the impact on portfolio market value of that spread widening. This can be measured by calculating how much of the portfolio duration (duration contribution) comes from the holdings in each issuer. This calculation should also be figured for the index. The basis-point impact on tracking of a spread-widening event will be the spread change (of the issuer) multiplied by the difference in duration contribution (portfolio − index) multiplied by (−1).

Exhibit 43-5 provides an example of this analysis. Issuer XXX Corp has an equal percent weight to the index, but its duration contribution is 0.16 greater. If an event occurred that would widen XXX Corp spreads by 100 basis points, the portfolio would suffer an unfavorable tracking difference of 16 basis points versus the index (100 basis point spread change × 0.16 duration contribution overweight × −1). If the same 100-basis-point widening were to occur to XYZ Corp bonds, the tracking difference would be a favorable 8 basis points even though the percent weight is matched to the index. For effective index fund management, duration contribution exposure limits (versus the index) need to be set at the issuer level.

ENHANCING BOND INDEXING

In sailing, speed comes from paying close attention to the details, not simply from watching the wind. And in bond management, the return versus the benchmark is a function of more than just interest-rate maneuvering. Portfolio managers can trim their portfolio sails to compete more efficiently in the investment management race. Some trimming strategies include lower costs, issue selection, yield-curve positioning, sector and quality positioning, and call-exposure positioning.

Why Enhancements Are Necessary

Since the index does not incur expenses or transaction costs, enhancements are needed just to provide a net return equal to the index. Operating expenses provide a significant headwind, but transaction costs associated with portfolio growth are a major contributor to return shortfalls.

Exhibit 43-6 shows the transaction costs and resulting tracking error associated with single contribution growth and compares it with multiple contribution growth. In this example, the single contribution portfolio has a tracking error of 18 basis points associated with investing net cash flow. In the multiple-contribution portfolio, the tracking error is significantly higher, at 41 basis points,

EXHIBIT 43-5

Issuer Exposure Comparison (Percent of Market Value vs. Duration Contribution)

	Portfolio			***Index***			***Portfolio – Index***	
	Percent of Market Value	**Duration**	**Duration Contribution**	**Percent of Market Value**	**Duration**	**Duration Contribution**	**Percent Difference**	**Contribution Difference**
XXX Corp	4%	8	0.32	4%	4	0.16	0%	0.16
ZZZ Corp	4%	4	0.16	4%	4	0.16	0%	0.00
XYZ Corp	4%	2	0.08	4%	4	0%	0%	–0.08

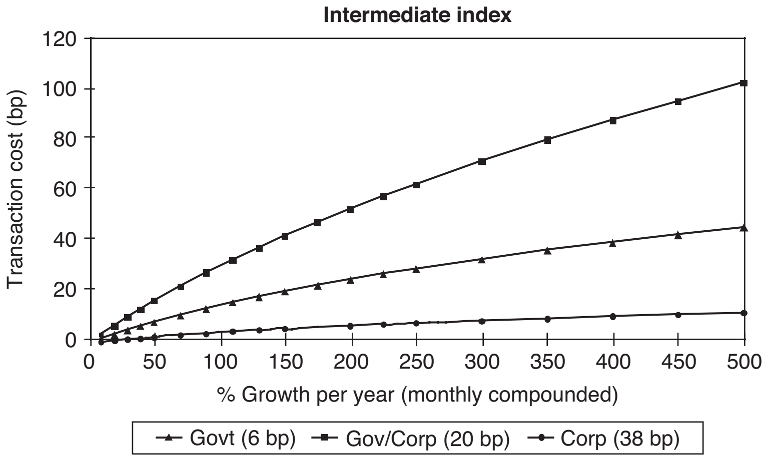
EXHIBIT 43-6

Single Contributionvs. Multiple Contributions

	Portfolio Market Value	Contribution	Trans. Cost ($ at 18 bp)	Now Portfolio Value	Tracking Error from Trans Cost (bp)	(bp)
Single contribution	$ —	$250,000,000	$450,000	$249,550,000	18.0	$\boxed{18.0}$
Multiple contributions	$ —	$ 50,000,000	$ 90,000	$ 49,910,000	18.0	18.0
	$ 49,910,000	$ 50,000,000	$ 90,000	$ 99,820,000	9.0	27.0
	$ 99,820,000	$ 50,000,000	$ 90,000	$149,730,000	6.0	33.1
	$149,730,000	$ 50,000,000	$ 90,000	$199,640,000	4.5	37.6
	$199,640,000	$ 50,000,000	$ 90,000	$249,550,000	3.6	$\boxed{41.2}$
		$250,000,000	$450,000			

EXHIBIT 43-7

Why Enhancements Are Necessary: Return Impact of Transaction Costs over One Year



even though the amount of transaction costs ($450,000) is identical. Therefore, portfolios with high growth rates will suffer additional negative tracking errors. So, enhancements are necessary simply to stay equal to a no-growth or slow-growth portfolio. Exhibit 43-7 shows, in graphical form, the cumulative adverse tracking impact resulting from portfolio growth for Treasury, government/corporate, and corporate portfolios. The greater the growth rate—and/or the less liquid the market—the greater the adverse impact on tracking error.

Lower-Cost Enhancements

One of the simplest, yet most overlooked, forms of enhancement is keeping costs low. Expenses/management fees and transaction costs have a significant impact on portfolio performance.

Active managers work hard—and usually unsuccessfully—to add an incremental 25 to 50 basis points per year to portfolio gross returns. Yet in the mutual fund arena, the average bond fund expense ratio is 50 to 80 basis points greater than that of the lowest-cost index portfolio. As a result, net returns of the high-expense-ratio funds are significantly lower. Even in the indexing arena, expenses vary by large margins. An investor can enhance returns simply by shopping around for the index fund with the lowest expenses, provided the net return is competitive with other index funds. For a plan sponsor with external index fund managers, having the current fund manager and one or two other reputable index fund managers rebid the business every few years will help ensure expenses are as low as possible.

Transaction costs are the other major cost factor. Since bond index funds have low annual turnover (about 40%) versus active portfolios (generally greater than 100%), transaction costs are significantly lower for index portfolios. In addition, electronic trading platforms, which enable managers to increase price competition among dealers, further reduce the transaction-cost impact. It's imperative to include a number of brokers in the bidding process. For rapidly growing portfolios, where most of the transactions are offerings, an effective competitive trading process is essential. An efficient system of comparing the relative value of real-time offerings of target issuers and issues from many different brokers will yield significant transaction cost savings and, as a result, further enhance returns.

Issue Selection Enhancements

For U.S. Treasury securities, the primary tool for selecting cheap bonds is comparing actual bond prices to the theoretical "fitted" price. The theoretical curve minimizes the pricing errors of all Treasury issues in the market, subject to various curve-smoothing rules. Each actual bond's yield is then compared to the bond's fitted yield, which is calculated using the theoretical curve. Bonds yielding more than the fitted yield are cheap; those yielding less are rich. Also useful is an analysis of the recent history of the bond yield versus the fitted yield. This analysis will indicate whether a cheap bond has been getting cheaper or richer.

Corporate issue selection enhancements come primarily from staying clear of deteriorating credits and owning improving credits. The greater the manager's confidence in the ability of the firm's credit analyst to add value via issuer selection, the larger the maximum issuer exposure limit. (See "Primary Bond Indexing Risk Factors—Issuer Exposure" in this chapter.) If the manager does not believe the firm's credit analysts can add value through issuer selection, the diversification among issuers must be greater.

Yield-Curve Enhancements

Various maturities along the term structure are consistently overvalued or undervalued. For example, the 10-year and 30-year Treasury regions tend to be consistently overvalued, due to the liquidity preference of those regions. Strategies that overweight the undervalued maturities and underweight the overvalued maturities, while keeping the same general term structure exposure, have tended to outperform the index. This is similar to looking for the maturities that have the more favorable "rolldown" characteristics—that is, the near-term passage of time may result in the bond rolling down the yield-curve. As a result, the security trades at a lower yield and has more opportunity for price appreciation. Cheap parts of the curve tend to have favorable roll down, while rich parts of the curve (for example, the 30-year area) tend to have little or no roll-down opportunities.

Sector/Quality Enhancements

Sector and quality enhancements take two primary forms: (1) ongoing yield tilt toward short duration corporates, and (2) periodic, minor overweighting or underweighting of sectors or qualities.

The yield-tilt enhancement (also called "corporate substitution") strategy recognizes that the best yield spread per unit of duration risk is available in short-term (under 5-year) corporates. A strategy that underweights 1–5-year government bonds and overweights 1–5-year corporates has tended to increase the yield of the portfolio with a less-than-commensurate increase in risk—except during periods of severe economic stress. An economic downturn that results in significant downgrades from investment-grade to high-yield or leads to significant defaults would prove disastrous to this strategy.

The strategy has proven effective primarily because the yield advantage of a broadly diversified portfolio of short-term corporates requires a significant corporate spread-widening move over a one-year period for short-term corporates to perform as poorly as short-term Treasuries. With the passage of time, the duration of corporate bonds shortens, and the yield spread over comparable Treasury securities generally narrows. These risk-reducing and return-enhancing forces, when combined with the yield-spread advantage, provide compelling reasons to overweight short corporates using a broadly diversified credit portfolio.

The risks involved in the strategy are recessionary spread widening risk and issuer default risk. The recessionary spread widening risk tends to be short-lived and quickly overcome by the increased yield advantage of the strategy. The issuer default risk can be minimized by broad issuer diversification (50 or more issuers), by limiting the strategy to A-rated and higher issuers, and by experienced credit analyst oversight.

The periodic overweighting or underweighting of sectors and qualities is a scaled-back version of active "sector rotation." This can be implemented on a cost-effective basis by allowing new cash flow (net new portfolio growth) to facilitate the mismatching. For example, if spreads are narrow going into the fourth quarter and the manager expects some widening, new money may be invested in Treasury securities to a moderate degree, resulting in a modest reduction in the corporate exposure versus the index. Once the corporate spread widening materializes, Treasury securities (with low transaction costs) can be sold and corporates overweighted. A strategy of outright selling of corporates to buy Treasury securities is always difficult to justify because of the higher corporate transaction costs involved, not to mention the yield "penalty" associated with Treasury securities.

Call Exposure Enhancements

The option-adjusted duration of a callable bond is the average of the model duration, if rates rise and fall marginally. These durations under rising and falling rates can be quite different for bonds trading at a price where the bond changes from trading to maturity, to trading to call (or vice versa). The result is a situation where the bond's actual performance could be significantly different than expected given its beginning-of-period option-adjusted duration.

Generally, the greater the expected yield change, the greater is the desire for more call protection. For premium callable bonds (bonds trading to call), the empirical duration (observed price sensitivity) tends to be less than the option-adjusted duration, resulting in underperformance during periods when rates are falling. For discount callable bonds (bonds trading to maturity), the empirical duration tends to be greater than the option-adjusted duration, resulting in underperformance in rising-rate environments. Any large deviations from the index exposure to call risk should recognize the potential significant tracking implications and the market directionality of the bet.

MEASURING SUCCESS

Of course, you can't manage what you can't measure. Managers understand this, but often find themselves without the proper measurement tools. Specifically, they lack accurate ways to gauge the extent of their bets, and the value added or lost from these bets. We've already covered measuring the extent of the bets in this chapter's sections on risk factors and enhancements. In this section, we'll explore how to measure whether any value has been added—and, if so, where the added value came from.

Outperform Adjusted Index Returns

Returning to the sailing theme, it's always critical to understand how the portfolio boat is faring against the index boat. Is the portfolio gaining any ground on the index? To evaluate relative performance, the portfolio returns must be adjusted for pricing, expenses, and transaction costs for growth and rebalancing. Pricing is a key consideration, especially in enhanced indexing, where deviations versus the index are small and pricing errors can hide valuable information. Whatever benchmark index is used, the portfolio needs to be repriced with the index providers' prices. Small differences in either the pricing time or the pricing matrix may result in significant differences (among pricing services) in periodic returns over short measurement periods. Over longer periods, these pricing differences will wash away. For value-added measurement purposes, though, periodic pricing accuracy is critical.

Since the index does not have transaction costs associated with asset growth, principal reinvestment, or income reinvestment, accurate adjustments to portfolio returns are needed to account for these differences. A simple way is to maintain a trading log with implied transaction costs as a percentage of total portfolio assets. The periodic summation of these implied costs provides a good estimate of tracking error drag associated with growth and income reinvestment.

Finally, an adjustment for expenses is required. As we discussed earlier, keeping expenses low is a simple way to enhance returns. Nevertheless, portfolio returns should be "grossed up" by these expenses to keep the portfolio on an equal footing with the index for measurement purposes.

An enhanced indexing strategy that has good risk management and diversified enhancements should be able to consistently outperform the index during most periods. Falling below the index return over the 12 months would most likely be the result either of not matching the index risk properly, of enhancement strategies that were not adequately diversified, or of significant market stresses (three or more standard deviation events) adversely affecting the enhancement strategies.

Low and Stable Monthly Tracking Differences

The other measure of indexing success is how closely the portfolio is exposed to the same risk factors as the index. This can be measured by evaluating the rolling 12-month standard deviation of *adjusted* tracking differences of the portfolio versus the index. If a portfolio is properly exposed to the index risk factors, the standard deviation will be low and stable over most periods, as we see. Periods of excessive market stress and spread volatility may result in higher standard deviations of tracking differences. However, the increases should be roughly proportional to the spread volatility increase or explainable by idiosyncratic credit risk (sample risk).

Consistent Positive Information Ratios

The information ratio is a good way to evaluate enhanced indexing success. This measures the amount of value added versus the index relative to the risk taken. It can be calculated by dividing the trailing 12-month tracking difference (adjusted for expenses, pricing, and transaction costs of growth) by the annualized trailing 12-month standard deviation of monthly adjusted tracking errors. An effective and diversified enhanced indexing strategy should keep this ratio in the range of 1 to 3 over most periods.

Detailed Performance Attribution

A manager needs excellent performance attribution tools to accurately measure the success of risk factor management and the enhancement strategies. The performance attribution analysis should attribute tracking error to term structure factors, sector bets, quality bets, and issue selection across sectors and qualities.

The term structure attribution should be analyzed at the portfolio level versus the index. The sector and quality attribution (allocation and issue selection) should be analyzed at the sector and subsector levels (detailed sector and maturity categories) with the ability to drill down to issue-level detail. Issue performance should be risk-adjusted (versus Treasury equivalent returns) with subsector, sector, and portfolio returns rolled up from the security level. This level of attribution will provide the manager with the tools to measure, with precision, the risk matching and return enhancing strategies. The result: winning the race against both the index and most managers.

KEY POINTS

- Full replication of a broad bond index is inefficient, if not impossible.
- Active bond managers intentionally position the portfolio with mismatches in risk factors in an attempt to add value above the index return.
- The core/satellite approach often uses low cost index strategies for the core portfolio and a variety of higher cost active strategies for the satellite strategies.
- The satellite portion of a portfolio focuses on the less liquid sectors which are expected to have lower correlations with the broad liquid core and where issue selection is expected to add value.
- Reasons to index bond include broad diversification, low cost, competitive performance, consistent relative performance, market performance predictability, and a time-tested record of success.
- In selecting an index for a given risk level, generally a broader index (sectors, maturities, issuers, etc.) is better than a narrow index.
- Subindices of a broad index can be created to capture different risk/return profiles (e.g., varying durations, varying credit exposures, etc.).
- For investors who are risk-averse (regarding possible loss of principal), a short-term or intermediate-term index is more appropriate than a long-term index.
- If stability and durability of income are the primary concerns, the long-term portfolio is the least risky, and the short-term portfolio the most risky.
- The primary bond index risk factors are portfolio adjusted duration, portfolio key rate duration exposures, portfolio sector and quality exposures (in percent and contribution to duration), mortgage coupon and maturity exposures, and issuer diversification.
- Since index returns are not adjusted to expenses and transactions costs, enhancements are needed just to provide a net return equal to the index.
- Return enhancements to help offset index portfolio management and transaction costs include lowering management and operating

costs, issue selection strategies, yield-curve strategies, sector/quality strategies, and optimal call exposure strategies.

- Measuring success entails evaluating value added relative to a benchmark in the context of risk assumed relative to the benchmark.

CHAPTER
FORTY-FOUR

TRADING IN THE BOND MARKET

Gueorgui S. Konstantinov, Ph.D., CAIA, FDP
Senior Portfolio Manager
LBBW Asset Management

Momtchil Pojarliev, Ph.D., CFA
Head of Currencies
BNP Paribas Asset Management

A substantial part of microstructure market analysis is focused on trading equities. As a natural development of academic research on equities, similar metrics are applied to trading fixed income. However, not only does fixed income behave differently to equities, but the metrics applied to analyzing trading activities, and specifically how bond managers make transactions, are impractical to some extent. At least these metrics and tools need adjustments or require new and sophisticated data to allow for gathering the appropriate information and thus to form a reliable basis for comprehensive investigation of liquidity, spreads, and other trading variables.[1]

Whereas the price of a publicly traded equity share is easily observable, a question such as "What is the price of the current 10-year U.S. Treasury bond?" is misleading. Corporate bonds, for example, trade in the over-the-counter (OTC) market, thus prices are not as observable and reliable as equities. The most applied measure of market liquidity is the bid–ask spread. Bid–ask spreads represent the difference between the highest price that a buyer is willing to pay for a bond and the lowest price that a seller is willing to accept. Moreover, bond prices in the real world are based on quantities traded, or are order-driven as opposed to quote-driven. More precisely, the ask bond price and then the executed price could diverge substantially for an order of \$1 million or \$10 million notional amount. In fact, this is the rule, not the exception. However, the rule makes it clear that price metrics could be approximative solutions within an analytical process. In the above

example, not only the quoted price but the executed price of a U.S. Treasury bond depends on the notional amount and thus on the order size. In reality, specific metrics are reliable indicators; however, the challenges arise when managing fixed income portfolios with real money, and in particular when managing cash bonds and not synthetic bond replicator products using derivatives.

In this chapter we focus on several problems, issues, challenges, tools, developments, and tendencies that help to mitigate the problems bond portfolio managers face when they trade. This chapter concentrates on how bond portfolio managers trade fixed income securities, and investigates the important aspects, common issues, and recent developments. The asset class to which fixed income securities is mostly related is foreign exchange (FX). In the following, we describe the developments and common ground in trading of both fixed income instruments (e.g., corporate and government bonds) and foreign exchange. However, prior to investigating these issues and challenges, we take one step back and first describe the state of the art and the current development in bond markets, trading, and portfolio management.

FIXED INCOME LIQUIDITY

Bond trading depends on liquidity. Fixed income trading has developed tremendously in recent years. The most important determinant of trading is for the assets to be liquid. Specifically, the structure of the market has changed so much that more and more fixed income instruments are exchanged electronically. What has caused this transition? The development of electronic trading has its drivers. Exploring the drivers of the growth reveals information about the complexity of the fixed income market. This complexity is driven by the growing number of interacting agents and the high number of transactions in today's financial world. However, this complexity is organized. The development of high-frequency trading is a simple catalyst for this progress. Perhaps the strongest driver of the development of electronic trading is liquidity. Specifically, there are three reasons for the growing need for liquidity in fixed income markets:[2]

1. Reduction in supply and demand for liquidity
2. The diverse market drivers of market liquidity
3. A regime shift

Supply–Demand Relationship

The current stage in the financial markets is largely described by lower supply and a large demand for liquidity. As market-maker activities are decreasing for

2. Committee on Global Financial System Fixed Income Market Liquidity, CGFS Papers No. 55, Bank of International Settlements (January 2016).

regulatory and cost-saving reasons, which results in less liquidity, the demand for liquidity remains high. In fact, rapidly decreasing interest rates in recent years have increased the supply of bonds in the market via new issues. Primary bond market activities turned profitable for investment banks. The growth in assets under management of asset managers and increased allocation to fixed income securities helped to grow the market. Now, asset management companies determine the demand for liquidity. This asymmetric structure in the market requires quick order matching, which becomes fragile in times of financial market stress.

What drives fragile markets is the liquidity itself. Whereas U.S. Treasuries, and European, and Japanese government bonds remain the most liquid fixed income securities with tiny bid–ask spreads, the liquidity of corporate bonds with less than investment-grade ratings has declined rapidly. Historical analysis provides information that government bonds barely react to fierce market stress and remain highly liquid. An interesting example is the situation in March 2011, when the Fukushima nuclear power plant exploded. A very few hours after the incident, liquidity in the Japanese bond market disappeared, leaving highly liquid bonds—for example, those of the largest Japanese automakers—completely illiquid.

The research on liquidity is mainly associated with investigating equity market liquidity. For equities, the bid–ask spread is widely used and often applied to fixed income securities. In fixed income, researchers measure liquidity as changes of the Chicago Board Options Exchange Volatility Index (VIX).[3] However, the practical applicability of such metrics departs significantly from theoretical metrics. Loistl and Konstantinov showed that the market emergence points to a larger order size and transactions, which in turn reflect the prices and services provided by market participants.[4] Thus, prices are determined by quantities and not vice versa. Given that the price is a function of the quantity of bonds ordered, the bid–ask spreads depend on market segment and the size of the notional amount. The primary bond market expansion has been tremendous in recent years. However, the expansion in trading volumes is slower than the growth in the market for new issues of corporate debt. The low-interest-rate environment is favorable for debt issuance as companies can refinance their debt at low interest rates.

Complexity of Market Drivers

The financial market as whole is in a state of transition. The growing velocity of information exchange as a result of digitalization and big data handling/storage facilities has enabled less cost-intensive data processing and execution of orders. The substantial growth of digital services and their application in finance have

made large cost savings possible; however, measures taken by some competitors have forced the crowd to follow. This translates into a shift of operating processes in organizations that has led to re-thinking of the standard business model of execution and trading. As funds grow in size, information flow in the markets has increased, and automated data processing in order management more efficiently satisfies the growing needs for liquidity.

The financial crisis in 2008 marked a focal point in the newest developments of regulation. Driven by a growing need to prevent fraud and enable a much higher level of transparency, banks, nonbank financial institutions, and investors faced the challenge of rethinking their market activities. The change forced financial players to restructure risk-taking and proprietary traders. In fact, market-makers continued to decrease inventories. This remains an issue, because inventories in corporate bonds remain low in difficult market situations, which signals diminishing capacity and inclination to provide market liquidity and funds. In a nutshell, dealers and market-makers engage in transactions only if they can easily and quickly match orders and execute orders. However, in the case of large market volatility, these dealers pull back from the market and cancel market-making activities. This has enormous effects on market liquidity, or more precisely, there is a lack of liquidity exactly when it is most needed.

Monetary policy has changed greatly in recent years. Specifically, central banks are involved in many liquidity-providing activities. The European Central Bank (ECB), the Federal Reserve (Fed), and the Bank of Japan (BoJ) are examples of monetary institutions engaged in providing activities to the market in the form of monetary operations such as asset purchases and the quantitative easing program in 2013. ECB has long been an example of an active market player for its policy for corporate and government bond purchase mechanisms, pumping liquidity into the market, and thus taking over the role of an investment bank market-maker.

An indication of the changing market conditions is the February/March 2020 overall market development as Covid-19 heavily hit worldwide financial markets. As a consequence, the U.S. High Yield All Sectors Option-Adjusted-Spread hit a record high level of 1091 bps. This is a tremendous increase from the average level of roughly 440 bps in normal market conditions. Despite the increased spreads, banks were not interested in taking risks. There were even many bonds for which it was not possible to get bids and to sell. To respond to the increased need for liquidity, central banks started purchase programs to buy corporate debt. However, under §14 of the Federal Reserve Act, the Fed was not allowed to purchase corporate debt securities. With a change in the Fed regulatory structure, purchases are now allowed, thus providing demand for and liquidity to the severely hit U.S. high-yield market. Both Fed and ECB purchase programs are increasing liquidity in the generally illiquid corporate bonds with long-term maturities. Therefore, central bank policy changes the structure of the market, influences bid–ask spreads and market risk, and as a result even shifts bond portfolio allocation to longer-duration bonds, with a biased barbell structure and risk–return profiles. In general, the purchase programs by the central banks announced in the March 2020 as a policy change is an example of the nonstationarity of bond markets, time-varying market risk that cannot be explained by constant factors and exposures. Bond managers must constantly adjust their views and expectations in accordance with the changing bond market structure. Thus, portfolios must be rebalanced as bond market–related factors are time-variant, as shown recently by de Jong and Fabozzi.[5] We will show the bid–ask and market relations in detail in the next sections.

Regime Shift

The market situation changed significantly after the Global Financial Crisis of 2008 (GFC). Pre-GFC market-making differed from post-crisis activities in terms of risk management, counterparty, market, and funding risks. The completely different set-up after 2008, and necessary market adjustments helped with the transition of liquidity to new platforms. In order to improve order matching and execution, technological innovations caused cost reductions. Since then, technology, algorithms, and data gathering/processing have heavily influenced financial markets. Major market-makers considered data processing and the development of algorithms in liquidity prediction. However, in periods of financial stress, banks refrain from providing liquidity. These issues reflect the advantages and disadvantages of circuit breakers.

New Market Environment

The new market environment grows in organized complexity as it allows multiple levels of control, risk management, effectiveness, flexibility, scalability, data processing, monitoring, and cost reduction. The various interacting entities in an electronic exchange allow both vertical and horizon integration of processes. Regulators might further focus on the impact of algorithms in trading. In general, the most liquid segments in the fixed income market such as spot deals in foreign exchange and government bonds have increased in liquidity even further. As a result, market depth has increased, and bid–ask spreads are narrowing. For example, the Committee on the Global Financial System of the Bank of International Settlements reports that global inventories for corporate bonds have been steadily declining since 2008. However, the inventories in government bonds remain stable and have even increased, most notably those of asset management companies and banks in Japan and diverse financial institutions from the Eurozone.

The rise in electronic trading and the set-up of electronic platforms in fixed income market gave birth to the strong growth of robo-advisors. Robo-advisors provide direct business-to-business (B2B) and business-to-clients (B2C)

5. Marielle de Jong and Frank J. Fabozzi, "The Market Risk of Corporate Bonds," *Journal of Portfolio Management* 46(2), 2020, pp. 92–105.

services, without intermediaries. This results in a very cost-effective and less time-consuming way to attract customers and execute trades. Investment managers such as Vanguard and BlackRock are notable examples of asset management companies with large fixed income assets under management, which offer such products. Thus, electronic B2B, and B2C platforms provide order-driven execution, which results in low bid–ask spreads and better liquidity.

TRADING APPROACHES

There are three types of trading. They differ in terms of the specific intention and mechanics.

- Request for quote
- Order-placement
- Auction-driven

The *request for quote* is a convenient way for a bond manager to request bond prices from multiple dealers. Upon receipt of a request, the dealers can respond with price quotes on specific nominal sizes. Execution occurs if a bid is hit or an ask is "lifted" (accepted). In this case, currency management in the case of multiple currency positions can be executed prior to the bond trade, or afterward. The risk in the former is that a price quote can significantly depart from the expected price of a certain nominal amount. As a consequence, a bond manager might withdraw from a trade and leave a currency position in a portfolio. Thus, bonds are often executed first, and foreign exchange transaction placed afterward.

In the case of an *order-placement* bond, managers place orders against quotes provided by market-makers or liquidity providers. Orders are executed when orders (quantities) submitted are matched with the quantities of market-makers. This is a highly specific issue for fixed income securities. The prices are usually quoted, but depend on quantities. Therefore, in corporate bonds and fixed income securities, prices are quoted; however, orders depending on the size, or notional amount, move the price significantly. For example, Bloomberg's operating management system "AIM" is a transparent and reliable system for placing orders, price quotes, and execution. After the order execution, a transaction confirmation is generated that can be assigned automatically to the back- and middle-offices of an asset management company.

When trading multicurrency bonds, the bond manager has several options. The first, and the most inconvenient, is to require automatic conversion in the basis currency. For example, a U.S.-based investor buys a German government bond and a French corporate bond with notional size of 10 million and 5 million, at the price of 102.95 and 109.52, respectively. Automatic conversion of the exchange rate is the most unfavorable choice of action because the seller (bank or market-maker) usually converts the amount using a price close to the middle price (between the bid and ask price) for the FX spot transaction. The second option is for a bond manager to place foreign exchange orders separately and thus use electronic trading for FX spot transactions, which allow for narrow bid–ask spreads and low costs. The third option is for the bond manager to apply an overlay strategy for the foreign-exchange exposure of the portfolio, which we describe in the last section of this chapter.

In general, the investment process determines the order sequence—which exposure should be prioritized.[6] In general, a discretionary manager responsible for both fixed income and foreign-exchange trading can apply tactically different strategies. For overlay strategies, however, the fixed income exposure is first determined, and the weights applied to trade foreign exchange.

New Issues (*Auctions*) are primarily used in new issues or book-building. In a general case, the lead manager of an issue supplies information regarding, for example, the issue size, maturity, yield, spread, issuer rating, and rules. Bond managers indicate interest and thus place orders in the new issues indicating the size and limit on the spread. For example, in a hard currency (EUR) of a BBB+-rated 30-year corporate bond new issue with an issue size of $500 million, a portfolio manager of a $400 million bond fund might place an order of $9 million and indicate a spread limit of +125 basis points.[7] Subsequently, the orders are summed up by the lead manager of the issue and allocation is made after closing the deal. Depending on the interest—for example, a 4.5× oversubscribed new issue might (and most likely will) result in less allocated capital as initially placed.

Now the bond portfolio manager can place a foreign exchange order in the spot market or use currency forwards to allocate capital for the bond for a future settlement day. This is an alpha source for bond managers to tactically make FX deals, in particular in the highly volatile currency market environment. Both trades are easily executed using electronic trading. If, for example, the new issue bond will be settled in seven days, the manager could use his or her skill in the foreign-exchange market to cover the position due in seven days. To illustrate this, imagine a bond manager participates in a new issue of a German corporate bond. The nominal value the bond manager should receive is EUR 10 million at a price of 99.699. The bond manager could buy euros at the spot market now and wait seven days. This is a passive set-up, or a good solution if the euro is expected to appreciate in the next few days. Alternatively, the manager can make a forward transaction. A more aggressive way to act is to consider the current EUR–USD and apply active foreign exchange management. If the manager expects the euro to depreciate in the next few days due to specific reasons, the manager could speculate and short sell and then buy euros cheaper to cover his bond position.

6. For more information, see Chapter 57.

7. These numbers are only informative and for illustrative purposes and may diverge depending on the market, yield curve, sector, and interest environment.

MECHANICS OF BOND AND FOREIGN EXCHANGE TRADING

In this section, we turn our attention to the practical issues of bond trading. Specifically, we describe the relation between liquidity, bid–ask spreads, portfolio size, and portfolio weights that result from portfolio optimizations. Moreover, we show several challenges bond managers face when executing orders and highlight how innovations in the bond market like electronic and algorithmic trading, ETFs, and execution platforms change the market structure. We start with the simple decomposition of bond prices and how they affect portfolio trading in general.

Determinants of Bond Prices

As a starting point, we can define the determinants of bond prices. The price of a fixed income security $P(t,Q)$ can be shown as

$$P(t,Q) = T\left(t, s_t + OAS_t + l_t + e_t\right)$$

In words, the bond price at time t is a function of the (local currency) interest rate curve s used to discount the cash flows, the option-adjusted spread (OAS) as a measure for credit risk, the liquidity premium l (or the degree of exertion to buy or sell a bond), and other residual factors e. A large OAS, or widening spread is a measure for higher risk, and vice versa. It is important to note that a fair value model based on a sector-specific spot curve might estimate the OAS and thus the theoretical price to match the observable bid or ask price of a bond; however, the true, or real, price might diverge from that fair value due to liquidity risk and/or other factors. A central part of the next sections in this chapter is the analysis of the liquidity as measured by the bid–ask spreads and the challenges to trade they pose for bond managers. The liquidity is single security dependent. Thus, a bond market sector liquidity is the sum of the specific single liquidity metrics of the bonds within this sector. However, a bond sector liquidity is vulnerable to several factors, which we show in the next sections.

Trading in the Bond Market

There are two important questions that are almost never explained in textbooks, and which we would like to discuss: How do bond managers trade bonds? How do bond managers calculate the specific quantity of a bond to buy? These questions are most relevant when considering a quantitative investment process with optimizations producing portfolio weights.

Imagine a specific allocation and selection investment process, according to which exact single security weights are derived. Then bond managers have to estimate the amount they need to cover that estimated exposure (weight). The variables the bond manager has to consider are portfolio volume (or available funds), weight, prices, and quantities (notional value). To show the relevance and relation of bond prices, bond notional bid–ask spreads, and even foreign exchange, consider the following simplified example of two 400 million bond portfolios and three bonds in Exhibit 44-1 with different basis currencies (euro and U.S. dollar). It is convenient to express the bid–ask spreads as basis points. Therefore, we compute the bid–ask spreads as log returns of ask and bid prices.

The results of a quantitative process show that the bond manager has three bonds to allocate capital to. The weight in a U.S. Treasury bond is 7.18%. Given quoted bond prices—specifically, the price as the manager buys the bonds—the portfolio weight w_i is multiplied by the portfolio volume V_{PF}, or the capital available for investing. Then, by dividing the product ($V_{PF}\, w_i$) by the ask bond price (102.83), the manager calculates the notional amount, which the manager has to buy. Therefore, we use ask prices. In our case, the notional amount is 27,920,000.

It is important to note that corporate bonds are quoted in 1/8 increments, while government bills, notes, and bonds are quoted in increments of 1/32. It is also important to note that a bond quote is the price at which a bond traded, expressed as a percentage of par value. For example, if a fixed income security is quoted at 102.83 that means it is trading at 102.83% of par value. The percentage notation must be considered when calculating the notional amounts. As the bond portfolio manager can recognize, the prices, bid–ask spreads, and notional amount are directly related. Large swings in the quoted prices would result in different notional amounts, which in turn would change the weight of the single security. This is an important issue as market volatility affects the bond prices and thus spreads. As a consequence, the current portfolio allocation would drift from the desired allocation. To mitigate this risk, basket trades are applied. The following equation describes the technique to estimate the notional amount of bond (q_i):

$$q_i = \frac{Portfolio\ Exposure_{Basis\ Currency}}{P_i^{ASK}} = \frac{V_{PF} * w_i}{P_i^{ASK}}$$

Let us extend the analysis and include foreign exchange and bond portfolio exposure in local currency debt instruments. The second and third bonds with weights of 2.82% and 3.68%, respectively, are allocated in EUR and NZD. Whereas the previous technique applies again, a division for the local currency exposure is necessary as the amount ($V_{PF}\, w_i$) would only estimate the capital allocated in EUR and NZD in the portfolio basis currency (the U.S. dollar for example). Therefore, dividing the product by the current ask price for NZD–USD would adjust the notional amount to reflect local currency exposure. Note, that to correctly adjust the volumes, price notation is used for the foreign exchange ($FX_i^{fx-\mathrm{BASIS}}$). The following equation describes the technique:

$$q_i = \frac{\text{Portfolio Exposure}_{\text{Basis Currency}}}{P_i^{\text{ASK}}} = \frac{V_{PF} * w_i}{P_i^{\text{ASK}} * FX_i^{fx-\text{BASIS}}}$$

EXHIBIT 44-1

It is easy to see that the bond prices are the same for every investor and are unrelated to the portfolio basis currency (U.S. dollar and euro). However, the notional amounts that the bond portfolio manager has to order depend on the basis currency and thus the demanded notional amount is effectively adjusted by the foreign-exchange ask price. A similar rule applies to selling fixed income securities considering bid prices. However, selling is easier as bond managers know the exposure and notional amount in their portfolios. Therefore, rebalancing portfolios is directly affected by bid–ask spreads, which in turn affect notional amounts.

An important adjustment is necessary when estimating the notional amounts for a bond portfolio. Often bonds trade in minimal pieces, or increments depending on the issue (for example 100, 1000, or 100,000,000). For example, a notional of 27,923,344 (which is the exact notional value) is not tradable. A reasonable size would be 27,920,000.

When and How Do Bond Managers Trade?

Bond managers might trade because of redemptions, inflows, allocation adjustments, regulatory issues, urgent client needs for liquidity, and the like. Whereas the question "when" do bond managers trade is to some extent misleading as it refers to timing, necessities, idiosyncratic and many other reasons, the major focus of this chapter is the mechanics of how bond managers trade.

Bond managers have in general two alternatives when trading. The first is discretionary, that is, trading single securities based on relative value analysis, rich/cheap valuation, new issues, portfolio adjustments involving high conviction trades based on news flows, changes in single bond fundamentals, corporate events, down rating or upgrades, and so on. The trading frequency of discretionary bond portfolio managers is irregular. Put differently, discretionary bond managers might implement bets sporadically as an immediate consequence of information flow. It is important to note that discretionary managers might base their decisions both on quantitative tools and/or qualitative analysis. The following simple example illustrates the discretionary style.

Suppose that a bond manager decides to buy long-term Italian government bonds in euros as a consequence of the loose monetary policy and re-started liquidity program of a central bank, despite the fact that spreads are widening, yields are rising, the economic system is becoming fragile, and institutional investors are avoiding Italian debt. At the same time, this decision can be based on quantitative indicators and analysis. Specifically, a discretionary fund manager might employ factor models as add-on tools, which have detected less crowded behavior in Italian debt. In addition, quantitative valuation techniques might provide information on the roll down returns, spreads, and duration positioning. As a consequence, the bond manager of an international bond portfolio might increase the exposure to the EUR-USD exchange rate, and thus emphasizes more carry returns based on a large interest rate differential versus the manager's basis currency (e.g., the U.S. dollar). A comparative analysis might show that an overweight of Italian government bonds versus Italian industrials is currently preferable. As the example illustrates, a single decision might affect more sub-asset classes (geographic allocation, industry, sectors, foreign exchange, duration, maturity allocation, etc.) that are part of a bond portfolio.

The second way is based on basket trades. More generally, basket trades have become the domain for systematic bond portfolios, or bond portfolios managed according to a quantitative investment process. Rebalancing of funds to reflect the changing market conditions or model reallocation, factor exposure, and related issues requires the execution of basket, or portfolio, trades that involve a large number of single constituents. Within a quantitative investment process, the duration, maturity allocation, and other risk-return metrics are considered in a process of rebalancing; thus, a basket comprises several buy and sell orders.

Following are the issues and challenges that affect portfolio trading and specifically the choice of trading method, functionality, and success:

- Bid–ask spreads
- Portfolio size and transaction costs
- Portfolio allocation
- Illiquid fixed income securities
- Market volatility

In fact, these challenges affect the bond manager's activities to a large extent, as markets constantly change, and bond portfolio complexity increases. The natural way to highlight how the different styles deal with and are affected by these four issues is to consider practical examples.

Slimane and de Jong observed that there is a positive relationship between bid–ask spreads, and maturity.[8] Bid–ask spreads are then inversely related to bond issue size, with larger issues having lower spreads. More complex bond portfolios allocated to different sectors, maturities, countries, currencies, and sub-asset classes result in larger bid–ask spreads and liquidity risk. Although the correlation coefficient between bid–ask spreads and credit rating seems to be 0.84, correlation is not causation and in the period after the GFC of 2008, the market has changed tremendously, making it even harder to detect and investigate causation.

Increasing bond market activities from central banks shift the real pricing. Bid–ask spreads are indicative for measuring bond market liquidity. However, they are only approximative solutions as indicators. Bond prices are results of notional amounts exchanged on the market; thus, prices depend on quantities. Bid–ask spreads help to indicate possible liquidity traps, but their magnitude and meaning diverge significantly from the real executed prices that depend on the nominal amount sold or bought, and market demand and supply. During financial turmoil,

8. Mohamed Ben Slimane and Marielle de Jong, "Bond Liquidity Scores," *Journal of Fixed Income* 27(1), 2017, pp. 77–82.

there is heavy involvement of central banks, which supply liquidity and engage in market activities. As mentioned earlier, the Fed, ECB, and the BoJ are just a few important examples for active market players trading fixed income securities. This results in a massive shift in the demand for eligible purchase securities, in particular short-term investment-grade bonds, and less demand for noninvestment-grade securities, which are not included in purchase programs. As a consequence, long-term investment-grade corporate bonds, which in general have a higher credit rating, price, maturity, yield curve, duration, and spread risk, become more liquid. Bid–ask quotes for short-term investment-grade securities become highly attractive and indicate liquidity; however, ask quotes are often only generic. As a result, there are two problems: (1) the biased power of bid–ask spreads to indicate liquidity and (2) the restricted ability to execute trades. The bid–ask spreads are heavily impacted by supply and demand, preferred allocation, interest rate dynamics, fundamentals, business cycle and market volatility, and the quantities exchanged.

The following two examples help to illustrate the problem. In Exhibit 44-2, a bond manager applies both fundamental analysis and quantitative-based yield curve analysis to a specific sector. As a result, a switch in short-term (1.5 years-to-maturity) and mid-term (roughly 5.5 years-to-maturity) bonds seems reasonable. The bond manager sells the short-term bond with a larger spread of 178 bps (rich) and buys a very favorable, fundamentally solid short-term bond with a similar roll down return and an OAS of −10 bps. Additionally, the bond manager sells a fairly valued bond and buys a cheaper alternative with a 1 bp higher roll down and OAS of 0.48%. The buying opportunities are favorable with stronger fundamentals—solid EBITDA margins, thus ability to pay debt. Whereas bid–ask spreads indicate the best liquidity in short-term bond SUFP 2 1/2 09/06/21, no market participant provides a reasonable price for this security, thus the trade is unexecutable (denoted by “N/A”). Counterintuitively, the bid–ask spread does not indicate illiquidity (the highest spread is only 35 bps). On the contrary, the low bid–ask spread suggests sufficient liquidity. A real price of 99.68 is offered for 1.5 million. There is an additional issue regarding the supply and demand, affecting spreads, which we will highlight shortly.

Alternatively, a bond manager tries to sell a high-yield bond with an issue size of $500 million and short-maturity (roughly 3.5 years-to-maturity) as shown in Exhibit 44-3. The bid–ask spread is the difference between the highest price that a buyer is willing to pay for a fixed income security and the lowest price that a seller is willing to accept. Although the quoted bid–ask spread indicates reasonable liquidity, the manager receives a rejected order for a notional amount of 500,000 from five brokers. However, although both the bid–ask and the volume-weighted bid–ask spread does not definitely indicate low volumes, a trade simply is not possible, not even at a price with a reasonable discount on the bid price. Thus, on a single trading level, it is impossible to sell the bond. The only option left is to sell it within a portfolio trade—a basket of securities.

A specific case has to be discussed that reflects the dynamics of the option-adjusted spread and the movement of interest rate curves. From the practitioner’s

point of view there are two possible dynamics in the credit spreads and interest rate movements: (1) a technical correlation and (2) fundamental correlation as measured for example between the five-year swap yield and the nonfinancial credit spreads. Whereas in a case of fundamental correlation a rise in yields is compensated by narrowing of spreads due to economic growth, for example, a technical correlation takes place as a result of allocation shifts. In the case of technical correlation, both spreads and yield move in the same direction. The latter case is typical in times with a low yield environment and times of financial stress—for example, in 2003, 2009, 2011, 2016, and 2020. The option-adjusted spreads in combination with liquidity might cause bond prices to drift further from the bid–ask quotes. This is in particular relevant in times of financial market turbulence. For the spread factor price movement, the approach suggested by Ben Dor, Dynkin, Hyman, Houweling, van Leeuwen, and Penninga is a suitable enhancement.[9]

The previous examples show that single trading of bonds electronically can produce unfavorable solutions as it seems to be impossible to sell bonds or, even worse, to consider bond market liquidity as merely measured by bid–ask spreads. This example stresses the challenges when dealing with illiquid securities. Due to the large impact of a "liquidity premium," this premium is only capitalized over long holding periods. However these periods could harm portfolio risk–return profiles. Thus, fund managers can mitigate the impact of illiquid securities by trading them in baskets using "Bid Wanted in Competition" (BWIC).

The bid–ask spreads under normal market conditions for several markets are shown in Exhibit 44-4. Typically, emerging market debt trades at larger spreads than developed market bonds.

9. Arik Ben Dor, Lev Dynkin, Jay Hyman, Patrick Houweling, Erik van Leeuwen, and Olaf Penninga, "Duration Times Spread," *Journal of Portfolio Management* 33(2), 2007, pp. 77–100.

Finally, to show the effects of the bid–ask spreads, portfolio size, and transaction costs, we show a basket portfolio that comprises multiple asset classes executed as single trades. A current portfolio basket of $50 million, comprising 63 bonds, is summarized in Exhibit 44-5. Specifically, this is an example of portfolio turnover in international government bonds, financials, foreign exchange, utilities, banks, and domestic government bonds.

EXHIBIT 44-5

Single Bond Electronic Trading of a Real Bond Portfolio

Sector	Bid–Ask Spread	Executed Price (Bid/Ask) vs. Quoted Bid/Ask
GOVERNMENT BONDS (NATIONAL)	0.004	–0.007
BANK	0.057	0.101
FINANCIAL	0.017	0.056
SPECIAL PURPOSE	0.005	0.033
INDUSTRIAL	0.038	0.123
UTILITY	0.017	0.095
GOVERNMENT BONDS (INTERNATIONAL ex EM)	0.011	0.086
FOREIGN EXCHANGE (AUD, CAD, GBP, SEK, NOK)	0.108	0.073

In general, a portfolio basket of that size allows for a quick turnover and moderate transaction costs. When considering bid–ask spreads, one can easily observe that they are narrow, with the largest liquidity issues associated with banks, industrials, and utilities. However, when comparing the bid–ask spreads using the real executed prices, a different picture emerges. Specifically, the bid–ask spreads for the local currency debt, banks, industrials, and utilities are much larger than those initially assumed or revealed by the simple quoted bid and ask prices. More importantly, it is the magnitude of change between the bid–ask quotes and the real execution that matters. Put differently, whereas the bid–ask spread might indicate some liquidity issues for fixed income securities, the real prices indicate that the liquidity issues are much larger. To add additional complexity, the market risk of international bonds comprises multiple interest rate curves, as noted by de Jong and. Fabozzi.[10] More precisely, a bid-size spread signaling sufficient liquidity does not necessary indicate robust price setting.

10. De Jong and Fabozzi, "The Market Risk of Corporate Bonds."

Determinants of Bid–Ask Spreads

The last few examples help to answer the question: What impacts the bid–ask spreads? The bid–ask spreads are heavily influenced by portfolio size, market cycle and market volatility, demand and supply, monetary policy (in particular, purchase programs), and allocation. There is a further important factor that deserves attention. In fact, a low-interest-rate environment is supportive for new issuance. On-the-run bonds come at higher liquidity, and thus the off-the-run securities decrease in liquidity and prices drop as yields rise. As interest rates decrease, yields (and eventually spreads) on outstanding bonds rise relative to new issues that are paying lower cash flows, discounted with lower yields. Remember, there is an inverse relationship between cash flows (coupon size) and duration. Furthermore, lower cash flows are discounted much stronger compared to large coupons. The central bank purchase activities amplify the demand for new issues in the corporate bond market. The new securities become largely oversubscribed in the primary market, leaving existing bonds drying out. Bid–ask spreads and the demand and supply are largely amplified and even exaggerated by central bank purchases, and by demands from investors, and in particular by other bond managers, to buy them and later to sell them to central banks.

Portfolio allocation directly affects portfolio trading in the real world. However, contrary to academic research, aligning target or desired tactical portfolio allocation and a model allocation might be a challenging task. The reason is that the traditional model often does not apply to fixed income allocation and thus is impossible to implement in real portfolios (at least not with cash bonds). For example, fixed income allocation to the BRIC (Brazil, Russia, India, and China) countries in local currency bond exposure is not possible. The reason is that offshore bond managers cannot invest in local currency Brazilian and onshore Chinese bonds. Let us consider an example. Allocation weights in emerging markets must account for low liquidity and even the impossibility to invest if a fund of $1 billion decides to allocate 15% of its assets in an illiquid and small government bond market. Similarly, increasing the portfolio allocation of a mid-size fund by 15% in high-yield European bonds might be a challenging task in a market of rising yields and spreads. A reasonable question is then at what cost is the reallocation possible? A larger transaction cost might evaporate manager alpha in illiquid segments. The last few examples reveal challenges associated with a discretionary management style. The development of electronic trading helps to mitigate these issues.

Therefore, rebalancing portfolios is directly affected by bid–ask spreads, which in turn affect notional amounts. However, market volatility directly affects bid–ask spreads. As spreads are widening and liquidity dries up, the current portfolio allocation departs from what is desired.

There are a four important conclusions: (1) the prices of fixed income securities are determined by notional amount exchanged, (2) the bid–ask spreads as a liquidity indicator are indicative and approximate and depend on market volatility, (3) the portfolio size and allocation affects transactions costs with portfolio baskets of reasonable size ($300 million) gaining from the best execution costs as captured by the bid–ask spreads, and (4) portfolio basket execution of single bonds with a number of brokers using a "best execution" policy, or as BWIC, leads to different results.[11]

The major problem why certain equity-based components cannot be applied strictly to fixed income securities reflect the nonstationarity of bond characteristics. This issue has been recently stressed by de Jong and Fabozzi.[12] Bonds have time-varying risk properties related to maturity, duration, credit rating, interest rate level, credit spread, and slope and curvature of the yield curve. The relationships are simply nonlinear. Adding an explanatory factor in bond investing does not correspond linearly to the existing factor model. Fixed income securities and thus bond portfolios cannot have stationary market risk components as measured by spreads, interest rate risk, credit ratings, prices, and so on. The transition of risk can be only modeled if bond portfolios are rolled and rebalanced so that the market risk remains stable.

The Fundamental Law of Active Management and Bond Trading

To illustrate this relationship more precisely, consider an opportunistic bond portfolio investing globally, in different currencies, corporate sectors, maturities, security types, and so on. Specifically, a portfolio invests in eight asset classes—high-yield, foreign exchange, industrials, utilities, financials, covered bonds, domestic government bonds, and local currency government bonds. If a manager wants to generate a high information ratio, he has to increase his breadth. However, this means, that a fund manager has to predict, or at least *nowcast* (using data analysis from electronic exchange as opposed to forecasting economic variables), different interest rate regimes, credit spreads, durations, convexities, volatilities, currency exchange rates, and so on.

More importantly, these effects interact in multiple ways. Specifically, a U.S. bond manager investing in French investment-grade corporate bond (with a credit rating of A+) is related to the entire Eurozone interest rate dynamics, ECB policy, EUR-USD exchange rate, U.S. yield curve, Fed policy, spread dynamics, and investment flows in the Eurozone as more and more investors pursue European corporate debt for attractive fixed income and variable price-related returns. These effects cannot be modeled linearly using a stationary model, as bond price does not reflect interest rate and spread movement linearly. As Kahn once observed: "It's hard to be a bond manager." This claim can be easily

11. The "Best Execution" policy is set in Article 27 of MiFID II, by the Markets in Financial Instruments Directive (MiFID) as a requirement for fund managers to take all necessary steps to the best order execution for their clients. The following criteria are strict requirements: price, cost, speed, notional, and probability of execution and settlement, as well as other material factors affecting order execution. See https://www.esma.europa.eu/document/best-execution-under-mifid; https://www.sec.gov/fast-answers/answersbestexhtm.html.

12. De Jong and Fabozzi, "The Market Risk of Corporate Bonds."

shown using the Fundamental Law of Active Management and estimating the Information Ration (*IR*) originally proposed by Grinold in in 1989:[13]

$$IR = IC\sqrt{B}\,TC$$

where *IC* is the information coefficient, or the measure of skill as computed as Pearson correlation, or Spearman correlation, and *B* is the breadth, or the number of independent bets, and the *TC* is the transfer coefficient denoting possible restrictions when applying a strategy. The *TC* ranges between 0 and 1, with 1 meaning no restrictions. Furthermore, the *TC* might capture both hard restrictions, like ones on short selling, specific sectors, and so on, and soft restrictions referring to transaction costs resulting from excessive trading. In this line of thought, higher transaction costs and illiquidity directly affect the *TC* coefficient.

As shown in Exhibit 44-6, an opportunistic global bond manager investing in eight assets and rebalancing them on a monthly basis would have higher breadth and would take more risks. The annual breadth would be 96 for eight assets and 960 if the bond manager considered 10 bonds per asset class. Let us assume that the IC is constant at 0.1. Then a low *TC* coefficient as a result of high transaction costs and liquidity pulls the *IR* lower. It is important to note that the numbers are generic for the purpose of illustrating the principles.

EXHIBIT 44-6

Information Ratios with Different Breadth and Transfer Coefficients

IR	*IC*	*B*	*TC*
0.1	0.1	96 (8*12)	0.1
0.31	0.1	960 (8*12*10)	0.1
0.05	0.1	96	0.05
0.15	0.1	960	0.05

These issues make clear that *IR*, transaction cost, portfolio allocation, and illiquidity are interacting factors, which might diminish alpha.

As a consequence, high bid–ask spreads and transaction costs impose serious pressure on a fund manager's information ratio. The recent financial market developments have brought a novel and reliable way to lower the impact of illiquidity in fixed income trading and execution, and this is particularly useful for investment-grade and lower-grade corporate bonds.

13. Richard C. Grinold, "The Fundamental Law of Active Management," *Journal of Portfolio Management* 15(3), 1989, pp. 30–37. See also Richard C. Grinold and Ronald N. Kahn, "Information Analysis," *Journal of Portfolio Management* 18(3), 1992, pp. 14–21.

ELECTRONIC TRADING

Foreign-exchange (FX) markets have surpassed the development of fixed income markets in terms of electronic trading.[14] The global foreign-exchange turnover increased from $1.2 trillion in 2001 to roughly $6.6 trillion in 2019 according to the Bank of International Settlements. Almost every FX spot transaction has been executed fully electronically. In addition, the majority of FX forwards, FX options, and FX swaps are primarily executed using electronic platforms. According to the Securities Industry and Financial Markets Association (SIFMA), roughly 78% of both the volume and the transactions in the FX spot market are executed electronically. Although U.S. Treasuries and European government bonds enjoy large liquidity in the market, their liquidity has recently been driven by a significant number of transactions executed electronically. However, the development in the fixed income markets for investment-grade corporate bonds and high-yield bonds was less promising in 2015. Only slightly more than 20% of the high-yield cash bonds were traded electronically.

Corporate bonds are mostly executed OTC market. For example, in 2014, roughly 50% of the volume traded in European corporate bonds was executed electronically and roughly 74% of investors traded using electronic platforms. Compared to the end of 2008, as the financial crisis hit the markets, roughly 57% of investors traded corporate bonds electronically, which reflected only 20% of the volume. This tendency almost reflects the trading of cash bonds. However, corporate bonds have been executed much more often through electronic exchange since 2009. Investment banks build algorithms based on their transactions and databases to provide internal scores for the liquidity of fixed income securities.

The rise of electronic trading has been driven by the interaction of three factors:

- Technology development
- Increase of regulation
- Structural market change

At first glance, these three factors seem directly related to the drivers of fixed income liquidity. In fact, technology is used to lower costs further. Investors and asset managers face rising pressure as global yields decline. Reducing fees to literally zero in a fierce competition forced the development of new products. As a consequence, the total market structure changed. There has been a substantial growth in the ETFs of both investment-grade (IG) and high-yield bonds. Specifically, investment-grade ETFs rose from $66 billion in 2014 to $163 billion in 2019. High-yield ETFs grew from $42 billion in 2014 to $66 billion in 2019. The total number of fixed income ETFs grew from 291 in 2014 to 389 in 2019. This corresponds to a more than twofold increase of the assets under management

14. Markets Committee, "Electronic Trading in Fixed Income Markets," Bank of International Settlements, January 2016.

in ETFs, which grew from $419 billion in 2014 to $872 billion in 2019. As a consequence of all these factors, the asset management industry has changed to electronic platforms.

Petajisto investigated the ETF market structure and highlighted the differences in asset class pricing and trading.[15] Bond trading differs greatly from trading in equities or other asset classes. One of the reasons is that volume (nominal amount) and prices are not disclosed and transparent to other market participants. Specifically, bond prices are a function of a nominal quantity and thus order-driven prices might diverge from the quoted market prices. Therefore, the quoted bid–ask spreads for fixed income securities are only approximate indications of liquidity. The real bid–ask spreads diverge significantly from the quoted ones. With electronic trading, it is possible to gather data and build algorithms and thus generate a much more reliable picture of bond market liquidity. These two series could converge. However, often these data remain proprietary for the large dealers and market-makers.

A clarification of the platforms and types of order reveals more information regarding the complex nature of international bond portfolio management when also involving foreign exchange transactions.

Types of Trading Platforms and Pricing Technologies

Trading platforms differ by the number of participants and specific methodology.[16] Examples are Inter-dealer, Single-dealer Client, Multi-dealer Client, and Odd-Lot Trading Systems. The most interesting and growing type of system is the *Exchange*. Exchanges are anonymous trading platforms in which buyers and sellers directly match trades. A specific property is the absence of market-makers. Thus, liquidity is directly provided by the trading parties.

The factors driving liquidity and the drivers of the evolution of electronic exchanges gave birth to several cutting-edge platforms, which deserve mention. These electronic exchanges bypass human interaction (voice trading) to make algorithm-based (software) trades. The most common attribute they have is that they are highly sophisticated, algorithm-based, cloud-supported, and data-based structures. Bond pricing is based on algorithms, which also allows for high-frequency trading, storage facilities, documentation, processing, and best execution policies. The following are examples of platforms specializing in fixed income and foreign exchange trading:

- Tradeweb—a broad platform helping a broad range of market participants
- TruMid—a fixed income specialist platform

15. Antti Petajisto, "Inefficiencies in the Pricing of Exchange-Traded Funds," *Financial Analysts Journal* 73(1), 2017, pp. 24–54.
16. Marshall Nicholson, "Electronic Trading For Fixed Income Markets," chapter 4 in Frank J. Fabozzi (ed.), *The Handbook of Fixed Income Securities* (New York, McGraw-Hill, 2012).

- Marketaxess—the largest platform for corporate bonds, with market share of 85%
- Liquidnet—an open-source artificial intelligence platform
- Flextrade—an all-in order/execution management system
- Algomi—a fixed income market aggregation and market surveillance tool
- Bloomberg—the well-known platform

A brief overview of one of the platforms shows the technology-based solutions provide liquidity and prices for corporate bonds.[17] *TruMid* is an example of a high-tech platform whose pricing is based on two different algorithms. The first is a *matrix*-based algorithm searching for commonalities between recently traded bonds with similar characteristics (maturity, credit rating, size, and liquidity). In the language of data analysis, this is an eigenvector centrality score algorithm. The advantage is that such an algorithm provides pricing for less liquid bonds too. Therefore, large market participants and brokers with huge market activities can monitor and extract a large amount of data from the transactions and thus, when executing basket trades, they provide liquidity for less liquid securities. A disadvantage is that the solution depends on the sample size. The second algorithm is an *evaluated pricing* algorithm based on rigorous analysis and human judgment to evaluate new issues, current pricing, and broker/dealer quotes. The price can be adjusted to reflect the most efficient price in the current market stage.

Fixed Income Electronic Trading: Basket Trades

The described methods for trading fixed income securities are employed according to manager-specific needs. However, in a fully quantitative process, portfolio managers reallocate funds and as sellers they often do not like to reveal a strategy change. The appropriate approach is called *Bid Wanted in Competition* (BWIC). The aim is to find the best market price of a basket of securities. The fund manager receives a list with security price ranges and if the manager agrees upon these prices, the basket is executed within a specific, reasonable time. It is intuitive to suggest that achieving the highest possible prices for selling is not possible. However, the seller (i.e., the bond portfolio manager) immediately recognizes that specific prices are in line, some on the lower and some higher spread price range. For example, BWIC trades comprising securities from both developed and emerging markets' government bonds in 2012 (Canada, Sweden, Australia, New Zealand, Russia, Turkey, Hungary, Poland, etc.) resulted in prices that diverged from those expected. However, the BWIC allows favorable price making for different counterparties.

17. See https://www.trumid.com/files/FVMP-Whitepaper-10-20-17.pdf; https://www.liquidnet.com; https://www.algomi.com; https://www.flextrade.com; https://www.content.marketaxess.com; https://www.tradeweb.com.

There are specific issues related to electronic trading in fixed income, which clearly highlight the advantages of the new systematic trading:

- Traditional execution is limited to discretionary managers and a small number of trades and is cost-intensive and time-consuming.
- Portfolio execution, or basket trades, eliminates inefficiencies from idiosyncratic management choices regarding duration, spread, liquidity, and so on.
- The system allows a large number of trades; thus, an efficient tool for ETFs, passive products, and quant-driven funds.
- The system allows optimized beta hedging, and factor models for risk management and liquidity.
- Portfolio baskets move in close correlation to indexes and ETFs, which results in improved pricing.
- Volatility reduction for a portfolio, compared to single bond trades, results in improved bid–ask spreads and liquidity.
- Portfolio basket trades comprise in general large number of single securities in order to diversify the trade. For example, a meaningful global bond portfolio basket comprises at least 30 fixed income securities.

The mechanics of a portfolio trade can be described in the following way. A portfolio manager sends a list of securities to a broker. For example, a $500 billion portfolio needs to be rebalanced and the portfolio manager expects a quote within 30 minutes. Note that a short time period is always desired as market volatility could cause the final allocation to drift from the target allocation. After careful portfolio analysis, the broker can identify the liquid securities according to their credit rating, spreads, sector, and so on. The broker might analyze the current liquidity and turnover in various activities—for example, rebalancing and transactions in ETFs, daily trading of fixed income instruments, hedging activities in fixed income securities and currencies, rebalancing of index funds, and market-making.

The portfolio basket trades in a similar way to a single security (see Exhibit 44-7.) The advantage is that the components of the portfolio basket, such as different ratings, corporate sectors, and so on, are matched with other clients' needs, authorized participants, asset managers, ETF products and ETF managers, and ETF exchanges. The main advantages of electronic trading are the broad diversification in terms of notional size, strong operating efficiency, quick time to quote, aggressive pricing due to the narrow bid–ask spreads of ETFs, the fast execution, and the flexibility of matching specific portfolio constrains. In short, electronic exchange allows multilevel interaction of trading entities and the price mechanism is order-driven, in contrast to OTC trading, which remains quote-driven.[18] Thus,

18. SIFMA Insights – Electronic Trading Market Structure Primer, October 2019, https://www.sifma.org/wp-content/uploads/2019/10/SIFMA-Insights-Electronic-Trading-Market-Structure-Primer.pdf.

electronic portfolio trading provides sufficient and reliable metrics for liquidity as the trades are order driven. As a result, bid–ask estimates are reliable indicators of liquidity.

EXHIBIT 44-7

Portfolio Trade Decomposition

A broad number of active trading counterparties (funds, ETFs, etc.) represent a reliable source of information and contribute to efficient bond pricing. Thus, the portfolio basket can be split into multiple trading blocks. As a result, the time required for executing the whole portfolio basket is much shorter than the time for executing a portfolio engaging in normal trading activities.

This is particularly important for lower-rated portfolios with average ratings below investment grade, and long-term duration. As the liquidity of long duration, lower-credit-rating bonds dries up, portfolio managers often face the impossible situation of needing to rebalance all their funds, or at least to sell a significant portion of the assets held. However, BWIC enables portfolio managers not only to sell illiquid assets, but moreover to preserve market depth and liquidity. Specifically, for large corporate bond funds selling illiquid, long-duration, below-investment-grade bonds, the market price changes by several ticks. Nevertheless, even government bonds can suffer dramatically from illiquidity and their bid–ask spreads can differ substantially during normal conditions and during periods of financial turmoil.

Foreign Exchange Electronic Trading

For many years, the BIS Triennial Central Bank Survey has documented the way trades are executed (i.e., where and how orders are filled) in the FX market. The main trend in FX trade execution is that execution has become increasingly electronic, moving away from traditional "voice" execution. The 2019 Triennial Survey shows that the share of FX trading executed electronically is currently close to 60%. The market segment where electronic trading is the highest is dealer-to-customer transactions. Spot remains the instrument with the highest electronic trading share, which stood at 75% of dealer-to-client transactions. Interestingly, in contrast to its rise in dealer-to-customer markets, electronic spot trading in inter-dealer markets saw a decline in both relative and absolute terms, falling by 7% since 2016 to $368 billion per day in the latest Triennial Survey. As a result, inter-dealer trading accounted for less than a third of the total electronic spot market in 2019. This decline in electronic inter-dealer trading is driven principally by "internalization," whereby dealers temporarily keep risk arising from client flows until it is offset against opposing client flow. The ability of dealers to internalize depends on the ability to attract customers to trading via single-bank platforms or direct price streams.

The 2019 Triennial Survey confirms that, despite the overall trend, electronic trading is not progressing uniformly across all instruments and market segments. For example, inter-dealer trading of FX swaps has remained heavily voice-reliant, while dealer-to-customer trading has moved toward greater use of electronic execution methods.

There are several interrelated reasons for voice trading (i.e., voice execution), as opposed to electronic trading, retaining a higher share in FX swaps. First, swap trades involve particularly large notional amounts. Second, FX swaps are more difficult to price because balance sheet considerations play a larger role.

The 2019 Triennial Survey shows that trading on multi-bank platforms has been the fastest growing execution method from 2006 to 2019. The main driver for this trend is that clients have continued to become more cost-conscious. Trading on multi-bank platforms, or via liquidity aggregators bundling various venues and providers, has now surpassed single-bank platform volumes and other direct forms of electronic trading.[19]

KEY POINTS

- Bid–ask spreads represent the difference between the highest price that a buyer is willing to pay for a fixed income security and the lowest price that a seller is willing to accept. Moreover, bond prices in the

19. Andreas Schrimpf and Vladyslav Sushko, "Sizing Up Global Foreign Exchange Markets," *BIS Quarterly Review*, December 2019, pp. 21–38 and Maximilian Butz and Roel Oomen, "Internalisation by Electronic FX Spot Dealers," *Quantitative Finance* 19(1), 2019, pp. 35–56.

real world are based on quantities traded, or order-driven as opposed to quote-driven. More precisely, the ask bond price and then the executed price could diverge substantially for an order of 1 million or 10 million. In fact, this is the rule, not the exception. The bid–ask spreads are heavily influenced by portfolio size, market cycle, demand and supply, monetary policy—in particular, purchase programs, and allocation.

- As a consequence, high bid–ask spreads and transaction costs put serious pressure on a fund managers' information ratio. Bonds have time-varying risk properties related to maturity, duration, rating, interest level, credit spread, slope, and curvature. The relationships are simply nonlinear. Adding an explanatory factor in bond investing does not sum up to the existing factor model. Fixed income securities and thus bond portfolios cannot have stationary market risk components as measured by spreads, interest rate risk, ratings, prices, and so on.
- Fixed income securities' electronic exchanges are order-driven and not quote-driven. The rise in electronic trading now is significant in the United States, with the rest of the world catching up. The bond market is in a state of transition—from OTC to more electronic trading, allowing for higher liquidity, more transparency, lower costs, more diversification, and flexible execution times.
- The prices of fixed income securities are determined by notional amounts exchanged. Portfolio size and allocation affect transaction costs, with portfolio baskets of middle size gaining from the best execution costs. Portfolio basket execution of single bonds with a number of brokers preserving a "best execution" policy allows for better liquidity, diversification, and transparency.
- Increasing bond market activities from central banks shift the real pricing. Bid–ask spreads are indicative of bond market liquidity. However, they are only approximative solutions as indicators. Bond prices are the result of nominal sizes exchanged, thus prices depend on quantities. Bid–ask spreads help to indicate possible liquidity traps, but their magnitude and meaning diverge significantly from the real executed prices that depend on the nominal amount sold or bought, market demand and supply.

CHAPTER
FORTY-FIVE

BOND INDEXES AND BOND PORTFOLIO MANAGEMENT

Gueorgui S. Konstantinov, Ph.D., CAIA, FDP
Senior Portfolio Manager
LBBW Asset Management

Frank Osswald, CFA
Senior Portfolio Manager
LBBW Asset Management

The analysis of bond indexes is often a starting point in an investment process both for investors and portfolio managers. The reasons are easily understandable as the market for fixed income securities has substantially grown in recent years, even more than in the past. For example, eVestment's database included more than 40,000 funds as of 2015. The number of funds, portfolio allocation, and their size has increased. The net assets of regulated open-end bond funds grew from \$8,395 billion to \$10,633 billion from the first quarter of 2015 to year-end 2019.[1] A report by the Bank for International Settlements found that the assets under management (AUM) in fixed income funds including exchange-traded funds (ETFs) grew from \$0.5 trillion in 2006 to more than \$5 trillion in 2015. The aggregate size of global debt securities market driven by the large new corporate bond issues and sovereign bond debt grew from roughly \$36 trillion to \$95 trillion from 2001 to 2015. Two major groups of investors in fixed income are pension trusts and insurance groups. As the wealth of the private sector grew continuously, the AUM for pension funds grew in parallel. A substantial part of these savings was allocated to fixed income securities. The objective of these funds is to generate relatively safe cash flows. However, with a low-interest-rate environment globally, investors moved to illiquid segments such as global high-yield bonds.

As a consequence, there are two major purposes for bond indexes. The first purpose is for portfolio allocation and performance measurement. The second

The views expressed are those of the authors and do not necessarily reflect those of LBBW Asset Management.

1. The International Investment Fund Association www.iifa.ca and Markets Committee, *Electronic Trading in Fixed Income Markets*, Bank of International Settlements, January 2016.

purpose reflects passive management and products such as bond index funds and smart beta products.

Performance measurement of bond portfolios has gained in importance as a result of the rising number of bond funds. A sophisticated investment process makes it necessary to define a policy portfolio and thus an appropriate investment universe and a reliable source to measure performance. Performance measurement and performance attribution are inevitable for portfolio analysis. To be an appropriate benchmark, a bond index must fulfill certain requirements. As suggested by William F. Sharpe, requirements are:[2]

- *Knowable*: The constituents must be identifiable and both portfolio managers and their clients must agree on the index.
- *Investable and not easily beaten*: Portfolio managers must be able to hold the assets of an index.
- *Low in cost*: It must be possible to obtain and calculate the index and portfolio performance at low cost.
- *Diversified:* It must properly reflect the investment universe.

Whereas the pension fund allocation in the United States favors more equity market exposure in the allocation, the pension funds in Europe are more dedicated to fixed income assets, often exceeding 80% of the strategic asset allocation (SAA). Moreover, the market for fixed income products has grown globally. As markets gain in transparency, flexibility, transaction velocity, and sophistication, the growing allocation to fixed income securities from pension funds and institutional investors and demand for fixed income benchmarks have forced major providers of financial services to implement and manage liquid products based on fixed income benchmark tracking and factor investing. A specific example is smart beta products. These investment vehicles are also called bond index funds. One of the reasons for the growth of passive funds, ETFs, and similar structures is that historically many fixed income portfolio managers have not outperformed their benchmarks over long investment horizons. Bond index funds allow portfolio managers, allocators, and alternative investors like endowments to allocate to smart beta products. The rise of the bond ETFs helped to the development of electronic bond trading, which in turn improved the bond market's liquidity and depth.

BUILDING A BOND INDEX

Bond indexes have a high level of complexity, greatly exceeding that of equities. The compound nature of fixed income instruments makes the bond index

2. William F. Sharpe, "Asset Allocation: Management Style and Performance Measurement," *Journal of Portfolio Management* 18(2), 1992, pp. 7–19.

construction a challenging task. The complexity of fixed income has multiple causes.[3] The most prominent of them are:

- Heterogeneous currency, country, sector, and rating universe and different types of fixed income instruments—bullet bonds, callable and puttable bonds, inflation-linked, mortgage-backed securities, denomination currency, countries, interest rate regimes depending on currencies, ratings, etc. An index can include multiple bonds from the same issuer, denominated in different currencies for example. Alternatively, corporate issues from different subsidiaries can be included in an index with different ratings, cash-flow schemas, and structures. Most importantly, compared to stocks, fixed income instruments have a termination date, or maturity. Thus, at a certain point in time these instruments can no longer be part of an index and must be replaced. On the other hand, if new bonds are issued, they can become part of an index and the number of instruments in the index grows.
- The evolving nature of the fixed income markets and instruments depends on the business cycle, market complexity, and sophistication. The need for new instruments, solutions, and opportunities to diversify portfolios and satisfy investor demand. About 25 years ago, most indices started with a limited number of constituents, but now they include many thousands of instruments. As markets grow, the investors' need for fixed income exposure drove the development of new indexes representative of new investment universes.
- There is a large impact of the volatility of currencies, interest rates, dependencies on equity markets and ratings and their effects on bonds with embedded options, equity valuations reflecting corporate bonds, etc.
- The pricing of fixed income securities can be a challenging task. For example, corporate bonds are priced in an over-the-counter (OTC) market, thus sources of liquidity and transparency can be difficult to evaluate. This poses a serious risk for pricing and thus index construction. However, recent developments in electronic trading systems and platforms allow better price building.
- Many fixed income indexes are rebalanced monthly. That means on the rebalancing date the constituents of the index have to be defined. While some bonds will be dropped from the respective index—for example, because the maturity dropped below the minimum maturity or if an issuer's rating was downgraded below the minimum requirement—other bonds will be added to the index, especially newly issued bonds. After the rebalancing date, some index metrics may change greatly. For

3. Frank K. Reilly and David J. Wright, "Bond Market Indexes," chapter 3 in Frank J. Fabozzi (ed.), *The Handbook of Fixed Income Securities,* 8th edition (New York, McGraw-Hill, 2012).

instance, the average maturity or duration normally increase noticeably, with the effect that both passive and active portfolio managers also have to adjust their portfolios accordingly.

To illustrate how diverse the bond indexes might be, we consider three groups and show their differences in Exhibit 45-1.

The challenges in the construction and evaluation of bond indexes include two main issues. The first refers to the calculation of accrued interest on the bonds in the index. The second, and most specific and important, refers to the reinvestment of bond cash flows, which depends on the index provider. In general, there are a few possibilities in dealing with coupons and accrued interest:

- Immediate reinvestment of bond cash flows in the index
- Investing the cash flows using a money-market rate (LIBOR, EURIBOR, etc.) until the next rebalancing date (e.g., ICE BofA indexes)
- Simple reinvestment of the cash flows on the rebalancing date (e.g., J.P. Morgan indexes).
- No reinvestment of cash flows (e.g., Bloomberg Barclays indexes)

At this point it is necessary to consider the index documentation, since different index providers follow specific procedures. This is a crucial issue since different methodologies impact index metrics such as duration, yield to maturity, and convexity. More precisely, different reinvestment methodologies might result in performance bias of several basis points monthly due to the reinvestment techniques.

DESCRIPTION

Here we will focus on three groups of bond indexes. These are the U.S. investment-grade and high-yield indexes, European investment-grade and high-yield bonds, and international government, corporate, and aggregate bond indexes (i.e., global bond indexes). There are specific issues that are relevant to the indices and which provide overview and specific information regarding the investability and composition of an index. Reilly and Wright showed that among the most important descriptive components are:[4]

- The number of issues—exceeding 20,000 for global aggregate indexes
- The overall maturity—usually above one year of maturity
- The weighting structure—market vs. equal weighting schema
- Pricing sources and systematics—tradable security prices

* For all bond indexes in this table, the market value weighting methodology is used, rebalancing is done monthly, and the reinvestment type if total return.

Source: Constructed form data obtained from Bloomberg, LLC as of May 2020.

- The reinvestment risk—reinvestment of cash flows
- The issue size of the single constituents—usually >$500 million for corporate bonds

Whereas the previous factors reveal much more strategic and descriptive information about an index, specific information reveals details regarding tactical allocation and possibilities. For this purpose, it is always convenient to show an index in its sector, industry, credit rating, currency, allocation in maturity buckets, etc. In general, the presentation of a matrix structure reveals further details about a benchmark. For this purpose, the following matrices are possible ways to assign the index weights:

- Currency-maturity-buckets—for multi-currency bond indexes
- Country-maturity—for geographically vast indexes
- Sector-maturity—for broad indexes
- Sector-currency—for multicurrency broad and corporate indexes
- Sector-rating—for broad corporate indexes

In fact, the possibilities are vast and refer to specific tactical issues. Using matrix notation is a useful way to derive tactical allocation and estimate the performance attribution.

U.S. Investment-Grade and High-Yield Bonds

The U.S. bond market and the indexes have been central to fixed income management for decades. The most widely used by ETFs and active fund managers are the Bloomberg Barclays Capital Indexes. As a result, the U.S. bond indexes are the most liquid and well developed among all groups and regions. The U.S. bond indexes can be split into two major groups—U.S. investment-grade and U.S, high-yield bond indexes. Although the first group includes the most liquid instruments and diverse groups of fixed income securities like Treasuries, investment-grade corporate bonds (credits), and mortgage-backed and asset-backed securities, the second comprises less liquid bonds. The indexes comprising liquid fixed income securities have a minimum requirement for issue size. In general, an issue size of US$500 million represents the lowest level acceptable for bond managers to invest. During poor market conditions, investment-grade securities and Treasuries in particular are very liquid, thus enabling index pricing and trading. Therefore, market value weighting schemas properly reflect the current market valuation.

The second group comprises high-yield, or lower-rated fixed income securities. These indexes have in general a lower number of constituents, instruments with less liquidity, and fixed income securities with embedded options. These are high credit risk bonds. The liquidity issue that results in serious pricing problems arises from the fact that these instruments have low outstanding volumes, or their issue size is low. An issue size less than US$500 million often translates into low market liquidity. The pricing of high-yield bonds and index calculation thus is a challenging task. This issue becomes more serious during financial turmoil as a liquidity spiral occurs as a consequence of less demand, widening option-adjusted spreads, rising yields, and low trading volumes. Index pricing becomes a major issue during financial market stress.

Of course, alternative differentiation is common in the market as the specific needs require different types of analysis.

European-Investment Grade and High-Yield Bonds

The European market has grown in recent years due to the large regulatory requirements for pension funds. The fixed income SAA in European pension funds exceeds 80%, with a strong focus on European fixed income securities, including government bonds, corporate investment-grade bonds, covered bonds, high-yield bonds, and structured products. The foreign currency exposure has gained attention in recent years. International bond portfolio allocation is common, but does not represent a primary allocation target.

The growth of pension funds in Europe with structured, quantitative, and transparent investment process drives the development of real, tradable, transparent, representative, measurable, known indexes that serve as benchmarks. Some of the most well-known European indexes are ICE BofA European Broad Index, ICE BofA Corporate Bond Index, ICE BofA High Yield Index, J.P. Morgan EMU Government Bond Index, iBoxx Covered Bond Total Return Index, and the ICE BofA Financials index.

Global Bond Indexes

Major index providers for international bond indexes are J.P. Morgan, Citibank, Barclays, and ICE BofA. These indexes show striking similarities, which we will show in the next sections. These similarities result in a similar number of security and risk/return profiles. The number of index constituents increased in the last 20 years as international bond portfolios gained investors' interest. Global bond indexes offer multiple risk and return sources compared to traditional bond indexes. Investing in international bond indexes means taking currency, interest, spread, inflation, political, volatility, liquidity, and reinvestment risks, for example, which exceed the risks associated with domestic bond indexes.

There are two main types of global bond indexes: aggregate and government. Currently, the global government bond indexes have roughly 2,000 constituents. In contrast, the global aggregate indexes contain corporate and government bonds from multiple currencies and countries and have more than 20,000 constituents. The global sovereign indexes contain local currency government bonds from more than 40 countries.

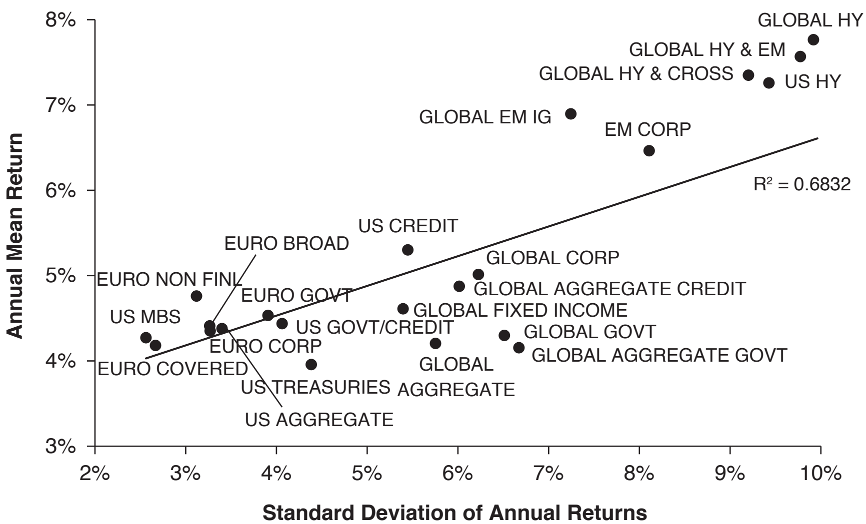
The most useful indexes in international bond portfolios with a focus on government bonds are the FTSE World Government Bond Index, which is identical to the Bloomberg Barclays Global Agg Treasuries Total Return Index, and the ICE BofA Global Government Bond Index. Overall, the Bloomberg Barclays Global Aggregate Index is the broadest globally invested index.

BOND INDEX RISK AND RETURN

As shown in Exhibit 45-2, the risk/return relationship between bond indexes is positive. The risk/return relationship increases as the credit rating of the index constituents decreases. Thus, global broad indexes and U.S. indexes including high-yield bonds have higher returns but suffer from higher risk as measured by the standard deviation. The highest returns in the period from 2000 to 2018 have been associated with the Global HY bond index. Alternatively, the lowest risk/return profile is associated with European Covered Bonds. Interestingly, both U.S. and European Broad indexes (EURO BROAD and U.S. AGGREGATE) offered similar risk/return profiles in the period from 2001 to 2018.

EXHIBIT 45-2

Risk/Return Relationship (January 2001 to December 2018)



U.S. Investment-Grade and HY Bonds

The U.S. indexes are broadly defined by number of securities, issuers, and diversified exposure. The U.S. HY index has a monthly average mean return of 59 basis points; however, its risk is substantial at 2.71% on a monthly basis.

The safest bond index exposure is associated with the U.S. mortgage-backed securities with a standard deviation of 0.75%, which also have positively skewed returns of 0.0882. We show the statistics in Exhibit 45-3.

European Investment-Grade and HY Bonds

Historically, European covered bond returns (iBoxx Euro Covered Bond Total Return Index) have low risk and return compared to the U.S. MBS index. Let us start with the descriptive statistics of the European bond indexes. The summary of the descriptive statistics is shown in Exhibit 45-4. The European HY index has the highest average monthly returns of 50 basis points, combined with an unsurprisingly high level of risk (3.4%). The covered bonds in Europe are among the safest instruments, with monthly index average returns of 26 basis points and standard deviation of the returns of 0.69%.

Global Bond Indexes

The descriptive statistics for the global indexes reveal that the Global HY index has the highest mean return of 65 basis points; however, it shows the highest risk of 2.86% as measured by the standard deviation. In the global bond index universe, the Global FixedIncome index has the lowest risk. This should not be surprising given the broad diversification of the global bond index universe. The statistics for the global bond indices are contained in Exhibit 45-5.

The bond index with the highest tail risk is the ICE BofA EM Corporate Index (EM Corp) with a skew of –4.8181 and kurtosis of 49.838. The risk also stems from the illiquidity of the index constituents.

BOND INDEX RELATIONSHIP

There are different ways to look at bond index relationships. The traditional method is to consider the pairwise Pearson correlations. The U.S. bond indexes show much higher correlations compared to the global bond indexes or the European bond indexes (see Exhibit 45-6). This suggests common underlying dynamics for the U.S. universe. We show the correlation coefficients for the European bond indices in Exhibit 45-7 and the correlation coefficients for the global bond indices in Exhibit 45-8.

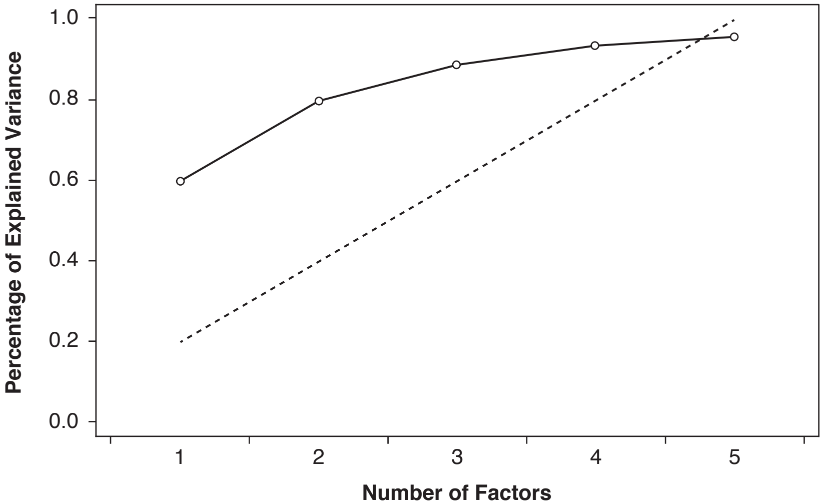
A natural question would be, is there any common factor that explains the variance of bond index returns? Using principal component analysis (PCA) and the groundbreaking work of Robert Litterman and Jose Scheinkman,[5] we show that five factors explain 96% of the variance of bond indexes returns. The first factor explains roughly 60% of the bond indexes variance of returns. The results in Exhibit 45-9 show that the first three factors explain roughly 89% of the variance of index returns.

EXHIBIT 45-9

Principal Component Analysis of Bond Market Indexes: Five Factors



The number of factors is on the x-axis, percentage of the explained variance is on the y-axis

Sometimes questions such as the following can arise: What is the most important bond index? How are bond indexes related? What are meaningful groups to take into account: corporate, government, HY, etc.? Traditional calculus methods cannot provide answer to these questions. Lopez der Prado and Fabozzi argued that portfolio managers and investment professionals need different toolkit to analyze complex market behavior.[6] A novel, data-driven, but very comprehensive approach to considering relationships is to present indexes as a graph, or to cluster the indexes. Specifically, an analysis focuses on the mutual links between the indexes and thus their relationships. Cluster analysis groups indexes

5. Robert B. Litterman and Jose Scheinkman, "Common Factors Affecting Bond Returns," *Journal of Fixed Income* 1(1), 1991, pp. 54–61.

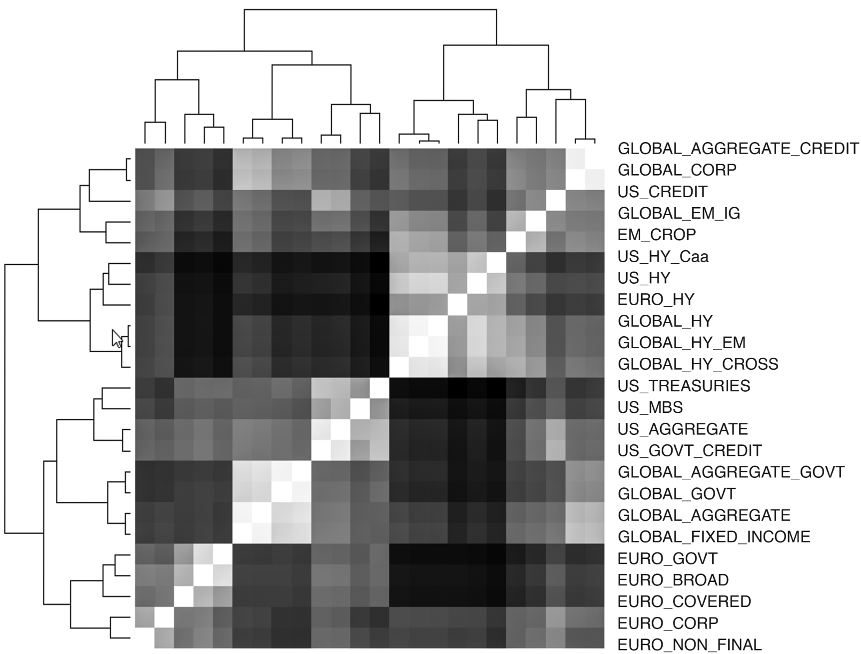
by their correlation similarity into groups. An underlying connecting property might be the Treasury yield curve—for government and investment-grade corporate bonds for example. As a starting point, we incorporate the pairwise correlation coefficients ρ_{ij}, but we transform them into distance metrics, which much more efficiently and correctly display their characteristics:

$$d_{ij} = \sqrt{2\left(1-\rho_{ij}\right)}, \text{ with } i \neq j$$

Exhibit 45-10 contains hierarchical clustering and heat map that show the bond indexes relationship. To identify groups (clusters), we can make a cut-off in the connecting lines and thus show that the bond indexes can be grouped into six clusters. These six clusters comprise indexes that have similar properties. For example, German government bonds and European government bond curves and the factors of shift, slope, and curvature might be central to a cluster comprising both European and global credit and government bond indexes.

EXHIBIT 45-10

Bond Indexes Clusters and Relationship: 2001–2018



In fact, assessing and observing relationships between different bond indexes constitutes a starting point for smart beta or factor investing.

BOND INDEXES AND SMART BETA

Smart beta funds in fixed income are the natural consequence of investor needs.[7] The needs for higher returns, diversification, and/or lower cost are the result of the disruptive innovation in finance called smart beta investing. In general, smart beta strategies are active strategies with some features of passive products. The advantage is that smart beta strategies use simple, quantitative, rule-based approaches to constructing portfolios that have exposure to specific benchmarks. However, they are actively managed products. The natural development followed the rise of factor investing and the arbitrage pricing theory developed by Stephen Ross. Since diverse risk factors explain the variance of returns of diverse indices, research focused on building active factor funds, or smart beta funds.

Factor investing in fixed income offers transparency, scalability, lower costs, and diversification.

As the global growth and demand for fixed income factor solutions increased, investors' focus shifted to finding quantitative smart beta products for fixed income securities. However, active management of bond portfolios has been disappointing, despite the high management fees and additional costs. Previous research has suggested that there is a mean reversion in historical returns of fixed income strategies and that factor exposure is cyclical.[8]

Specifically, there are few possible solutions for smart beta products to apply to fixed income benchmarks. The most widely used is a factor-based approach. There are a number of reasons for this. Factor-based solutions offer the following advantages applied to bond indexes. In fact, to some extent the development of bond benchmarks is closely related to the demand for passive products and the requirements for an index:

- Transparency
- Representative and meaningful index weights
- Liquidity of the tradable instruments and rebalancing
- Index methodology and documentation
- Scalability of products and solutions
- Quantification of investment processes and the growth of factor investing
- Management skill
- Diversification

7. Ronald N. Khan and Michael Lemmon, "The Asset Management Dilemma: How Smart Beta Is Disrupting the Investment Management Industry," *Financial Analysts Journal* 72(1), 2016, pp. 15–20.
8. Andrew Chin and Piyush Gupta, "Using Prime Alpha to Separate Skill from Luck in Fixed income-Fixed income Strategies," *The Journal of Investing* Vol. 26, No. 2 (2017), pp. 102-110.

These issues are closely related to the growing need for investment products. Transparency reflects the growing need for transparent solutions in investment management. Representative and meaningful index weights reflect the weighting schema of an index that properly represents and explains the respective market. For example, the weight of the U.S. dollar in a world government bond index must be meaningful compared to the weight of a smaller government bond market (e.g., Norway). Liquidity issues also reflect the investability of an index. More liquid securities might get higher weights and thus be easy to replicate.

The index methodology and documentation are important issues since investors can gain more insights about the repricing, weighting schema, and rebalancing. On the demand side, investors' growing appetite for scalable, low-cost products is the driving force behind bond index funds. Management skill is related to this, as fewer fund managers outperform benchmarks and investors' desire to reduce fees and costs force them to seek low-cost, transparent solutions. The search for less cost-intensive products, and the cost pressure have pushed forward a broad quantification of the investment processes. This, in turn, requires transparent solutions and methodologies. Smart beta products offer such advantages.

Finally, a transition from specialists to generalist investment teams, combined with cost minimization and a desire for diversification drives the demand for smart beta bond products. Thus, a smart beta bond fund might be a suitable and favorable solution to a broad fixed income allocation. Smart beta products offer a broad set of advantages:[9]

- Flexibility
- Transparency
- Lower fees
- Liquidity
- Diversification
- Active management

As previously noted, smart beta products are factor-based solutions. A factor model explains the variance of index returns. The underlying assumption is that factors explain a significant amount of index returns. Thus, a smart beta approach using factors aims at minimizing the tracking error of a specific index. By employing linear regression, the index returns are explained using a set of reasonable explanatory factors. The higher the explanatory power of a factor model, the higher the possibility to apply a factor model and to build a smart beta portfolio. There are four steps to creating a factor-based smart beta bond index product:

---

9. Hossein B. Kazemi, Keith H. Black, and Donald R. Chambers, *Alternative Investments*, Third Edition (Hoboken: New Jersey, Wiley, 2016).

1. Index choice and tracking error estimation based on the investment universe—HY, mortgage-backed securities, or government bonds for example
2. An appropriate choice of an investable and transparent broad factor set—a broad set is desirable
3. The length of the period considered to analyze factor exposure
4. Factor selection of investable factors—depending on the index and investment universe

The factor set should be broad and in many instances depends on the type of bond index considered. However, recent research has shown that the well-known Fama-French factors explain the variance of government, corporate, and high-yield index returns. However, the Fama-French factor model is not sufficient to capture market risk. There are additional factors that deserve attention which explain the variance of bond returns and, specifically, market risk. The research on factor investing in fixed income is extensive. Recent literature has focused much more on the dynamic nature of factors involved in bond investing.[10] The following are the most important factors:

- The duration factor—capturing the risk of changes in interest rates.
- The liquidity factor, or bid–ask spread—explaining the liquidity as measured by turnover, since corporate bonds are not easily tradable.
- The default, or credit factor—gauging the difference in corporate and government bond returns; the factor captures the ability of a company, or government to pay debt.
- The term factor—capturing the slope of the yield curve.

It is important to note that cross-sectional factor models aim to dynamically capture changing index exposure. Thus, model specification is crucial and reflects the problem of data snooping. A factor model has the following general form:

$$R_{i,t} = \alpha_i + \sum_{i=1} \beta_i F_{j,t} + \varepsilon_t$$

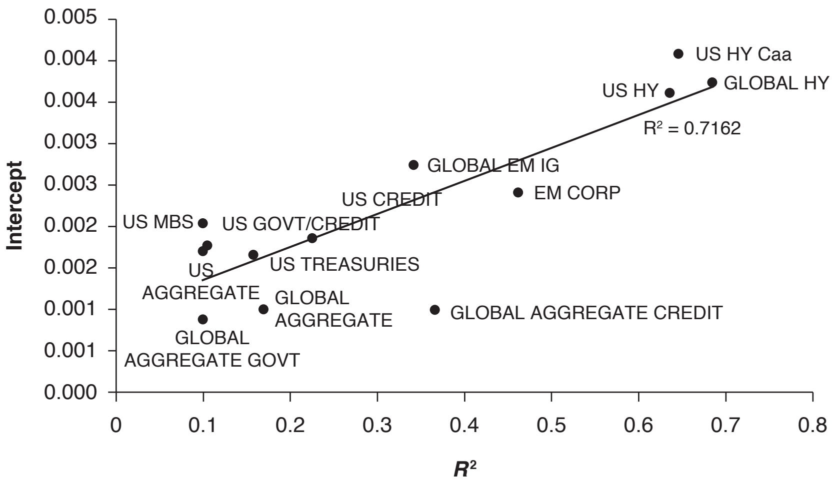
where $R_{i,t}$ is the total return of an index, α is the intercept, β is a coefficient that measures the sensitivity of an index's return to the factor, F is the beta factor premium that requires a systematic risk premium in the market, and ε is the random error term.

Fabozzi, "The Market Risk of Corporate Bonds," *Journal of Portfolio Management* 46 (2), 2020, pp. 92–105; Lidia Bolla, "Fundamental Indexing in Global Bond Markets: The Risk Exposure Explains It All," *Financial Analysts Journal* 73(1), 2017, pp. 101–120; Gueorgui Konstantinov, "On the Dynamics of EMU Bond Portfolios: Is the Diversification of Risk Factors Driving to Convergence of Fund Exposure?" *Journal of Investing* 26(2), 2017, pp. 91–102; and Demir Bektic, Josef-Stefan Wenzler, Michael Wegener, Dirk Schiereck, and Timo Speilmann, "Extending Fama-French Factors to Corporate Bond Markets," *Journal of Portfolio Management* 45 (3), 2019, pp. 141–158.

Exhibit 45-11 shows the Fama-French factor exposure for a sample of U.S. and international indexes. The R^2 of a factor model is a measure of the bond index variance that can be explained by the Fama-French five-factor model. Large R^2 values indicate that the variance of excess bond index returns can be explained by the Fama-French factors—U.S. HY Caa, Global HY, U.S. HY, and Global EM IG. Smart beta products could apply to these indexes. Alternatively, the Fama-French factors do not explain the variance of returns of both U.S. and global aggregate government bond indexes.

EXHIBIT 45-11

Variance of Excess Bond Index Returns Explained by Five Smart Beta Factors



An important issue is that the market risk is present in every market environment. Bond markets are nonstationary, and only factor models for smart beta that capture market nonstationarity are capable of capturing and explaining the heterogeneous nature of bond index returns. Thus, the major challenges to implementing smart beta index portfolios can be summarized by the following three issues:[11]

- Nonstationarity of bond returns
- Model uncertainty for factors related to bond indexes
- Data snooping and unstable factor premiums

11. Bradford Cornell, "Stock Characteristics and Stock Returns: A Skeptic's Look at the Cross Section of Expected Returns," *Journal of Portfolio Management* 46(7), 2020, pp. 131–142.

Because beta and factor premiums are time varying, for smart beta bond index products to be successful it is much more important to be centered on the main characteristics of the index rather than on the factor loadings. Thus, smart beta products must account for these three issues.

KEY POINTS

- The rising demand for fixed income securities from pension funds and both institutional and retail investors combined with increasing investor sophistication drive the development of new indexes and the expansion of the market.
- The European market has grown in recent years due to the large regulatory requirements for pension funds. The U.S. bond market and the indexes have been central to fixed income management for decades. As a result, these indexes are the most liquid among all groups and regions. The U.S. bond indexes can be split into two major groups—U.S. investment-grade and U.S. high-yield bond indexes.
- Global bond indexes offer multiple risk and return sources compared to traditional bond indexes. Investing in international bond indexes means, for example, taking currency, interest, spread, inflation, political, volatility, liquidity, and reinvestment risks, which exceed the risks associated with domestic bond indexes.
- Bond indexes have a high level of complexity, by far exceeding that of equities. The compound nature of fixed income instruments makes bond index construction a challenging task.
- Bond indexes are important sources of information for both managers and investors as regards performance measurement and new products such as smart beta portfolios.
- Smart beta products are factor-based solutions with growing demand because of the disappointing results, often paired with high fees, of active managers, and demand for transparent strategies.
- A factor model explains the variance of index returns. The underlying assumption is that factors explain a significant amount of index returns. Thus, a smart beta approach using factors aims at minimizing the tracking error of a specific index. An important issue is that the market risk is present in every market environment. Thus, the bond markets are nonstationary and only factor models for smart beta that capture market nonstationarity are capable of capturing and explaining the heterogeneous nature of bond index returns.

Most fixed income portfolios are managed relative to a benchmark. Depending on the portfolio's investment objective and style, the role of the benchmark varies. At one end of the spectrum are passive indexed portfolios that strive to match benchmark risk exposures and returns as closely as possible. At the other end are active portfolios with high risk tolerance that maximize outperformance by investing freely outside the benchmark that serves only as a nonbinding reference point. The majority of fixed income portfolios fall somewhere between these extremes. Typically, a sponsor, an investment committee, a chief investment officer, or some other party that sets the investment objective specifies both the benchmark and the permissible deviations from it. The portfolio manager is then judged by the achieved outperformance versus the benchmark, and the amount of risk taken to generate this outperformance.

For the portfolio manager, the benchmark represents the zero-risk position. Over time, unless the manager deviates substantially from the benchmark, the portfolio's absolute performance is determined largely by the choice of the benchmark. Consequently, the choice of a portfolio's benchmark is very important.

There is an ever-growing number of published bond market indexes. Often, an appropriate benchmark can be selected from this set of standard indexes.

But there are many cases when none of these serve the goals of the investor or plan sponsor. To ensure that the benchmark correctly reflects a given investment opportunity set and constraints, a new, highly specialized index may need to be constructed. Finally, for some investors, the right benchmark may not even be a traditional total-return market index.

Fixed income markets are very large and diverse, so most indexes tend to include hundreds or thousands of securities. The sources of risk affecting fixed income securities are equally diverse and often difficult to analyze. These conditions may turn even relatively straightforward portfolio tasks into complicated endeavors. For most portfolios, a seemingly trivial problem of "buying the benchmark" means selecting a relatively small subset of constituent securities while ensuring somehow that its behavior will be reasonably similar to the broad universe. Understanding portfolio risk versus a benchmark is equally complicated because of many relevant risk dimensions and intricate interactions among them.

As a result, essentially all functions of the bond portfolio management process are aided greatly by robust quantitative methods. This chapter reviews some major issues facing bond portfolio managers, as well as quantitative approaches for dealing with them: selecting and customizing a benchmark, analyzing portfolio risk and performance, maintaining adequate liquidity, replicating benchmarks, and optimizing portfolio structure to improve its risk-adjusted performance.

SELECTION AND CUSTOMIZATION OF BENCHMARKS

Financial literature lists several desirable qualities for performance benchmarks. A good benchmark is defined as investable, transparent, known in advance, and objective. While all these are important attributes, first and foremost, the benchmark should be *appropriate*. An appropriate benchmark matches the required strategic allocation of portfolio assets, so that the portfolio's performance will be broadly consistent with the investor's overall objectives. A benchmark should also be investable so that a manager can "buy the benchmark" when and if he so decides. When comparing portfolio performance to the benchmark, it is critical to know when any difference owes to the manager's decisions and not to any in-built mismatches beyond the manager's control. Any constraints that limit the portfolio opportunity set must be reflected in the benchmark as well.

An index may provide an accurate gauge of the performance of a particular segment of the fixed income markets, but that does not necessarily make it an appropriate benchmark. For example, while the Bloomberg Barclays U.S. Aggregate Index is a widely used benchmark for the U.S. investment-grade fixed income market, the average duration of this index (5.85 as of January 31, 2020) may make it unsuitable for portfolios funding long-duration liabilities.

Reflecting Investor Opportunity Set and Constraints

When an investment policy requires specific allocations to certain asset classes or imposes other restrictions such as a duration target, a customized index may be a more appropriate benchmark. In the simplest case, a customized index merely changes relative weights of standard components while still including all securities in the standard index. Often, an investment policy may impose a minimum credit-rating threshold on the securities the portfolio can buy. Limitations may be placed on maximum exposure to an industry, country, and so on. Many other security attributes, such as minimum or maximum maturity, age, coupon, and so on, may also be controlled, requiring corresponding changes to the benchmark. In all cases, though, the goal should be to keep the benchmark as broad-based and well-diversified as possible while still meeting all the investment policy requirements. However numerous the modifications to the original market-based index, one important benchmark property always should be preserved: objectivity. The benchmark should be based on a set of rules specified beforehand and kept constant. The rule-based nature of a benchmark also allows for a historical analysis of its past behavior. Such analysis can be quite useful at the stage of selecting a benchmark.

One widely used method to achieve outperformance is investing outside the benchmark. Such investments (e.g., high-yield credit or emerging market debt) are frequently referred to as "core-plus." Even when an exposure to core-plus assets is constantly present in the portfolio, many managers still prefer to keep such assets out of the benchmark. Their motivation, of course, is to keep this potential source of outperformance at their disposal. However, a case can be made for inclusion of frequently used core-plus assets into the benchmark. First, by including these assets in the benchmark, the manager's relative performance can be more fairly measured if the manager has a persistent allocation to these assets. Second, it is often difficult to short-sell core-plus assets. Yet a manager who has expertise in these markets can benefit from a short position just as much and as frequently as from a long position. An easy way to short such assets is to underweight them versus the benchmark. This, of course, is only possible when they are included in the benchmark. Such a benchmark decision should be made only after ensuring that with the inclusion of these asset classes, the benchmark remains appropriate for the portfolio's investment objective and style.

Benchmarks for ESG Investing

A growing number of investors select the companies to invest in based on Environmental, Social, and Governance (ESG)[1] criteria. Several different approaches have been taken to do so. Some investors use negative screening, in which a portfolio mandate precludes investment in an entire industry viewed as objectionable, such as tobacco, weapon manufacturing, or coal mining. Others prefer a more nuanced positive-screening approach, in which companies are ranked by their business practices across a broad range of ESG-related categories and a portfolio is assembled by choosing among the better-ranked companies in each industry.

The implementation of such a policy involves many subjective decisions that can be difficult to encapsulate in strict rules. ESG is an umbrella term that

1. Other terms used in the industry to represent similar considerations include "socially responsible" and "sustainable" investing.

covers a company's impact on the society across a broad range of issues, from carbon footprint to data privacy to diversity of the executive board. Which of these are to be given greater weight when judging a particular company or industry? A number of dedicated providers have emerged that calculate ESG scores for companies, and each has developed its own distinctive methodology for navigating this complex set of criteria; the ranking of firms within an industry can thus vary substantially from one provider to another. Even the ostensibly simpler negative-screening approach is more difficult than it may sound. For example, many modern corporations have diversified business models. What percentage of revenue from an objectionable source should be allowed?

Index providers have designed benchmarks for investors using either of these approaches, often in cooperation with a provider of ESG scores. For example, the Bloomberg Barclays family of indexes includes two types of ESG-related benchmarks produced jointly with MSCI ESG Research. Their Socially Responsible Indices exclude issuers involved in activities that are in conflict with investment policies, values, or social norms, using MSCI's Business Involvement Screening Research to identify exposures to controversial business lines. Another series of benchmarks, the Sustainability indexes, use a best-in-class approach based on ESG ratings from MSCI ESG Research to choose the best-ranked subset of index bonds within each industry.

Once a decision is made to adopt a specific ESG benchmark, managing a portfolio against it should be largely the same as with any other benchmark (except that investors may want to see some additional statistics when comparing the portfolio and benchmark in terms of various ESG metrics). However, when ESG-related constraints are imposed on a portfolio measured against a standard benchmark, or when evaluating a potential change in benchmark, questions may arise about the potential effect of these decisions on portfolio performance. In this context, negative screening of entire industries has a larger effect on the systematic exposures of the portfolio; if bonds from the excluded industries perform better or worse than the market as a whole, portfolio returns will differ from those of the benchmark. Positive-screening techniques should allow managers to integrate ESG ratings into their security selection process without forcing major shifts in overall risk exposures. However, always favoring issuers with high ESG ratings can lead to unintended biases in systematic risk related to quality, spread, and geography. It is therefore essential that a benchmarked portfolio controls for these biases while selecting bonds from high ESG issuers. Research into the historical returns of risk-controlled index-replicating portfolios with an ESG tilt, using ESG ratings from either MSCI ESG Research or Sustainalytics, has shown that this approach has not harmed portfolio performance, and even produced increased returns.[2]

2. See Albert Desclée, Lev Dynkin, Jay Hyman, and Simon Polbennikov, "Sustainable Investing and Bond Returns," October 2016, Barclays Impact Series, No. 1; available on Barclays' public website.

Liability-Based Benchmarks

Sometimes a customized benchmark is necessary not because of sector, quality, or other allocation constraints but because the portfolio is expected to have a particular term-structure exposure. For example, some portfolios are managed to provide a particular cash-flow stream to fund a set of liabilities. At the simplest level, portfolio duration may be kept equal to the duration of the liability stream. Dedication is another widely used method for ensuring the necessary cash flows while (usually) minimizing the portfolio cost. Of course, funding the future liabilities is the main investment objective in such cases. Yet, investment policies of liability funding portfolios can be quite liberal, providing an opportunity for outperformance while still ensuring sufficient cash flows.

Such portfolios would benefit from a diversified benchmark with a cash-flow profile that matches the expected liability stream and at the same time fully reflects the manager's opportunity set. Consider, for example, a liability funding portfolio that is free to invest in any security in the Bloomberg Barclays Credit Index. An appropriate benchmark for such a portfolio could match the sector and quality distribution of the index while matching the cash-flow profile of the liabilities. Such a "liability-based" benchmark retains many of the desirable attributes of a broad market-based index: it is objectively defined, so the portfolio manager can stay neutral to it, and its returns are calculated using market prices. Because this benchmark consists of marketable securities, its performance can be calculated and published by a third-party index provider.[3]

Even outside the asset/liability context, many fixed income portfolios are managed with a specific duration target. If this target is not close to the duration of any standard (published) index, an appropriate benchmark may be constructed as a weighted blend of two published indexes, one of which is longer and the other shorter than the target. Although the weights needed to achieve a desired duration may have to be adjusted at regular intervals, they typically remain fairly stable (e.g., for indexes that consist mainly of option-free securities).

Things get more complicated for portfolios containing a large proportion of securities with embedded optionality. Duration of such portfolios is likely to be unstable, changing in response to interest-rate movements. For example, the duration of mortgage-backed securities (MBS) can be quite volatile. If maintaining a stable duration is important, managers may engage in such techniques as delta hedging to overcome the effect of negative convexity and keep duration relatively constant. Hedging techniques entail various costs, from the more obvious transaction costs to the less obvious but potentially more significant "whipsaw" costs.[4] It is unfair to judge the performance of a manager who must

---

3. For a detailed discussion, see chapter 10 in Lev Dynkin, Anthony Gould, Jay Hyman, Vadim Konstantinovsky, and Bruce D. Phelps, *Quantitative Management of Bond Portfolios* (Princeton, NJ: Princeton University Press, 2007).

4. Negative convexity causes duration to decline with falling rates. The term *whipsaw* refers to having to add duration after rates have just fallen and prices have gone up and to shed duration after the opposite movement.

engage in costly delta hedging against a benchmark that does not bear similar costs. Two possible solutions are (1) to apply delta hedging to the benchmark or (2) to construct a "constant duration" index that provides a fairer benchmark for a delta-hedged mortgage portfolio.[5] An example of such a benchmark could be a market-weighted MBS index dynamically hedged according to a set of rules, with a liquid leveraged overlay of Treasuries or futures contracts.

Asset-Swapped Indexes

Some investors can take credit positions but are required to match the interest rate exposure to their funding source (e.g., three-month LIBOR). For example, some bank and insurance investment managers must manage their portfolios to a short duration target for asset-liability management purposes but are free to exercise their credit skills in asset selection. Leveraged investors often concentrate on credit exposure but minimize interest-rate exposure by managing the portfolio duration to the short-term LIBOR funding. In an environment of moderate credit spreads and low interest rates (and worries about rising rates), traditional total return managers are also likely to keep durations very short while maintaining an overweight to spread sectors. These managers want to exercise their credit skills but avoid term-structure risk.

The most straightforward way to create and maintain such exposures is to turn to the floating-rate note market. However, given limited issuance, this may create an unintended concentration of systematic sector exposures or issuer idiosyncratic risk. Ideally, the manager would want to match systematic spread-sector risks (i.e., credit quality and sector exposures) of a broad credit market index while simultaneously removing exposure to all systematic Treasury key-rate risk factors except, perhaps, the shortest (e.g., three- or six-month) key rate. The challenge of designing a benchmark for such a portfolio is to ensure a very short Treasury duration and at the same time match the overall index allocations to the credit sectors.

To exercise their spread-sector timing skills while minimizing interest-rate exposure, investors can buy fixed-rate spread assets on an "asset-swapped" basis. Asset swaps are combinations of a fixed-rate bond (and its credit exposure) and an iinterest rate swap that exchanges the fixed-rate coupons for floating-rate coupons. In essence, an asset swap gives an investor an opportunity to take spread-sector exposure with little term-structure risk.

There are no formal indexes of asset swap performance. To benchmark an asset-swapped portfolio effectively, the benchmark must represent a "neutral" spread-sector allocation. Then the manager's deviations from neutral may lead to outperformance of the benchmark. Using three-month LIBOR as a benchmark is inadequate because LIBOR reflects only a single type of spread risk (i.e., swap

5. Lev Dynkin, Jay Hyman, Vadim Konstantinovsky, and Ravi K. Mattu, "Constant Duration Mortgage Index," *Journal of Fixed Income,* 10 (2000), pp. 79–96.

spreads) and does not represent the wide array of spread-sector choices that may be available to the manager. An ideal design for asset-swapped portfolios is a floating-rate benchmark that reflects a diversified set of spread-sector exposures. One approach to constructing such benchmarks[6] starts with the creation, for each asset class, of a "mirror" swap index, which is a portfolio of interest rate swaps with the same key-rate duration profile as that of the "mirrored" asset class. Then short positions in these mirror-swap indexes are combined with long positions in the corresponding asset-class indexes, as well as with a long position in a short-term asset (e.g., one-month LIBOR). This creates "asset-swapped indexes" for all asset classes in the benchmark. Finally, individual asset-swapped indexes are merged into the final composite benchmark according to the portfolio's "neutral" allocations.

Book Accounting Based Indexes

Fixed income investors typically measure portfolio performance by calculating returns using market prices at the beginning and end of the performance period. Consequently, the portfolio's market value fluctuates with changing Treasury yields, spreads, and prepayments. Most standard fixed income indexes are market return based, and many analytical tools make the same assumption about portfolios.

However, there is a large class of investors (e.g., insurance companies and banks) less concerned about short-term market fluctuations. They purchase fixed income assets to match a set of liabilities whose net present value is based not on market prices, but on book, or purchase, prices. Typically, these fixed income portfolios are relatively static. Investors expect the portfolio to earn an adequate spread over the cost of the liabilities, assuming that the assets do not default or prepay at a rate unanticipated at the time of purchase. Given that liabilities are valued using book accounting, these investors (and their regulators) need to measure asset portfolio performance similarly, either by the portfolio's "book return," which is book income divided by book value, or the portfolio's "book yield," which is its internal rate of return calculated at time of purchase. However, how can such investors measure their investment skill when most indexes are market return based?

Book accounting based investors can measure their performance relative to book accounting based indexes that, in theory, might be replicable investment portfolios. For example, suppose that in January an investor restricted to assets in the Bloomberg Barclays Aggregate Index must fund a newly acquired liability. The investor can passively invest in a book acounting based index constructed as of the end of January. The composition of this index is set to reflect the Aggregate Index as of that date, and its book yield and book return will be calculated every

6. For a detailed description of this methodology, see chapter 12 in *Quantitative Management of Bond Portfolios*.

month. Over the course of the next month, the index will generate cash flow (coupon, prepayments, proceeds from maturities), which is re-invested in the February Aggregate Index. Consequently, by the end of February, the January-constructed book accounting index becomes a conglomeration of the initial investment in the January Aggregate Index plus a smaller investment in the February Aggregate Index. This process is repeated every month. The performance of the January-constructed index, expressed in book accounting terms, reflects what the investor would have achieved by passively investing in the Aggregate Index starting in January, and thus can be directly compared to the book accounting performance of the investor's actual portfolio.[7]

Strategy-Based Indexes

Finally, some portfolio managers must operate under severe performance constraints such as "over the next three months generate as much return as you can, but don't lose any money!" Many official institutions manage their Treasury portfolios under such constraints. What is an appropriate benchmark for these investors? While a cash benchmark (i.e., zero duration) would not suffer any losses, it would severely limit income. In contrast, a longer-duration benchmark would likely generate more income but put the portfolio at risk of losses over the holding period.

The right benchmark would have a duration that maximizes expected returns subject to the risk constraint. But, how best to generate expected returns to determine the benchmark? Using historical Treasury returns data is one approach. An advantage of historical returns is that they are nonsubjective estimates of expected returns. However, historical returns are poor predictors of future returns. Another approach is to use expected returns embedded in the current term structure. These estimates are also nonsubjective (i.e., "no-view") because they assume only that the yield curve will remain unchanged. These no-view expectations reflect current market conditions, whereas historical returns do not.

A benchmark can be constructed using no-view expected returns and historical volatilities to maximize expected return subject to a risk constraint of not having a return less than zero with a pre-specified probability. The solution to this optimization problem is a Treasury portfolio that would serve as the benchmark. The manager would then be responsible for outperforming it. Alternatively, the manager could simply hold the benchmark if he did not wish to take any risk. This "no-view" Treasury benchmark is an example of how benchmarks can be objectively designed to reflect investment goals and constraints.[8]

8. For a discussion of no-view optimization and benchmarks, see chapter 22 in *Quantitative Management of Bond Portfolios*.

DIVERSIFICATION ISSUES IN BENCHMARKS

Issuer-specific risk always is an important consideration in credit portfolios. Excessive exposure to individual issuers is a concern not just for portfolio managers. Plan sponsors examine benchmark design and pay close attention to large single-issuer concentrations. This is a serious issue even for the users of very broad market indexes. As Exhibit 46-1 shows, as of January 2020, the top 10 issuers in the Bloomberg Barclays U.S. Corporate Index accounted for 16% of the overall market value (reaching as high as 24% in some years). For some plan sponsors, this is too much security-specific risk. An asset manager benchmarked to this index may feel compelled to have exposure to these large-cap issuers simply because they have significant weights in the benchmark. The concerns about the high level of absolute issuer risk in some commonly adopted benchmarks led to a number of developments in benchmark design that attempt to mitigate this risk.

Issuer-Capped Benchmarks

A cap on the market-value weight that an issuer can have in the index limits exposure to the issuer's idiosyncratic risk. When such a cap (e.g., 1%) is imposed, every issuer's capitalization is checked against this ceiling. The market value in excess of the cap is "shaved off" and redistributed to all other issuers in the index in proportion to their market-value weights. Different caps can be chosen for various credit ratings, reflecting the differences in issuer-specific risk between higher and lower credit qualities. While issuer-capped portfolios have existed for quite a while, issuer-capped benchmarks are more recent and emerged in response to the increased levels of issuer-specific risk in credit markets.

	Aaa–Aa	A	Baa	Industrial	Utility	Financial
Average	–2.62%	–0.39%	3.00%	3.17%	1.31%	–4.48%

Issuer-capped indexes may seem very straightforward. However, the cap level and the redistribution rule can have a significant impact on the risk and return characteristics of an index. Some redistribution rules can limit the benefits of issuer-capping by inadvertently introducing unfavorable sector-quality risk exposures relative to the uncapped index.[9]

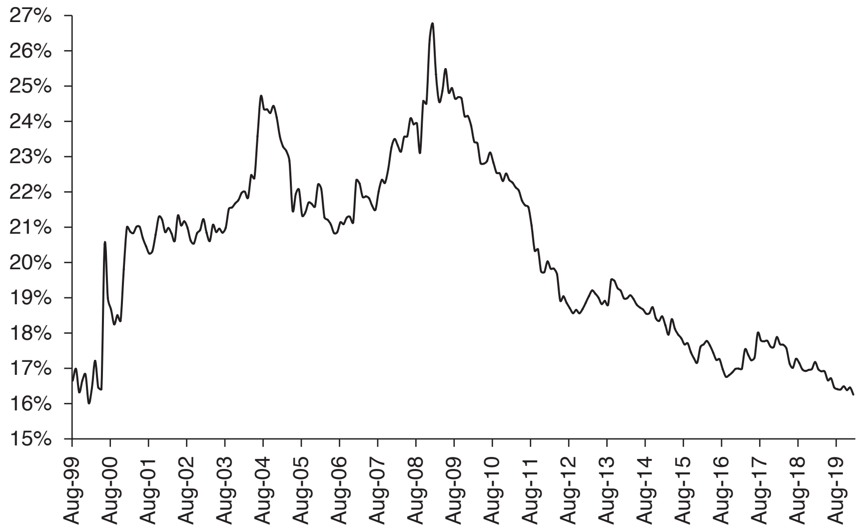
For example, an "index-wide" redistribution rule allocates the "excess" market value across all noncapped issuers in the index in proportion to their weights. However, this procedure may produce an index with very different

9. For a discussion of issuer-capped credit benchmarks, see chapter 13 in *Quantitative Management of Bond Portfolios*.

(and most likely unintentional) sector and quality exposures compared with the uncapped index. For example, Exhibit 46-1 covering the period August 1989 through October 2010 shows that the index-wide redistribution rule in a 1% issuer-capped Bloomberg Barclays Corporate Index produces significant overweights in Baa-rated and industrial issues and a significant underweight to financials compared with the uncapped Corporate Index:

EXHIBIT 46-1

Market-Value Weight of the Top 10 Issuers in the Bloomberg Barclays Corporate Index, August 1999 to January 2020



Source: Barclays

This inadvertent introduction of potentially unfavorable sector-quality risk exposures can be avoided by a "quality-sector-neutral" redistribution rule that preserves the sector and quality profiles of the uncapped index.

Another side effect of capping large issuers in an index is the increase in weights of smaller ones. By construction, in a capped index the market-value weights of smaller issuers exceed their actual weights in the marketplace, sometimes dramatically so. This raises a practical concern that the available market supply may not allow the manager to match (if desired) the required allocation in the issuer-capped index.

Issuer-capping has also been applied to sovereign indexes. The distribution of sovereign issuers is highly concentrated. For example, based on market-value weights, Japan represents about 27% of the Bloomberg Barclays Global Treasury

Index (as of January 2020), and the United States 30%. Within geographical regions these country weights are even larger, as Japan Treasuries account for over 76% of Asian Pacific Treasury bonds, while U.S. Treasuries account for 94% of Treasuries in the Americas. The skewed distribution of sovereign issuers may make issuer-capping attractive to investors. However, as with issuer-capped credit indexes, care must be exercised when redistributing any excess capped market value.

A simple sovereign-capping scheme of redistributing any excess market value above a cap level across all smaller sovereign issuers in the index does little to reduce the volatility of the index. This is because the excess capped market value gets proportionally re-allocated to countries economically closely related to the capped countries. A more productive sovereign-capping scheme is first to cap the market value weight of economic regions, and redistribute excess market value across other regions. Then, cap individual sovereigns within a region and redistribute any excess capped market value within the region. Such a two-tier capping scheme reduces the volatility of the index, compared to the uncapped sovereign index, and does not hurt the index's performance.

An alternative sovereign-capping scheme is to adjust index market value weights depending on the relative economic fundamentals across countries. For example, countries whose Debt/GDP levels are below average would have their index market value weights increased, while countries with above-average debt levels would have their weights lowered.[10] Such "fundamentals-based" weighting schemes have become more popular as sovereign creditworthiness has become less certain.

Despite these subtle issues, issuer-capped indexes are now a permanent fixture of the investment management landscape. With good judgment, investors can design issuer-capped indexes that meet their risk-management preferences in dealing with issuer-specific risk.

Swap-Based Benchmarks

A somewhat radical approach to dealing with issuer-specific risk in credit benchmarks is not to have this risk at all. Apart from the naive solution of adopting an all-Treasury benchmark, one type of popular benchmark is based on interest-rate swaps. Swaps offer excellent liquidity, a virtually unlimited market supply, low idiosyncratic or "headline" risk, and an opportunity to capture some of the long-term spread advantage of investing in non-Treasury product. Swaps have been a key feature of the debt markets since the early 1990s. In fact, in several ways the swap market is larger and more heavily traded than the U.S. Treasury market.

Swap payments are usually based on LIBOR, and therefore, the par swap rate curve can be viewed as a generic yield curve for large, highly rated banks

10. For a detailed description of one such index, see "Barclays Capital Fiscal Strength Weighted Bonds Indices," Barclays Capital, July 2011.

whose interbank lending rates constitute the LIBOR index.[11] Correspondingly, the swap spread (to the Treasury curve) is considered a generic proxy for high-grade credit spreads. (While the swap spread does not reflect the counterparty risk, it can be effectively dealt with via collateral management.)

This relationship between interest rate swap spreads and high-grade credit spreads has prompted some investors to consider swaps as total return benchmarks for their credit portfolios. However, unlike returns on regular fixed income securities, returns on swaps are not directly observable in the marketplace. In addition, while cash fixed income securities have an underlying market value that serves as the base on which to calculate returns, par swaps at initiation have zero market value. While swap yields and spreads are available from many sources, swap returns are not. To create total return indexes for the swap market, a new index methodology is needed.

The Bloomberg Barclays interest rate swap index methodology[12] relies on the creation of hypothetical constant-maturity swap "securities" from the swap curve. At the start of every month a set of par receive-fixed swaps is identified with swap rates taken from the specific maturity points on the swap curve. To create, say, the 10-year swap index, the 10-year par swap is paired with a cash investment in three-month LIBOR equal to the notional amount of the swap. Over the course of the month, the mark-to-market return of the 10-year swap is combined with the mark-to-market of the LIBOR deposit, divided by the initial notional value, to produce a 10-year swap index return. There are as many swap indexes as there are maturity points on the swap curve. Interest rate swap indexes exist for several major currencies.[13]

The individual swap indexes can be combined to produce a swap index with any desired term-structure profile (e.g., to match a particular liability duration target). Recall the earlier discussion on asset-swapped benchmarks where each asset class had an associated swap index (the mirror swap index) with a matched key-rate duration profile. A credit portfolio manager who has a swap index as a benchmark is completely free to hold only those credits that he thinks will outperform and to avoid credits expected to underperform duration-matched swaps. Credits on which the manager is neutral or has no view need not be in the portfolio at all. In contrast, if the benchmark is a market index, the manager is under pressure to have at least some exposure to the largest issuers in the benchmark. Even when managers have a negative view on a large issuer in the corporate index, they are unlikely to hold a zero weight because that creates a large active bet against the benchmark.

11. In the near future LIBOR may be replaced by another benchmark rate, such as Secured Overnight Financing Rate (SOFR).

12. Lev Dynkin, Yuri Greenfield, and Dev Joneja, "The Lehman Brothers Swap Indexes," *Journal of Fixed Income* 12 (2002), pp. 28–42.

13. In addition to interest rate swap indexes, CDX and iTraxx measure the total return of a funded investment ("selling protection") in these popular credit default swap portfolio indexes.

Downgrade-Tolerant Benchmarks

Most investment-grade credit indexes stipulate that a bond downgraded below investment grade be dropped from the index. Accordingly, portfolios benchmarked to the index may have to sell these bonds. Usually, this happens precisely when the spreads of such bonds are particularly wide, often wider than justified by any subsequent default losses. This bad timing may cause the index-benchmarked investors to forfeit, at least partially, the credit spread premium.

An alternative is to design a benchmark that allows managers to hold on to downgraded bonds and choose their own timing in selling such bonds.[14] Such a "downgrade-tolerant" Corporate Index has captured a spread premium almost 80% higher than the standard index. Exhibit 46-2 plots a yearly comparison between the two indexes, for the period from 1990 through 2009. The downgrade-tolerant index delivers a higher premium in every one of these 20 years, with virtually the same risk profile as the standard index![15]

These results suggest that if managers are allowed to hold on to bonds that the Corporate Index discards, they should be able to harvest a considerably higher spread premium and significantly improve their performance versus the benchmark.

EXHIBIT 46-2

Estimated Annual Credit Spread Premium, 1990–2009, % per year

PORTFOLIO ANALYSIS RELATIVE TO A BENCHMARK

The selection of the investment guidelines and appropriate benchmark marks the beginning of the portfolio management process. Once a portfolio is established, investors continually monitor its positioning relative to the benchmark. Apart from investing new funds, periodic transactions help maintain desired exposures and express changes in market outlook.

Certain portfolio-monitoring activities are typically performed at regular intervals (e.g., monthly) and in a set sequence. Other analyses are performed as the need arises and not necessarily in a fixed order. Yet, however different the operational details might be, there are certain common functions that portfolio managers must perform and certain types of tools necessary to do so. Typically, at the start of a performance period, managers will use forward-looking, or *ex ante,* analytics to create and ascertain the desired portfolio positioning. At the end of the period, managers will use backward-looking, or *ex post,* analysis to review and explain the realized performance, which, in turn, guides portfolio adjustments.

Analyzing Portfolio Risk: A Cell-Based Approach

The most obvious way to analyze portfolio-versus-benchmark risk is a structural comparison of the two by partitioning them into a matrix of cells. Different choices of partition variables put the focus on different aspects of portfolio composition. Corporate portfolios, for example, are likely to be divided by quality and industry category (e.g., basic industry, consumer cyclical, and energy). Segmenting by duration highlights the yield-curve exposure. The amount and quality of information a portfolio manager can derive from such reports depend on the appropriateness of the chosen risk dimensions and on the portfolio and benchmark attributes (beyond market-value percentages) available for comparison.

The fundamental assumption behind the use of structural reports is that the contribution of a mismatch in a given cell to the overall portfolio-versus-benchmark risk is primarily a function of the magnitude of the mismatch and the weight of the cell. Clearly, a portfolio that matches its benchmark in all cells (along *all* possible dimensions) is risk-neutral to the benchmark.

While the simplicity of such analysis is attractive, there are two major problems with its basic assumption. First, the risk consequences of a particular mismatch depend not only on its apparent magnitude but also on its nature, that is, the volatility of the underlying exposure. A mismatch in spread duration contribution of 1.0 in a low-risk sector has a very different risk than the same-size mismatch in a high-risk one. Experienced portfolio managers have a feel for the portfolio performance implications from the magnitudes of individual mismatches.

The second problem is equally important and, arguably, more difficult to compensate for with experience. The cross-correlation among the multiple sources of risk in a portfolio makes the task of judging overall risk a daunting one without quantitative tools. Two mismatches in two different cells, each entailing significant risk in isolation, may cancel each other if low (or even negative) correlation between them reduces their joint contribution to risk. Conversely, a few mismatches that could easily be ignored individually may represent a serious risk if the correlations among them are positive and high. Needless to say, when the number of mismatches reaches dozens, as it can even in relatively simple portfolios, finding the common risk denominator by "eyeballing" the structural mismatches is unrealistic.

Analyzing Portfolio Risk: Multifactor Risk Models

One reliable approach to quantifying a portfolio's active risk (i.e., risk versus benchmark) is multifactor risk analysis. Its primary goal is to help managers structure portfolios with desired risk exposures relative to the benchmark. As such, it is generally used not as an *ex post* control tool but rather as an *ex ante* tool for portfolio structuring. One obvious need is to measure the expected risk of return deviation in portfolios that track a benchmark. Another is to form a reliable estimate of risk for active managers with a particular outperformance, or "alpha," target. There is a well-established consensus among investment professionals regarding realistic levels of *information ratio,* or risk-adjusted outperformance, versus the benchmark. A realized information ratio above 0.5 generally is considered to be quite high, with 1.0 often seen as a practical upper limit. As a result, quantifying active risk allows managers to test the feasibility of a specified alpha target. For example, a portfolio with a required alpha target of 50 basis points per year should be allowed an active risk somewhere in the range of 50 to 100 basis points per year. If, as a result of policy constraints, the projected risk is estimated to be much lower, the manager should make a case for either relaxing portfolio constraints or lowering the alpha target.

Active risk has *systematic* and *idiosyncratic* components. The former is a result of the differences between the portfolio and benchmark sensitivities to common market *risk factors* (e.g., movements of the key rates, credit sector spreads, or volatility). The latter, sometimes referred to as "diversifiable risk," reflects unequal exposures (usually overweights in the portfolio) to individual issuers and can be present even when all systematic exposures are eliminated. This type of risk reflects residual spread movements of individual issuers, not explained by anything that happens to their peer group. Apart from the risk of typical idiosyncratic spread movements, there is default risk that is particularly important in lower-quality credit portfolios. In some risk models, default risk is modeled and reported separately from market risk. Conceptually, default risk contains both systematic and idiosyncratic parts. Correlated defaults across different issuers create a systematic risk component. To the extent that defaults are uncorrelated and reflect events specific to a particular issuer, the default risk is idiosyncratic risk. Separating the systematic and idiosyncratic components of default risk is quite difficult.

To quantify the systematic risk, multifactor risk models use historical volatilities and correlations of a relatively small set of risk factors. These are processed into a *covariance matrix* that is the cornerstone of the model. The idiosyncratic risk is quantified by measuring the differences between the portfolio and benchmark concentrations in a specific issue or issuer. These weight differentials are then multiplied by idiosyncratic spread volatilities specific to a given issuer or its peer group.

These risk components are combined to produce the key output of such models—*tracking-error volatility* (TEV), defined as the projected standard deviation of the monthly return differential between the portfolio and the benchmark. TEV is an extremely useful measure because it provides a common unit for many different sources of risk, enhancing comparisons of diverse exposures and greatly facilitating portfolio risk management and risk budgeting. Well-developed models not only compute TEV but also provide useful information on its components, for example, offering detailed analysis of the TEV sources, their relative contribution to the total, and their interdependence.[16]

Of course, the reliance on historical observations exposes the multifactor analysis to criticism that risk-factor correlations are unstable and depend (as do volatilities) on the economic cycle. These concerns, however, are easily addressed.

Different historical periods can be viewed as more or less relevant to the current environment. Some asset classes evolve over time, and their risk characteristics change. For example, the dramatically increased refinancing efficiency in the U.S. residential mortgage market made MBS prepayment history up to the early 1990s largely irrelevant for estimating prepayment risk in subsequent periods. Economic and market conditions also may justify emphasizing a particular historical period while downplaying others. Risk models can accommodate these risk dynamics—for example, by imposing time decay on the historical data series to give greater weight to more recent data.

The idiosyncratic component of active risk presents a bigger challenge to history-based risk models. To quantify the issuer-specific risk, a model needs estimates of residual spread volatility in all market segments. These estimates can be derived only from the historical time series of individual securities' residual returns, that is, parts of each bond's return unexplained by all the systematic risk factors. This requires a large body of individual security-level historical data.

As with systematic risk, there is the issue of choosing a relevant historical period for the idiosyncratic risk estimation. Conservatism is usually a good rule of thumb. After a spike in issuer-specific volatility, such as the one that happened in the U.S. credit market in 2008, a risk model needs to "learn" quickly from recent experience. Applying time decay to the historical data accomplishes this and makes the model produce higher estimates of idiosyncratic risk going forward. Sometimes, however, a risk model should pay less attention to recent experience. After a long period of calm, the model should revert to the equal weighting of historical data to avoid underestimating issuer risk.

16. For an example of such a model, see chapter 26 in *Quantitative Management of Bond Portfolios*.

Analyzing Portfolio Risk: Liquidity

Liquidity is one of the most important characteristics of financial markets. Liquidity has several dimensions and can have different meanings in different contexts. What is more, frequently used definitions of liquidity are often difficult to quantify rigorously and represent market aggregates, such as total trading volume, the number of bonds traded, and dealer inventories. However, a liquidity measure truly useful for portfolio managers has to be security-level. Such a measure can be used for monitoring and analyzing market liquidity while allowing full flexibility in defining the universe of interest, from large fixed income markets like USD investment-grade credit to very narrowly defined market segments suited for some particular inquiry. Investors often compare today's liquidity environment with various periods in the past. Aggregated to market level, a bond-level measure makes such comparisons rigorous, providing hard numbers as opposed to qualitative opinions often unsupported by evidence. It makes it easy to factor liquidity into a multitude of investment decisions: for example, selecting a bond universe for portfolio rebalancing, monitoring desk inventories, testing the feasibility of alpha strategies, and quantifying liquidity risk.[17]

Bond-level liquidity measures can be used by asset managers and plan sponsors in a variety of applications. For example, in portfolio structuring and benchmark replication, liquidity is one of the most important considerations. One of the challenges of managing a portfolio with a limited number of bonds against a broad market index is narrowing down the investable universe. A portfolio manager cannot evaluate thousands of bonds and must impose some selection constraints. Liquidity is always among them. Having a single metric defined consistently for every bond in the benchmark streamlines this process and makes it more robust. Once a liquid investable universe is in place, the manager can proceed to construct or to rebalance a replicating portfolio without worrying about the feasibility of the implementation.

An intra-market liquidity distribution can be as useful as historical liquidity patterns. It provides valuable information about the current market conditions, beyond simple statistics such as a market value-weighted average or median. Side-by-side distributions for various markets highlight differences between their liquidity structures. Cross-sectional distributions for the same market at different points in time can be equally instructive. For example, such analysis reveals that during the Global Financial Crisis of 2008, when market liquidity decreased dramatically, the distribution also became much wider, emphasizing the liquidity gap between more and less liquid market segments.

An important application of bond-level measures is adjusting tail risk models for liquidity. In times of market upheavals that often trigger massive portfolio

---

17. An example of such a measure is the transaction cost–based Barclays Liquidity Cost Score (LCS®). LCS measures the cost of an immediate, round-trip transaction of a typical institutional size and is expressed as a percent of the bond's price. See Vadim Konstantinovsky, Kwok Yuen Ng, and Bruce D. Phelps, "Measuring Bond-Level Liquidity," *Journal of Portfolio Management* 42(4), 2016.

liquidations, portfolio managers find it difficult to realize the mark-to-market value of their holdings. As a result, actual losses may far exceed the estimates by traditional VaR models based on published bid prices. To correct for this, one needs to recognize that losses in tail events are exacerbated by high transaction costs.

Among many other applications of bond-level liquidity measures are monitoring and reporting on portfolio liquidity; analyzing liquidity risk; decomposing a bond's spread into risk premium, default, and liquidity components; intra-market liquidity ranking; and understanding drivers of liquidity in various markets.

History-Based Scenario Analysis

In one form or another, scenario analysis is used widely by portfolio managers to study portfolio (and benchmark) behavior in various yield-curve, spread, volatility, prepayment, or exchange-rate environments. Managers may focus on what they consider to be the most likely scenarios or unlikely but potentially damaging scenarios. Scenario analysis complements multifactor risk analysis. It allows managers to stress-test benchmarked portfolios by subjecting them to extreme conditions ("three-standard-deviation events") not necessarily consistent with the history underlying the risk model. Such analysis may highlight potential sources of return deviations that do not manifest themselves under normal (by historical standards) circumstances.

When using scenario analysis, investors usually make explicit forecasts for specific, observable market dimensions: key interest rates, credit spreads for certain market sectors, particular exchange rates, and such. It is very difficult, however, to formulate scenarios that are consistent in both direction and magnitude across many different market sectors and to estimate the probability of such scenarios. This is similar to analyzing risk simultaneously along many dimensions. Thus the solution also can be the same as in multifactor risk models. A covariance matrix estimated from historical observations can be used to build "maximum-likelihood scenarios." Such scenarios incorporate a few explicit forecasts provided by the investor and then infer historically consistent realizations (forecasts) for all other factors in the matrix. Then the full set of stated and derived factor forecasts is translated into expected returns for individual securities.

Explicit forecasts may represent unlikely scenarios. For example, the projection of a one-month parallel yield change of 50 basis points represents a 2.3% probability event if the historical yield curve volatility is only 25 basis points per month (assuming a normal distribution). Similarly, historical correlation patterns would not support an expectation of credit-spread widening at the same time with an increase in Treasury yields because yield and spread changes typically are negatively correlated. A scenario-generation model can be made to assess the likelihood of an explicit forecast in light of the covariances that underlie the analysis and to allow a rescaling of forecasts to meet pre-specified likelihood targets. The views can be relative as well as absolute. A yield-curve slope forecast is an example of a relative forecast because it does not express an opinion on the overall direction of interest rates. Individual forecasts can be accompanied by degrees of confidence in them. For example, investors are often more confident in their views on credit spread movements than on currency and interest-rate changes. A robust scenario analysis framework should be able to incorporate this information.

Attribution of Portfolio Performance Relative to a Benchmark

A comprehensive performance-attribution framework must account for all potential sources of portfolio performance and quantify the contribution from each of these sources. Performance attribution of past returns is perhaps the most important tool that asset managers can use to substantiate their claims on expertise in a given style of investment. If, for example, a fund claims to be adept at finding undervalued credits, performance attribution can be used to determine what share of the fund's past outperformance was due to credit bond selection. Unless there is hard proof that the generated returns came from the advertised source, investors may worry that past superior performance might have been luck rather than skill and may, in fact, be a sign of imprudent risk taking.

Asset management companies also benefit from using performance attribution in the internal analysis of portfolio performance to help determine their skill in managing different kinds of exposures and the areas that may require improvement. Sources of achieved outperformance should be matched with sources of ex ante risk. Quantitative analysis of return deviations from the benchmark may point out unintended portfolio exposures that need to be corrected. This is particularly important for large funds with decentralized decision-making in which separate groups or individuals are responsible for yield-curve positioning, sector and quality allocations, and name selection. Performance attribution can help evaluate individual manager performance in such an organization. Flexibility is critical in this analysis. A performance-attribution framework will only be useful (and used) if it is aligned with the actual decision-making process behind the portfolio investments. This process differs across firms and may vary over time within a single firm.

For multicurrency portfolios, the analysis normally starts at the global level, where outperformance results from two basic sources: exchange-rate exposures and asset allocation exposures to different markets. The ability to implement currency hedges as an overlay using FX futures or forwards empowers managers to separate the asset allocation and currency allocation decisions. The attribution framework should explain the performance due to each.

After multicurrency outperformance is assessed, portfolio positions generally should be segregated by currency, and the performance of each single-currency portfolio evaluated separately (versus appropriate single-currency benchmarks). In a developed fixed income market, such as the United States, local returns can be divided into three main components: Treasury (yield curve), volatility, and spread.

Robust performance-attribution models rely on key-rate durations[18] to compute outperformance owing to the Treasury curve positioning. Both the portfolio and the benchmark are replaced by hypothetical portfolios of Treasuries with exactly the same yield-curve exposures, that is, with matching key-rate duration profiles. Then the returns of these "Treasury-matched" portfolios are compared. Any difference comes exclusively from their disparate curve exposures. The bonds in the Treasury-matched portfolios usually are not real securities but rather points on the par yield curve and contribute no pricing noise (such as owing to the richness of on-the-run issues). The model can break down this component of outperformance even further, to individual key-rate exposures.

A shift in implied volatility affects prices of bonds with embedded optionality. Quantifying outperformance owing to differences in volatility exposure requires a good term-structure model that can estimate the implied volatility of the Treasury curve, and the analytics to compute volatility sensitivity (or vega) for all securities in the portfolio and in the benchmark.

Outperformance owing to spread exposure can be broken into an asset-allocation part (asset class, sector, industry, quality, etc.) and a security-selection part. The former occurs when the portfolio had larger allocations to winning asset classes (or smaller to losing) than the benchmark. Security-selection outperformance comes from picking names that outperform their peers. Both measures depend strongly on the definition of asset classes or security peer groups.

Performance attribution is arguably one of the most complex elements in a suite of methodologies and tools that modern asset managers need. There are many technical points and subtleties, such as aggregating daily results, accounting for intraday trading, or dealing with pricing and return conventions that differ between the portfolio and the benchmark.

QUANTITATIVE APPROACHES TO BENCHMARK REPLICATION

Besides index funds whose investment mandates explicitly call for tracking benchmarks with the minimum possible deviation, "buying the benchmark" is often a reasonable tactic even for managers who normally pursue active strategies. For example, in times when managers have no definite views on particular segments of the market, matching index returns in those segments is a sensible strategy. Sometimes, when managers have accrued significant outperformance before the year is over, they decide to switch to passive benchmarking for the rest of the year to preserve their gains. Finally, investors sometimes use so-called

18. Rather than measuring sensitivity to a parallel shift of the entire yield curve, each key-rate duration measures the sensitivity of a security's price to changes at one specific point (key rate) along the curve, holding the rest of the curve unchanged. Measuring sensitivities to several key rates gives a more detailed view of a portfolio's rates exposure. See Thomas S. Y. Ho, "Key Rate Durations: Measures of Interest Rate Risks," *Journal of Fixed Income* September 1992.

proxy portfolios that replicate broad market indexes for modeling purposes rather than for direct investment. The main reason usually is to apply the same in-house models to both the portfolio and the benchmark, eliminating "model noise" that can be quite significant. Sometimes it is not feasible to include the actual benchmark in the analysis because of constraints on either processing time or data availability. Computer-based analysis gets simpler when applied to a small set of well-priced securities as opposed to potentially thousands of bonds in an index. Hence the term *proxy portfolios*.

As pointed out earlier, the replication of a diverse market index that has multiple sources of return is not trivial and requires complicated techniques and tools. There are two main techniques: replication with actual, or "cash," securities and replication with derivative instruments (e.g., futures and swaps). The replication strategies vary greatly, reflecting diverse characteristics of various fixed income markets, as well as objectives and constraints of different investors. For example, in markets with high idiosyncratic risk, it is relatively more important to match the issuer distribution of the benchmark. Where systematic risks dominate, the replication techniques should pay close attention to matching benchmark allocations along the important risk dimensions. For portfolios experiencing very dynamic cash inflows and outflows, replication strategies using derivatives may be preferred because of their liquidity and low transaction costs. Derivatives replication is also popular with investors engaged in "portable alpha" strategies that use liquid derivatives that require little or no cash investment to replicate index returns and then invest the available cash in overlay strategies outside the index to generate alpha.

Of course, the simplest way to replicate an index is to buy most of its securities. However, this method is practical only for the few largest index funds that have had years to accumulate many of the index issues. For smaller and newer portfolios, maintaining the required proportions of a large number of bonds would lead to buying and selling odd lots with limited availability and overwhelming transaction costs. Furthermore, this strategy is appropriate only for portfolios that intend to remain neutral versus the benchmark for a long time.

For many investors, cash replication involves buying a small set of index bonds to track the index. The problem of selecting the right subset of index securities is solved by one of two basic approaches: cell matching (stratified sampling) or tracking error minimization using a risk model. The relationship between the two parallels closely that between the cell-based and the risk-model approaches to measuring portfolio risk.

Replication with Cash Instruments: Stratified Sampling

Sampling is the "commonsense" approach. To replicate an index, one attempts to match its contribution to each important segment with a few securities. In the simplest case, the total market-value weight of holdings in a particular segment is set to match the index weight. More often, holdings are selected and scaled so that, collectively, they match the segment's contribution to the index duration. To improve tracking further, the manager may target other characteristics of each individual segment, such as convexity or credit quality. Of course, the more securities purchased in each segment, the more closely the portfolio will track the index.

This approach may work quite satisfactorily in homogeneous markets, such as U.S. governments or MBS. One very simple but effective approach to replicate governments requires just six securities. The index is partitioned into three market-specific maturity segments. The choice of these segments may reflect such market characteristics as auction cycles, maturity distribution, or refunding policies. Within each segment, the bonds are divided into two groups: one with durations above the segment's average and one below. One liquid bond is selected from each half-segment. These two bonds are weighted in such a way that the total duration of the pair matches the duration of the segment they represent. The three pairs of bonds are then given appropriate weights to match the contributions of their segments to the index. This simple procedure ensures sufficiently close matching of the term-structure allocation that is the primary source of risk in government markets.

Stratified sampling also works well for the U.S. MBS market that has little idiosyncratic risk. For MBS replication it is usually sufficient to sample the index along just three dimensions: program (GNMA 30-year, conventional 30-year, and all 15-year), seasoning (seasoned, unseasoned), and price (premium, cusp, and discount).[19] Stratified sampling works less well for markets with much idiosyncratic risk (e.g., credit). Simply matching broad risk dimensions still leaves the proxy portfolio vulnerable to issuer-level risk because, by necessity, the proxy portfolio overweights each issuer relative to the benchmark. This important question of how to control the issuer-specific risk of a portfolio is discussed below.

Sometimes stratified sampling is simply the only available replication method—for example, in markets where multifactor risk models are not available. The actual techniques, while still based conceptually on sampling, may get quite sophisticated. First of all, special rules may be used for selecting individual bonds in each segment (e.g., starting from the largest, or most liquid, issuers), as well as for setting the level of diversification in each segment (e.g., based on the segment's historical volatility). The sampling process may be performed within an optimization context. In this case, satisfying constraints is the main goal, with the objective function being a secondary consideration (yield, spread, or liquidity may be maximized, for example). The number of securities that end up in the replicating portfolio can be regulated by tightening or relaxing constraints.

The fundamental issues with replication techniques based on stratified sampling are the same as with the cell-based approach to analyzing risk. Matching some cells may be more critical than matching others because return volatility

---

19. Partitioning the MBS universe by price is essentially equivalent to partitioning by coupon. The advantage of using price is that the cutoff levels defining the boundaries do not change over time.

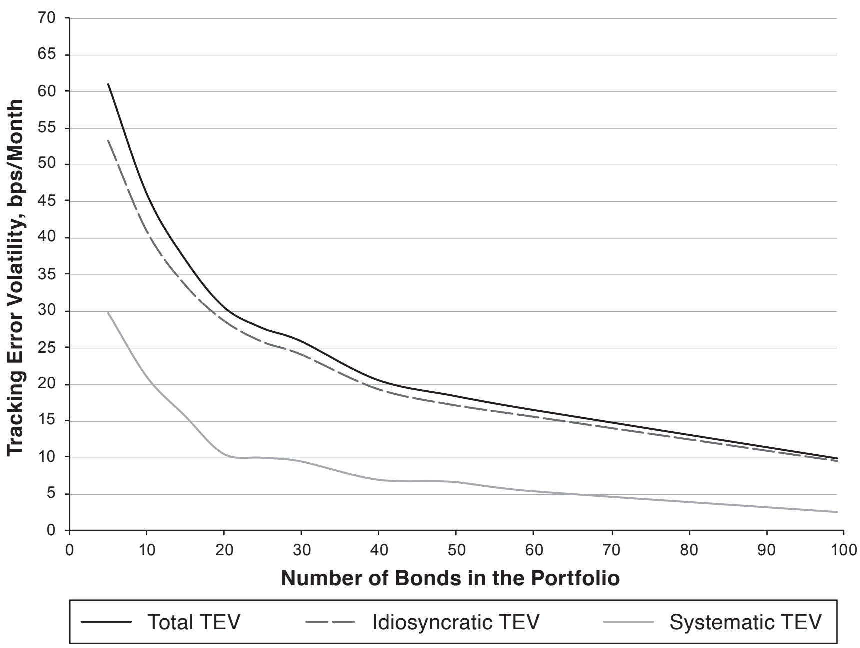
associated with these cells is higher. And sampling-based techniques ignore the all-important correlations among cells.

Replication with Cash Instruments: Tracking-Error Minimization

As mentioned earlier, multifactor risk models usually provide more accurate estimates of portfolio risk than sampling techniques that attempt to match the index risk parameters "naively," often ignoring historical variances and correlations of risk factors. Besides performing their primary function of measuring risk, multifactor models can be augmented with optimization capabilities. Given a set of securities representing the investable universe, a benchmark, and a set of constraints, an optimizer based on a multifactor model can pick a sample of bonds (a portfolio) with the minimum projected tracking error versus the benchmark. This may be done in one step, with the model being essentially a "black box" cranking out a solution. Or the model may allow the manager to step through the optimization one bond at a time, using his knowledge of relative value to select the best bond to buy from a list of candidates.

EXHIBIT 46-3

Tracking Error Volatility vs. the Bloomberg Barclays Corporate Index as a Function of the Number of Bonds in the Portfolio



Source: Barclays

Tracking-error minimization has been used successfully to construct replicating portfolios for broad benchmarks of the U.S. and global government and credit markets. This method also has proved very effective in replicating the Bloomberg Barclays MBS Index.[20]

The realized performance of most actual replicating portfolios has been within the model-projected range. The level of tracking achieved by a replicating portfolio depends, of course, on the number of bonds it contains. As more bonds are added to the portfolio, tracking risk decreases. Exhibit 46-3 illustrates this trade-off by showing how the projected monthly TEV of a corporate replicating portfolio versus the Bloomberg Barclays Corporate Index declines with the increase in the number of securities. At first, adding more securities to the portfolio reduces tracking error quickly, but gradually, the rate of decline slows. The explanation lies in the difference between systematic and idiosyncratic risk. As the plot shows, after the 60-bond level, the systematic risk ceases to be a concern. Consequently, even relatively small portfolios can match the systematic risk exposures of a broad market index surprisingly well. The dominant type of risk for small portfolios is idiosyncratic. By the time the portfolio size reaches 100 bonds, the idiosyncratic risk contributes almost 100% of the total TEV and declines very slowly as more bonds are added to the proxy portfolio.

Multifactor risk models rely on historical experience over the calibration period. Such models may ignore a significant structural mismatch between the proxy and index that historically did not result in return volatility. There is always a chance that historical patterns will not hold over to the next month, and that a mismatch will prove more consequential than the model assumed. This is why stratified sampling analysis may be useful even in the presence of a powerful risk model. It may alert the portfolio manager to structural mismatches ignored by the model. In such cases, managers may use their judgment in deciding whether to rely on historical patterns.

Replication with Derivatives

Derivatives effectively reduce the number of dimensions in the portfolio management problem and simplify asset allocation shifts and deployment of cash inflows. Because of this, derivatives can be particularly useful in replicating the benchmark at the start-up phase, when diversified cash investments in tradable sizes are not easily available. Derivatives can also be used in portable alpha strategies, in which a manager's value-added from one strategy is "transported" into another strategy.

Treasury futures have been widely used as a duration-adjustment tool because of such advantages as no disruption in cash holdings, ease of establishing and unwinding positions, and low transaction costs. A derivatives version of the cell-matching technique using a mix of Treasury futures contracts can be

20. Lev Dynkin, Vadim Konstantinovsky, and Bruce Phelps, "Tradable Proxy Portfolios for an MBS Index," *Journal of Fixed Income* 11 (2001), pp. 70–87.

effective in replicating the term structure exposure of any fixed income index. In one such methodology,[21] an index is divided into maturity (duration) cells, and the market value allocations and dollar durations of each are matched with a combination of cash and the appropriate futures contract. The cash can be invested in Treasury bills or other short-term instruments. For an added benefit, cash may be invested more aggressively into riskier and higher-yielding instruments such as commercial paper or floating-rate notes. For investment funds with frequent and significant cash inflows and outflows, replication of benchmark returns with exchange-traded futures and, increasingly, with ETF are often the preferred strategies. Similarly, a large asset allocation shift may be initiated with futures because of their liquidity and low trading costs. Less liquid cash assets can then be deployed gradually as opportunities arise.

While the term-structure exposure can be matched effectively with Treasury futures alone, spread risk needs to be hedged separately. The next level in derivatives replication techniques introduces Eurodollar futures and swaps to replicate indexes with credit spread exposure. Replication strategies based on these instruments rely on the positive correlation between credit or MBS/ABS spreads on the one hand, and the Treasury-Eurodollar (TED) and swap spreads on the other. These strategies can successfully replicate credit and mortgage benchmarks.

A further enhancement introduces TBAs to replicate the mortgage component and portfolio credit default swaps to replicate the credit component. TBAs offer two key advantages over mortgage pools in replication strategies: they are more suitable for unfunded strategies, and the back office aspects are much simpler because monthly interest payments and principal paydowns are avoided. Portfolio credit default swaps (CDX and iTraxx) are liquid instruments that investors can use to take a long or short position in credit. Credit yields can be broken down into two parts: the swap yield and a credit spread to swaps. Accordingly, the exposure to movements in swap yields can be matched by using interest-rate swaps, and the exposure to movements in credit spreads to swaps—by using CDX. For example, such widely traded portfolio products as CDX.NA.IG represent baskets of equally weighted CDS in 5- and 10-year maturities and can be useful in replicating credit indexes. TBAs and CDX swaps help reduce TEV for derivatives replication of the Bloomberg Barclays U.S. Aggregate Index.[22]

Finally, derivatives can be employed to replicate the broadest, multicurrency fixed income benchmarks. A global index presents investors with a portfolio management problem involving multiple yield curves and exchange rates, as well as credit and issuer risk in several markets. This diversity of exposures makes global indexes particularly good candidates for replication with derivatives.

Typically, the single-market components of a global index are replicated separately and then combined into one tracking portfolio. The greater number of

21. Lev Dynkin, Jay Hyman, and Peter Lindner, "Hedging and Replication of Fixed-Income Portfolios," *Journal of Fixed Income* 11 (2002), pp. 43–63.

22. Lev Dynkin, Anthony Gould, and Vadim Konstantinovsky, "Replicating Bond Indices with Liquid Derivatives," *Journal of Fixed Income* 15 (2006), pp. 7–19.

risk dimensions in a global index provides better opportunities for diversification of the TEV for each subcomponent of the index. For example, the tracking risk associated with replicating the U.S. MBS component is not likely to be highly correlated with the tracking risk in replicating the Euro-credit component. This will reduce the overall portfolio's TEV.

It is apparent that investors have a wide range of choices for derivatives replication of a cash index. For example, an investor wishing to replicate the Bloomberg Barclays U.S. Aggregate Index can choose among the following strategies: Treasury futures only; a blend of futures and interest rate swaps; futures, swaps, and TBAs; futures, swaps, TBAs, and CDX; swaps only; and so on. In addition, it may, at times, be possible for an investor to find a counterparty with whom to enter into a total return swap on the index itself. With an index TRS, the investor agrees to receive the total return on the index from the counterparty in return for paying LIBOR plus a spread. The choice of a derivatives replication strategy will depend on the investor's sensitivity to monthly tracking errors versus cumulative tracking over time, and the cost (both transactions cost and monitoring cost) of maintaining the replication strategy.

Some investors have little time or inclination to manage a large set of derivatives positions. To accommodate these investors some broker/dealers may offer a total return swap based on the total returns of a *basket of derivatives*, with the basket components automatically rebalanced every month to minimize the expected tracking error to the underlying index. Because the replicating basket contains very liquid derivatives instruments (e.g., futures and swaps), such total return bond replicating index swaps are inexpensive and liquid.

CONTROLLING ISSUER-SPECIFIC RISK IN THE PORTFOLIO

Credit crises like the one of 2008 usually prompt portfolio managers to adopt a more disciplined approach to diversifying portfolio risk (although a few years of calm often erode this discipline). At the simplest level, managers try to avoid large exposures to single issuers and hold as many different issuers in their portfolios as practical. A more nuanced approach, described below, places stricter diversification requirements on lower-rated bonds, as event risk is more significant in lower credit strata, both in frequency and in loss severity.

Managers who do not pursue alpha via name selection may not buy cash securities at all, choosing alternative ways of getting credit sector exposure. Such "bondless" portfolios assume the net issuer risk of the benchmark. For sufficiently broad market indexes, such risk is usually much smaller than the issuer risk of a typical cash portfolio. Well-developed and liquid swap markets in several currencies provide a viable means of getting credit exposure without acquiring actual securities and the associated exposure to their issuers. The credit derivatives markets, particularly credit default swaps, provide managers with even more flexibility in controlling credit exposures in their portfolios.

Sufficient Diversification in Credit Portfolios

The need to reduce issuer-specific risk by diversification is obvious to any credit manager. However, diversification should not be viewed as an unqualified benefit, because there is a downside to it as well, from increased transaction costs as more bonds are purchased to the dilution of the value of credit research as bonds with less perceived upside are added solely to increase diversification. This issue has been addressed in a study of optimal diversification levels in credit portfolios.[23] A simple model of downgrade risk was proposed, based on the observed historical underperformance of downgraded bonds and transition probabilities published by rating agencies.

The study helps to answer the following question: for a portfolio of a given number of bonds, how many bonds of each credit quality should be held to achieve the lowest tracking error due to downgrade risk? The optimal allocations are skewed in their diversification levels (i.e., in maximum allowed position sizes) across qualities. For the study period from August 1988 through September 2010, the optimal ratio of position sizes for the three major investment-grade credit categories was found to be roughly 3:1.5:1. In other words, the optimal position size in Baa-rated bonds, for example, was one-third the position size of Aaa-/Aa-rated bonds. Compared to earlier periods, this ratio is not very skewed because, in the credit crisis of 2008 higher quality bonds, primarily A- and Aa-rated financials, experienced significant turmoil.[24] The ratio reflects only one type of idiosyncratic risk—the risk of a credit rating downgrade. Of course, issuer-specific events can give rise to significant spread changes without an accompanying downgrade. Indeed, this type of volatility usually dominates in the higher-quality segment of the market. When one takes into account the spread volatility not caused by rating transitions, the position size ratio becomes less skewed, but still indicates smaller position limits in lower qualities.

Clearly, these ratios should never be used as a literal directive when structuring credit portfolios. They depend heavily on the methodology and the historical period covered by the study. Yet the very clear and enduring lesson is that to lower the overall issuer-specific risk, it is most important to diversify exposures to lower-rated issuers. This conclusion has implications for plan sponsors as well: portfolio guidelines that establish maximum position limits to force diversification should not do so evenly across credit qualities.

To counterbalance the desire to reduce event risk as much as possible, managers should carefully consider the costs associated with increasing the number of issuers in a portfolio. First, transaction costs increase as the portfolio transacts more and in smaller amounts. Second, there is the overhead of monitoring a larger number of issuers. Finally, as managers push to add issuers for diversification's sake, they will be forced to add issuers less highly regarded by their credit analysts. Consequently, the optimal level of diversification is determined by the trade-off

23. For the original study, see Lev Dynkin, Jay Hyman, and Vadim Konstantinovsky, "Sufficient Diversification in Credit Portfolios," *Journal of Portfolio Management* 29 (2002), pp. 89–114.
24. Over the period 1988–2002, for example, the ratio was a more dramatic 10:3:1.

between the reduction of issuer-specific risk and the dilution of outperformance. The development of quantitative models that pinpoint this optimal level is possible but not trivial. Such models need to consider both the marginal cost and the marginal value of credit research, as well as the portfolio's size and many other factors.

Swaps as a Total-Return Investment

Interest rate swaps traditionally have been used as a risk-management tool to adjust portfolios' term structure and spread exposures. However, swaps can be used as a total-return investment as well.

Changes in the credit risk premium influence both swap and credit spreads. Expectations of significant changes in the future Treasury supply, for example, as well as "specialness" of individual Treasury securities affect the spreads over Treasuries of swaps and other spread product. Total returns of interest rate swap indexes can help investors analyze and use swaps as just another asset class, complete with pricing, returns, and analytics.

As mentioned earlier, among the published swap indexes are so-called mirror indexes that match the term-structure (i.e., key rates) exposure of various popular fixed income benchmarks. Despite monthly tracking volatility, over the long period from August 1992 through January 2020, the cash components of the Bloomberg Barclays Aggregate Index performed roughly in line with their mirror swap indexes, as interest-rate exposures are the key determinant of fixed income asset performance. However, during periods of market stress, swaps tend to outperform. In 2008, for example, every single sub-index of the Aggregate Index underperformed its mirror swap index by a wide margin. Although that was a time of extreme market conditions, and there were historical periods when swaps underperformed, it is clear that swaps have a performance potential that investors should consider along with other spread asset classes.

EXHIBIT 46-4

Correlation Matrix: Excess Returns over Treasuries, July 1992 to January 2020

	Aggregate	Credit	Agency	MBS	ABS	5-Yr Swaps
Aggregate	1.00	0.93	0.65	0.68	0.64	0.42
Credit		1.00	0.54	0.43	0.63	0.36
Agency			1.00	0.50	0.35	0.64
MBS				1.00	0.35	0.39
ABS					1.00	0.20
5-Yr Swaps						1.00

Source: Barclays

Swap spreads usually are aligned with credit spreads, although certain factors can cause them to diverge. For example, in a steep yield-curve environment, swapping activity by corporations intensifies, leading to the tightening of swaps spreads unaccompanied by a corresponding tightening of credit spreads. Although such factors diminish the value of swaps as a credit proxy, they promote the role of swaps as a means to diversify systematic risk in total return portfolios. Exhibit 46-4 shows that for the period from July 1992 through January 2020, five-year swaps had a noticeably lower excess return correlation with the Bloomberg Barclays Aggregate Index than did any of the index's four main spread components. The low excess return correlation implies that adding five-year swaps to a diversified portfolio of agencies, credit, mortgage-backed, and asset-backed securities may reduce risk.

The treatment of swaps as a total-return investment should be considered from a tactical as well as a strategic asset allocation perspective. The outperformance and diversification properties of swaps make them a valuable tool for total-return portfolio managers.

Credit Default Swaps as Protection Against Issuer Risk

Credit default swaps (CDS) have a place in many portfolios. CDS can be used to hedge existing credit exposures in the portfolio and to create new exposures that may be difficult to create otherwise, for example, taking short positions to express a negative view. A conventional cash corporate bond bundles exposures to interest rates, swap spread, credit spread (over swaps), and possibly, currency risk as well. CDS allow investors to pick from this bundle of exposures only the desired one. With CDS, investors can separate their views on a particular credit (issuer) from views on the market segment to which that issuer belongs.

Besides their primary function of hedging out the default risk of particular issuers, CDS are used in a number of other ways. Some investors place bets on the "CDS-cash basis," that is, the spread between a CDS and corporate debt of the same issuer, or express relative views on two issuers. Finally, CDS are often more liquid than the underlying corporate bonds, providing an easier and cheaper way to get a desired exposure.

QUANTITATIVE METHODS FOR PORTFOLIO OPTIMIZATION

Optimization has been an important part of investment practice since the introduction of mean-variance analysis more than 60 years ago. The asset management problem lends itself quite naturally to optimization techniques. Almost always, it is a multi-variable, multi-constraint task with a well-defined objective. A portfolio of financial assets has two essential characteristics: investment return and risk (i.e., uncertainty about the magnitude of return). Therefore, the countless optimization methods and tools developed over the past decades target one of these two characteristics while controlling the other.

Historically, the usual objective function of portfolio optimization has been to maximize expected return relative to risk. This requires upfront estimates for expected returns of every asset considered in the optimization. Historical data, whether long-term or recent, are poor predictors of future performance. Analysts' forecasts are imperfect as well. This section examines two examples of optimization techniques that do not rely on explicit predictions of asset performance.

Optimal Risk Budgeting Based on Skill

Management of large, multi-asset portfolios is usually a collective effort. Various managers, analysts, or teams form opinions relevant to particular segments of the overall portfolio. Then all these opinions are considered by some central decision-making authority. This may be a committee of the very same portfolio managers responsible for individual portfolio segments, often supervised by a chief investment officer. Multiple recommendations have to be reconciled: "go long duration," "overweight the 10-year segment of the curve," "underweight industrials," "buy current coupon mortgages," and so on. How can the strategic decision maker establish the magnitudes of exposures along all these dimensions? They need to consider the interaction among all the intended exposures and the resulting overall portfolio risk. But first and foremost, they estimate (explicitly or implicitly) the degree of confidence in each particular recommendation, which depends on the perceived skill of those who made that recommendation.

The manager's skill is a critical factor that largely determines portfolio performance. While this is obvious, oddly enough the notion of skill is rarely used formally when allocating portfolio risk or projecting expected outperformance. Even more surprisingly, skill rarely is measured in any disciplined way.

Several studies have examined the role of skill in the historical performance simulation of various investment strategies.[25] These skill-based historical simulations produced an interesting conclusion. The information ratios of very diverse strategies were very similar for a given skill level. Apparently, when performance is measured on a risk-adjusted basis, the particular nature of an investment strategy plays a minor role. Performance is essentially determined by the skill and dimensionality (the number of independent decisions) of the strategy.

These empirical results confirm the "Fundamental Law of Active Management" defined by Grinold and Kahn.[26] This law states that the information ratio of an investment strategy is determined by two factors: the "information coefficient" based on correlation between predictions and realizations (and closely related to the probability-based skill) and "breadth," or the number of independent decisions made by the strategy.

25. For example, see chapters 24 and 25 in *Quantitative Management of Bond Portfolios*.
26. Richard Grinold and Ronald N. Kahn, *Active Portfolio Management* (New York, McGraw-Hill, 1999).

Because the information ratio is outperformance (alpha) divided by risk (tracking-error volatility), the law can be expressed slightly differently by stating that a strategy's alpha is proportional to risk, skill, and the number of independent decisions.

This idea has fundamental implications for portfolio optimization. Asset managers traditionally have used the mean-variance approach to find the optimal asset allocation that maximizes expected outperformance, or alpha, for a given level of risk (or minimizes risk for a given alpha). The Achilles' heel of this approach is the expected returns of asset classes (or strategies) used in the optimization.

The Barclays proprietary risk-budgeting methodology—*ORBS* (Optimal Risk Budgeting with Skill)—relies on skill levels, breadth, and directional views to allocate the total risk budget among macro strategies to maximize portfolio alpha. Skill at timing a given strategy is defined as a percentage of directionally correct forecasts for this strategy minus the percentage of directionally wrong forecasts. The risk allocated to an individual strategy is then translated into the size of an active position that corresponds to that risk. At the core of this risk-budgeting methodology is a covariance matrix of returns for the asset classes underlying all considered strategies. This framework is very flexible and can be applied to essentially any set of asset classes and investment strategies with any number of different constraints.

Asset Allocation for Buy-and-Hold Investors

A corporate bond provides investors with a relatively small spread over Treasuries during its lifetime in compensation for the risk of a large, albeit unlikely, loss from default. While default risk is issuer-specific and can be reduced via diversification, correlation of defaults among issuers makes it impossible to eliminate it completely. This asymmetric risk/return profile of credit investing corresponds most closely with the considerations of a long-term investor who intends to hold bonds to maturity. In contrast, most total-return investors have a much shorter time frame and perceive a very different, less asymmetric risk/return profile. For a total-return investor, the dominant risks are spread volatility (essentially symmetric) and possible loss of liquidity. At least in investment-grade markets, credit-quality deterioration typically occurs gradually, so the primary risk for a total-return investor is not default but rather downgrade and the accompanying spread widening.

This difference in perspective has major implications for buy-and-hold investors. The spreads observed in the market result from interactions among all market participants, many of whom are total-return investors. If these investors expect high short-term spread volatility or liquidity risk, they can drive spreads much wider than would be justified by long-term default risk alone. This action can work to the benefit of long-term credit investors unaffected by short-term risks.

The asymmetric nature of the risk/return profile for long-term investors should be reflected in their asset allocation process. The most common approach to asset allocation, mean-variance optimization, generally is not suitable for buy-and-hold investors. In mean-variance optimization, risk is represented by the standard deviation of asset returns, which implies a symmetric distribution. For very asymmetric return profiles, standard deviation is not a particularly helpful measure of risk. In fact, no single measure of risk is universally appropriate for dealing with extreme, or "tail," events. The treatment of this "tail risk" must be customized to the needs and risk tolerance of each investor. One approach to asset allocation focuses on the downside risk, that is, the part of the return distribution that is below a certain minimum required return. This approach, though, requires a fuller description of the return distribution; the mean and standard deviation are not sufficient.

The central problem in the buy-and-hold asset allocation process is the fundamental trade-off between current credit spreads and expected horizon defaults. When is credit "cheap" from a buy-and-hold perspective? The answer depends on the level of default risk in the portfolio. To what extent can the default risk be reduced by issuer diversification, that is, how many issuers should a portfolio contain to limit default loss to a certain threshold with a given level of confidence? Or what allocation among different credit qualities will maximize spread within a given limit of the tail risk? Sophisticated quantitative models and techniques have been developed to address these matters.[27] There is an extensive body of research literature dealing with modeling default risk and particularly with default correlation.

SUMMARY: PORTFOLIO MANAGEMENT TOOL SET

The challenge for building a good quantitative portfolio-level system comes from the simultaneous need for broad asset class coverage and consistency of analytics across all asset classes. Specialized systems usually offer advanced analytics for specific asset classes. The objective for a portfolio system is to treat a wide range of asset classes within a single consistent framework without giving up too much accuracy.

At the foundation of a powerful analytical suite are basic security-level analytics, such as cash-flow projection, spread-to-price conversion, and duration calculation. The word *basic* belies the enormous complexity of this task. The variety of financial assets available to investors is ever-expanding and necessitates powerful underlying yield-curve, mortgage-prepayment, option-pricing, and volatility models that need to be maintained and updated.

Built on security pricing models is a broad set of portfolio-level analytics, that is, portfolio management tools that help managers analyze portfolio risk exposures, estimate the effect of various changes to portfolio structure, construct

27. See chapter 16 in *Quantitative Management of Bond Portfolios*.

optimal portfolios, and attribute achieved performance. An important part of this analytical suite is a multifactor risk model. When such a model is enhanced with optimization capabilities, it becomes a powerful tool for portfolio construction.

A useful complement for history-based risk modeling is flexible scenario analysis. An advanced scenario analysis engine is able to expand a few user-provided inputs into a complete set of maximum-likelihood scenarios for all relevant risk factors. A flexible performance attribution model is another essential component of the analytical suite. Various portfolio optimization tools, such as the risk-budgeting framework described earlier, complete the picture. Each of these building blocks requires sophisticated financial modeling and computer implementation effort. The added challenge is to ensure consistency among various tools. The conclusions a manager derives from the risk model should not contradict those from scenario analysis. The ex post return analysis should attribute the achieved outperformance to the risk exposures highlighted in the ex ante risk analysis.

KEY POINTS

- Portfolio management entails two essential functions: forming market views at a macro and/or security level and optimally implementing those views in the portfolio.
- Portfolio managers usually focus on the first task. Success in uncovering relative value by market timing, sector, or name selection requires experience and intuition and is usually equated with portfolio management talent.
- Constructing actual portfolios that reflect the desired views is just as vital for ultimate performance. It is this task that is greatly aided by quantitative methods and benefits from the methodologies, tools, and studies described in this chapter.
- Quantitative approaches can add value at each step of the portfolio management process: selection, customization, and replication of benchmarks; construction and optimization of benchmarked portfolios; risk analysis; performance attribution; and empirical support of investment decisions.

Factor investing offers access to structural sources of long-term excess returns (i.e., the factor premiums) that are well-grounded in economic theory. Factor investing has been a well-embraced concept in equity markets for many years. More recently, it has been applied to fixed income markets, providing investors opportunities for attractive risk-adjusted returns. In this chapter, we explain the concept of factor investing and how it works in fixed income markets. We discuss academic evidence and empirical results on factors in government bonds and in investment-grade and high-yield corporate bonds. Factor investing in fixed income securities offers superior risk-adjusted returns., Fixed income portfolios with positive exposure to factors generate consistently higher returns than the index, without taking on additional risk. A multi-factor fixed income portfolio is an efficient way to earn market risk premiums for interest rate and credit risks, as well as to consistently add value from fixed income factor premiums.

FACTOR INVESTING

Investors are increasingly allocating to factors to build investment portfolios. A factor is a characteristic of a group of assets that systematically drives its returns and thereby accrues a premium in excess of the market return. Factor investing is the practice of allocating to factors as building blocks of portfolios with the goal to efficiently harvest these factor premiums. Factor investing differs from traditional investing in the sense that it follows a systematic, rules-based approach to select securities. A well-documented example is the value factor premium: securities that are attractively priced relative to their fundamental value, e.g., stocks exhibiting a low book-to-price ratio, tend to outperform in the long run. An equity portfolio consisting of stocks with a low book-to-price ratio should thus in the long run benefit from this exposure to the value factor and generate a higher return than a comparable portfolio consisting of stocks with a high book-to-price ratio.

Factor investing originates from a tremendous amount of academic research conducted since the 1960s in the field of asset pricing. Most notably was the development of the Capital Asset Pricing Model (CAPM). In the CAPM, there is a single structural return driver, the market factor, that compensates investors for exposure to nondiversifiable and systematic market risk. Since the 1970s, the investment industry started to incorporate these findings by offering easy, transparent, and often lower-cost exposures to the main market factors via the launch of equity and bond index funds. Nowadays, by far most investors allocate to these market factors in their portfolios. Research on the CAPM was followed by the development of another major asset pricing theory that allows for multiple factors driving returns, Stephen Ross's Arbitrage Pricing Theory (APT). Since the start of the 1970s, academics have put forward convincing evidence for the existence of such additional factors that provide a return over and above the market factor. Well-known examples are the value factor,[1] the momentum factor,[2] and the low-risk factor,[3]

Since the 2010s, factor investing has taken an enormous growth in equity markets. An important trigger was the (nowadays dubbed) "professors' report" of three renowned professors: Andrew Ang, William Goetzmann, and Stephen Schaefer. These professors were commissioned by the Norwegian Government Pension Fund, one of world's largest investment funds, to investigate its performance after large losses in the 2008 financial crisis. They critically evaluated the active performance of the fund and found that 97% of the fund's return could be explained by movements in the benchmark and that approximately 70% of the remaining active performance could be explained by exposures to various systematic factors. Their analysis further highlighted that these factor exposures were actually a by-product of bottom-up active manager selection by the fund.

---

3. Robert A. Haugen, and A. James Heins, "On the Evidence Supporting the Existence of Risk Premiums in the Capital Market," Working Paper, http://ssrn.com/abstract=1783797.

This all triggered the professors to advise the Norwegian Fund to incorporate an explicit top-down exposure to proven factors to maximize returns. We believe this recommendation is applicable to a very broad investor base.

In the ensuing years, factor investing has rapidly gained popularity among investors around the world. Asset managers and index providers have also dived in and increased the breadth of their offering in this field. Estimates of the amount of money invested in factor strategies vary from one source to another, ranging from USD 1 to 2 trillion globally in most cases. In a report published in 2017, Morgan Stanley estimated that almost USD 1.5 trillion was invested in smart beta, quant, and factor-based strategies and that assets under management have been growing by 17% per year on average since 2010.[4] According to a survey by FTSE Russell, already 58% of asset owners worldwide have implemented smart beta—in other words, factor-based strategies—in their portfolios in 2019.[5] This growth has not only taken place in equity markets, but also in multi-asset and fixed income portfolios.

There are several reasons for the popularity of factor investing, as it brings several benefits to investors. First, factor portfolios deliver higher Sharpe ratios than the market over the long term, as we also will show in this chapter for fixed income markets. Second, factors provide a diversifying source of returns, both over market exposure and discretionary sources of alpha. In fact, as shown by Ang, Goetzmann, and Schaefer[6] and by Van Gelderen and Huij,[7] factors are responsible for a part of the alpha of successful managers. Third, factor investing has a strong rules-based foundation and therefore has the potential to make the investment process more transparent and is often accompanied by lower costs than traditional active management. These reasons are also highlighted by asset owners in the annual industry survey by FTSE Russell, with the top four reasons to engage in factor investing being "return enhancement," "risk reduction," "improve diversification," and "cost savings."

In fact, factor investing is seen by many investors as a third way of investing, as summarized in the Exhibit 47-1: it has features in common with passive investing, such as its transparent and systematic, rules-based nature and lower costs, but also with active investing, as its positioning deviates from the market, aims to add additional performance, and has the ability to integrate other goals, such as Environmental, Social, and Governance (ESG) considerations.

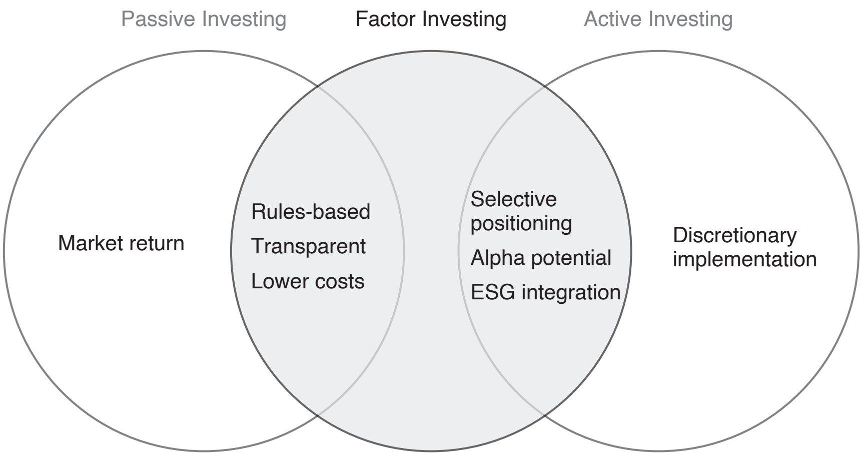
EXHIBIT 47-1

Factor Investing as a Third Way of Investing Between Passive and Active Investing



Although most research on factor investing focuses on the equity market, the concepts and benefits of factor investing apply equally well to other markets, including fixed income markets, as we will describe in this chapter.

WHICH FACTORS?

A key question to answer in factor investing is which factors should an investor focus on? This is especially relevant as academics have documented a "zoo of factors" (for example, in equity markets alone over 300 factors have been documented), and many only seem to work over short periods of time or in a limited number of segments of the market. In other words, many documented factors are not well-exploitable factors for investors. Further, researchers are subject to data-mining biases (often unintentionally and unconsciously), implying that the findings of many documented studies will fail to hold out-of-sample. For example, a study by Harvey, Liu, and Zhu[8] analyzed over 300 stock factors and found that most of these factors are likely to be "false positives." Another study, by Hou, Xue, and Zhang,[9] also found that most stock anomalies reported in the academic literature failed to hold up when thoroughly tested.

8. Campbell R. Harvey, Yan Liu, and Caroline Zhu, ". . . and the Cross-Section of Expected Returns," *Review of Financial Studies* 29, 2016, pp. 5–68.
9. Kewei Hou, Chen Xue, and Lu Zhang, "Replicating Anomalies," *Review of Financial Studies* 33, 2020, pp. 2019–2133.

So how exactly should we choose which factors to invest in? To be relevant for investors we believe a factor should meet five strict criteria:

1. *Performing*: A factor should produce better risk-adjusted returns than the broad market over the long term.
2. *Proven*: A factor should be able to overcome attempts (within academia and in-house research) to discredit its validity.
3. *Persistent*: A factor should be observable in different markets, stable over time, and robust to different definitions.
4. *Explainable*: A factor should have a plausible economic rationale for its existence, with strong academic underpinnings.
5. *Executable*: A factor should be implementable in practice and outperform after trading costs and other market frictions.

In other words, factors should be well-grounded in economic theory and have earned sizable net premiums over the long run that are robustly observed. In this chapter, we focus on four universal, common factors that pass these criteria: value, momentum, low risk, and size, where the latter applies specifically to corporate bonds.

- *Value* is the tendency of cheap securities, relative to their fundamentals, to outperform over the longer term, and for expensive securities to underperform.
- *Momentum* is the tendency of securities that have performed well in the recent past to continue to perform well, and for securities that have performed poorly to continue to perform poorly.
- *Low risk* refers to the observation that low-risk securities tend to earn higher risk-adjusted returns than high-risk securities.
- *Size* is the tendency of bonds issued by companies with little debt outstanding to outperform the market.

FACTORS PREMIUMS IN GOVERNMENT BONDS

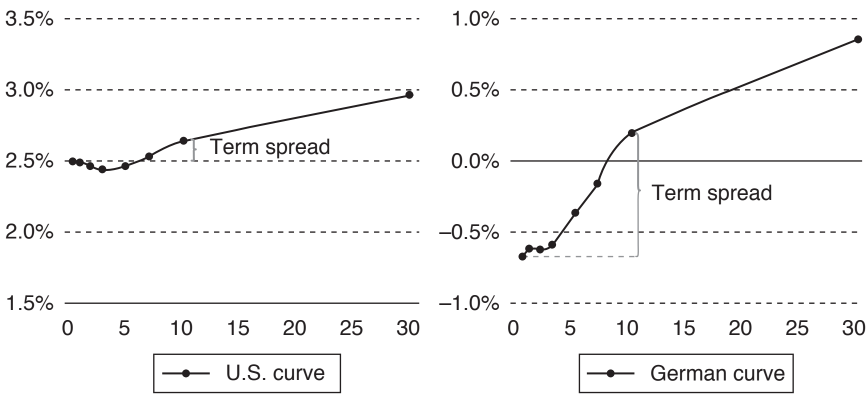
Having explained the concept of factor investing and the factor selection, we next turn to the theoretical and empirical grounds of factor premiums in global government bond markets. We examine three factors for developed market government bonds: value, momentum, and low risk.

Value

Value investing entails buying cheap assets and avoiding expensive ones. This requires a measure of relative valuation. In the case of stock selection, the price of a stock can be compared to its book value to measure whether the stock is over- or undervalued. For government bonds, however, there is no direct equivalent to the book value. A widely used value measure for government bonds in the academic literature is the term spread: the difference between the bond yield and the cash rate. In the example shown in Exhibit 47-2, the U.S. 10-year yield of 2.65% is just 0.15% above the dollar cash rate of 2.5%, while the German 10-year yield of 0.2% is 0.85% above the euro cash rate of –0.65%. Put differently: a German bond pays its owner a premium of 0.85% per year to hold a 10-year bond rather than cash, while a U.S. bond offers its buyer only 0.15% more than cash. The term spread is thus higher for German bonds than for U.S. bonds, even though the U.S. bond yield is higher than the German yield.

EXHIBIT 47-2

U.S. and German Yield Curve, Example for January 2019



Source: Robeco, Bloomberg.

The term spread is directly related to the yield available to an international bond investor who hedges currency risk. When hedging a foreign currency, one pays the foreign short-term rate and receives the local cash rate instead. The yield on a foreign bond investment, taking into account the FX hedging costs, is thus equal to the foreign bond yield minus the foreign cash rate, plus the local cash rate. In the example above, a U.S. investor who buys the German bond and hedges the currency risk faces negative hedging costs of –0.65% – 2.5% = –3.15%. The yield of the German bond hedged to U.S. dollar is thus 0.20% – (–3.15%) = 3.35%. This is indeed 0.85% higher than the U.S. cash rate, with 0.85% being the German term spread. The term spread can thus be used to compare the valuation of bonds from different countries on an FX-hedged basis.

The academic foundation for the term spread as a value measure is phrased in terms of forward rates. The term spread is large when yields on long-term bonds are higher than those on short-term bonds, so when future yield rises are already discounted in the current bond prices. In this case, the forward rate is higher than the current yield.

Fama already showed in 1984 that forward rates can be used to forecast bond returns: bonds for which large yield rises are discounted generally outperform bonds for which smaller yield rises are discounted.[10] This result thus underpins value investing in government bonds using the term spread as value measure.

Momentum

The momentum effect is that past winners tend to be future winners and, similarly, that past losers tend to be future losers. The momentum factor for equities thus selects stocks that have performed better than their peers, as this outperformance is likely to continue. For government bonds, this effect also exists and has been demonstrated in academic papers[11] comparing bonds from different countries. The momentum factor thus compares U.S. government bonds to, for example, Australian and Japanese government bonds, based on their recent performance. This performance is measured in terms of the excess return of the country's bonds over cash. This boils down to comparing international bonds based on currency-hedged returns, and thus purely based on the performance of the local bond market and independent of the movements in the currency. The momentum factor favors government bond markets that are performing well over markets that lagged recently.

Low Risk

The low-risk effect is that low risk securities within an asset class outperform the higher risk securities in the same asset class. The academic literature on equities provides extensive explanations for the low-risk effect, most notably leverage constraints of investors and behavioral biases.[12] These explanations are not specific for equities and apply to other asset classes as well, including government and corporate bonds. The first paper to document the low-risk effect in government bonds is Haugen and Heins.[13] They show that U.S. Treasury bonds with lower risk generate higher risk-adjusted returns. Their findings go against the basic CAPM notion that portfolios with higher risk should deliver higher returns. Surprisingly, the 1975 published article resulting from this working paper omitted

the results for bonds entirely.[14] The low-risk effect was therefore only formally documented in 2006 for U.S. Treasuries, and in subsequent studies for international bonds.[15] Maturity is typically used as risk measure in these studies given that interest rate sensitivity rises with maturity. The low-risk effect in government bonds thus means that shorter-dated bonds generate higher Sharpe ratios than longer-dated bonds. This can be seen in Exhibit 47-3 for U.S. Treasuries: longer-dated bonds have generated higher returns, but not sufficiently so to compensate for their higher risk.

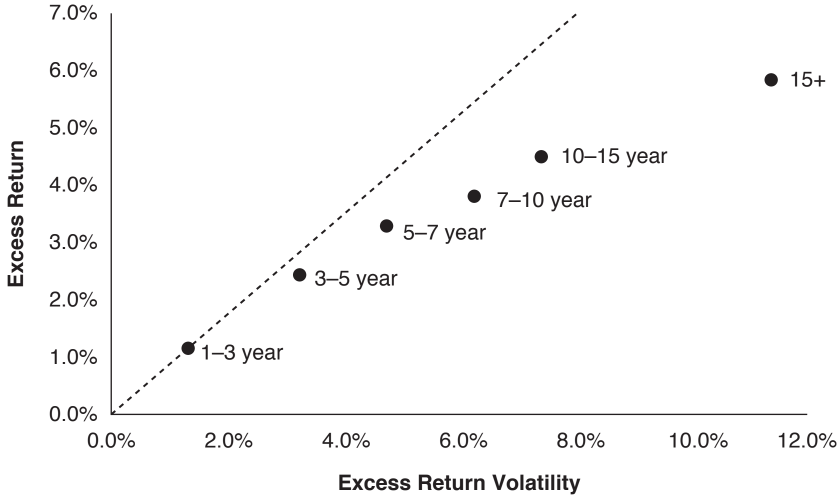
Average Excess Return and Volatility for U.S. Government Bonds of Various Maturities, 1999–2019



Source: Robeco, J.P. Morgan.

Factor Portfolios in Government Bonds Show Superior Risk-Adjusted Returns

We next examine the performance of portfolios of government bonds selected based on the value, momentum, and low-risk factors. To evaluate the aforementioned factors, we use monthly data from 1994 to 2019 for the constituents of

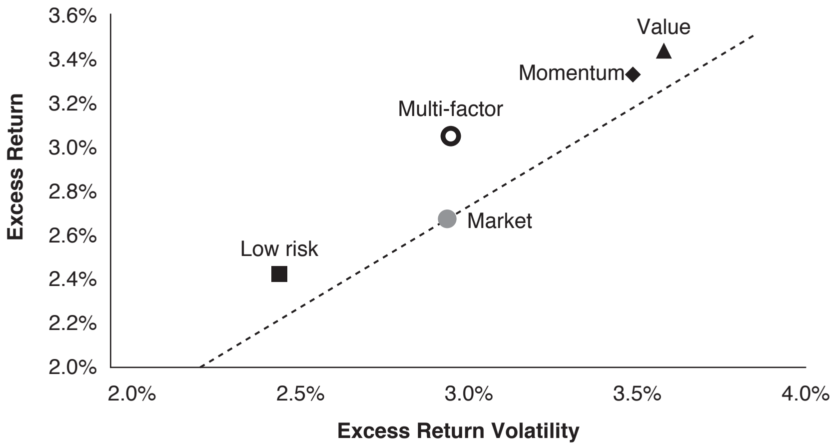
14. Robert A. Haugen, and A. James Heins, "Risk and the Rate of Return on Financial Assets: Some Old Wine in New Bottles," *Journal of Financial and Quantitative Analysis*, 1975, pp. 775–784.

15. Eugene A. Pilotte and Camden Frederic P. Sterbenz, "Sharpe and Treynor Ratios on Treasury Bonds," *Journal of Business* 79, 2006, pp. 149–180, and Andrea Frazzini and Lasse Heje Pedersen, "Betting Against Beta," *Journal of Financial Economics* 111, 2013, pp. 1–25.

the J.P. Morgan global government bond Index: Australia, Belgium, Canada, Denmark, France, Germany, Italy, Japan, Netherlands, Spain, Sweden, the United Kingdom, and the United States. We use the following maturity buckets: 1–5 years, 5–10 years, and 10+ years. The low-risk factor is constructed by being the 1–5Y maturity bucket of each country. Following Exhibit 47-3, it therefore has a lower return and a lower volatility than the market (which invests in all maturities), but a better Sharpe ratio. The value portfolio each month buys the four countries with the highest term spread. The momentum portfolio each month buys the four countries with the highest past 12-month returns.

EXHIBIT 47-4

Excess Return vs. Excess Return Volatility for Factor-Sorted Portfolios, Global Government Bonds, 1994–2019

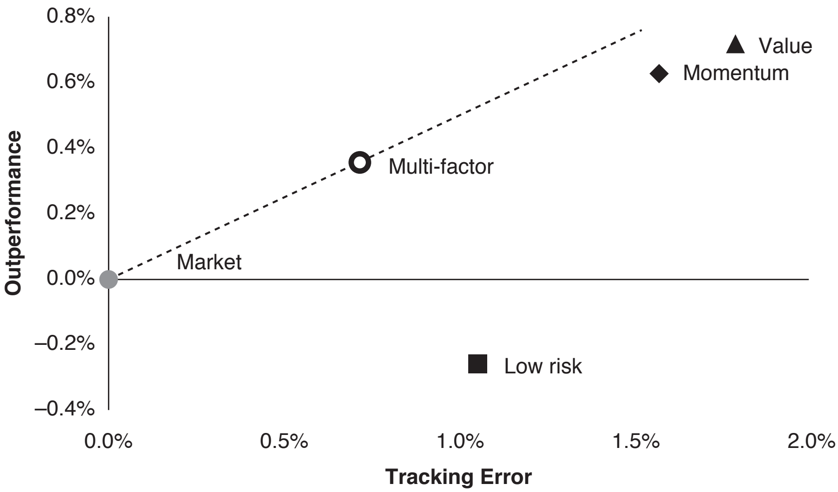


Source: Robeco, J.P. Morgan.

Exhibit 47-4 plots the results. Shown are the excess return and its volatility of the factor portfolios and of the global government bond market. The dotted line in the exhibit illustrates all risk/return combinations with the same Sharpe ratio as the market. The Sharpe ratio of the market is 0.87 (as we have seen a secular decline in yields over our sample). All three factor portfolios are located above the dotted line (i.e., they achieve higher risk-adjusted returns than the market portfolio). Note that the excess return is somewhat lower for the low-risk portfolio than for the market, but this is more than compensated for by its lower volatility. The value and momentum portfolios have a higher volatility, but this is more than offset by a higher return. Hence, each of the factor portfolios offers a higher Sharpe ratio than the government bond market portfolio, with 0.95 for low risk, and 0.91 for both momentum and value. To examine the added value of a combined, multi-factor portfolio we also combine the above three factors in an equally weighted factor portfolio. This portfolio has a similar risk level as the market and higher returns, with a Sharpe ratio of 0.99 which is significantly higher than the 0.87 Sharpe ratio for the market.[16]

EXHIBIT 47-5

Outperformance vs. Tracking Error for Factor-Sorted Portfolios, Global Government Bonds, 1994–2019



Source: Robeco, J.P. Morgan.

Exhibit 47-5 shows the same portfolios, evaluated relative to the market, so plotting tracking error versus outperformance. That means the market automatically has zero outperformance and zero tracking error (versus itself). The dotted line represents the portfolios with the highest information ratio (i.e., outperformance/tracking error) over the market. From a relative perspective, the low-risk factor portfolio on average underperforms the market. However, please note that this is expected, as it also runs at a lower absolute level of risk. When correcting for the lower bond market risk, the low-risk factor offers a positive alpha over the market portfolio, in line with the superior Sharpe ratio of the low-risk factor. Momentum and value offer outperformance over the market. Similarly, the multi-factor portfolio, by construction, has the average outperformance of

16. Here and later we use the Jobson-Korkie test (J. D. Jobson, and Bob M. Korkie, "Performance Hypothesis Testing with the Sharpe and Treynor Measures," *Journal of Finance* 36, 1981, pp. 889–908) for Sharpe ratios, corrected by Memmel (Christoph Memmel, "Performance Hypothesis Testing with the Sharpe Ratio," *Finance Letters* 1, 2003, pp. 21–23).

the three individual factors and hence also outperforms the market. Due to the diversification benefits between the factors, the tracking error of the multi-factor portfolio is lowest (the correlations between factors vary between –0.28 to 0.01). Consequently, it offers the highest information ratio, as represented by the dotted line.

FACTOR PREMIUMS IN CORPORATE BONDS

Next, we turn to the theoretical and empirical grounds of factor premiums in global corporate bond markets, both in the investment-grade (IG) and high-yield (HY) segments. In contrast to the academic literature on equity markets, where factors have been extensively documented since the 1970s, the evidence for corporate bond markets is more recent and more limited.[17] Below we show evidence for four factors: value, momentum, and low risk, just like for government bonds, as well as a corporate bond-specific size factor. Other factors have been investigated too in the academic literature. For example, Kyosev, Hanauer, Huij, and Lansdorp[18] document a quality factor for corporate bonds. We do not include the quality factor here because we focus on factors that can be calculated with bond market information, while the quality factor requires accounting data of the firm. Other studies have investigated a carry factor but found that it does not offer a significant premium over the market;[19] therefore, we do not include the carry factor here. In what follows we use the factor definitions of Houweling and Van Zundert,[20] who examine thoroughly the presence of factors in developed corporate bond markets. Other studies on developed markets include Israel, Palhares, and Richardson[21] and Bektic,Wenzler, Wegener, Schiereck, and Spielmann.[22] For evidence of factor premiums in emerging market corporate bond markets we refer to Dekker, Houweling, and Muskens.[23]

Value

Value investing entails buying cheap assets and avoiding expensive ones. L'Hoir and Boulhabel[24] and Correia, Richardson, and Tuna[25] are early studies on value investing in the corporate bond market. They show that bonds that are undervalued versus their "fair" value subsequently outperform the market, and bonds that are overvalued, underperform. They estimate the fair credit spread using a variety of risk measures. Exhibit 47-6 illustrates the value concept for corporate bonds, using rating and maturity as risk measures, by plotting the fair value credit spread curves for rating categories A and BBB. Bond 1 is an A-rated bond that is above the curve of A-rated bonds, and is therefore a cheap bond; bond 2, on the other hand, is an expensive BBB-rated bond versus its peers. Following Houweling and Van Zundert,[26] we choose rating, maturity and the three-month change in the credit spread as risk measures in a cross-sectional regression on credit spreads. The value factor portfolio consists of the 10% most undervalued bonds (i.e., bonds whose market spread is high compared with the fair value spread of other bonds with similar risk).

EXHIBIT 47-6

Example of the Value Factor in Corporate Bonds

25. See Maria Correia, Scott Richardson, and Irem Tuna, "Value Investing in Credit Markets," *Review of Accounting Studies*, 2012, 17, pp. 572–609.
26. Patrick Houweling and Jeroen Van Zundert, "Factor Investing in the Corporate Bond Market," *Financial Analysts Journal*, 2017, pp. 100–115.

Momentum

The momentum effect is that past winners tend to be future winners and, similarly, that past losers tend to be future losers. Previous research shows that this effect is strong in the high-yield market, but weaker in investment grade. Just like for government bonds, we sort corporate bonds on past returns to construct the momentum factor. Specifically, we follow Jostova, Nikolova, Philipov, and Stahel[27] by defining momentum as the past six-month credit return. The 10% bonds with the highest past returns are selected for the momentum factor portfolio.

Low Risk

The low-risk effect is that low-risk securities within an asset class outperform the higher-risk securities in the same asset class. Previous studies show that corporate bonds with lower risk generate higher risk-adjusted returns, where maturity and/or rating are typically used as risk measures.[28] So, portfolios of shorter-dated and higher-rated bonds historically had higher Sharpe ratios than the market. This is demonstrated in Exhibit 47-7, which shows credit return and credit volatility of corporate bond portfolios created within the U.S. Investment Grade market by first assigning bonds to maturity terciles (each containing one-third of the index constituents) and then to rating groups within those terciles. Clearly, shorter-dated bonds had lower volatilities than longer-dated bonds, as expected given their lower duration, but they did not have lower returns, thus generating higher Sharpe ratios. Within the rating dimension, lower-rated bonds did have higher returns, but not sufficiently so to compensate for their higher volatility. Within each maturity segment, bonds with lower ratings thus had lower Sharpe ratios than bonds with higher ratings.

To construct our low-risk factor portfolio for investment grade, we first select all bonds rated AAA to A– and so exclude the riskiest bonds rated BBB+, BBB, or BBB–. Each month we then select those with the shortest maturity, so the portfolio is made up of 10% of the total number of bonds. For high yield, we follow the same procedure, selecting bonds rated BB+ to B– and excluding the riskiest ratings CCC, CC, and C.

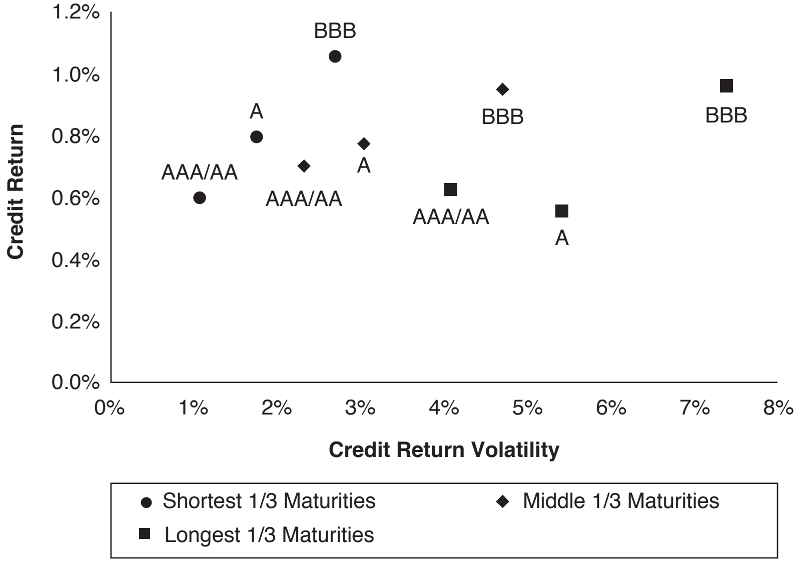
EXHIBIT 47-7

Credit Return vs. Credit Return Volatility for Maturity X Rating Double-Sorted Portfolios, USD Investment-Grade Corporate Bonds, 1994–2019



Source: Robeco, Bloomberg Barclays.

Size

The size effect is the tendency of bonds issued by companies with little debt outstanding to outperform the market. Smaller companies tend to be under-researched because investors typically aim to efficiently cover a large percentage of the market capitalization using a limited number of analysts. From that perspective, it is more efficient to cover companies with a larger weight in the index than those with a smaller index weight. Therefore, to define the size factor in the corporate bond market, we use the total size of a company's public debt rather than the size of an individual bond. In addition to an "under-researched" or information compensation, the size factor also captures an illiquidity compensation, as smaller companies tend to issue smaller bonds and smaller bonds tend to be less liquid than larger ones. Every month the size factor portfolio invests in 10% of the bonds belonging to the smallest companies in the index.

Factor Portfolios in Corporate Bonds Show Superior Risk-Adjusted Returns

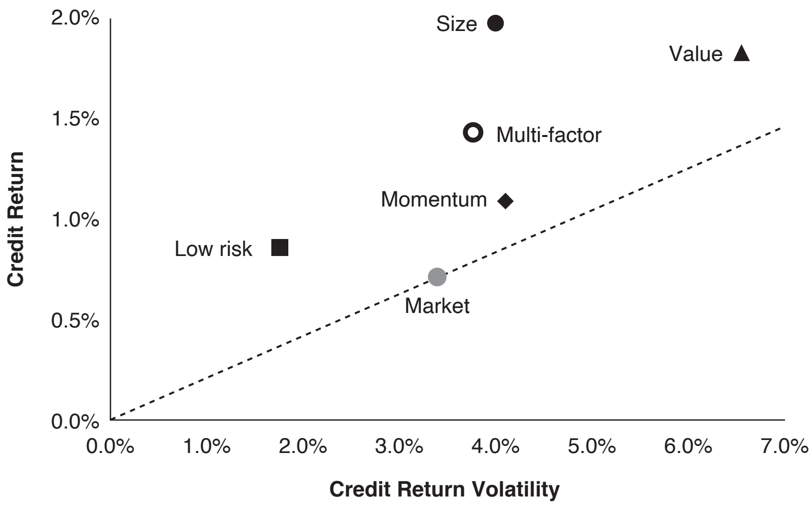
To evaluate the factors, we use 26 years of monthly data from January 1994 to December 2019 on all constituents of the Barclays U.S. Aggregate Corporates index, U.S. High Yield Corporates index, Euro Aggregate Corporates index, and

Euro High Yield Corporates index, hence covering a global sample of corporate bonds. Every month, we create equally weighted portfolios based on the factor definitions described above. In addition to the single-factor portfolios, we also construct a multi-factor portfolio that invests equal proportions in each of the single-factor portfolios. We analyze the credit return of each bond (i.e., its excess return over duration-matched Treasuries) to properly filter out the interest rate component (i.e., the term premium). We have two reasons for doing this, namely, (1) most institutional investors manage the interest rate exposure of their total portfolio separately, for example, using interest rate swaps or bond futures, and (2) investors buy corporate bonds primarily to harvest the default premium rather than the term premium because the latter can be more efficiently harvested by investing in government bonds.

Exhibit 47-8 plots the credit volatility and credit return of each factor portfolio in the investment-grade market. We note that each factor has a distinctive risk/return profile. The low-risk portfolio has a somewhat higher return than the market, but a much lower volatility. Value, on the contrary, has a higher volatility, but this is more than compensated for with a higher return. Momentum and size have a volatility similar to that of the market, but with higher returns. The Sharpe ratios of the size portfolio (0.49) and the low-risk (0.49) are significantly higher than the market Sharpe ratio of 0.21, while the Sharpe ratios of value (0.28) and momentum (0.27) are closer to that of the market, yet still higher. The multi-factor portfolio is in between (Sharpe ratio of 0.38, which is significantly above the market), with a volatility that is similar to the market and return that is 0.70% higher.

EXHIBIT 47-8

Credit Return vs. Credit Return Volatility for Factor-Sorted Portfolios, Global Investment-Grade Corporate Bonds, 1994–2019

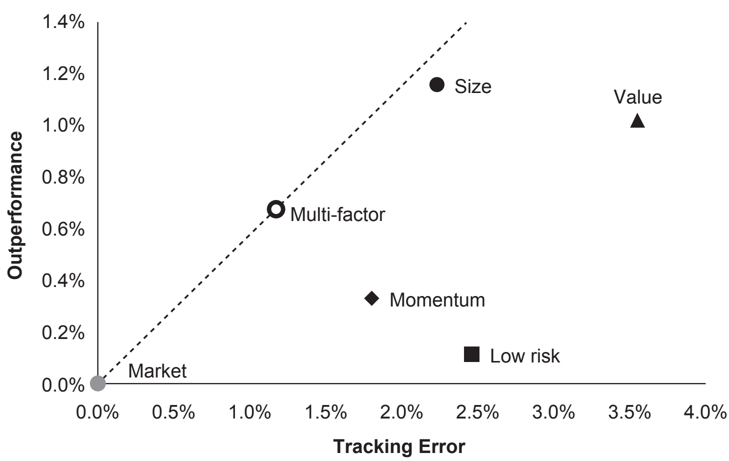


Source: Robeco, Bloomberg Barclays.

Exhibit 47-9 shows the same portfolios, evaluated relative to the market, so plotting tracking error versus outperformance. The results show that from this perspective the individual factors are less attractive. Low risk and value have particularly large tracking errors due to their large beta deviations. For value, a substantial outperformance of 1.1% a year compensates for this, but low risk only offers a modest outperformance of 0.1%, resulting in an information ratio of around 0. However, it has among the highest Sharpe ratios. This highlights the importance of a long investment horizon because the single factor-portfolios can be risky in the short term for benchmarked investors. The multi-factor portfolio, on the other hand, combines its high Sharpe ratio of 0.38 with an attractive information ratio of 0.62. The reason is that it diversifies across the individual factors, mitigating the possible underperformance of one or more factors for prolonged periods of time. This leads to a lower tracking error than that of the individual factors, while maintaining the outperformance.

EXHIBIT 47-9

Outperformance vs. Tracking Error for Factor-Sorted Portfolios, Global Investment-Grade Corporate Bonds, 1994–2019



Source: Robeco, Bloomberg Barclays.

Exhibits 47-10 shows the risk and return of the high-yield factor portfolios. The results are similar to those for investment grade. Low risk has a much lower volatility than the market and value a higher volatility. The Sharpe ratios of the four factors range from 0.47 (momentum) to 0.71 (size) and are all significantly larger than the market Sharpe ratio of 0.30. The multi-factor portfolio's volatility is again similar to the market's, but its Sharpe ratio is twice as high (0.61 versus 0.30) due to its higher return. Exhibit 47-11 shows the high-yield factor portfolios in a relative risk framework. As in investment grade, low risk has the lowest information ratio, only 0.26. The other factors have information ratios ranging from 0.47 (momentum) to 0.74 (size). Again, combining the four factors in a multi-factor portfolio leads to the highest information ratio, 0.83.

FIXED INCOME FACTORS IN MULTI-ASSET PORTFOLIOS

Having established the evidence on factor premiums within the government bond segment and the investment-grade and high-yield corporate bond segments, we next examine factor portfolios that bring together these segments across the overall global bond market. In addition, as investors usually invest not only in fixed income but also in other asset classes, most importantly equities, we also examine the added value of factor investing in fixed income securities in a multi-asset portfolio context.

To this end, we first construct equity factor portfolios. We obtain monthly returns for the value (i.e., book-to-market ratio) and momentum (i.e., past 12-month returns skipping the last month) factors for the global stock universe over the period January 1985 until December 2019.[29] We augment these factors with a low-risk factor portfolio (i.e., past 36-month stock volatility) based on Hanauer and Windmueller.[30] For all three equity factors, we follow the Fama-French methodology of averaging the small cap and large cap top factor portfolios. Therefore, we tilt factor portfolios to smaller caps, as for corporate bonds. Blitz, Baltussen, and Van Vliet,[31] among others, show that equity factor premiums tend to be stronger in smaller caps, and hence having exposure to smaller caps leads to more efficient factor portfolios.

For government bonds and corporate bonds, we use the same data as in the previous sections, and use returns in excess of the one-month T-bill rate for all assets. Note that this implies that for corporate bonds, we add back the interest rate return component to the corporate bond indices and factor portfolios to compare the asset classes on an equal footing (in previous sections we analyzed the excess returns over duration-matched government bonds).

First, we show the Sharpe ratios of all asset classes and the associated multi-factor portfolios in Exhibit 47-12. In every asset class, factor portfolios offer superior risk-adjusted returns versus passively investing in the market index. We also show an overall fixed income portfolio, constructed by equally weighting the government bond, investment-grade, and high-yield corporate bond portfolios (labelled "Bonds" in Exhibit 47-12). Historically, the Sharpe ratio increases from 0.85 to 1.12 when investing in the global multi-factor fixed income portfolio instead of in the market. In other words, factor investing in fixed income securities offers superior risk-adjusted returns.

29. The returns are obtained from the online data library of Professor Kenneth French (http://mba.tuck.dartmouth.edu/pages/faculty/ken.french/data_library.html). We also obtain the equity market portfolio from this source.

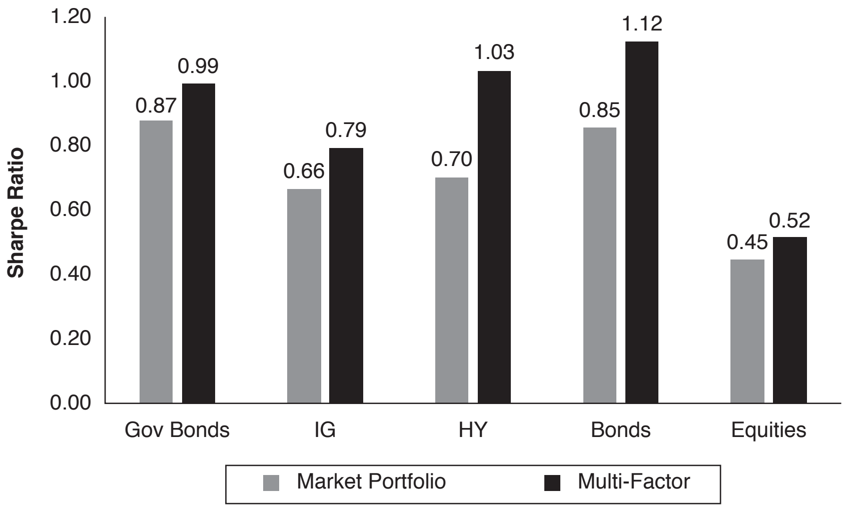
EXHIBIT 47-12

Sharpe Ratios Market and Factor Portfolios over the Risk-Free Rate for Government Bonds, Investment Grade (IG), High Yield (HY), Fixed Income in general (Bonds), and Equities



Source: Robeco, Bloomberg Barclays, Data Library Kenneth French. Period: 1994-2019.

Next, we analyze the correlation between the outperformances of the multi-factor portfolios across the various asset classes, as shown in Exhibit 47-13. Outperformance is computed versus the respective market index for each asset class. Overall, correlations are low, which suggests that harvesting factor premiums in multiple asset classes is beneficial. The highest correlation is observed between the investment-grade and high-yield multi-factor corporate bond portfolios, which makes sense given that these segments both consist of corporate bonds.

EXHIBIT 47-13

Correlation Matrix of Outperformances of Global Government Bond ("Govt"), Global Investment-Grade Corporate Bond ("IG"), Global High-Yield Corporate Bonds ("HY"), and Global Equity ("Eq") Multi-factor Portfolios over Their Respective Market Portfolio, 1994–2019

	Govt	IG	HY	Eq
Govt		–0.01	0.01	0.09
IG			0.55	0.12
HY				0.12

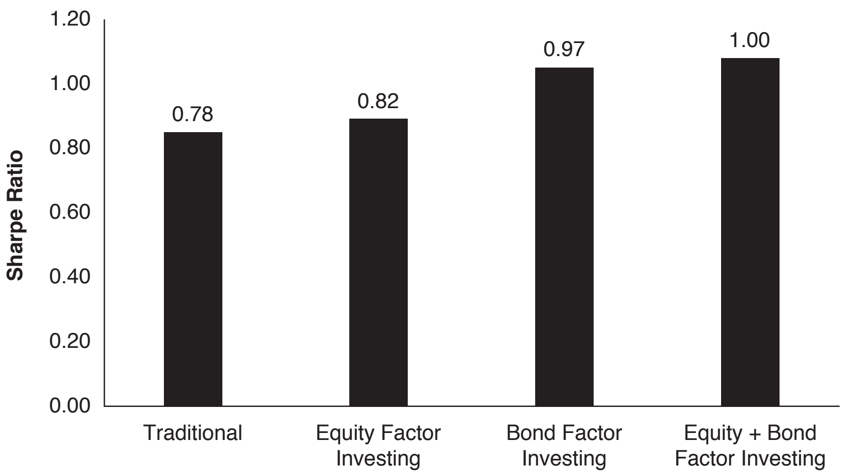
An investor might already be allocating his equity portfolio to factors and wondering about the added value of factor investing in his fixed income portfolio. To answer this question, we analyze a simple multi-asset portfolio containing 25% allocations to equities, government bonds, investment-grade corporate bonds, and high-yield corporate bonds. First, we evaluate a traditional portfolio, in which all asset class allocations are invested in market index portfolios. Next, we test three alternative allocations, where we (1) allocate only the equity portfolio to a multi-factor equity portfolio, (2) allocate only the bond portfolios to the multi-factor portfolios, and (3) allocate both the equity and bond portfolios to the multi-factor portfolios. The results are shown in Exhibit 47-14.

EXHIBIT 47-14

Sharpe Ratios Multi-Asset Portfolios over the Risk-Free Rate



Source: Robeco, Bloomberg Barclays, Data Library Kenneth French. Period: 1994-2019.

Factor investing also offers superior risk-adjusted returns in a multi-asset context. When only applying equity factor investing, the Sharpe ratio of a passive traditional multi-asset portfolio improves from 0.78 to 0.82, an improvement of 5%. With bond factor investing (but no equity factor investing), the Sharpe ratio improves from 0.78 to 0.97, an improvement of 24%. When applying multi-asset factor investing (so both in equities and bonds), the Sharpe ratio is highest at 1.00, a 27% improvement over the passive multi-asset portfolio.

KEY POINTS

- Factor investing offers access to structural and persistent sources of returns (i.e., the factor premiums) over the long run that are well grounded in economic theory.
- Factor investing provides investors with attractive risk-adjusted returns, diversification, increased levels of transparency via a disciplined, rules-based investment processes, and is often accompanied by lower costs than traditional active management.
- Factors like value, momentum, low risk, and others provide consistent and attractive returns across government bonds, investment-grade corporate bonds, and high-yield corporate bonds.
- Multi-factor fixed income portfolios are an effective way to apply factor investing in fixed income, and consistently add value for a variety of investors.
- Complementing equity factor investing with fixed income factor investing offers superior risk-adjusted returns for multi-asset investors.

Fixed income investing has undergone a sea change in the past decade. By tossing out some active management orthodoxies and embracing new technologies and quantitative techniques, we can capture unique insights and excess returns. Several investment shops, however, have cast this as a binary choice between relatively new quantitative approaches and "traditional" active approaches, practitioners of which remain steadfast in the fundamental economic laws of capital markets. We think this quantitative versus active debate sets up a false dichotomy. In this chapter, we provide an active fixed investment management approach driven by quantitatively derived insights.

ACTIVE QUANT FIXED INCOME

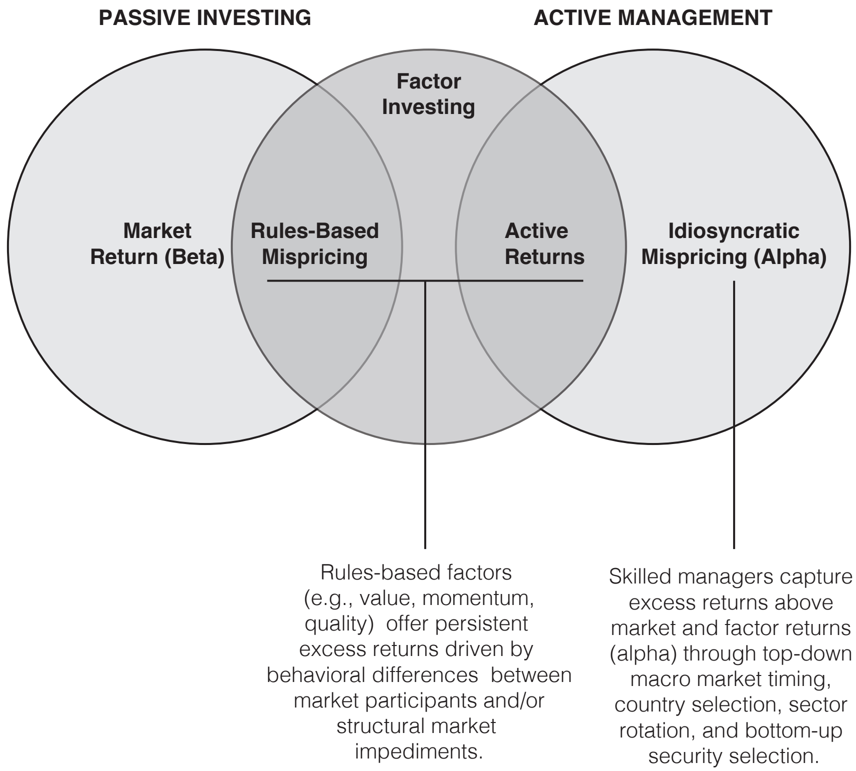
Investing in fixed income markets has undergone a significant transformation in recent years. For starters, factor investing that was originally popularized by index providers like MSCI and commonly found in equity portfolios is now spreading into fixed income.[1] Sometimes called "smart beta" or "systematic investing,"

1. Sophie Baker, S, "Factor-Based Investing Arrives for Fixed Income," *Pension & Investments* 16O) ctober 2017).

these quantitative ("quant") investment strategies seek to capture excess returns by using rules-based factors. Factors, like value, momentum, and quality, explain the outperformance of certain securities relative to other securities in the same asset class. These quant-oriented approaches belong to a new investment category (shown in Exhibit 48-1) that theoretically sits between passive index strategies offering market beta and active managers who deliver alpha (i.e., excess returns not explained by the overall market's rate of return, or beta).[2]

EXHIBIT 48-1

Factors Sit Between Beta and Alpha



2. Jennifer Bender, Remy Briand, Dimitris Melas, and Raman Aylur Subramanian. "Foundations of Factor Investing," MSCI Research Insight, December 2013.

Factor investing is still relatively new, but the underlying asset pricing mechanisms have been studied for decades in academic literature by the likes of Eugene Fama and Kenneth French,[3] who explained equity market excess returns, and the risk factor pioneer Barr Rosenburg. The real sea change came when quant managers and index providers devised transparent methods to measure and capture these factors. Suddenly, active managers did not need an army of credit analysts pouring through corporate financial statements to construct cash-flow models. Why bother if quantitative programs could achieve the same results with a factor lens?

The arrival of bond factor strategies has sparked some robust exchanges between quants and active bond managers. One such exchange that made headlines in 2018 started when a white paper by a quantitative asset management firm asserted that most active bond managers offer little in the way of true alpha. Any excess returns, it was claimed, comes mostly from "passive" exposure to corporate credit risks.[4] Members of one active bond portfolio management firm fired back in its own paper, pointing out in careful detail why the claim was false.[5] Rather, it argued, skillful security selection from seasoned credit analysts still matters.

Factor investing, however, is not the only quantitative trend bubbling up in fixed income. Among active managers and hedge funds, whose primary mission is generating alpha, an explosion of big data and machine learning algorithms has ushered in a new investing paradigm that some call the "Fourth Industrial Revolution."[6] If machines can drive cars and translate human speech, then algorithms can surely pinpoint market signals and investible opportunities that traditional active managers might miss. In this machine versus human scenario, some hedge funds now claim that data science and machine learning models hold the keys to unlocking real alpha and effectively managing risks.

It is worth stating upfront that we think this quant versus active and machine versus human debate sets up a false dichotomy. Look under the hood of any bond factor strategy or quant-oriented hedge fund, and you will find a deep roster of classically trained economists, portfolio managers, and traders—all steeped in the fundamental laws of economics. Machine learning algorithms cannot entirely replace human intuition. Further, since machine learning models are applicable for the regimes in the training period, they cannot account for the regime transition into regimes that are not in the training periods. So sophisticated models, if not properly guided by professionals with specific financial expertise,

can lead to erroneous conclusions. Fundamental credit analysts still uncover valuable insights that factor-based equations gloss over and do not understand. A purely quantitative approach (which we do not think exists in all practicality) is no match for navigating highly dynamic capital markets driven by the economic forces of profit maximization.[7]

Factors Are Not Foolproof

So, why do some factor-based managers shun "active investing approaches" in their marketing pitches? It is unclear, especially given recent evidence that factors alone are not foolproof solutions. Case in point: factor-based equity strategies suffered from "terrible" performance in 2019—a blunt confession from a quant pioneer at Morningstar's annual mutual fund conference.[8]

Why the bad performance? Amidst the late-cycle market gyrations of 2019, factors like value and momentum that historically moved in opposite directions began moving in unison. Quantitative managers long recognized that systematic factors are sensitive to macroeconomic forces; individually, they can underperform for long stretches of time. Building noncorrelated multifactor strategies theoretically alleviated this problem. These diversified factor strategies appeared to work . . . until they didn't. Anxious equity investors were told to remain calm and sit tight; this mercurial environment will be short-lived.

Some managers think static multifactor exposures are partly to blame. Factor exposures should fluctuate dynamically in response to shifting macro forces like the rate of unemployment or the overall credit quality of corporate debt markets. Others pound the table and proclaim this poor showing is proof that skilled security selection trumps factors. There is also another suggestion: Why not capture unique insights from traditionally active approaches and factor approaches at the same time?

Some managers refer to this combination of perspectives as "orthogonal thinking"—a term used in science to describe a process where unique insights are discovered by drawing on seemingly unrelated perspectives. This orthogonal process was a crucial element, for example, in the discovery of human genetic code when physicists moved into the field of biology.

Machine Learning to the Rescue?

If factor-based strategies are not fool-proof solutions, does machine learning offer a better way to generate alpha? The headlines coming out of tech hubs like Silicon Valley tell us data-driven algorithms are accomplishing the unthinkable.

Machines now have computer vision, pack groceries in warehouses, drive cars, and predict your creditworthiness or even how you will vote.

In some areas, machines really do have the upper hand. Who else but a machine can identify cats in a stack of 20 million pictures with 95% accuracy in less than five minutes? In other areas, humans still prevail. Consider a commuter successfully navigating their car through rush hour traffic while holding a work conversation (something computers cannot do) and a crying baby in the back seat. Meanwhile, self-driving cars are still crashing into stationary objects and can become disoriented in the rain.

Now, step out of that car and ask yourself this: How can algorithms navigate incredibly complex capital markets that are overflowing with signals and noise? It turns out, algorithms are hard-pressed to complete basic tasks inside the noisy environment of finance where signals are weak and transitory. Scientists describe these environments as having low signal-to-noise ratios.

But there's good news. Algorithms can be highly effective when paired with skilled investment professionals (economists and portfolio managers). By themselves, machines have trouble anticipating the complicated human responses of politicians and central bankers that can drive market regime changes. However, when operating within the framework of an economist's hypothesis, for example, algorithms can forecast expected returns with much welcomed precision—far better than traditional statistical methods, where forecasts remain deeply shrouded in approximation and estimation errors.

Actively Guiding Quantitative Insights

We think the future of fixed income investing requires moving beyond the active versus quant stalemate. So, the ideal investment process starts with two familiar dimensions: top-down macroeconomic research and bottom-up fundamental security analysis.

The reasons for this division of labor are relatively straightforward: The performance of nearly every fixed income security (outside sovereign bonds) is influenced by unique mixtures of macroeconomic fundamentals—like inflation and stages of credit cycle—and sources of bottom-up mispricing tied to individual credit issuers. The skills of a trained economist are different from a credit analyst who specialized in the micro economy of an industry. It takes both viewpoints to capture excess returns, as shown in Exhibit 48-2.

Two additional dimensions—active fundamental and quantitative science—are also necessary for alpha generation, also illustrated in Exhibit 48-2. Factor-based security selection and machine learning techniques bring new skills and fresh insights to fixed income investing. The goal of combining active with quantitative views, however, is not to mix them inside a portfolio like a kitchen blender.

In some instances, quantitative techniques can sharpen fundamental insights with greater precision. Other times, they can challenge assumptions made by fundamental credit analysts and portfolio managers. Through discussion, quantitative views might lead fundamental analysts toward a different conclusion or reconfirm their original hypothesis after a healthy debate and deeper inspection.

It has been our experience that quantitative methods ultimately work best when combined with "traditional" human insights derived from the academic disciplines of macroeconomics and fundamental security analysis. Yes, machines offer much-needed precision in predicting asset returns. But we still need deep human expertise to make sense of market complexity. Machines are not good at assessing turning points in the business cycle or anticipating crowding behaviors from profit-driven traders.

In the next section, we explore top-down macroeconomic research and bottom-up security selection, as shown in Exhibit 48-2. In terms of top down, we discuss the process of transforming macroeconomic research into precise return forecast with algorithms. These serve as a bridge for communicating macroeconomic views across sector teams who speak different languages. In terms of bottom up, we compare factor-driven insights with fundamental credit analysis. Although factors offer precision across a breadth of securities, deep credit research is still critical for assessing risk premia.

EXHIBIT 48-2

Active Quant Investment Process

ACTIVE QUANT TOP DOWN

In this section, we provide details of the top-down approach for the asset allocation process. This is accomplished by translating macroeconomic forecasts from economists to sector returns using tree-based machine learning algorithm. These sector return forecasts in turn provide asset allocation, that is, sector weights, across fixed income sectors.

Anchored in Macroeconomics

Developing a well-informed macroeconomic outlook is critical to identifying what academic finance refers to as "risk premia" (i.e., expected returns in excess of the risk-free rate). This type of research is typically the cornerstone of the investment process for active fixed income managers and quant-oriented hedge funds who are paid to deliver alpha. Given the complexity and dynamic nature of capital markets, experienced economists are critical to understanding how a myriad of economic variables can shape expected asset returns.

The sets of signals a macroeconomic team uses to generate an outlook are generally quite diverse and driven by an understanding that business cycles are themselves an aggregation of sub-cycles that drive growth (e.g., personal consumption, residential and nonresidential loans, industrial production, services, external demand, etc.). These sub-cycles are interdependent and jointly drive monetary and fiscal policy feedback loops, which in turn impact asset returns.

The Science of Translation

Forecasting sector returns has traditionally been a laborious exercise ripe with measurement errors. Analysts typically use statistical techniques like mean reversion (a theory that asset prices eventually revert to long-term averages) or smoothing techniques like moving averages to extrapolate price trends. Some analysts prefer looking backward in time to cherry-pick a previous environment they think best matches the current market regime. All of these methods are prone to subjectivity and the likelihood that bond returns may take longer than expected to return to average. Luckily, data scientists have found a better way.

Published research on machine learning forecasting of asset returns reflect our own experience modeling expected sector returns (i.e., spreads) using proprietary algorithms. The researchers find that algorithmic models—particularly regression trees that accommodate complex nonlinear relationships between multiple variables—improve return over traditional approaches and can in turn improve portfolio Sharpe ratios.[9] A key strength of algorithmic regression trees is their ability to logically capture complex nonlinear interactions between multiple

9. Shihao Gu, Bryan Kelly, and Dacheng Xiu, "Empirical Asset Pricing via Machine Learning," *Review of Financial Studies* 33(5), 2020, pp. 2223–2273.

variables—relationships that human analysts typically find difficult to map out, even with substantial effort and time.

Our active quant process starts with a macroeconomic outlook provided by trained economists. In the case of our macroeconomic team, they provide our data science team with a range of economic forecasts across variables such as oil prices, exchange rates, equities, rates, and inflation-related instruments. The data science team translates these views into standardized macro variables that feed into the regression tree algorithm, as shown in Exhibit 48-3.

The output from the regime modeling algorithm effectively serves to translate the macroeconomic team's outlook into sector views that each sector team can understand. The algorithm serves as a bridge to having more fruitful discussions between team members, allowing them to compare and contrast forecasts.

We then translate the reconciled sector views into 12-month expected returns across the global multisector fixed income universe. This forms the basis of our proprietary sector allocation process. Determining the optimal mix of weights starts by acknowledging spread uncertainties, which are calculated by using the volatility and correlations of a covariance matrix and our market regime models. The results point to an ideal allocation or "starting point" along efficient allocation frontier. Next, by analyzing all the mandated portfolio constraints, the data science team generates a range of allocations that all fall within the "neighborhood" of the ideal starting point—and that still meets the portfolios' risk and return parameters.

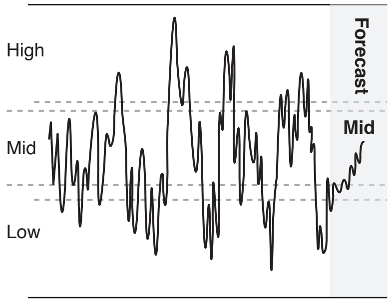
As illustrated in Exhibit 48-4, this optimization process gives managers the flexibility to allocate across allocation bands. In this hypothetical example, the portfolio managers chose to underweight U.S. investment-grade credit by the minimum allowed underweight, while overweighting bank loans and credit risk transfers. This process ensures that risk premia in our portfolios are efficiently allocated across the portfolio manager's highest conviction views and done in a manner that is consistent and repeatable.

EXHIBIT 48-3

Example Macro Variables Feed Our Regression Tree Algorithms

MACROECONOMIC FORECASTS

Forecasting performance (i.e., spreads) starts with our team's 12-month macro outlook. We analyze a series of macro variables, including equities, commodities, currencies, and inflation to forecast not just the level of each variable but also the trend and volatility (where applicable). Instread of assigning numerical values, the team determines whether variables will fall into the low, mid, or upper ends of their historical ranges. In this hypothetical example, we think the oil trend will increase to mid-range over the next 12 months.*



MACHINE LEARNING INPUTS

With outlooks in hand for a range of macro variables, our data science team uses a machine learning decision tree to convert these variables into a macroeconomic regime forecast. Within the context of this expected regime, the algorithm calculates how different sectors will respond by producing spread forecasts* across our fixed income universe (bank loans, high yield, taxable munibonds, etc.). This algorithm helps teams of poeple who may speak different languages communicate in a formalized, repeatable manner.

	Oil		U.S. Dollar		Yield Curve	
	Current	Forecast	Current	Forecast	Current	Forecast
Level	Mid	Mid	High	High	Low	Mid
Trend	Low	Mid	High	High	Mid	High
Volacility	Mid	Mid	Low	Low	Low	Mid

BOND SPREAD FORECASTS

Our spread forecasts allow each sector team to visualize how the expected macro regime might impact spreads in their setor. Importantly, the output not only indicates whether spreads might tighten or widen, but also indicates the distribution of spreads as represented by the shape of the curve. In this hypothetical illustration, we see expected spreads are likely to increase (per the dotted black line) while the spread distribution is quite wide (per solid black line).* This bimodal curve suggests a high degree of uncertainly—spreads could remain relatively unchanged or widen dramatically. The data team explains macro variables have the most impact on spreads.

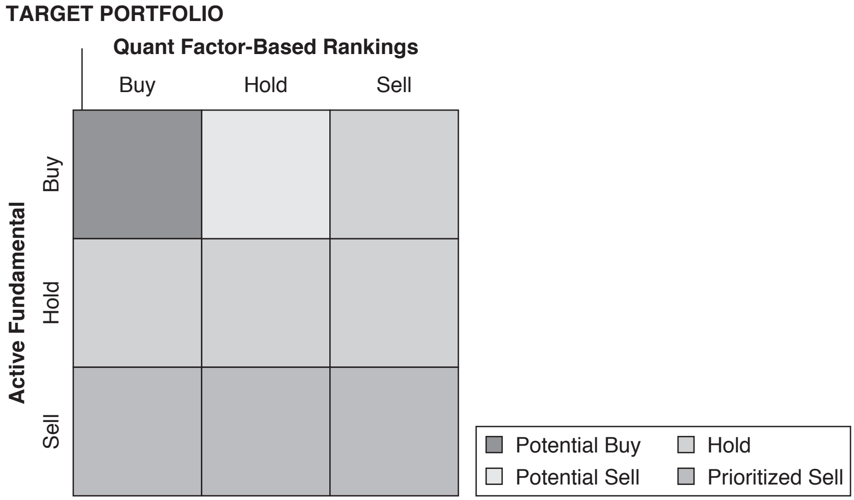
ACTIVE QUANT BOTTOM UP

In this section, we provide details of the bottom-up approach for the security selection process of corporate credit portfolios. This is accomplished by identifying factors that drive corporate credit portfolio returns. This approach explicitly accounts for the macroeconomic sensitivity of the factors, by dynamically weighting factors ("factor-tilt") using machine learning, so as to maximize portfolio Sharpe ratio. It is worth noting that this factor-tilt approach is not specific to corporate credit portfolio and can be used for any asset class, for example, Fama-French factors for equity portfolios. The return forecast then used in conjunction with credit analyst recommendations to arrive at the optimal corporate bond portfolio using the process shown in Exhibit 48-5.

This approach also allows for calculation of subsector allocation—in this case, industry weights of corporate credit portfolio.

EXHIBIT 48-5

Combining Active and Quant Recommendations



Source: Franklin Templeton, for illustrative purposes only.

Removing Blind Spots

When you boil down the key benefits of bond factor strategies, the standard marketing pitch usually goes something like this: factor-based bond strategies systematically implement fundamental investment ideas (using factors like value or momentum) without taking on risks that would not be compensated (i.e., excessive credit or interest rate risks). The claim implies that active managers may be doing the opposite—implementing fundamental ideas unsystematically (perhaps sloppily) that leads to risk exposures that will not pay off.

We agree that factor-based strategies offer some advantages, including the ability to methodically analyze a wide breadth of securities using precise measures that are not subject to bias. But factors also have an Achilles' heel: they are blind to what is causing bond spreads to widen or tighten. On the surface, wide spreads might look attractive to a factor, but the factor can be entirely unaware that long-term storm clouds are signaling caution. This blindness can be risky if not supplemented with fundamental research from a seasoned credit analyst.

It is the job of the credit analyst to understand how both macro- and microeconomic mechanisms can drive asset prices and explain what is potentially in store for future returns. The credit analyst brings a wealth of information to bear on his or her analysis, from the intricacies of a corporate business model, the peculiar genius (or folly) of a management team, to environmental, social, and governance issues.

In the simplified illustration, Exhibit 48-5, we have captured how our active quant process brings together factor-based security rankings and active fundamental credit recommendations together into prioritized potential buy and sell lists at the security level.

It is important to understand, the factor models and credit analysts operate independently from each other, ensuring each team's views remain their own. At the industry level, the "best ideas" from each side are presented in formalized "industry reconciliation" meetings where credit analysts, portfolio managers, and the data teams discuss why and how the views are either synchronized or opposed. Opposing views are welcomed and typically lead to deeper analysis and discussion before a resolution is made.

Taken together, the active quant process combines potential buy and sell lists with frank discussions and analysis. The goal is to populate the portfolio with the team's highest conviction (i.e., highly scrutinized) securities within an industry that also satisfy other risk and strategy-specific constraints.

Factor-Based Security Rankings

Factor-based investing initially became popular as a stock selection strategy by identifying broad, persistent drivers of excess return through quantifiable factors that historically earned positive long-term results. Similar to equity factors, the factor styles for corporate bonds with the longest track records include value, momentum, and quality factors. Each of these factors is grounded in commonly observed market dynamics, such as behavioral biases and structural impediments (rules and restrictions) that create opportunities that fundamental factor investors can exploit:

Value factors: The basic concept driving value factors is that cheap bonds (i.e., spread relative to fundamental risks) have tended to outperform expensive bonds over the long run. There are a multitude of ways to construct a value factor, though most methods start with a bond's current option-adjusted spread (OAS) and compares this to a range of risk characteristics such as credit rating and/or return volatility. Our data science team uses three distinct factor calculations that fall under the value umbrella. The first is the Spread-to-Credit relative value factor, which focuses on OAS relative to credit risks (i.e., credit ratings) and cyclicity, by controlling for industry. The second two factors measure also include credit ratings and industry, but also account for volatility/momentum and spread duration. Measures of volatility and momentum are 12-month excess return volatility and 3-month spread change, respectively.

Momentum factor: Corporate bonds from publicly listed issuers with strong recent equity performance tend to perform well since the bonds are senior to equity in the capital structure. Our data scientists use three-month equity return to construct the equity momentum factor.

Quality factors: Corporate bonds with low probabilities of default can outperform higher-yielding credit during credit downturns. Our data scientists use two distinct measures: (1) leverage, which captures the ratio of total debt to the sum of net debt and market equity (i.e., enterprise value), and (2) coverage, which is based on corporate profitability (i.e., earnings before interest, taxes, depreciation and amortization, EBITDA) relative to 12-month interest expenses.

Historically, factor-based bond managers combine multiple factors into a diversified strategy to help mitigate underperformance of any single factor. All bonds factors are sensitive to macroeconomic changes and therefore can underperform for stretches of time. Factor styles like value and quality tend to have low correlations and have different sensitivities to the macro environment. So, maintaining fixed exposures to a group of style factors has generally reduced the length of underperformance regardless of shifting macro environments.

But, what if we could implicitly forecast the near-term credit cycle? Then a machine learning algorithm could dynamically optimize factor weighs according to expected macro environment, with a goal of reducing potential drawdowns, by tilting away from the factors that are expected to underperform. This in turn increases portfolio's Sharpe ratio.

Algorithmic Factor Tilting

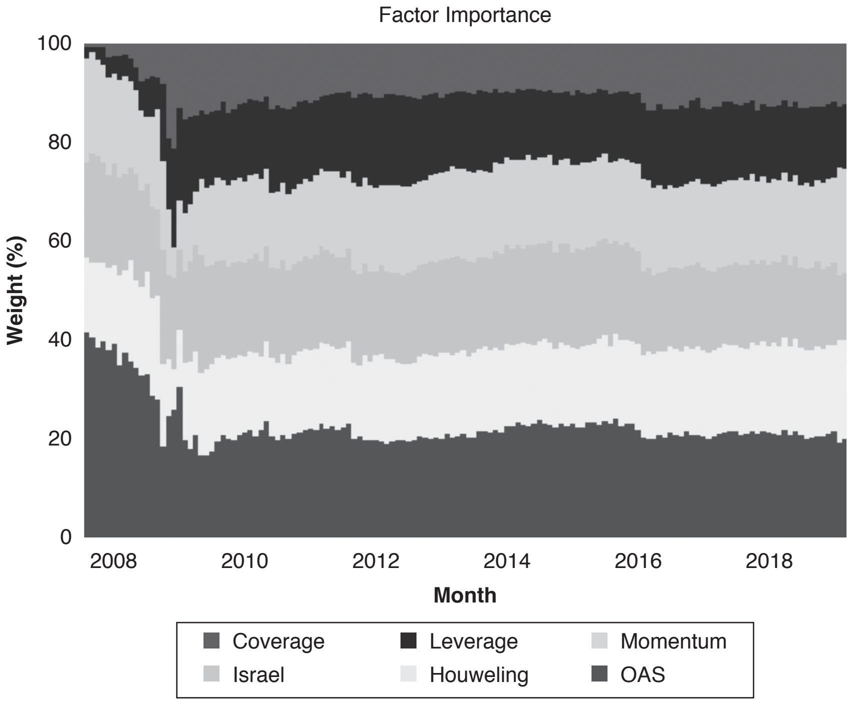
To forecast the credit environment, we use a customized gradient-boosting algorithm, which uses macroeconomic features such as the unemployment rate, the U.S. Federal Reserve's balance sheet, and the credit quality of the investment grade and high-yield bond markets. Based on the combination of these variables, the algorithm predicts the future relative performance of our six style factors spanning the value, momentum, and quality categories. In back-testing, the algorithm dynamically adjusted factor exposures during global financial crisis by increasing exposures to quality factor while decreasing exposure to other factors.

As shown in Exhibit 48-6, the algorithm began in July 2007, with 76% exposure to value, 21% to momentum, and just 3% to quality. For historical context, four months later, in October 2007, the Dow Jones Industrial Average peaked at over 14,000 points. As economic conditions worsened the following year, the algorithm incrementally increased exposure to quality factors while decreasing exposure to other factors. Following the dramatic collapse of Lehman Brothers in September 2008, which triggered a global panic, the algorithm increased quality exposures to 41% in November 2008.

Instead of a static buy-and-hold approach, our factor tilt algorithm shift factor exposures dynamically to better match overarching macroeconomic environments.

EXHIBIT 48-6

Factor Tilt



FOUR-DIMENSIONAL CHESS

In today's rapidly evolving investment landscape, the ability to deliver consistent excess returns to investors has seen profound changes in the tools and techniques available to institutional fixed income managers. Outspoken quants who championed the arrival of factor-based strategies are challenging the status quo—daring active managers to prove their worth.

Many active heavyweights say they are more than ready (thrilled in fact) to meet this challenge, while simultaneously getting their arms around big data and machine learning techniques to sharpen their edge. By incorporating data science alongside human insights, a simpler two-dimensional process of top-down and bottom-up analysis has morphed into four-dimensional chess that incorporates fundamental research and quantitative science.

Some managers claim that quants have the upper hand given today's digital technologies. This is not how things are shaping up in practice, however. Algorithms cannot drive themselves in noisy financial environments nor operate successfully without human intuition. Data scientists who lack financial expertise and intuition often do not produce desired investment results.

In the end, the most important skill sets in fixed income investing remain the ability of trained professionals to explain the underlying economic mechanisms that drive market regimes and the signals that data science can track and analyze. The future of fixed income lies in successfully marrying quantitative science with fundamental-based active management.

The fixed income portfolio management team should formulate a seamless active quant approach—where portfolio managers, analysts, traders, and data scientists work as one team to create a synergistic loop between quantitative and fundamental analysis. We believe marrying data science and fundamental expertise will allow for better portfolio performance by enabling managers to better navigate challenging investment environments.

KEY POINTS

- The active quant approach presented in this chapter combines unique insights from traditionally active and quantitative factor approaches at the same time.
- The active quant portfolio incorporates best ideas from both quantitative research/data scientists and credit analysts.
- The top-down active quant approach allows for sector allocation for fixed income sectors by translating macroeconomic forecasts from economists to sector returns.
- The factor tilt machine learning approach presented here for corporate credit maximizes portfolio Sharpe ratio by accounting for factor sensitivities to macro environment. This factor tilt approach is also applicable to other asset classes, such as Fama-French factors for equity portfolios.
- The active quant bottom-up approach in addition to providing security selection also provides subsector allocation (e.g., in the of case corporate credit portfolio, it provides industry weights).

CHAPTER
FORTY-NINE

INTRODUCTION TO MULTIFACTOR RISK MODELS IN FIXED INCOME AND THEIR APPLICATIONS

Barclays

Risk management is an integral part of the investment process. Risk models are central to this practice, allowing managers to quantify and analyze the risk embedded in their portfolios. Risk models provide managers with insight into the different sources of risk in a portfolio, helping them to control their exposures and understand the contributions of different portfolio components to total risk. They help portfolio managers in their decision-making process by providing answers to important questions such as: How does my long-duration exposure affect portfolio risk? Does my underweight in diversified financials hedge my overweight in banks? Risk models are also widely used in various other areas such as in portfolio construction, performance attribution, and scenario analysis.

In this chapter we introduce linear multifactor risk models and illustrate how they can be helpful for the analysis of the risk of fixed income portfolios. We review the major sources of risk in fixed income securities and introduce a set of appropriate risk factors. We also present several applications of risk models for effective portfolio construction and management. In Chapter 50 we will go through a detailed risk model report of a specific portfolio and highlight the information and insights it can provide to a portfolio manager.

MOTIVATION AND STRUCTURE UNDERLYING FIXED INCOME MULTIFACTOR RISK MODELS

In this section, we discuss the motivation and structure behind fixed income multifactor risk models.

This chapter was coauthored by Anthony Lazanas, António Baldaque da Silva, Radu C. Gabudean, and Arne D. Staal when they were employees of Barclays.

Let us assume that a portfolio manager wants to estimate and analyze the volatility of a large portfolio of fixed income instruments. A straightforward idea would be to compute the volatility of the historical returns of the portfolio and use this measure to forecast future volatility. However, this framework does not provide any insight into the relationships between different securities in the portfolio or the major sources of risk. For instance, it does not assist a portfolio manager interested in diversifying a portfolio or constructing a portfolio that has better risk-adjusted performance. Additionally, the characteristics of a fixed income portfolio change substantially over time, for instance, as instruments mature or are subject to credit events.

Instead of estimating the portfolio volatility using historical portfolio returns, a portfolio manager could utilize a different strategy. The portfolio return is a function of individual instrument returns (e.g., Treasury securities, corporate bonds, credit derivatives, municipal bonds, interest rate swaps, and so on) and the market weights of these securities in the portfolio. Using this, the forecasted volatility of the portfolio (σ_P^f) can be computed as a function of the weights (w) and the covariance matrix (Σ_S) of the instrument returns in the portfolio:

$$\sigma_P^f = \sqrt{w^T \times \Sigma_S \times w}$$

where the superscript T denotes a matrix transpose. This covariance matrix can be decomposed into individual instrument volatilities and the correlations between returns.

Volatilities measure the riskiness of individual instrument returns, and correlations represent the relationships between the returns of different instruments. By measuring these correlations and volatilities, the portfolio manager can gain insight into her portfolio related to the riskiness of different parts of the portfolio or how the portfolio can be diversified. As outlined above, to estimate the portfolio volatility we need to estimate the correlation between each pair of instruments. Unfortunately, this means that the number of parameters to be estimated grows quadratically with the number of instruments in the portfolio.[1] For most practical portfolios, the relatively large number of constituents makes it difficult to estimate the relationship between instrument returns in a robust way. Moreover, this framework uses the history of individual instrument returns to forecast future security return volatility. However, instrument characteristics are dynamic and hence using returns from different time periods may not produce good forecasts.[2] These drawbacks constitute the motivation for multifactor risk models discussed in this chapter.

One of the major characteristics of multifactor models is their ability to describe the return of a portfolio using a relatively small set of variables, called *factors*. These factors should be designed to capture broad (systematic) market fluctuations, but should also be able to capture specific nuances of individual portfolios.

1. As an example, if the portfolio has 10 instruments, we need to estimate 45 parameters, with 100 instruments we would need to estimate 4,950 parameters.

2. This is especially the case over crisis periods, in which instrument characteristics can change dramatically over very short periods of time.

For instance, a broad fixed income market factor would capture the general movement in the fixed income markets, but not the varying behavior across types of instruments. If, for example, a portfolio is heavily biased toward the long end of the U.S. Treasury yield-curve, or is tilted toward credit bonds of particular industries, the broad market factor may not allow for a good representation of the portfolio's return. Other factors might be needed to capture these more specific sources of risk.

Most factor models are linear, in the sense that the total return is decomposed into the sum of the contributions of the factors (referred to as the *systematic return*) and an idiosyncratic component. *Systematic return* is the component of total return due to movements in the common (market-wide) risk factors. On the other hand, *idiosyncratic return* can be described as the residual component that cannot be explained by the systematic factors. Under most factor models, idiosyncratic returns are uncorrelated across issuers. Therefore, correlations across securities of different issuers are driven by their exposures to the systematic risk factors, and the correlation between those factors.

The following equation demonstrates the systematic and the idiosyncratic components of total return for security s:

$$r_s = L_s \times F + \varepsilon_s$$

The systematic return is the product of the instrument's loadings (L, also called sensitivities) to the systematic risk factors and the returns of these factors (F). The idiosyncratic return is given by ε_s.

Under these models, the portfolio volatility can be estimated as

$$\sigma_p^f = \sqrt{L_p^T \times \Sigma_F \times L_p + w^T \times \Omega \times w}$$

Here L_p are the loadings of the portfolio to the risk factors (determined as the weighted average of individual instrument loadings) and Σ_F is the covariance matrix of factor returns. Ω is the covariance matrix of the idiosyncratic security returns. Typically, the idiosyncratic return of securities is assumed uncorrelated. Therefore, this covariance matrix is diagonal, with all elements outside its diagonal being zero.[3] As a result, the idiosyncratic risk of the portfolio is diversified away as the number of securities in the portfolio increases. This is, of course, the diversification benefit attained when combining uncorrelated exposures.

For most practical portfolios, the number of factors is significantly smaller than the number of instruments in the portfolio. Therefore, the number of parameters in Σ_F is much smaller than in Σ_S, leading to a generally more robust estimation. Moreover, the factors can be designed in a way that they are relatively more stable than individual stock returns, leading to models with potentially better predictability. In this setting, the changing nature of each particular instrument can be captured through its loadings to the different risk factors.

3. In more detailed factor models, idiosyncratic correlation may not be zero. For example, securities of the same issuer have typically positive correlation; in such case, the idiosyncratic covariance matrix is block-diagonal.

Another very important advantage of using factor models is the detailed insight they can provide into the structure and properties of portfolios. These models characterize instrument returns in terms of systematic factors that (can) have intuitive economic interpretations. Linear factor models can provide important insights regarding the major systematic and idiosyncratic sources of risk and return. This analysis can help managers to better understand their portfolios and can guide them through the different tasks they perform, such as rebalancing, hedging, or tilting of their portfolios.

Naturally, the success of a risk model depends on its ability to interpret historical and current data in order to formulate estimates of future portfolio risk. It should therefore seek to discover properties of the data that are *quasi-predictable*; that is, that the error in the estimate of future realizations—given all information known today—is relatively small. For example, it is notoriously difficult to predict the expected return of a financial asset. On the other hand, historical data contain sufficient information to allow risk models to provide good estimates of the volatility of future returns. Nevertheless, one should never forget that even the most sophisticated risk model can only provide an *estimate* of risk. It is well known that financial markets are subject to *event risk* (i.e., a sudden change in market conditions caused by geopolitical or financial events). Such events are usually followed by a period of large negative returns of risky assets, large positive returns of assets considered as safe havens, significantly higher volatility, and very high (positive or negative) correlations. It is impossible for a risk model to predict when such events will occur. Therefore, it is useful to complement model-based risk management and portfolio construction with *what-if analysis,* which estimates portfolio return and risk under *stressed conditions*; that is, scenarios with extreme realizations of market returns and a covariance matrix with much higher volatilities and absolute correlations.

FIXED INCOME RISK MODELS

Fixed income securities are exposed to many different types of risk. Multifactor risk models in this area capture these risks by first identifying common sources along different dimensions, the *systematic fixed income risk factors*. All risk not captured by these systematic factors is considered *idiosyncratic*, and is determined by the choice of systematic risk factors. Typically, fixed income systematic risk factors are divided into two sets: those that influence securities across asset classes (e.g., yield-curve risk) and those specific to a particular asset class (e.g., prepayment risk in securitized products).

There are many ways to define systematic risk factors. For instance, they can be defined purely by statistical methods, observed in the markets (e.g., a yield-curve), or estimated from asset returns. In fixed income, the standard approach is to use pricing models to calculate the analytics that are the natural candidates for risk factor loadings (*L,* in the notation presented earlier). In this setting, the risk factors are either observable (e.g., the movements in the yield-curve) or estimated from regressing cross-sectional asset returns on instrument sensitivities. This is the approach taken in the Global Risk Model,[4] which is the model used for illustration throughout this chapter.

In this risk model, the forecasted risk of the portfolio is driven by both a systematic and an idiosyncratic (also called specific, nonsystematic, or concentration) component. The forecasted systematic risk is a function of the mismatch between the portfolio and the benchmark in the exposures to the risk factors, such as yield-curve or spreads. The (net) portfolio exposures are aggregated from security-level analytics. The systematic risk is also a function of the volatility of the risk factors, as well as the correlations between the risk factors. In this setting, the correlation of returns across securities is driven by the correlation of systematic risk factors these securities load on. Because the model uses security-level returns and analytics to estimate the factors, it can recover the idiosyncratic return for each security. This is the return net of all systematic factors. The use of detailed level analysis of idiosyncratic returns allows for the estimation of rich specifications of idiosyncratic risk.

Systematic Risk Factors

The precise definition of systematic risk factors depends on the purpose of the factor model, but in general we can highlight several categories of risk factors that drive fixed income risk.

Curve Risk

Curve risk is the major source of risk across fixed income instruments. This kind of risk is embedded in virtually all fixed income securities; therefore, mismatches in curve profiles relative to a benchmark are often the main drivers of portfolio risk.

When analyzing curve risk, we should use the curve of reference in which we are interested. Depending on the portfolio and circumstances, this is typically the government or swap curve.[5] In calm periods, the behavior of the swap curve tends to match that of the government curve. However, during liquidity crises (e.g., the Russian crisis in 1998 or the credit crisis in 2008), they can diverge significantly. To capture these different behaviors adequately, one may use the following decomposition: for government products, the curve risk is assessed

4. The model was available through POINT, a portfolio management tool that at the time this chapter was written was an offering by Barclays. It is a multi-currency cross-asset model that covers many different asset classes across the fixed income and equity markets, including derivatives in these markets. At the heart of the model is a covariance matrix of risk factors. The model has several hundreds of factors, many specific to a particular asset class. The asset class models are periodically reviewed. Structure is imposed to increase the robustness of the estimation of such large covariance matrix. The model is estimated from historical data. It is calibrated using extensive security-level historical data and is updated on a monthly basis.

5. Other curves that can be used are, for instance, the municipals (tax-free) curve, the inflation-adjusted (real rate) curve, etc.

using the government curve. For all other products in the portfolio (that usually trade off the swap curve), this risk is measured using both the Treasury curve and swap spreads (i.e., the spreads between the swap and the government curve). Other curve decompositions are also possible.

The risk associated with each of these curves can be described by the exposure the portfolio has to different points along the curve combined with the volatility and correlation of the movement of such curve points. Sometimes a convexity term is required to capture the second-order exposure to curve changes of instruments with long tenors or embedded optionality, such as mortgage-backed securities. For a typical portfolio, a good description of the curve can be achieved by looking at a relatively small number of points along the curve (called key-rates), for example 6-month, 2-year, 5-year, 10-year, 20-year, and 30-year. An alternative set of factors used to capture yield-curve risk can be defined using statistical analysis of the historical realizations of the various yield-curve points. The statistical method used most often is *principal component analysis* (PCA). This method defines factors that are statistically independent of each other. Typically three or four such factors are sufficient to explain the risk associated with changes of yields across the yield-curve. PCA analysis has several shortcomings and must be used with caution. Using a larger set of economic factors like the key-rate points described above is more intuitive and captures the risk of specialized portfolios better. For these reasons, many portfolio managers favor the key-rates approach in most risk analysis problems.

Credit Risk

Instruments issued by corporations or entities that may default are said to have credit risk. The holders of these securities demand additional yield—in excess of the risk-free yield—to compensate for that risk. This extra yield is usually measured as a spread to a reference curve. For instance, for corporate bonds the reference curve is usually the swap curve. The level of credit-spreads determines to a large extent the credit risk exposure associated with the portfolio.[6]

There are several characteristics of credit bonds that are naturally associated with systematic sources of credit-spread risk. For instance, depending on the business cycle, particular industries may be going through especially tough times. So industry membership is a natural systematic source of risk. Similarly, bonds with different credit ratings are usually treated as having different levels of credit risk. Credit rating could be another dimension one can use to measure systematic exposure to credit risk. Finally, the country of the issuer is another source of systematic risk for credit bonds. Given these observations, it is common to see factor models for credit risk using country, industry, and rating as the major systematic risk factors. Recent research suggests that risk models that directly use the spreads of the bonds instead of their ratings perform better for risk analysis

6. Spreads are also compensation for sources of risk other than credit (e.g., liquidity), but for the sake of our argument, we treat them here as major indicators of credit risk.

over relatively short/medium horizons.[7] Under this approach, the loading of a particular bond to a credit-risk factor would be the commonly used spread duration, but now multiplied by the bond's spread. The loading is termed *D*uration *T*imes *S*pread (denoted DTS) and is described in Chapter 53. By directly using the spread of the bond in the definition of the loading to the credit risk factors, we do not need to assign specific risk factors to capture the rating or any similar quality-like effect. It will be automatically captured by the spread level incorporated into the bond's loading to the credit risk factor, and will adjust as the spread of the bond changes. In this setting, we still could use different systematic risk factors, for example, to distinguish among credit risk coming from different industries.[8]

Prepayment Risk

Securitized products are generally exposed to prepayment risk. The most common of the securitized products are the residential mortgage-backed securities (RMBS or simply MBS). These securities represent pools of deals that allow the borrower to prepay their debt before the maturity of the loan/deal, most typically when prevailing lending rates are lower. This option means an extra risk to the holder of the security, the risk of holding cash exactly when reinvestment rates are low. Therefore, these securities have two major sources of risk: interest rate (including convexity) and prepayment risk.

Some part of the prepayment risk can be expressed as a function of interest rates via a prepayment model. This risk will be captured as part of interest-rate risk using the key-rate durations and the convexity. Convexity, which is usually negative for these instruments, is a significant source of risk. Negative convexity has a detrimental effect on the market value of an instrument—compared with one with positive or zero convexity—when interest rates move significantly in either direction. Indeed, decreasing interest rates cause prepayments to increase thereby reducing the price appreciation because of the falling rates. Conversely, rising interest rates intensify the price depreciation the instrument suffers with higher rates.

---

7. For details, see Arik Ben Dor, Lev Dynkin, Patrick Houweling, Jay Hyman, Erik van Leeuwen, and Olaf Penninga, "A New Measure of Spread Exposure in Credit Portfolios," Barclays Publications, February 2010.

8. The general principle of a risk model is that the historical returns of assets contain information that can be used to estimate the future volatility of portfolio returns. However, good risk models must have the ability to translate the historical asset returns to the context of the current environment. This translation is made when designing a particular risk model/factor and when implemented delivers risk factors that are as invariant as possible. This invariance makes the estimation of the factor distribution much more robust. In the particular case of the DTS, by including the spread in the loading (instead of using only the typical duration), we change the nature of the risk factor being estimated. The factor now represents percentage change in spreads, instead of absolute changes in spreads. The former has a significantly more invariant distribution. For more details, see Antonio B. Silva, "A Note on the New Approach to Credit in the Barclays Global Risk Model," Barclays Publications, September 2009.

The remaining part of prepayment risk—that is not captured by the prepayment model—must be modeled with additional systematic risk factors. Typically, the volatility of prepayment speeds (and therefore of risk) on MBS depends on three characteristics: program/term of the deal, if the bond is priced at discount or premium (e.g., if the coupon on the bond is bigger than the current mortgage rates), and how seasoned the bond is. This analysis suggests that the systematic risk factors in a risk model should span these three characteristics of the securities.

Implied Volatility Risk

Many fixed income securities have embedded options (e.g., callable bonds). This means that the expected future volatility (implied volatility[9]) of the interest rate or other discount curves used to price the security plays a role in the value of that option. If expected volatility increases, options generally become more expensive, thereby affecting the prices of bonds with embedded options. For example, callable bonds will become cheaper with increasing implied volatility since the bondholder is short optionality (the right of the issuer to call the bond). Therefore, the exposure of the portfolio to the implied volatility of the yield-curve is also a source of risk that should be accounted for. The sensitivity of securities to changes of implied volatilities is typically measured by *vega*, which is calculated using the security pricing model. Implied volatility factors can be either calculated from the market prices of liquid fixed income options (caps, floors, and swaptions), or implied by the returns of bonds with embedded options within each asset class.

Liquidity Risk

Many fixed income securities are traded over-the-counter, in decentralized markets. Some trade infrequently, making them illiquid. It is therefore hard to establish their fair price. These bonds are said to be exposed to liquidity risk. The holder of illiquid bonds would have to pay a higher price to liquidate a position, usually meaning selling at a discount. This discount is uncertain and varies across the business cycle. For instance, the discount can be significant in a liquidity crisis, such as the one of 2008. The uncertainty about this discount means that, everything equal, a more illiquid bond will be riskier. This extra risk can be captured through liquidity risk factors. For instance, in the Treasury markets, one generally refers to the difference in volatility between an on-the-run and an off-the-run Treasury bond as liquidity risk.

Inflation Risk

Inflation-linked securities are priced based on the expectation of future inflation. Uncertainty about this variable adds to the volatility of the bond over and above

9. The volatility is called implied because it is calculated from the market prices of liquid options with the help of an option-pricing model.

the volatility from other sources of risk, such as nominal interest rates. Expected inflation is not an observed variable in the marketplace but can be extracted from the prices of inflation-linked government bonds and inflation swaps. Expected inflation risk factors can be constructed by summarizing this information. The sensitivity of securities to expected inflation is calculated using a specialized pricing model and is usually called *inflation duration*.

Tax-Policy Risk

Many municipal securities are currently tax-exempt. This results in added benefit to their holders. This benefit—incorporated in the price of the security—depends on the level of exemption allowed. Uncertainty around tax policy—tax-policy risk—adds to the risk of these securities. Once again, tax-policy risk factors cannot be observed in the marketplace and must be extracted from the prices of municipal securities. The return of municipal securities in excess of interest rates is driven partially by tax-policy expectations changes. However, it is also driven by changes in the creditworthiness of the municipal issuers as well as other factors. In this case, it is difficult to separate tax-policy risk factors from other factors driving municipal bond spreads. Therefore, instead of specific tax-policy factors, we usually extract factors representing the overall spread risk of municipal securities. This exercise is performed in a similar way to the credit risk model, in which securities are partitioned into groups of "similar" risk by geography, bond type (general obligation vs. revenue), tax status, and the like.[10]

There are other sources of systematic risk we did not detail in this section. They may be important sources of risk for particular portfolios. Specific risk models and factors can be designed to address them.

Idiosyncratic Risk

Once all systematic factors and loadings are determined, the residual idiosyncratic return of a security can be computed as the component of its total return that cannot be explained by the systematic factors. Idiosyncratic return can be a significant component of total return for individual instruments, but tends to decrease rapidly for portfolios of instruments as the number of instruments increases and concentration decreases (the aforementioned diversification effect).

The major inputs to the computation of idiosyncratic risk are instrument characteristics and historical idiosyncratic returns of the instruments. The use of idiosyncratic residual returns allows the risk modeler to find empirical relationships between characteristics such as instrument spread, spread duration, industry membership, and idiosyncratic volatility. This mapping of instrument characteristics to idiosyncratic volatility allows for the modeling of new issues and issues with characteristics that change over time. As mentioned before,

10. For more discussion, see Arne Staal, "U.S. Municipal Bond Risk Model," Barclays Publications, July 2009.

idiosyncratic returns of different issuers are assumed to be uncorrelated. However different securities from the same issuer, or securitized products with related underlying instruments, can show a certain level of co-movement, as they are all exposed to specific events affecting their common issuer that are not captured by systematic risk factors. Interestingly, this co-movement is not perfect or static. Certain news can potentially affect the different securities issued by the same company (e.g., equity, credit default swaps, bonds, or equity options) in different ways. Moreover, this relationship changes with the particular circumstances of the firm. For instance, returns from securities with claims to assets of the firm should be more highly correlated if the firm is in distress. A good multi-asset class risk model should be able to capture these phenomena regarding idiosyncratic risk.

APPLICATIONS OF RISK MODELING

In this section, we illustrate several standard risk model applications used for portfolio management. All applications make use of the fact that the risk model translates the characteristics a portfolio may have across many different dimensions, into a common, comparable set of numbers. In some of them—risk budgeting and portfolio rebalancing—an optimizer that uses the risk model as an input is the optimal setting to perform the exercise.

The investment process of a typical portfolio manager involves different stages. Given the investment universe and objective, the steps usually consist of portfolio construction, risk prediction, and performance evaluation. These steps are iterated throughout the investment cycle over each rebalancing period. The examples in this section highlight the portfolio construction and risk analysis steps that employ a factor model. Additionally, scenario analysis can be employed in both the portfolio construction and risk evaluation phases of the portfolio process. This exercise allows the manager to gain additional intuition regarding portfolio exposures and how the portfolio may behave under particular economic circumstances. It usually takes the form of stress testing potential portfolio losses under historical or hypothetical scenarios. It can also show the sensitivity of the portfolio to particular movements in economic and financial variables. The last application in this chapter illustrates this kind of analysis.

Portfolio Construction and Risk Budgeting

As discussed, fixed income portfolios are exposed to a diverse set of risk factors. During the portfolio construction exercise, the manager must carefully choose the exposure to such factors in order to achieve the highest possible portfolio return subject to risk and other constraints. Risk models help portfolio managers achieve this in an objective and quantifiable way and are increasingly used for portfolio construction, usually with the help of an optimization engine. In this section, we illustrate how a portfolio manager would use this engine to formulate client objectives and constraints in the context of risk model-based portfolio construction.[11]

Portfolio managers can have a broad array of mandates. Some—typically referred to as *indexers*—are required to follow a given benchmark index with the minimum possible deviation. Their goal is to minimize the tracking error volatility of the portfolio versus the index while also keeping portfolio transaction costs as small as possible. Others, the *enhanced indexers*, are allowed some leeway to deviate from the benchmark in order to achieve superior returns. The leeway can be expressed as a set of rules constraining the exposure to risk factors, but it is often prescribed as a *risk budget*; that is, an upper limit in a statistical measure of deviation between the portfolio and its benchmark. The *tracking error volatility* (TEV) of the return of the portfolio net of the benchmark is the most common of such measures. Finally, the *absolute return* portfolio managers, do not have to track a benchmark but are instead aiming at the highest possible portfolio return, potentially subject to leverage, portfolio composition, exposure, and risk constraints. In all cases, the manager has to merge all views and constraints into a final portfolio. When constructing the portfolio, how can the competing views be managed, while respecting the risk budget? How can the views be combined to minimize the risk? What tradeoffs can be made? Risk models are widely used to perform this exercise in a systematic and objective manner: They can measure the risk of each view as well as the correlation between different views, and arrive at portfolios that optimally trade-off the risks and expected returns associated with each of the views.

We illustrate this by a simple example of a portfolio construction exercise using a risk model. Consider a fixed income portfolio manager who is benchmarked to the Bloomberg Barclays US Aggregate Index. The manager's mandate is to outperform the benchmark with a risk-budget of 20 bp/month (i.e., the portfolio's TEV should remain within this bound on a monthly basis). Before formulating views and constraints, and deciding how to implement them, the manager needs to choose an investment universe. Since the benchmark is the Bloomberg Barclays US Aggregate Index, the manager could choose the investment universe to be all issues in this index with outstanding amount in excess of $300 million. The selection of this investment universe ensures that securities with small amounts of outstanding notional will not be selected in the portfolio, potentially increasing overall portfolio liquidity and decreasing transaction costs. With the risk budget in mind, the manager chooses to minimize total portfolio TEV relative to the benchmark. (The manager could potentially consider other risk-based objectives such as maximizing the Sharpe ratio.) This means the manager is giving leeway to the risk model to choose a portfolio from the tradable universe that minimizes the risk relative to the benchmark, in this case the Bloomberg Barclays US Aggregate Index. Finally, the manager formulates constraints and views.

Let us assume for the purpose of this illustration that the amount of funds to be invested is $100 million. With that in mind, and in order to avoid buying small

11. In our examples, we use the POINT optimization engine.

amounts of securities, the manager decides to implement the portfolio using a maximum of 100 positions. Given views on the market environment, the manager wants the portfolio to be long duration against the benchmark, between 0.40 and 0.60 years, and have a spread advantage of 150 bp to 200 bp over the benchmark. Finally, to ensure a certain amount of diversification in portfolio positions, the manager imposes a maximum under/overweight of 3% per issuer relative to the benchmark.[12]

Our portfolio manager incorporates all these settings into an optimization problem, and finds a solution that reflects the optimal tradeoff between the constraints and risks through the optimization engine. The result is a recommended portfolio that satisfies the constraints while minimizing total risk. Specifically, the resulting portfolio—that we will follow throughout this section—consists of 100 securities and has a predicted TEV of 15.1 bp/month, interest-rate duration of 5.44 years, and option-adjusted spread of 206 bp (Exhibit 49-1). Using a factor-based risk model and an optimization engine, the resulting portfolio incorporates the manager's views while staying within its risk budget and ensuring that all additional constraints are satisfied.

Analyzing Portfolio Risk

The main application of risk models is risk measurement of portfolios relative to their benchmark. Risk analysis based on multifactor models can take many forms: from a relatively high-level aggregate approach, to an in-depth analysis of the risk properties of individual instruments and groups of instruments. Multifactor fixed income risk models provide the tools to perform the analysis of portfolio risk in many different dimensions, including exposures to risk factors, security/factor contributions to total risk, and risk analysis at the issuer level. For instance, as previously described, this risk can be decomposed into a systematic and an idiosyncratic component. Exhibit 49-2 shows that the portfolio has total TEV of 15.1 bp/month, systematic TEV of 10.4 bp/month, and idiosyncratic TEV of 10.1 bp/month. Since

EXHIBIT 49-1

Portfolio and Benchmark Characteristics of Sample Portfolio

	Total TEV (bp/month)	Duration (years)	Spread Duration (years)	Spread (bp)
Portfolio	15.1	5.44	5.23	206
Benchmark		5.02	4.92	55

Source: POINT.

12. Another way to ensure diversification would be to include the minimization of the idiosyncratic TEV as a specific goal in the objective function.

systematic risk and idiosyncratic risk are independent, they constitute isolated (uncorrelated) risk sources of the portfolio and therefore we have

$$\text{Total TEV} = \sqrt{\text{Systematic TEV}^2 + \text{Idiosyncratic TEV}^2}$$

An alternative way to describe the manner in which different risk sources impact overall portfolio risk is through *risk attribution*. Risk attribution allows a manager to decompose portfolio volatility in an additive way into contributions to TEV. Exhibit 49-2 reports that the contribution to total TEV (CTEV) from systematic risk factors is 8.3 bp/month, whereas idiosyncratic risk contributes 6.8 bp/month.[13]

The risk attribution approach can be used to further decompose overall portfolio risk into contributions from different buckets. The buckets can represent groups of securities (e.g., industry buckets) or risk factors (e.g., factors related to curve or to credit-spreads). This flexible decomposition allows portfolio managers to gain a detailed understanding of how different securities and risk exposures affect overall portfolio risk.

Exhibit 49-3 shows the isolated TEV as well as the contributions to TEV for the sample portfolio. In this exhibit, we choose to partition risk across systematic risk factors (plus the idiosyncratic risk), but many other partitions are possible. In this example, the largest contribution within systematic risk comes from the exposure to "Curve" factors, with a CTEV of 5.2 bp/month. As we saw before, idiosyncratic exposure is also a large component of the risk in this portfolio, with a contribution of 6.8 bp/month to total risk. Notice the difference between isolated TEV and contribution to TEV for our factor partition—isolated TEV reflects the risk of the partition buckets in isolation—while contribution to TEV includes risk driven by correlations among the different buckets.

EXHIBIT 49-2

Portfolio Risk Results of Sample Portfolio in bp/Month

	Isolated TEV	CTEV
Total	15.1	15.1
Systematic	11.2	8.3
Idiosyncratic	10.1	6.8

Source: POINT.

13. In this case, because the systematic and idiosyncratic components of the TEV are uncorrelated, the CTEV can be computed easily. Specifically, the CTEV from the systematic risk is computed as $11.2^2/15.1 = 8.3$ and from the idiosyncratic as $10.1^2/15.1 = 6.8$. Note that by definition they sum up to the total TEV. In Chapter 50 a more detailed and general discussion is provided.

EXHIBIT 49-3

Portfolio Risk Contributions of Sample Portfolio in bp/Month

Risk Factor Partition Bucket	Isolated TEV	CTEV
Total	15.1	15.1
Systematic	11.2	8.3
Curve	11.4	5.2
Swap Spreads	2.6	0.6
Volatility	0.4	0.0
Spread Gov-Related	3.4	0.0
Spread Credit and EMG	7.5	2.6
Spread Securitized	3.0	–0.1
Idiosyncratic	10.1	6.8

Source: POINT.

In addition to overall portfolio TEV and partition-based contributions to TEV, there are many additional risk analytics that can be computed on the basis of a linear factor risk model, such as betas with respect to the benchmark, liquidation effect to TEV, and marginal contributions to risk. Different users will use these analytics for different purposes and to different degrees.

Portfolio Rebalancing

Most managers rebalance their portfolios at regular intervals to reflect changing views and market circumstances. For instance, as time goes by, the characteristics of the portfolio may drift away from targeted levels. This may be due to the aging of its holdings, changes in the market environment, or issuer-specific events such as defaults. The periodic realignment of a portfolio to its investment guidelines and changing investment views is called *portfolio rebalancing*. Similar needs arise in many different contexts: when managers receive extra cash to invest, receive minor changes to their mandate, want to tilt positions toward their views, and the like. As with the initial portfolio construction, a risk model is very useful in the rebalancing exercise. During rebalancing, typically the portfolio manager seeks to sell bonds currently held and replace them with others having properties more consistent with the overall portfolio goals. Such buy and sell transactions are costly and their cost must be weighed against the benefit from moving the portfolio closer to its desired profile. A risk model can tell the manager how much risk reduction (or increase) a particular set of transactions can achieve in order to evaluate the risk adjustment benefits relative to the transaction cost.

As an example, suppose the portfolio manager in our illustration wants to reduce the imbalances the portfolio has against the benchmark. Specifically, the manager wants to lower the net portfolio duration from 0.42 years to a value between 0.2 years and 0.4 years. After looking at the portfolio's industry profile, the manager also decides to reduce the existing 6% overweight in the banking industry to about 4%. In addition, the manager lowers the minimum acceptable excess spread to 100 bp. To avoid high transaction costs, the manager also imposes the rebalancing to be done with no more than 30 trades. Finally, let us assume no portfolio inflows or outflows so the portfolio market value must remain unchanged. Starting from the original portfolio of 100 securities, a risk model and optimization engine can be employed to achieve optimal rebalancing by adjusting some of the constraints to reflect the portfolio manager's new objectives.

Exhibit 49-4 shows the largest trades suggested by the optimizer, in terms of market value. Not surprisingly, the largest sell recommendations are of financial companies. To replace them, the optimizer—using the risk model—recommends a larger position of Treasury and corporate bonds. (Corporates are required in order to keep the spread of the portfolio at the desired level.)

Interestingly, the rebalancing and extra constraints imposed on the optimization problem did not materially change the risk of the portfolio. Exhibit 49-5 shows that the total TEV of the portfolio actually decreased to 13.4 bp/month. This is largely due to an extra 13 positions added to the portfolio in the rebalanc-

ing (that now has 113 securities). These extra securities allowed the portfolio to reduce both its systematic and idiosyncratic risk.

Scenario Analysis

Scenario analysis is a popular tool both for risk management and portfolio construction. In this section, we illustrate a way to construct scenarios based on factor models. In this context, a portfolio manager expresses views on the returns of particular financial variables, indices, securities or risk factors and the scenario analysis tool (using the risk model) calculates their impact on the portfolio's (net) return.

Typically in this kind of scenario analysis, the views one has are only partial. This means one can have specific views on how particular macro variables, asset classes, or risk factors will behave, but it is unlikely to have views on all risk factors to which the portfolio under analysis is exposed. This is where risk models can be useful. At the heart of the linear factor models lies a set of risk factors and the covariance matrix between them. Under certain statistical assumptions, the covariance matrix can be used to "complete" specific partial views or scenarios and deliver a complete picture of the impact of the scenario in the return of the portfolio. Mechanically, what happens is the following. First, the manager translates the views into realizations of a subset of risk factors. Next the scenario is completed—using the risk model covariance matrix—to get the realizations of *all* risk factors. Finally, the portfolio's (net) loadings to all risk factors are used to get its (net) return under that scenario (by multiplying the loadings by the factor realizations under the scenario). This construction implies a set of assumptions that should be carefully understood. To begin with, it is assumed that the manager can represent or translate views as risk factor returns. So a view about the unemployment rate, which is typically not used as a risk factor,[14] cannot be used in this context. Also, to "complete" the scenario, we generally assume a stationary and normal multivariate distribution among all factors. Although these assumptions make this

14. Unemployment rate is not used as a factor in most short- and medium-term risk models.

analysis less appropriate for looking at extreme events or regime shifts, for instance, the analysis can be very useful in many circumstances.

As an example, consider using factor-based scenario analysis to compute the model-implied empirical durations of the original portfolio of a 100 securities (i.e., before rebalancing) analyzed in detail previously in this chapter. In particular, suppose the portfolio manager has the view that interest rates will fall by 25 bp over the next month. Exhibit 49-6 shows that under this scenario, the portfolio returns 116 bp, against the 111 bp of the benchmark. As expected given the longer duration, the portfolio outperforms the benchmark. Due to the other exposures present in the portfolio and benchmark and their average negative correlation with the curve factors—for instance, a 25-bp fall in rates under this setting implies a 5% increase in corporate spread levels—the model duration implied by the scenario for the portfolio is 4.64 (= 116/25), while the analytical duration is 5.44. The scenario shows a similar decrease in the benchmark's duration. The net model duration of the portfolio is only 0.22, almost half of its 0.42 net analytical duration.

Another characteristic imposed while constructing the portfolio was a targeted higher spread. The portfolio construction exercise resulted in an OAS for the portfolio of 206 bp against a spread level of 55 bp for the benchmark. The portfolio manager might be concerned with portfolio losses should spreads increase. To evaluate this risk, the portfolio manager can construct two scenarios. In the first scenario, credit-spreads widen by 20%, other spread risk factors move as implied by the credit-spread moves, but interest rates remain unchanged. In the second scenario, interest rates moves are implied by the credit-spread move. Exhibit 49-7 displays the results of the two scenarios. In the first scenario, the portfolio suffered significant losses of 0.84%. The benchmark which has a much lower spread, suffers lower losses of 0.64% and the net result is –20 bp of net return. This number is very different from a back of the envelope calculation that uses portfolio-level analytics to estimate the return. The calculation is much more intricate and takes into account the security level portfolio composition, as well as the implied moves of other sources of risk such as swap and mortgage spreads.

EXHIBIT 49-6

Net	–20	–9

Source: POINT.

Things look better in the second scenario, where the net return of the portfolio versus the benchmark is only –9 bp. In fact, in this case both the portfolio and the benchmark exhibit positive returns of 0.49% and 0.58%, respectively, illustrating that this is a very different type of scenario. Indeed, the large spread widening implies a 25-bp fall in interest rates, which is sufficient to overcome the losses from the spread widening for both the portfolio and the benchmark. Since the portfolio has interest rate duration that is 0.42 years longer than the benchmark, it enjoys a relative improvement in net return of about –0.42 × –25 bp = +10.5 bp that partially offsets the losses from the widening of credit-spreads.

These very simple examples illustrate how one can look at reasonable scenarios to study the behavior of the portfolio or the benchmark under different environments. This type of factor-based scenario analysis can significantly increase the intuition the portfolio manager has regarding the results from the risk model.

KEY POINTS

- Risk models describe the different imbalances of a portfolio using a common language. The imbalances are combined into a consistent and coherent analysis reported by the risk model.
- Risk models provide important insights regarding the different tradeoffs existing in the portfolio. They provide guidance regarding how to balance them.
- The fundamental systematic risk of all fixed income securities is interest rate and term structure risk. This is captured by factors representing risk-free rates and swap spreads of various maturities.
- Excess (of interest rates) systematic risk is captured by factors specific to each asset class. The most important components of such risk are

credit risk and prepayment risk. Other risks that can be important are volatility, liquidity, inflation, and tax policy.

- Idiosyncratic risk is diversified away in large portfolios and indices, but can become a very significant component of the total risk in small portfolios. The correlation of idiosyncratic risk of securities of the same issuer must be modeled very carefully.
- A good risk model provides detailed information about the exposures of a complex portfolio and can be a valuable tool for portfolio construction and management. It can help managers construct portfolios tracking a particular benchmark, express views subject to a given risk budget, and rebalance a portfolio while avoiding excessive transaction cost. Further, by identifying the exposures in which the portfolio has the highest risk sensitivity, it can help a portfolio manager reduce (or increase) risk in the most effective way.

CHAPTER
FIFTY

ANALYZING RISK FROM MULTIFACTOR FIXED INCOME MODELS

Barclays

Portfolio managers constantly monitor their exposures, typically net of a benchmark, and routinely ask themselves: What is the portfolio interest-rate duration? How risky is the overexposure to Treasuries? How does it relate to the exposure to credit? What is the exposure to specific issuers? Knowing portfolio holdings and exposures is not enough for portfolio managers, they increasingly rely on quantitative techniques to translate this information into a standard risk language, which allows comparisons across diverse portfolios or situations. Risk models present a consistent view of the portfolio, its exposures, and how they relate to each other. They quantify the risk of each exposure and its contribution to the overall risk of the portfolio.

Chapter 49 covered linear factor models for fixed income portfolios. In this chapter we detail an application of the models for risk forecasting that can be used to monitor risk and gain insightful information regarding the exposures of a portfolio.

APPROACHES USED TO ANALYZE RISK

Throughout this chapter we analyze the risk of a particular bond portfolio, going through the various aspects of risk typically looked at by a manager. We follow a portfolio manager. We assume the following:

- The Bloomberg Barclays US Aggregate Index is the portfolio manager's benchmark.
- The portfolio manager believes interest rates are coming down. To capitalize on this view, the manager seeks to create a portfolio with

This chapter was coauthored by Anthony Lazanas, António Baldaque da Silva, Radu C. Gabudean, and Arne D. Staal when they were employees of Barclays.

interest-rate duration longer than the interest-rate duration of the benchmark. A portfolio with interest-rate duration that exceeds that of the benchmark is referred to as being "long duration" and it outperforms the benchmark when interest rates fall and all other market factors remain unchanged.

- The manager seeks a portfolio with higher yield than the one of the benchmark. Such a portfolio creates superior carry return (also known as *income*) relative to the benchmark but is subject to increased risks. The total yield of a portfolio can be decomposed into a risk-free yield and a spread over the risk-free yield. Because the portfolio is expected to contain securities with longer maturities to satisfy the long duration target, it will earn a risk-free yield that is different from the risk-free yield of the benchmark (higher most of the time since typically interest-rate curves are upward sloping). To further enhance the portfolio yield, the manager wants to target a portfolio spread that is also higher than the spread of the benchmark. Higher spread typically exposes the portfolio to liquidity and issuer default risks. If defaults occur, or if the portfolio manager is forced to sell securities at a significant discount because of lack of liquidity, then the incurred losses may cancel out the higher yield advantage and could lead to portfolio underperformance relative to the benchmark. The manager must be comfortable that such risks are sufficiently compensated by the higher carry return associated with higher portfolio spread.
- The portfolio manager is required to maintain the difference between the returns of the portfolio and the benchmark at around 20 basis points, on a monthly basis. Therefore, the portfolio manager must calibrate the long duration and high-yield portfolio positions in order to abide by this constraint.

To summarize, the portfolio manager has the mandate to track the benchmark, but is allowed to deviate from it up to a point in order to express views that may lead to superior returns. As mentioned in Chapter 49, a portfolio manager with such a mandate is called an *enhanced indexer*. The amount of deviation allowed is called the *risk budget* (20 basis points in our example) and can be quantified using a risk model. The risk model produces an estimate of the volatility of the difference between the portfolio and the benchmark returns, called *tracking error volatility* (TEV).[1] TEV gives the forecasted magnitude of the typical tracking error. The manager should keep the portfolio's TEV at a level equal to or less than that specified in risk budget. The final portfolio, which we will analyze, contains 100 securities and is consistent with the manager's views and risk budget.

1. In this chapter we refer to TEV, risk, and "the standard deviation of the portfolio net returns" interchangeably.

Market Structure and Exposure Contributions

The portfolio manager starts the analysis by comparing the portfolio holdings with the holdings of the benchmark. Exhibit 50-1 shows that the portfolio composition has several important mismatches relative to the benchmark. The portfolio is underweighted in Treasuries and government-related securities by a combined 9.0%. This is compensated with a combined overweight of 11.2% in Corporates, especially in the Industrials and Financials sectors. These sectors have almost double the weight in the portfolio versus the benchmark. Other mismatches include an underweight in agency mortgage-backed securities (agency MBS) by 3.8% and an overweight in commercial mortgage-backed securities (CMBS) by 1.9%. Notice that the quest for yield pushed the manager out of the relatively safe (in terms of default risk) Treasury and agency MBS sectors and into more risky corporate and CMBS sectors.

If the manager were focusing on equities instead of fixed income, this kind of information—for example, applied to the different industries or sectors of the portfolio—would be of paramount importance for portfolio risk analysis. For a fixed income portfolio, this is not the case. Although important, this analysis tells us little about the true active exposures of a fixed income portfolio, owing to the diverse nature of fixed income securities. What if the Treasuries in the portfolio have significantly longer duration than those in the benchmark—would we be

EXHIBIT 50-1

CMBS	4.4	2.5	1.9

Source: POINT

really "short" in this asset class? What if the spreads from CMBS in the portfolio are much smaller than those in the benchmark—is the weight mismatch that important?

To answer these kinds of questions, we turn to another typical dimension of analysis: the portfolio exposure to major sources of risk, measured with analytics such as interest-rate duration. Exposures to other sources of risk typically monitored include spread duration, convexity, spread level, and Vega (if the portfolio has many securities with optionality, such as mortgages or callable bonds). Their associated risks have been discussed in Chapter 49.

In Exhibit 50-2 we present these analytics at the aggregate level for the portfolio, benchmark, and the difference between the two. We can see that

- The portfolio is long interest-rate duration (0.38 years), reflecting the forecast the manager has regarding the direction of interest rate moves.
- In terms of spread duration, the mismatch is smaller (0.29 years). The manager wants to minimize the exposure to spread changes as much as possible given the manager has no view on this source of risk. However, the spread duration mismatch cannot be zero because spread risk is related to other risks that she does have a view on, such as rates.
- The portfolio and the benchmark have convexity with opposite signs (0.14 for the portfolio versus –0.04 for the benchmark). This is attributable to the smaller weight MBS have in the portfolio.
- The portfolio also has a higher negative Vega, but the number is reasonably small for both universes.
- The portfolio has significantly higher spread (148 bp) than the benchmark. This mismatch is consistent with the manager's goal of having a higher yield in her portfolio than the benchmark.

EXHIBIT 50-2

Analytics	Portfolio	Benchmark	Difference
Interest-Rate Duration	5.36	4.98	0.38
Spread Duration	5.20	4.91	0.29
Convexity	0.14	–0.04	0.18
Vega	–0.03	–0.02	–0.01
Spread	204	56	148

Source: POINT

We can combine the analysis in Exhibits 50-1 and 50-2 to create a more detailed picture of where the different risk exposures are coming from. Exhibit 50-3 shows one such example for the portfolio interest-rate duration. The majority of the mismatch in interest-rate duration contribution (market weighted duration exposures) comes from the Treasury component of the portfolio (0.60 years). Interestingly, even though the portfolio is short in Treasuries, it is actually long in terms of interest-rate duration for that asset class. This means that a Treasury sell-off, meaning an increase in rates, would impact the portfolio more negatively than the benchmark. Because the portfolio is net short Treasuries, this result must mean that the Treasury portfolio is longer in interest-rate duration than the benchmark's Treasury component. Conversely, Corporates have negative contribution to net interest-rate duration, even though they are over-weighted in terms of market value. This means that on average the corporate bonds in the portfolio are significantly shorter in interest-rate duration than those in the benchmark. Note that this kind of analysis could be applied to other analytics of interest, such as to spread or spread duration.

Adding Volatility and Correlations into the Analysis

The analysis above gives the manager some basic understanding of the portfolio exposures to different kinds of risk. However, it is still hard to understand how the portfolio manager can compare the level of risk across these different exposures. What is more risky, the long interest-rate duration exposure of 0.38 years, or the extra spread of 148 bp? How can the portfolio manager quantify how serious is the portfolio's Vega mismatch? Specifically, the risk of the portfolio is a function of the exposures to the risk factors, but also of how "risky" each of the factors is.

To enhance the analysis we must bring factor volatilities into the picture. Exhibit 50-4 shows the outcome of this addition to our example. In particular, it

EXHIBIT 50-3

Duration Contribution per Asset Class

Source: POINT

displays the risk of the different exposures of the portfolio in isolation (that is, if the only active imbalances were those from that particular set of risk factors). For example, this exhibit shows that if the only active weight in the portfolio were the mismatch in the yield-curve exposures, the risk of the portfolio would be 11.3 bp/month. By adding volatilities into the analysis, the manager can now quantify that the mismatch of 0.38 years in interest-rate duration "costs" the portfolio 11.3 bp/month of extra volatility, when taken in isolation, and therefore refer to this as the Isolated TEV.[2] Remember that the portfolio's total risk budget is 20 bp/month. Similarly, if the only mismatch were the exposure to corporate spreads, the risk of the portfolio would be 6.9 bp/month. We also see that both the Government-Related and Securitized sectors have nontrivial risk. Interestingly, this is inconsistent with the small interest-rate duration imbalance reported in Exhibit 50-3. Therefore, these sectors must have other sources of risk that are important. By bringing volatilities into the analysis, we can now compare and quantify the impact of each of the portfolio imbalances.

For future reference, let us compute the volatility of the portfolio assuming that all these sources of risk are independent (e.g., correlations are zero). This number is 13.9 bp/month.[3] Of course, this scenario is unrealistic, as these sources of risk are not independent. Also, this analysis does not allow us to understand the interplay between the different imbalances. For instance, we know that the isolated risk associated with the curve is 11.3 bp/month. But this value can be achieved both by being long or short interest-rate duration. So the isolated number does not allow us to understand the impact of the curve imbalance to the total risk of the portfolio. The net impact certainly depends on the sign of the

2. For an explanation of Isolated TEV, see Chapter 49.

3. We arrive at this number by taking the square root of the sum of squares of all the numbers in the table: $13.9 = \sqrt{(11.32{+}0.22{+}3.32{+}6.92{+}2.92)}$.

EXHIBIT 50-5

Contributions to Total Risk per Category

Source: POINT

imbalance. For instance, a long exposure in curve may be diversified away by a long exposure in credit (due to negative correlation between rates and credit-spreads). In contrast, an opposite (short) curve exposure would add to the risk of the long exposure in credit. The risk is clearly smaller in the first case.

To alleviate these shortcomings, we bring correlations into the picture. They allow us to understand the net impact of the various exposures to the portfolio's total risk and to detect potential sources of diversification among the portfolio imbalances. Exhibit 50-5 reports the contribution of each of the risk factor groups to the total risk, once all correlations are taken into account. We refer to this quantity as the contribution to tracking error volatility, or CTEV.[4] The total risk (10.4 bp/month) is smaller than the zero-correlation risk calculated before (13.9 bp/month) due to generally negative correlations between the curve and the spread factors. The exhibit also allows us to isolate the main contributors to risk as being curve (6.9 bp/month) and credit-spreads (2.9 bp/month), in line with the evidence from the earlier isolated analysis. However, the risk of the Government-Related and Securitized spreads is significantly smaller once correlations are taken into account.

The difference in analysis between the isolated risk reported in Exhibit 50-4 and the contributions to total risk in Exhibit 50-5 deserves further discussion. For simplicity, assume there are only two sources of risk in the portfolio—yield-curve (Y) and spreads (S). The total systematic variance of the portfolio (P) can be illustrated as follows:

$$\begin{aligned} VAR(P) &= VAR(Y + S) = VAR(Y) + VAR(S) + 2COV(Y, S) \\ &= Y \times Y + S \times S + 2(Y \times S) \end{aligned}$$

4. For a further discussion of this risk measure, see Chapter 49.

where we use the product to represent variances and covariances. Another way to represent this summation is using the following matrix:

$$\begin{bmatrix} Y \times Y & Y \times S \\ Y \times S & S \times S \end{bmatrix}$$

The sum of the four elements in the table is the variance of the portfolio. The isolated risk (in standard deviation units) reported in Exhibit 50-4 is the square root of the diagonal terms. So the isolated risk due to spreads is represented as:

$$Risk_{Spreads}^{Isolated} = \sqrt{S \times S}$$

It would be a function of the exposure to all spread factors, the volatilities of all these factors and the correlations among them.

The contribution to total risk reported in Exhibit 50-5 is:

$$Risk_{Spreads}^{Contribution} = [Y \times S + S \times S] / \sqrt{VAR(P)}$$

that is, from the matrix above, we sum all elements in the row of interest (row 1 for Y, row 2 for S), and normalize it by the standard deviation of the portfolio. This normalization (1) takes into account correlations and (2) ensures that the contributions to risk of all factors add up to the total risk of the portfolio given by[5]

$$Risk_{Curve}^{Contribution} + Risk_{Spreads}^{Contribution} = \sqrt{VAR(P)} = STD(P)$$

The difference between isolated and contribution to risk, due to the interplay of the two sources ($2(Y \times S)$), is allocated equally to each source of risk. In cases when one type of risk on isolated basis is much smaller in magnitude than the other, the ($Y \times S$) term may have an oversized effect. To summarize, isolated risk takes into account only the individual behavior of each source of risk, while the contribution to correlated risk looks at the joint behavior of various risk sources.

The generic analysis we just performed constitutes the first step in the description of the risk associated with a portfolio. The analysis refers to categories of risk factors (such as "curve" or "spreads"). However, a factor-based risk model allows for a significantly deeper analysis of the imbalances the portfolio may have. Each of the risk categories referred to above can be described with a rich set of detailed risk factors. Typically in a fixed income factor model, each asset class has a specific set of risk factors, in addition to the potential set of factors common to all (e.g., curve factors). These asset-specific risk factors are designed to capture the particular sources of risk the asset class is exposed to. In the following section, we go through a risk report built in such a way,

5. In this example, we focus only on the systematic component of risk. Later, the normalization is with respect to the total risk of the portfolio, including idiosyncratic risk.

emphasizing risk factors that are common or particular to the different asset classes. Along the way, we demonstrate how the report offers insights from both a risk management and a portfolio construction perspective.

A Detailed Risk Report

In this section, we continue the analysis of the portfolio introduced previously, a 100-bond portfolio benchmarked against the Bloomberg Barclays US Aggregate Index. The report package we present was generated using POINT, a cross-asset portfolio analysis and construction tool the offered by Barclays, and gives a detailed picture of the risk embedded in the portfolio.[6] The package is divided into four types of reports: summary reports, factor exposure reports, issue/issuer level reports, and scenario analysis reports. Some of the information we reviewed earlier can be thought of as summary reports.

Summary Report

Exhibit 50-6 illustrates a typical risk summary statistics report. It shows that the portfolio has 100 positions, but from only 48 issuers. This number implies limited ability to diversify idiosyncratic risk, as we will see below. The report confirms that the portfolio is long interest-rate duration (5.36 years for the portfolio versus 4.98 years for the benchmark) and has higher yield (4.55% for the portfolio versus 2.97% for the benchmark) and coupon (5.07% for the portfolio versus 4.24% for the benchmark).

The exhibit also reports that the total volatility of the portfolio (127.7 bp/month) is higher than that of the benchmark (121.2 bp/month). This is not surprising: longer interest-rate duration, higher spread, and less diversification all tend to increase the volatility of a portfolio. Because of its higher volatility, we refer to the portfolio as riskier than the benchmark. Looking into the different components of the portfolio volatility, the exhibit reports that the idiosyncratic volatility of the portfolio is significantly smaller than that of the systematic one (10.5 bp/month versus 127.3 bp/month), which is what we expect from a medium-sized portfolio of investment-grade bonds.

Given the fact that the systematic and idiosyncratic components of risk are independent by construction, we can calculate the total volatility of the portfolio as

$$\text{TEV}_{Portfolio} = \sqrt{127.3^2 + 10.5^2} = 127.7$$

6. The model was available through POINT, a portfolio management tool that at the time this chapter was written was an offering by Barclays. It is a multicurrency cross-asset model that covers many different asset classes across the fixed income and equity markets, including derivatives in these markets. At the heart of the model is a covariance matrix of risk factors. The model has several hundreds of factors, many specific to a particular asset class. The asset class models are periodically reviewed. Structure is imposed to increase the robustness of the estimation of such large covariance matrix. The model is estimated from historical data. It is calibrated using extensive security-level historical data and is updated on a monthly basis.

There are two interesting observations regarding this number:

1. The total volatility is smaller than the sum of the volatilities of the two components.
2. The total volatility is very close to the systematic one.

The first observation is the diversification benefit that comes from combining independent sources of risk. The second observation may suggest that the idiosyncratic risk is irrelevant. That is an erroneous and dangerous conclusion, as we will see later. In particular, when managing against a benchmark, the focus should be on the net exposures and risk, not on their absolute counterparts.

In Exhibit 50-6, the total TEV is reported as 14.2 bp/month. This means that the model forecasts the portfolio return to be typically around 14 bp/month higher than or lower than the return of the benchmark. This number is in line with the risk budget of the manager. The exhibit also reports idiosyncratic TEV of 9.6 bp/month, which is close in magnitude to the systematic TEV (10.4). Therefore, when measured against the benchmark, half of the risk is idiosyncratic, contrary to the conclusion one could draw by looking only at the portfolio's volatility. The TEV of the portfolio is also greater than the difference between the volatilities of the portfolio and benchmark. It would be equal to the difference only if the portfolio and benchmark were perfectly correlated.

Finally, the report shows that the portfolio has a beta of 1.05 to the benchmark. This statistic measures the co-movement between the portfolio and the benchmark. We can read it as follows: the model forecasts that a movement of 100 bp in the benchmark leads to a movement of 105 bp in the portfolio in the same direction. Note that a beta of less than one does not mean that the portfolio is less risky than the benchmark; it just means that the portfolio is less sensitive to movements in the benchmark. To see this more clearly, consider the limit case when the portfolio and benchmark are uncorrelated. The portfolio beta in this case is zero but obviously that does not mean that the portfolio has zero risk. Finally, one can compute many different "betas" for the portfolio or subcomponents of it.[7] A simple and widely used one is the "interest-rate duration beta," given by the ratio of the portfolio interest-rate duration to that of the benchmark. In our case this ratio is 5.36/4.98 = 1.08. This implies that the portfolio has a return from yield-curve movements around 1.08 times larger than that of the benchmark. This beta is larger than the portfolio beta (1.05), meaning that net exposures to other factors (e.g., spreads) "hedge" the portfolio's net curve risk.

This first summary report (Exhibit 50-6) allows the manager to get a glimpse into the risk of the portfolio. However, the manager wants to know in more detail what the sources of this risk are. Risk can be broken down along various dimensions, two of which we briefly looked at above: security groups (asset classes) and risk factors. The next two summary reports present the detailed risk breakdown along these two dimensions. In the first, risk is partitioned across

7. For example, see Exhibit 50-13 later in this chapter.

Source: POINT

exhibit reports in the first column the isolated TEV, that is, the risk associated with that particular set of risk factors only. We see that in an isolated analysis, the systematic risk and idiosyncratic risk are balanced at 10.4 and 9.6, respectively.

The report also shows the isolated risk associated with the major components of systematic risk. As discussed before, all components of systematic risk have nontrivial isolated risk, but only curve and credit-spreads are relevant when we look into the CTEV. If we look across factors, the major contributors are idiosyncratic risk, curve, and credit-spreads. Other systematic exposures are relatively small.

Another look into the correlation comes when we analyze the liquidation effect reported in Exhibit 50-7. This number represents the change in TEV when we completely hedge that particular group of risk factors. For instance, if we hedge the curve component of the portfolio, the TEV drops by 1.1 bp/month—from 14.1 to 13.0. One may think that the drop is rather small given the magnitude of isolated risk the curve represents. However, if we hedge the curve, we also eliminate the risk reduction effect of the negative correlation between curve and spreads. Therefore, there is a more limited impact when hedging the curve risk than what is expected based on previous numbers. In fact, for this portfolio we see that hedging any particular set of risk factors has a limited effect on the overall risk.

The TEV elasticity reported in the last column gives another perspective into how the TEV changes when risk loadings change. Specifically, it tells the manager what the percentage impact on TEV is if the exposure to that particular set of factors is changed. For example, if the manager reduces the exposure to

Source: POINT

corporate spreads by 10%, the TEV would decrease by 10% × 15.1% = 1.51% and therefore it would become 14.2 bp × (1 – 1.51%) = 14.0 bp.

We perform a similar analysis in Exhibit 50-8, but apply it to a security partition. That is, instead of looking at individual sources of risk (e.g., curve) across all securities, we now aggregate all sources of risk within a security and report analytics for different groups of these securities (e.g., subportfolios). Exhibit 50-8 reports results when securities are grouped by asset class. It shows that the majority of risk (7.8 bp/month) comes from the Treasury component of the portfolio. Most of this risk is systematic, which is what we expect given the typically low idiosyncratic risk of the sector and the significant interest-rate duration mismatch. Corporates are also a major contributor to the portfolio's risk, mostly coming from idiosyncratic risk. This reflects the portfolio's large net market weight (NMW) to this sector. The lack of systematic risk contribution by the corporate sector comes from the hedging effect of spreads to the overall curve risk in the portfolio. Note that because the analysis is at the portfolio level, the interplay between net curve risk of Treasuries and spread risk of corporates is partly reflected in the total risk attributed to corporates. The same story applies to other spread sectors, all of which contribute little to systematic risk. Both agency MBS and CMBS contribute non-trivially to idiosyncratic risk. Since the portfolio manager's goal is the replication of a very large benchmark with only 100 positions, the manager has to be comfortable with the issuers selected. This report highlights the significant name risk to which the portfolio is exposed.

Exhibit 50-9 completes the analysis, reporting other important risk statistics about the different asset classes within the portfolio. These statistics mimic the analysis done in terms of risk factor partitions in Exhibit 50-7, so we will not repeat their definitions and focus on the results. Looking at isolated TEV, we see that Corporates have risk of 16.7 bp/month, which is higher than the total risk of the portfolio. This means that the exposures to the other asset classes, on average, hedge the Corporates portfolio. The same can be said about Treasuries. We can even take the analysis a bit further: the next column shows through the liquidation effect that if we eliminate the imbalance the portfolio has on Corporates, we actually would increase the total risk of the portfolio by 4.6 bp/month. In short, we would be eliminating the hedge this asset class provides to the global portfolio, therefore increasing its risk. Because a similar analysis holds for Treasuries, we can conclude that the exposures to Treasuries and Corporates were built to balance each other in the portfolio. Finally, Exhibit 50-9 also reports the TEV elasticity of the different components of the portfolio. This number represents how much a relative change in NMW translates into a relative change on TEV, so we need to read the numbers with an opposite sign if the NMW is negative. In particular, if we decrease the weight of the agency portfolio (making it more negative, or "more short") by 10%, we would actually increase the TEV by 10% × 12.2 % = 1.22% making it equal to 14.2 bp × (1 + 1.22%) = 14.4 bp. This result shows that the position in agencies provides hedging "on average," but further increasing the exposure to this sector would actually increase the risk of the portfolio. In other words, the hedging went beyond its optimal value.

CMBS	3.5	0.0	2.7

Source: POINT

This set of summary reports gives us a clear picture of the major sources of risk and how they relate to each other. In what follows, we focus on the more detailed analysis of the individual systematic sources of risk.

Factor Exposure Reports

At the heart of a multifactor risk model is the definition of the set of systematic factors that drive risk across the portfolio. As described in Chapter 49, there are many different types of risk sources a fixed income portfolio is exposed to. In what follows we focus on the three major types: curve, credit, and prepayment risk. To illustrate credit and prepayment risk, we use the Corporates component and the agency MBS component of the portfolio, respectively. Moreover, to keep the example simple, we show only a partial view of all relevant factors for these sources of risk.

Curve Risk ***Exhibit*** 50-10 details the risk in the portfolio associated with the U.S. Treasury curve. It starts by describing all risk factors the portfolio or benchmark load on. In particular, we use six key-rate (KR) points on the curve plus the convexity term as the risk factors associated with U.S. Treasury risk. They are described in the first column of panel A in the exhibit and measure the risk associated with moves of that particular point on the curve. Exposure to these risk factors is measured by the key-rate durations (KRD) for each of the six points. The description of the loading is in the exhibit's second column, while its value for the portfolio, benchmark, and the difference is displayed in the next columns. Key-rate durations are also called partial durations, as they add up to the interest-rate duration of the portfolio. For instance, for the portfolio, the sum of the key-rate durations is 0.13 + 0.47 + 1.74 + 0.93 + 1.00 + 1.09 = 5.36, the total interest-rate duration of the portfolio. Their loadings are constructed by aggregating partial durations across all the securities.

Looking at the exhibit, we see significant mismatches in the duration profiles between the portfolio and its benchmark, namely at the 10-year and 30-year points on the curve. Specifically, we are short 0.44 years at the 10-year point and long 0.41 years at the 30-year point. Moreover, we are also significantly long at the 5-year and 20-year points. How serious is this mismatch? Looking at the factor volatility column, it can be seen that these points on the curve have been fairly volatile at around 30 bp/month. If we interpret this volatility as a typical move, the first two columns of panel B show us the potential impact of such a movement in the return of the portfolio, net of benchmark. For instance, a typical move up (+32.2 bp/month) in the 10-year point of the Treasury curve, when considered in isolation, will deliver a positive net return of +14.2 bp.[9] In isolation, the positive

9. This number is obtained by simply multiplying the net exposure by the factor volatility. The sign of the move depends on the interpretation of the factor. In the case of the yield-curve movements, we know that $R = -KRD \times \Delta KR$, where KRD is the duration associated with the KR point. In our example $-(-0.44) \times 32.2$ bp = +14.2 bp.

EXHIBIT 50-10

Treasury Curve Risk

A. Exposures and Factor Volatility

Factor Name	Units	Exposure: Portfolio	Exposure: Benchmark	Exposure: Net	Factor Volatility

USD Convexity	0.9	1.2	0.4	0.5

Source: POINT

impact is expected because we are short that point of the curve. More interesting may be the correlated number on the exhibit. It states the return impact but in a correlated fashion. In the scenario under analysis, a movement in the 10-year point will almost surely involve a movement of the neighboring points on the curve. So contrary to the positive isolated effect documented above, the correlated impact of a change up in the 10-year point is actually negative, at –5.5 bp. This result is in line with the overall positive interest-rate duration exposure the portfolio has: general (correlated) movements up in the curve have a negative impact on the portfolio's performance.[10] As another expression of the high correlation among curve points, we can see that correlated changes on various points on the curve have a similar impact on the final portfolio, even though their associated exposures vary greatly. Finally, and broadly speaking, the ratio of the correlated impact to the factor volatility gives us the model-implied partial empirical interest-rate duration of the portfolio. For instance, if we focus on the 10-year point, we get 5.5/32.2 = 0.17. This smaller empirical interest-rate duration is typical in portfolios with spread exposure. This spread exposure tends to empirically hedge some of the curve exposure, given the negative correlation between these two sources of risk. In addition, Exhibit 50-10 shows the risk associated with convexity. We can see that the portfolio is long convexity while the benchmark is short, so higher order changes in the yield-curve have an opposite impact on the portfolio than on the benchmark.

There are many other statistics of interest one can analyze regarding the Treasury curve risk of the portfolio. The portfolio manager may ask questions such as: If I want to reduce the risk of my portfolio by manipulating my Treasury curve exposure, what could I change? What is the most effective move? By how much would my risk actually change? The statistics reported in columns "Marginal Contribution to TEV" and "TEV Elasticity (%)" of panel B are typically used to answer these questions. Regarding the marginal contributions, the 30-year point has the largest value, showing us that an increase (reduction) of one unit of exposure (in this case one year of duration) to the 30-year point leads to an increase (reduction) of 12.8 bp in the TEV.[11] In other words, if we want to reduce risk by manipulating the exposure to the yield-curve, the 30-year point seems to present the fastest track. In addition, the exhibit shows that all Treasury risk factors are associated with positive marginal contributions. This means that an increase in the exposure to any of these factors increases the risk (TEV) of the portfolio. This conclusion holds even for factors for which we have negative exposure (e.g., the 10-year key-rate) because increasing exposure to it means decreasing the negative exposure. To

10. This reversal is clearly related to the fact that the 10-year point on the curve is usually highly correlated to the 5-, 20-, and 30-year ones. In our case, our short position on the 10-year point is more than compensated by the positive exposure to the other points in the curve. Netting out, the positive exposure effect (long duration) dominates when all changes are taken in a correlated fashion.

11. The marginal contribution is the derivative of the TEV with respect to the loading of each factor, so its interpretation holds only for small moves. Therefore, a more realistic reading may be that if we reduce the exposure to the 30-year by 0.1 years, the TEV would be reduced by around 1.3 bp.

put it differently, the result is a consequence of the portfolio's overall long interest-rate duration exposure. Adding more duration exposure, regardless of the specific point where the manager does it, will result in an increase in portfolio risk.[12] This result holds because we take into consideration the correlations between the different points in the Treasury curve.

Exhibit 50-10 also reports the TEV elasticity of each of the risk factors, a concept introduced earlier. The interpretation is similar to the marginal contribution, but with normalized changes (percentage changes). This normalization makes the numbers more comparable across risk factors of very different nature. It is also useful when considering leveraging the entire portfolio proportionally. In our case, if we increase the exposure to the 10-year key-rate point by 10%, from –0.44 to –0.484 (effectively reducing the long interest-rate duration exposure), the TEV would be reduced by 3.79% (from 14.2 to 13.7 bp/month).

We now turn the analysis to the other component of the curve risk described above: the risk embedded into the portfolio exposure to swap spreads, that is, the differences between the swap and Treasury curves. Many securities trade against the swap curve, making it the natural choice as the base risk curve for those markets. To unify the analysis with markets that use Treasuries as the base curve, we break the swap curve into the Treasury curve (analyzed in Exhibit 50-10) and excess over the Treasury—the swap spread.[13]

All the securities that typically trade against the swap curve (e.g., corporates and securitized bonds) are exposed, in our methodology, to both Treasury and swap spread (SS) risk. The analysis of the latter follows very closely that of the Treasury curve, so we only highlight the major risk characteristics of the portfolio along this dimension. Exhibit 50-11 shows that in general the exposure to swap spreads is smaller than of the exposure to the Treasury curve. Remember that Treasuries do not load on this set of risk factors, so the market-weighted exposures are consequently smaller. Comparing the swap spread volatilities with those from the Treasury curve (see Exhibit 50-10), we can observe significant differences. Looking at the profile of factor volatilities, one can see that its term structure of volatilities is U-shaped, with the short-end being quite volatile and the 5-year point having the lowest volatility. This is typically the case during periods when liquidity risk is high. Regarding net exposures, the exhibit shows that the largest mismatch is at the 10-year point, where the portfolio is short by 0.35 years. Interestingly, this is not the most expensive mismatch in terms of risk: when looking at the last column, we see that we would be able to change risk the most by manipulating the short end of the exposure to the swap spread curve, namely the 6-month point.

The previous exhibits allow us to understand the portfolio exposures to the different types of curve risk and their impact both on the return and risk of

12. This is a rationale similar to the one used before, where we see all correlated impact with the same sign.

13. For a more detailed discussion, see Chapter 49.

portfolios. They also guide us regarding what changes we can introduce to modify the risk profile of the portfolio. We continue our analysis with sources of risk that are more specific to particular asset classes.

Credit Risk Credit risk may be analyzed along various dimensions such as geography, industry, debt seniority, credit rating, or spread level. As discussed in Chapter 49, a powerful determinant of credit risk of a bond for relatively short horizons is given by its *duration times its spread*, or DTS. Under this setting, the spread return of the security is given by the product of its DTS and the percentage change in its spread.[14]

Assuming that the percentage change in spread has similar statistical properties across a group of bonds, we can select this common component as one driver of systematic spread changes, giving rise to the *DTS systematic risk factor*. Apart from DTS, many other characteristics may explain systematic changes in spreads. Examples would be systematic differences along debt seniority or credit rating. However, these differences are typically well captured by the DTS levels of each security. Therefore, they do not justify risk factors in addition to the DTS. On the other hand, there are bonds with similar DTS that may behave very differently, depending on their geography or industries membership, for instance. This difference is relevant enough to grant the typical use of different risk factors across these dimensions. In the framework under analysis here, this is achieved by introducing several DTS factors, one for each combination of region and industry considered in the risk model.

The results of such an approach to the analysis of the portfolio in our example are displayed in Exhibit 50-12, which shows the typical industry risk factors associated with credit risk. The portfolio has exposure to a single region (U.S.) and has net positions in 27 industries, spanning all three major sectors: Industrials (IND), Utilities (UTI), and Financials (FIN). We saw before that the portfolio has significant net exposure to Financials in terms of market weights (3.7%, see Exhibit 50-1). In terms of risk exposure, Exhibit 50-12 shows that the net DTS attached to the Banking industry is 0.62[15], clearly the highest across all sectors. However, the marginal contribution to TEV that comes from that industry is comparable to almost all other industries, even with ones that have an almost zero net exposures, such as Brokerage. This observation suggests that all these industries are close substitutes to each other in the context of the current portfolio.

Another interesting point is highlighted by the fact that the marginal contribution is negative for all industries, even though some (such as Retail and

14. More specifically Spread Return = $-SD \times \Delta S = -SD \times S \times (\Delta S/S) = -DTS \times \%\Delta S$, where SD stands for spread duration, S for spread, and Δ for change.

15. The DTS units used in the report are based on an OAS duration (OASD) stated in years and an OAS in percentage points. Therefore, a bond with an OASD = 5 and an OAS = 200 bp would have a DTS of 5 × 2 =10. The DTS industry exposures are the market-value weighted sum of the DTS of each security in that industry.

Healthcare) are significantly over-weighted. The analysis suggests that if we increase the risk exposure to them, the risk would actually decrease. This result is again driven by the strong negative correlation between spreads in these industries and the yield-curve. For example, the exposure in banking is partially hedging out the significant long interest-rate duration position. This kind of analysis is only possible by accounting for the correlations across factors, underscoring the importance of the quality of the correlation estimates used by the model.

Although the risk factors used to measure risk are predetermined in a given factor model, there is flexibility on the way the risk numbers can be aggregated and reported.[16] For example, the credit risk model used to generate the risk report presented in Exhibit 50-12 does not use credit ratings as drivers of systematic credit risk. Instead, it uses the DTS concept. However, once generated, the risk numbers can be reported using any portfolio partition.

As an example, Exhibit 50-13 shows the risk breakdown by rating. As reported in this exhibit, the majority of risk is coming from the AAA exposure (11.3 bp/month), the bucket with the biggest mismatch in terms of net weight (–12.1%). This bucket includes Treasury and government-related securities, sectors that are underweighted in the portfolio, leading to significant risk. This is even clearer when we look into the isolated TEV numbers. If the manager had mismatches only on AAA's, the portfolio risk would be 22.8 bp/month, instead of the actual 14.2: the other exposures hedge the risk from AAA's. This report also identifies the systematic betas associated with each of the rating sub-portfolios. These betas add up to the portfolio beta, when we use the portfolio weights (not NMW) as weights in the summation. For example, the exhibit allows us to infer that a movement of 10 bp in the benchmark leads to a 12.6 bp return in the AAA sub-component of the portfolio. On the other hand, the beta of 0.22 for the BAA2 component of the portfolio does not signal low volatility for this sub-portfolio. It indicates mainly low correlation with the benchmark, possibly a result of the significant role of idiosyncratic risk for this set of bonds. Systematic betas of zero identify buckets for which the portfolio has (close to) no holdings.

Prepayment Risk Most securitized bonds, such as MBS or asset-backed securities (ABS), have uncertain cash flows due to the borrower's option to prepay the bond at any time. Interest rates strongly drive this prepayment behavior, as explained in Chapter 49, thus adding an extra channel of exposure to interest-rate risk that is absent from other bonds (e.g., corporate bonds with no optionality). Typically, interest and prepayment models can accommodate this feature only imperfectly. Moreover, there are other factors influencing prepayment risk. To accommodate these limitations, risk models incorporate other major characteristics that can be associated with prepayment risk. Examples are the program/term

of the deal, if the bond is priced at discount or premium (i.e., if the coupon on the bond is bigger than the current mortgage rates) and how seasoned the bond is.

Exhibit 50-14 shows a potential set of risk factors that capture these characteristics. Programs identified as having different prepayment characteristics are the Conventional (FannieMae and FreddieMac) 30-year bonds (the base case used for the analysis), the 15-year Conventional bonds, as well as the Ginnie Mae 30- and 15-year bonds. The age of bonds is captured by factors distinguishing between new and aged (seasoned) deals. Finally, each bond is also classified by the price of the security—discount, current, or premium. In this example there are no seasoned discounted bonds, suggesting that the market rates at the time of the analysis are at historical lows. In terms of risk exposures, the exhibit shows that the manager is underweighting 15-year and over-weighting 30-year Conventional bonds (the base case).

Interaction Between Sources of Risk So far we have analyzed the major sources of spread risk: credit and prepayment. To do this, we conveniently used two asset classes—Corporates and Agency MBS, respectively—where one can argue that these sources of risk appear relatively isolated. However, recent developments have made clear that these sources of risk appear simultaneously in other major

EXHIBIT 50-14

asset classes, including nonagency MBS, home equity loans, and CMBS.[17] When designing a risk model for a particular asset class, one should be able to anticipate the nature of the risks the asset class exhibits currently or may encounter in the future. The design and ability to segregate between different kinds of risk depends also on the multitude of the bond indicatives and analytics available to the researcher. For this last point, it is imperative that the portfolio manager understand the pricing model and assumptions made to generate the analytics typically used as inputs in a risk model. This allows the portfolio manager to fully understand the output of the model, as well as its applicability and shortcomings. Other sources of risk—for example, liquidity risk—may be important for particular fixed income portfolios. They were discussed in Chapter 49.

Issue-Level Reports

The previous analysis focused on the systematic sources of risk. We now turn our attention to the idiosyncratic or name-specific risk embedded in the portfolio. This risk measures the volatility the portfolio has because of events specific to the individual issues/issuers it holds. Therefore, idiosyncratic risk is independent across issuers and diversifies away as the number of issuers in the portfolio increases: events with negative impact for some issuers are canceled by events with positive impact for others. Even for medium-sized portfolios, the idiosyncratic risk may be a substantial component of the total risk. Exhibit 50-7 indicates that the idiosyncratic volatility is 10.5 bp/month, more than double the idiosyncratic volatility of the benchmark (4.7 bp/month). When looking at the tracking error volatility net of benchmark, Exhibit 50-6 shows that the idiosyncratic risk is 9.6 bp/month and close to the systematic component (10.4 bp/month). This means that a major component of the monthly net return is typically driven by events affecting only individual issuers. Therefore, monitoring these individual exposures is of particular importance.

The idiosyncratic risk of each bond is a function of two variables: its net market weight and its idiosyncratic volatility. This latter variable depends on the nature of the bond issuer. For instance, a bond from a distressed firm has much higher idiosyncratic volatility than one from a government-related agency.

Exhibit 50-15 provides a summary of the idiosyncratic risk for the top 10 positions by market weight in the manager's portfolio. Not surprisingly, 7 out of 10 are Treasury or agency MBS securities, in line with the constitution of the index used as benchmark. Moreover, these positions have significant market weights, given that the portfolio contains only 100 positions. Even though we see large concentrations, the idiosyncratic TEV for these holdings is small, as they are not exposed to significant issuer risk. The last column of the exhibit shows that within this group the bonds with the highest idiosyncratic risk are corporate bonds, one issued by CVS Corporation (CVS) and another issued by Kennametal

17. For more discussion on this point, see Radu Gabudean, "US CMBS Risk Model," Barclays Publication, October 2010.

Inc. (KMT). This is not surprising, as these are the type of securities with larger event risk. Even within corporates, idiosyncratic risk can be quite diverse: in particular, it usually depends on the industry, spread duration, and level of distress of the issuer (usually proxied by rating, or by the spread of the bond). For instance, the net position for both the CVS and KMT bonds is similar (3.06% and 3.00%, respectively), and even though their maturity is similar, the CVS bond spread is higher, resulting in higher idiosyncratic risk (3.5 versus 2.6 bp/month). To manage the idiosyncratic risk in the portfolio the portfolio manager should pay close attention to mismatches between the portfolio and benchmark for bonds with large spreads or long spread durations. These would tend to affect disproportionally the idiosyncratic risk of the portfolio.

Although important, the information in Exhibit 50-15 is not enough to fully assess the idiosyncratic risk embedded in the portfolio. For instance, a portfolio manager could buy credit protection on CVS through a credit default swap (CDS), thereby significantly reducing the exposure to this issuer's bond. The position reported in this exhibit would still look significant because the CDS protection would not be reflected in it.

A better way is to look at idiosyncratic risk at the issuer rather than at the issue level. While idiosyncratic risk is usually independent across issuers, one may not assume that the idiosyncratic risk of securities of the same issuer is uncorrelated because they are all subject to the same company-specific events. A good risk model should account for such correlation and try to quantify it for different issuer and security types. For example, all types of securities (bonds, equities, convertibles, etc.) of an issuer in financial distress tend to move in a correlated fashion because they all represent claims to the same distressed assets. Adding more securities from such an issuer to a portfolio does not generally deliver additional diversification. On the other hand, securities from issuers in strong financial health can move quite differently from each other, driven primarily by liquidity or capital structure effects rather than credit. In this case, a portfolio manager can achieve some diversification of idiosyncratic risk (although limited) even when adding issues from that same issuer into the portfolio.

In order to understand the net effect of all such interactions, it is useful to review the contributions of individual issuers to the portfolio's total idiosyncratic risk. When aggregating risk from the issue (as shown in Exhibit 50-15) to the issuer level, the correlations referred to above should be fully taken into account. Exhibit 50-16 shows the results of this exercise for the 10 issuers with the highest isolated idiosyncratic TEV. The riskiest issuer exposure in the portfolio comes from Mellon Capital, with isolated idiosyncratic risk of 4.0 bp/month. Note that no single security from this issuer appears as a top holding in the portfolio (see Exhibit 50-15). This highlights the importance of aggregating idiosyncratic risk at the issuer level. We can also observe that idiosyncratic TEV is not monotonic in the NMW: Mellon Capital and Ameren Corp have similar NMW, but the former is significantly riskier (4.0 versus 1.3 bp/month). It is also possible to have important idiosyncratic risk even for issuers the portfolio does not hold, namely for bonds from issuers that have significant market weight in the benchmark.

Finally, note that because the idiosyncratic risk across issuers is independent, the cumulative risk of several issuers can be easily calculated. For example, the total idiosyncratic risk of the top two issuers in Exhibit 50-16 is given by:

$$\mathrm{TEV}_{idio}^{BK+GS} = \sqrt{4.0^2 + 3.5^2} = 5.3$$

As is the case in most portfolios tracking a benchmark, most issuers present in the portfolio are over-weighted relative to the benchmark. This is a natural consequence of the fact that, in practice, portfolios hold far fewer positions than the benchmark. It may be difficult for the manager to hold positive views in all issuers selected in the portfolio. In fact, some of these positions may be selected to build exposure to specific systematic factors, such as a particular industry or asset class, and not to a particular issuer. However, it is important that the manager hold positive views for the issuers with the largest contribution to idiosyncratic risk. If this is not the case, then the manager is assuming a significant unintended name risk that should be promptly taken out of the portfolio, in favor

of another issuer with similar characteristics for which the manager does have a positive view. This interactive exercise can easily be performed with a good and flexible portfolio construction tool and the help of an optimizer.

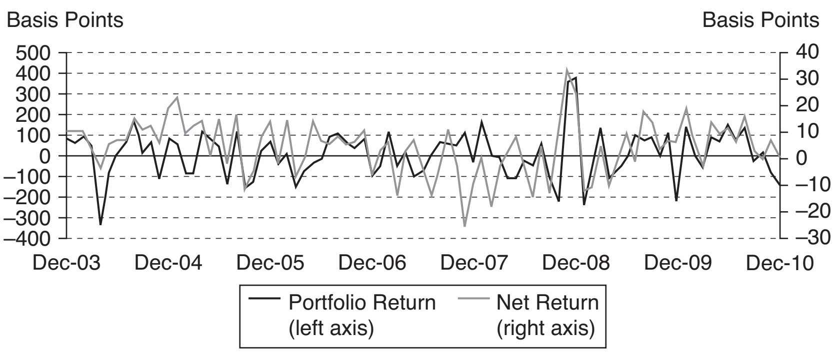
Scenario Analysis Report

Scenario analysis provides an additional perspective on the portfolio's risk. This exercise can be performed in several ways. For instance, a manager may want to reprice the whole portfolio under a particular scenario on risk factors, such as interest rates or spreads, and look at the hypothetical return under that scenario. Alternatively, a portfolio manager may wish to evaluate how the portfolio would have performed under particular historical scenarios (e.g., the 1987 equity crash or the Asian crisis in 1997). One particular problem with this approach is the fact that, given the dynamic nature of the securities, the current portfolio with its current characteristics did not exist during such historical episodes. Some of the portfolio securities may have not even been issued during such periods. A solution might be to price the current securities with the market variables at the time. While a valid solution, it is difficult to implement because pricing models require inputs possibly not available during that historical period.

An alternative is to represent the current portfolio as the set of loadings to all systematic risk factors in a linear factor risk model. We can then multiply these loadings by the historical realizations of the risk factors. The result is a set of historical systematic simulated returns. Exhibit 50-17 presents monthly returns for the period between December 2003 and December 2010. The dark line represents the absolute portfolio returns and the lighter line represents the portfolio's return net of the benchmark. Note that this analysis uses only one set of static portfolio loadings. Therefore, these simulated returns can be interpreted as the hypothetical returns a portfolio with these characteristics would have, if submitted to the historical episodes. As expected, the largest volatility was realized during the crisis of

EXHIBIT 50-17

Historical Systematic Simulated Returns (basis points)



Source: POINT

2007–2009, when the portfolio registered returns between –300 and 400 bp. The largest underperformance against the benchmark occurred in November 2007 at about –25 bp, followed by other months during the crisis such as February and September 2008. The largest outperformance (about +30 bp) was registered at the end of 2008, when the portfolio—being long interest-rate duration—benefited from the sharp drop in interest rates registered during that period.

This analysis has some limitations, especially for the portfolio under analysis, where idiosyncratic exposure is a major source of risk. This kind of risk is always hard to capture and obviously less relevant from an historical perspective, as the issuers in the current portfolio may have not witnessed any particular major idiosyncratic event in the past. However, these and other types of historical scenario analyses are important because they give managers some indication of the magnitude of historical returns the portfolio might have encountered. They are usually the starting point for any scenario analysis. The manager should always complement them with other non-historical scenarios relevant for the particular portfolio under analysis. In particular, the risk model can be used to express such scenarios, as discussed in Chapter 46.

KEY POINTS

- A good risk model provides detailed information about the exposures of a portfolio. Risk analysis starts with weight imbalances in the portfolio, when compared to the benchmark. For fixed income portfolios, the analysis of market weights has to be complemented with other analytics for a better description of the portfolio's exposure to the different sources of risk.
- The relevance of a risk source is given by the product of its volatility—how risky it is—and the portfolio's exposure to it. To get an aggregated description of risk, we have to bring into the analysis correlations between the different risk sources the portfolio is exposed to. The combination of these elements results in the overall risk of a portfolio versus a benchmark, or its tracking error volatility.
- There are many different ways to analyze the risk of a portfolio. We can do it by type of risk factor (e.g., interest-rate risk) or by type of security (e.g., corporates). Many different metrics—such as contribution to TEV, liquidation effect on TEV or TEV elasticity—can provide further understanding of the overall risk of the portfolio.
- Risk analysis can be significantly enhanced using scenario analysis. There are several methods to perform it. One method is to look at the historical performance of a theoretical portfolio with constant loadings. This analysis allows a manager to study the potential behavior of a portfolio with such characteristics across major historical events.

CHAPTER

FIFTY-ONE

CASH-FLOW MATCHING

Ronald J. Ryan, CFA
Chief Executive Officer
Ryan ALM, Inc.

Cash-flow matching has a long and respected history as a way to fund pension benefits. It has its roots in portfolio immunization, first introduced in the high-interest-rate environment of the early 1980s by Martin Leibowitz.[1] The objective of this chapter is to explain cash-flow matching and its application to pension fund management.

WHAT IS CASH-FLOW MATCHING?

Cash-flow matching is a fixed income methodology to match and fund with high certainty a stream of liability cash flows. It has become known as cash-flow driven investment (CDI). In defined benefit pensions, the liability cash flows are an actuarial projected benefit payment schedule. Since actuarial projections are not an exact science, there can be some actuarial noise or uncertainty depending on which projected liability payments you are attempting to match. There are three types of pension liabilities: Retired Lives, Terminated Vested, and Active Lives.[2] Given their greater certainty, cash-flow matching is used only for pension Retired Lives. CDI is a bond portfolio of cash flows that include the principal at maturity (or call date), periodic interest income, and the reinvestment of any excess cash flows greater than the benefit payments that the strategy is funding (liability cash flows). If such reinvestment of excess cash flows is at positive interest rates, the additional earned income will reduce the future funding costs. If risk is defined as the uncertainty of achieving the objective (funding liability payments), then cash-flow matching is one of the best approaches to de-risking a pension liability schedule.

The objective of a pension is to secure benefits in a cost-efficient manner. CDI is one of two ways to secure benefits. The other way is through insurance

1. Martin L. Leibowitz, "The Dedicated Bond Portfolio in Pension Funds – Part 1: Motivations and Basics," *Financial Analysts Journal* 42(1), 1983, pp. 68–75

2. Retired Lives included workers who have terminated employment and are receiving monthly benefit payments. Active Lives includes workers who have not been terminated and benefits are not yet determined.

annuities, which tend to be expensive. Bond mathematics proves that the longer the maturity and the higher the bond yield, the lower the bond cost. It is all about the time value of money (present value versus future value). As a result, CDI will skew the weights of its portfolio holdings to longer maturities to reduce cost. The bond yield curve is typically positive sloping such that the longer the maturity the higher the yield to maturity (YTM). This allows cash-flow matching to use the interest income of longer bonds to partially fund every six months shorter projected liabilities especially if such longer bonds have a greater yield than shorter-maturity bonds. Since projected pension benefits are monthly, cash-flow matching requires sophisticated modeling techniques, such as a cost optimization model, to build a bond portfolio of numerous maturities to cash-flow match efficiently the liability cash-flow projections at the lowest cost to the pension plan sponsor.

The efficiency of the cash-flow matching model is best determined by the amount of excess cash flows to be reinvested. The goal is for no or little excess cash-flow reinvestment, but this is quite difficult to achieve. It is ideal, if not a requirement, that the bonds used for cash-flow matching are free of options that would disturb the certainty of the cash flows such as call options, put options, floaters, pass-throughs, and so on. In addition, the pension plan sponsor will put constraints on the cash-flow matched portfolio (as true for any bond portfolio) from its investment policy statement (IPS). This would include rating, sector, issuer, and issue constraints on the percentage weighting in the portfolio. Fortunately, the fixed income universe available for cash-flow matching is immense allowing for great selection.

An exact match of bond maturities to liability payment dates could theoretically be accomplished by using U.S. Treasury STRIPS (zero-coupon bonds), but this would not be cost effective due to the fact that STRIPS tend to be the lowest yielding fixed-income securities and the time value of money. Such an exact match is referred to as defeasance for accounting purposes, where the liability is defeased and removed from the balance sheet provided the liability cash flows are certain. Prefunded municipal bond issues are an example of a defeasance.

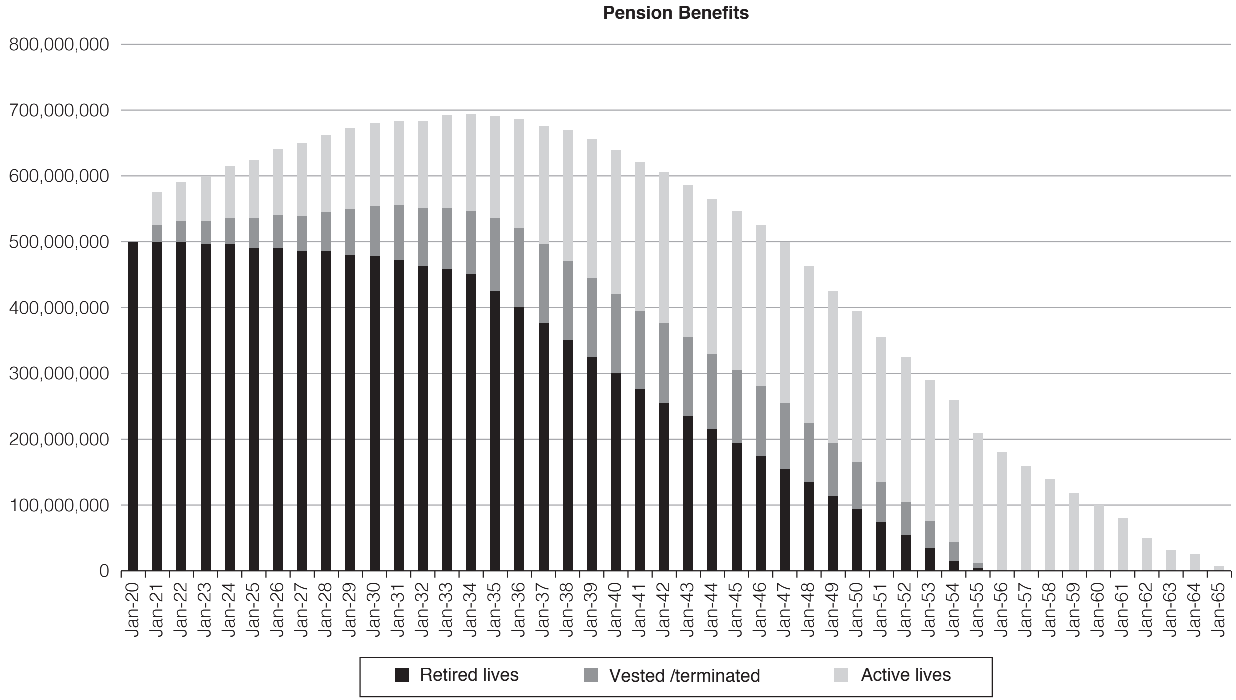
The actuarial projected pension benefit schedule is actually a series of projected benefit schedules for (1) Retired Lives, (2) Vested Terminated,[3] and (3) Active Lives. Exhibit 51-1 shows a typical series of projected benefit payments. The most certain and imminent is the Retired Lives benefit payment schedule. As a result, CDI is a best fit to match and fund Retired Lives and that should be the focus of this investment strategy.

A pension plan's asset allocation should strongly consider Retired Lives in determining the bond allocation and focus rather than versus a generic bond index benchmark whose cash flows look nothing like the Retired Lives benefit schedule. Pension liability cash flows are like snowflakes, you will never find two alike due to a different labor force, salaries, mortality, and plan amendments.

3. Vested Terminated is comprised of workers who have terminated employment but have not started receiving benefit payments.

EXHIBIT 51-1

Projected Benefit Payment Schedules



Source: Nuveen Asset Management, "How Old is Your Pension Plan," 2017.

Retired Lives = terminated employment and receiving monthly benefit payments.

Active Lives = not terminated and benefits are not yet determined

Until you receive the actuarial projection of Retired Lives, the bond allocation is lost without a proper objective. As the actuary updates the projections annually, there may be a need to rebalance the CDI to best match and fit the revised Retired Lives benefit projections.

THE CDI METHODOLOGY

A lower-cost and lower-risk way to secure benefits is to *cash-flow match* the projected future value benefit payments of Retired Lives. In the early 1980s, dedication strategies (cash-flow matching) with corporate bonds was in vogue for pensions. This strategy became less common as pension consultants and accounting rules focused on present values (Funded Ratio and Funded Status), not future values. This led to considerable confusion as to what discount rate to use to calculate the present value of liabilities.

Since contributions are the initial source to fund benefits, current assets need to fund net liabilities (projected benefits minus contributions). So, the first step in CDI is to identify with accuracy what you are funding, which is net liabilities. The next step is to identify a universe of bonds that qualify under the client's IPS (i.e., investment-grade bonds). Then several iterations are needed to create a bond portfolio that can fund monthly net liabilities at low cost that is in conformity to the client's IPS. A cost optimization model is needed here to achieve low cost by skewing the weights to longer maturities and higher-yielding bonds in conformity with the clients' investment policy within the liability benefit payment schedule we are funding. The present allocation to bonds (plus cash) will determine how far out CDI can cash-flow match Retired Lives chronologically (i.e., 1–10 years Retired Lives).

An efficient CDI model should be able to reduce funding costs by 8% to 15% on a 1–10 years Retired Lives projected benefit payment schedule, and much more if the strategy is funding longer liabilities, currently estimated at 25% to 40% on 1–30 years. This is a serious cost reduction and should be a major consideration of any asset allocation strategy as the *core portfolio*. Funding costs reduction is defined as the difference between the total benefits funded and the cost to purchase bonds for the CDI model. In truth, cash-flow matching the liability benefit payment schedule (liability cash flows) at low cost is the ideal way to de-risk a pension plan.

Shown in Exhibit 51-2 is a sample cash-flow matching model. The cash flows from principal and interest are used to fund projected liability payments for Retired Lives out 30 years. Note that the portfolio is skewed to longer maturities to take advantage of bond mathematics and achieve lower cost. In fact, there are no bonds shorter than five years. If there is any excess cash flow, it is reinvested at current U.S. Treasury STRIPS rates for the next benefit payment date(s) to be funded. The total cash flow (annually) is then compared to the benefit payment (annually) and a cumulative difference is shown.

It is critical that there are no cumulative cash-flow deficits or negative differences. This sample cash-flow model was able to fund $1 billion in projected benefit payments at a cost of $558,334,794 for a funding cost savings of $441,665,206 or 44.2% without any cash-flow deficient years. This is a considerable funding cost savings that could truly help to stabilize a pension fund. If the model is run using only U.S. Treasury STRIPS as a defeasance model, the funded costs savings would be 17.4%, which is still a noteworthy savings. Importantly, the plan sponsor gets this savings upon implementation of the cash-flow matching model rather than having to wait for uncertain future returns, which will take many years to occur as in active bond management.

Matching Retired Lives liabilities chronologically will buy time for the nonbond assets (which we referred to as the "Alpha assets") to perform and outgrow Active Lives liabilities. Given time (10+ years) most nonbond asset classes tend to outperform bonds. Since liabilities behave like bonds given their present value interest rate sensitivity, there is a high probability that nonbond asset classes should outperform liability growth of Active Lives and Terminated Vested over an extended time horizon especially in today's low-yield environment. This outperformance would enhance the funded status allowing for reduced contribution costs or increased Active Lives benefits or both. The benefits of a CDI strategy are numerous:

Secures Benefits: Cash-flow matches and funds monthly Retired Lives benefits chronologically.

Enhances Funded Ratio /Status: CDI portfolios biased to corporate bonds will outyield a liability discount rate, which creates alpha.

Reduces Costs: CDI reduces funding costs (8% to 15+%) and may reduce contribution costs.

Reduces Volatility: Reduces volatility of (1) funded ratio and (2) contribution costs.

Reduces Risk: (1) Risk = uncertainty of funding benefit payments and (2) funds benefit payments (future values have no interest rate sensitivity).

Enhances Return on Assets (ROA): CDI should *outyield* most active bond managers.

Buys Time: (1) CDI matches and funds net liabilities *chronologically,* (2) moves deficit out longer, extending the investment horizon, and (3) buys time for nonbond assets (Alpha assets) to outgrow Active Lives and Terminated Vested.

FUTURE VALUE VERSUS PRESENT VALUE

Actuarial practices use present values (PV) to calculate the pension funded ratio and funded status. But pension benefit payments are future values (FV). This suggests that the future value of assets versus the future value of liabilities is the most critical evaluation. However, it is anyone's guess as to the future value of most asset classes. This is why the PV is used to calculate the funded status. Only bonds (and insurance annuities) have a known future value and have historically been used to cash-flow match liabilities (i.e., defeasance, dedication). To prove this point as to the potential misinformation with using a PV calculation, let's use a simple example.

Consider the following two pensions, A and B, both at $100 million market value and thus having the same funded ratio in PV dollars:

Pension	Composition	Yield to Maturity	PV	FV
A	100% Treasuries	2.00%	$100 million	$181.7 million
B	100% Corporates	3.00%	$100 million	$244.3 million

As can be seen, pension B is 100% invested in corporate bonds that outyield pension A (100% invested in Treasuries) by 100 bps per year over 30 years. Certainly, plan B has a much greater FV (at 34.5% higher) and funded status than plan A if future values are used. This suggests that the funded ratio and funded status may not be that accurate or even good indicators of the true economic solvency of a pension plan.

The point of all this is that we need to focus more on the FV of assets versus liabilities. This is what CDI is all about. It is matching and funding future values (projected benefit payments minus contributions). If you discount liabilities at market rates, they will have discount rates of AA corporates (FASB method) or perhaps, U.S. Treasury STRIPS (defeasance method). A corporate bond portfolio matched to liabilities that outyields liabilities would enhance the funded ratio on a future value basis thereby reducing funding costs. Moreover, a cash-flow matched portfolio skewed to longer maturities reduces funding costs significantly because of the greater yield associated with longer-dated maturities in a positively sloping yield curve. This is due to the time value of money or present values versus future values, which is integral in CDI construction. This is why cash-flow matching of liability future values is the most prudent methodology for lowering risk and cost when de-risking a pension through asset liability management (ALM).[4]

4. For a further discussion, see "Pension Confusion: Present Value vs. Future Value," Ryan ALM, Inc. (2019).

INTEREST RATE RISK

The greatest risk of bonds is their interest rate sensitivity. The longer the maturity and duration of any bond portfolio, supposedly the higher the interest rate risk. But since cash-flow matching is focused on funding projected benefits (future values), interest rate risk is neutralized or eliminated. Critically, future benefit payments are not interest rate sensitive. The volatility of interest rates will not cause any volatility in projected benefits or future values. As a result, CDI is not concerned about interest rates except for the reinvestment of excess cash flows. In contrast to active bond management where rising interest rates are bad in that they deteriorate bond prices, with CDI higher interest rates are good allowing the cash-flow matched portfolio to reinvest at higher interest rates and lower cost.

CDI VERSUS ACTIVE BOND MANAGEMENT

A cash-flow matching strategy is focused on generating asset cash flows that will fund liability cash flows (benefit payments). It is not focused on total returns or performance versus a bond index benchmark. Another benefit with a CDI is the low portfolio turnover, which will reduce transaction costs. Active bond management is focused on outperforming the returns of a generic bond index benchmark. As a result, cash flows are not a consideration here, only the relative total returns to the index benchmark are considered (performance measurement). But no matter what generic bond index is chosen; active fixed income asset management cannot produce enough cash flows to fund benefits, since only interest income is used to fund benefits. As a result, actively managed bonds will require help from the Alpha assets to fund benefits. This will create dilution and disruption of the growth rate of such performance assets. With a CDI strategy in place as the pension plan's *core portfolio* to fund the shorter Retired Lives net liabilities (1–10+ years), the Alpha assets are now free to grow without being diluted or unencumbered to pay any benefits. The return on Alpha assets will be volatile, but the liability Beta assets (CDI) buy time (10+ years) for the Alpha assets to grow. The following example illustrates the cash flow difference of bonds managed to a generic index versus cash-flow matching to liabilities:

Assumptions
Bond allocation = $150 million
Net Benefits = $20 million per year for next 10 years

Bond management vs. generic bond index

- YTM = 2.50% (Index YTM = 2.00%)
- Cash flow = $3.75 million annual ($2.50% × $150 million)
- Annual cash-flow shortfall = $16.25 million ($20 milion − $3.75 million)
- Requires dilution of Alpha assets cash flow to fund net benefits

Cash-flow matching

- YTM = 3.50% (skewed to A/BBB corporate bonds)
- Cash flow = $20 million annual (principal + income + reinvestment of excess)
- No dilution of Alpha assets cash flows (assets allowed to grow unencumbered)

From this illustration, we see that generic bond index management cash flows look nothing like the projected benefit payment schedule of a pension. This leads to a mismatch of cash flows and risk/reward behaviors, which are serious issues over time. Alpha assets need time to perform without any dilution of their cash flows to pay benefits. CDI matches and funds benefit payments chronologically. CDI will outyield most current bond managers and enhance the return on asset assumption (ROA). CDI buys time for Alpha assets to grow unencumbered. Moreover, bonds managed versus generic bond indexes have the following issues:

- Does not fund benefits plus expenses.
- Cash flows do not match a plan's liability cash flows.
- Generic bond index skewed to long bonds and Government securities.
- Low yielding, similar to index benchmark (Aggregate index = 1.42%).

CDI VERSUS LDI

Liability driven investments (LDI) are usually duration-matching strategies or immunization. The pension funded ratio and funded status are present value calculations, anything that affects the PV of liabilities is the concern of LDI or immunization. Since liabilities behave like bonds, then the PV of liabilities is extremely affected by the discount rate(s) used to price liabilities. To immunize the pension against this interest rate risk and sensitivity, LDI uses several approaches with the main focus on duration matching liabilities. LDI may use interest rate swaps, futures, derivatives, risk overlays, and the like to assist in duration matching liabilities. They are all hedging tools to help assets match the liability growth rate. Unfortunately, they do not match or fund the liability cash flows.

There are several difficult, if not erroneous, data-gathering choices in duration matching strategies, as explained below:

1. **Average Duration of Liabilities.** Where do you get the average duration of liabilities? Most, if not all, actuarial reports do not provide this calculation. Moreover, they do not provide the projected liability benefit payment schedule, which you would need to calculate duration. In addition, actuarial reports are annual reports usually lagged three to six months, rendering the information seriously delayed. The duration

calculation is a PV calculation (not a FV) at a precise moment in time such as the balance sheet. As time and interest rates change, so will duration. Moreover, current assets are funding *net liabilities after contributions,* which is not calculated by the actuary. Only a *Custom Liability Index* (CLI) based on each pension's unique projected Retired Lives benefit payment schedule and projected contributions could provide an accurate and monthly projected benefit payment schedule and duration profile. But most LDI strategies try to match the growth rate of total gross liabilities not net Retired Lives after contributions. As mentioned earlier, Active Lives are not certain and contain actuarial noise (assumptions that are hard to forecast and maintain over time).

2. **Discount Rates.** Since the duration of liabilities changes with interest rates (discount rates), this calculation needs to be refreshed and updated on a frequent and accurate basis. According to pension accounting rules[5] and federal funding standards,[6] there is an assortment of discount rates required to price liabilities. Which one to use and what source to use could create several discount rate versions. If a generic bond index is used as a liability proxy, there are more difficulties. Generic bond indexes do not use any of the required pension accounting discount rates, instead preferring market rates! The yield difference could be serious. Any difference in yield creates a difference in the calculation of duration and liability growth rates. Only a custom liability index benchmark using the appropriate discount rates could provide an accurate duration and liability growth rate calculation.
3. **Generic Bond Indexes.** A common proxy for the average duration of liabilities is to use a generic bond market index, often the Bloomberg Barclay's long corporate index. Such a proxy creates several erroneous data issues. This index has no bonds shorter than 10 years and no durations longer than 19 years, although it is heavily skewed to long coupon bonds. This certainly does not represent any pension liability schedule even if the average durations were similar. Accounting standards and actuarial practices price liabilities as a portfolio of zero-coupon bonds with a single average discount rate based on the present value of this zero-coupon liability portfolio. There are no generic bond indexes that use zero-coupon bonds as their portfolio. There are no generic bond indexes that use pension discount rates in accordance with FASB, GASB, and PPA guidelines. Every pension plan's liabilities are different and unique to that plan due to different labor force, salaries, mortality, and plan amendments. There is no way any generic bond market index could represent any pension plan liability term structure. Only a custom liability index benchmark could properly represent and measure any

6. 6 Ryan ALM, Inc., Pension Confusion: Present Value vs. Future Value, 2019.

pension plan's liabilities providing all of the critical data calculations needed to de-risk the plan and manage assets versus liabilities.

4. **Limitations of Duration.** Originally formulated by Frederick R. Macaulay in 1938, the duration calculation was created as a way to measure a bond's average life.[7] Duration is defined as the average life of a bond's cash flow in present value dollars. Hopewell and Kaufman demonstrated that the measure of duration as suggested by Macaulay is related to interest rate sensitivity of a bond and the measure derived is referred to as modified duration.[8] Unfortunately, modified duration has very limited use as an indicator of interest rate sensitivity. It has the following inconsistencies as a way to match price or interest rate sensitivity. I call them the "seven flaws of duration":[9]

   Proportionality: Doubling the duration does not produce twice the total return. Duration only measures price sensitivity and not income returns.

   Same Duration: Even when durations are matched, if income returns are not matched, total returns will not be matched.

   Time: Duration is a present value calculation and changes with time so the ending duration will be different than the beginning duration. The longer the time horizon, the more likely that variations will occur in the duration calculation. Over time, the same-duration zero-coupon bond and coupon bond will diverge significantly on their ending duration.

   Maximum Duration: Duration actually peaks out at high-yields such that an extension of maturity will shorten duration.

   Large Yield Moves: Modified duration times large yield moves results in large price return mismatches. The larger the yield move the larger the error.

   Spot Calculation: Duration is a PV calculation that is only good for a one-day horizon. Every day forward, duration can and should change, especially on zero-coupon bonds.

8. M.H. Hopewell and G.G. Kaufman, "Bond Price Volatility and Term to Maturity: A Generalized Respecification," *American Economic Review* 63(4), 1973, pp. 749–753.

9. For a further discussion, see Ronald J. Ryan, "The Seven Flaws of Duration," Ryan Labs, Inc., 1986.

Averages: Using portfolio average durations gives totally inaccurate information. Duration is a function of coupon, yield, and maturity. If any one of these features is distorted, future duration changes will be distorted. The reason for the distortion is that duration is not linear such that a six-year bond will not exhibit the same price sensitivity as a portfolio of equally weighted 2-year and 10-year duration bonds. The classic example of a portfolio average duration problem was the Lehman Government/Corporate bond index for July 1990, which reported the following: coupon = 9.13%, maturity = 9.99 years, price = $100.00, and YTM = 8.57%. How could a portfolio average coupon of 9.13% at an average price of $100.00 equal an 8.57% YTM?

The resulting portfolio duration of 5.24 years and its interest rate sensitivity is then suspect too. Unfortunately, most bond active management is based on its portfolio average versus the index benchmark portfolio average to determine its risk/reward characteristics.

5. **Interest Rate Sensitivity.** Every one year of duration difference between the liability proxy and the actual duration of each plan's benefit payment schedule results in a 1% mismatch in liability growth for every 100 bps of discount rate change. In truth, the duration mismatch is more likely to be three to five years rather than one year. Given that pension cost for the actuary, administration, asset managers, and consultant are usually way less than 1% a year; such a duration mismatch could be very costly, representing years of pension cost. Moreover, most duration matching strategies are heavily skewed to maturities longer than 10 years. This makes the duration matching strategy extremely interest rate sensitive. Given today's historic low yields, there is a high probability of higher rates and negative growth on duration matching strategies over time.
6. **Funding Liabilities.** Imagine a 12-year average duration liability benefit payment schedule. It could have many different term structure shapes to come up with an average 12-year average duration. Imagine 100% of the assets as the 12-year average duration bond portfolio. If interest rates rise 50 bps in a year, assets and liabilities supposedly would both have a –6% price return (interest rate movement × duration [as a negative number]). If they had the same income return of 4%, they would match again (note that assets usually do not match the income or yield of liabilities). However, if the duration matching assets are used to *fund* liabilities, then a –2% loss (–6% + 4% = –2%) on assets could be funding a one-year liability, which should have a small positive growth rate. So, the assets could be taking a loss each year to fund the next year's liability benefit payments if interest rates continue to rise. This could get to be a serious costly mismatch if interest rates began a secular trend to

higher rates for the next five years. But the point is that there is no cash-flow matching here, only a duration match, so there is both funding and interest rate risk!

7. **Derivatives.** Interest rate swaps and futures are contracts not true nominal assets. There is no cash flow or funds available to make the liability cash-flow payments. They are hedges versus the liability growth rate. In fact, these strategies introduce new risk: counterparty risk, interest rate risk, nonmatching risk of assets purchased (usually equities) versus liabilities and leverage. In addition, interest rate swaps and futures have all of the problems associated with a liability proxy data gathering.

KEY POINTS

- Cash-flow matching is a fixed income methodology to match and fund with high certainty a stream of liability cash flows and has become known as cash-flow matching investment or cash flow driven investment (CDI).
- CDI is the preferred approach to de-risk a pension.
- The pension objective is to secure benefits in a cost-efficient manner. CDI stands alone as the most prudent and efficient way to achieve the true pension objective. Insurance annuities are not cost effective.
- Retired Lives is the most certain and imminent benefit payment schedule. It also represents the employees who have the longest tenure. These are the liabilities that should be cash-flow matched as a high priority and in compliance with the true pension objective.
- CDI reduces the cost to fund Retired Lives immediately upon implementation of the CDI portfolio. The plan sponsor gets these cost savings up front rather than over a long horizon as return-oriented strategies suggest or promise that they will do. The longer the projected benefit payment schedule the higher the funding cost savings. CDI should reduce funding costs by 8% to 15% on 1–10 years of Retired Lives and up to 40% on 1–30 years. The cost savings gets to be invested in the Alpha assets that will likely reduce pension costs in the future.
- The projected Retired Lives benefit payments are future value numbers. Duration matching and performance-oriented strategies all deal with present value numbers (returns, funded ratio, funded status). These projected FV benefits are not interest rate sensitive, whereas PV strategies (liability driven investments, LDI) are extremely interest rate sensitive.
- For LDI, duration matching and immunization strategies are not proper or accurate de-risking strategies.

- LDI does not fund benefit payments and is full of calculation inaccuracies as well as even erroneous data gathering.
- Duration of liabilities is not an easy or static calculation. There are seven flaws of duration that should be known or understood if a pension sponsor wants to focus on duration matching. Since the actuary does not provide the duration calculation, the data miseries start there.

CHAPTER

FIFTY-TWO

BUILDING CORPORATE BOND PORTFOLIOS

Marielle de Jong, Ph.D.
Associate Professor in Finance
Grenoble Ecole de Management

From an investor's point of view, corporate bonds are all-round securities that can suit many investment purposes. It is the wide range of market exposures that corporate bonds provide that gives them this status, considering that they bear credit risk on a detailed, firm-specific level on top of interest-rate risk and exchange-rate risk. A triple market exposure comes in handy when building investment strategies, the more so since the exposures can be controlled individually on a security level by picking the right bond and/or by making use of derivative instruments. A corporate bond may be held for targeting a specific credit-risk exposure or an interest-rate exposure, or even for the sole purpose of placing a currency bet. For the latter, it suffices to pick a bond that is denominated in the currency with a short duration and with a high credit quality so that the inherent interest-rate and credit-risk exposures become negligibly small.

The exposure to interest-rate risk can be reduced in three ways by (1) selecting bonds of short duration, (2) holding floating-rate notes (FRNs) that pay out coupons that are indexed on the interest rates, or (3) installing a duration hedge via bond futures. A bond's credit risk can also be hedged out, namely, by adding credit default swaps (CDS). In sum, a corporate bond can adopt the risk profile of a currency, of a sovereign bond, or of a pure credit debt-security, and of any combination among those. A corporate bond can even come close to a stock in terms of its risk/return profile. Investors who seek equity exposure via bonds can select low-rated securities or purchase hybrids or convertible bonds with a high potential that they will be converted into the underlying stock.

Furthermore, the risk profile of a corporate bond depends on what investors intend to do with it. If a bond is held until maturity, mark-to-market risk becomes irrelevant, meaning that the market valuation of interest-rate movements and of credit rating downgrades that may occur no longer matter. The only thing that matters is the income that the bond generates (i.e., the coupon payments). Liquidity risk ceases as well. Such an investment bears default risk essentially as well as exchange-rate risk when the bond's currency differs from the local currency of the investor. Note that default risk is not the same thing as credit risk, for it does not cover rating downgrades, which have a real impact on the firm's capacity to attract new capital. For an investor, credit risk and default risk are quite distinct phenomena, and may for that matter be counted separately in the list of market exposures that corporate bonds embed.

The list gets longer when non-standard bonds are taken into consideration. Certain niche-bonds pay out coupons that are indexed to the inflation rate for example, which effectively turns them into inflation hedgers. Covered bonds, which are issued by banks based on pooled mortgage loans, bear real-estate risk to a certain extent. And green bonds, first launched by the World Bank in 2008, add a new exposure: climate risk. These bonds finance firms' transition projects, going toward an environmentally sustainable production line. The risk a green bond bears depends on the timing of its issuance; if it is issued early in the transition project, it bears the risk of the project succeeding. If it is issued late and serves to label an accomplished climate-friendly firm, it represents safety more than risk. From an investor's standpoint, the first green bond is a typical pick for an impact-investing strategy, whereas the second may on the contrary serve as a hedge against climate risk.

The multitude of performance targets that can be envisaged and the number of investment strategies that are being pursued using corporate bonds is fascinating. In this chapter, several of them are discussed, in two sections. The first section covers the so-called buy-and-hold investment strategies, which are passive investments, in the sense that—as the name indicates—the key decisions are made at the launch of the fund. The second section covers the more common actively managed investment strategies. They include the index-tracking strategy, for which the objective is to replicate the performance of the market index, and tilted strategies, whereby outperformance is sought with respect to the market by building tilts, or biases, in the portfolio. Since the latter two strategies are defined with respect to a market index, or benchmark, they are referred to as the benchmarked strategies in this chapter.

BUY-AND-HOLD INVESTING

Investment Objectives

A buy-and-hold portfolio remains unaltered in principle over the entire holding period. Such an investment can serve two purposes: First it can be part of a liability-driven investment (LDI), whereby the primary purpose is to generate cash amounts over time that best match a pre-defined schedule of payment obligations. The second purpose is that it can serve long-term saving schemes. Usually the investment is geared toward seizing a risk premium. Especially for the purpose of long-term savings, bonds are selected that are lowly valued due to a specific concern, and the investor will be compensated if that concern will eventually prove unfounded. Buy and hold is a form of value investing in that sense.

Plenty of occasions for seizing a premium arise in the corporate-bond markets, which in effect trigger plenty of buy-and-hold fund launches.

At times conditions are particularly favorable for initiating buy-and-hold investments. For example, during the sovereign debt crisis in Europe (between 2010 and 2012) the bond markets were rattled by concerns about cumulated sovereign debts of certain Eurozone member states, in particular, Greece. Although the concerns were predominantly about sovereign debt, driving a wedge between the core and the peripheral member states, corporate bonds got dragged into the crisis in the same manner. Bonds that were issued by Portuguese, Italian, Irish, Greek, and Spanish firms—disrespectfully called the PIIGS—got severely hit, and in the belief that the market valuation at the time was not in accordance with the fundamental creditworthiness of the issuing firms, holding these bonds until maturity was an effective means to cash in the value premium.

Another buy-and-hold investment opportunity arose for callable bonds in the late 2000s. Even though for these bonds elaborate calling schemes are designed with precise call dates and prices through time, the standard convention had always been for the issuing firm to call at the first possible date. This was the case until Deutsche Bank, a German commercial bank, decided otherwise in December 2008. This seeming nonevent caused panic and instilled a fear as if bonds, and in particular perpetual bonds, were never going to be called again. That notion of risk, which got the name "extension risk," devalued callable bonds generally. In the belief that the fear was unfounded, opportunity was left for grabs to cash in the so-called extension-risk premium.

Convertible bonds are also interesting picks for buy-and-hold investors at times, particularly those for which the conversion into stock is highly unlikely (i.e., those with a low delta). Such convertible bonds effectively become ordinary corporate bonds without an embedded option, yet with the disadvantage of being relatively illiquid and not eligible to be part of any standard bond market index. Those bonds tend to trade at a discount as a result and that gives them an edge as soon as mark-to-market risk is taken out of the equation. Interestingly, during the Covid-19 crisis in spring 2020 when both the stock and the bond markets were depressed, the low-delta convertible bonds were being targeted by buy-and-hold investors.

The examples given above are typical value investments—deep value—even where the active bet is that undervalued assets will eventually recover. In that respect, the investment strategy is not passive at all; on the contrary, the mark-to-market performance of a buy-and-hold portfolio is liable to be radically different from that of the market index, meaning that its active risk, or tracking error, is high.

Structuring Buy-and-Hold Funds

Buy-and-hold funds are closed-end funds with relatively long running periods, between 5 to 10 years. The way these funds are structured depends on what they are destined for. If a fund serves as part of a liability-driven investment, bonds are selected such that they generate cash at the same pace as that of the scheduled payment obligations. The bond maturity dates must match the schedule closely to avoid cash positions that would otherwise be a drag on the fund's return performance. Hence, the bond maturity date is an important criterion in the selection process, along with the risk of default. In the context of an LDI-investment, a minimum credit rating is usually imposed by the regulator. To mitigate the impact of defaults further, the portfolio is stratified by selecting bonds of distinct sectors and countries, so as to avoid a domino effect.

For buy-and-hold savings products, especially those that make one lump-sum redemption payment at maturity, the bonds' effective maturity dates are selected so as to be grouped together closely toward the redemption date to avoid cash drags. There is usually no credit-rating threshold imposed by the regulator for these products, but there are precise rules about how to communicate the fund's performance and risk outlook. How much the fund is expected to yield must be expressed in terms of the internal rate of return (IRR) that is based on the effective payout schedule and on the management fees that will be charged. In case performance fees are set, the probability that they will be charged must be made explicit at the fund's launch as well.

To provide those estimates, Monte Carlo simulations are run over a large number of credit event scenarios. The scenarios are designed by assigning default probabilities to the bonds that are in the portfolio in accordance with their credit ratings. Default probabilities are estimated and published by rating agencies on a regular basis. The recovery rates that are used in the calculations in case of default are also retrieved from the rating agency statistics. Other than that, default correlations are usually incorporated into the simulation, which account for contagion risk. This is done by taking grouped random draws from a multivariate Gaussian distribution. Correlation levels are set somewhere between 0.3 and 0.6 depending on whether the bond issuers belong to the same economic sectors and/or countries. Based on the simulations, the expected yield, the expected number of defaults, and the amount of fees are estimated.

If the same buy-and-hold fund is to serve several investors who do not share the same risk appetite, tranches can be introduced, in much the same way as in a collateral debt obligation (CDO). Typically, there are three tranche levels in such an investment product—namely, the so-called equity tranche, which is the riskiest one; the mezzanine tranche; and the senior tranche, the least risky one. Investors who have subscribed to the mezzanine tranche for example will start losing income only once the defaults, which may or may not take place, have wiped out the equity tranche entirely. The payouts, which may be paid annually or in a lump sum at the fund's maturity, are fixed per tranche at launch. Again, the risk and return expectations are established by means of Monte Carlo simulation. In these simulations the default correlations that are assumed are critically important compared to a single-tranche fund, as it affects the tranches not in the same way. The higher the contagion risk, the riskier will be the equity tranche.

BENCHMARKED PORTFOLIOS

Portfolio Optimization

Although benchmarked investment strategies always require an active management of the portfolio over the entire life of the fund, they are qualified as passive as soon as the objective is to track, or replicate, the market index. The idea of a tracking strategy is to obtain a neutral exposure to the corporate bond market as a whole. Tracking strategies are often in the form of exchange traded funds (ETFs) or simply via open-end funds. A benchmarked strategy is qualified as active as soon as outperformance is sought via portfolio tilts. Such strategies are commercialized via open-end funds more than via ETFs. This section describes how bond managers approach the portfolio optimization problem that comes into play when pursuing benchmarked investment strategies.

As explained in Chapter 46, there are basically two[1] popular approaches to building corporate bond portfolios: either bond managers engage in traditional mean-variance optimization[2] or they use stratified sampling techniques. Mean-variance optimization is extensively discussed in finance textbooks, albeit the focus in these books is strongly on equities. How the methodology adapts to the bond-investment problem is not evident and is in fact not much commented upon in the literature. A few comments on how mean-variance optimization is, or can be, applied to corporate bond portfolio constructions are made at the end of this section, after discussing the stratified sampling approach. The term *stratified sampling* stems from the field of survey statistics,[3] and was introduced into the finance profession in the early 1980s.[4]

In the sampling approach, the problem of building a portfolio that best fulfils the given target objectives is simplified by dividing it into subproblems. The investment target, which can be the market index or an enhanced index, is divided into cells or samples. The crux is to stratify these samples effectively, meaning that they each possess distinct group characteristics and that in sum they bring about the key characteristics of the investment target. Or to state it more formally, the grid of the sample framework should accord with the covariance structure that underlies the bond price movements. Once the samples are set, the task is to replicate them one by one by "mini-portfolios."

The advantage of the sampling approach is that the risk parameters with which tracking, or replication, capacity is measured are directly observed, as opposed to the mean-variance approach where they must be estimated. Under the

premise that the risk of a corporate bond is predominantly determined by two factors—interest rate and credit risk—the risk of a bond is measured via its sensitivities to these factors, in particular by its duration for the first, and by a combination of duration and credit spread level for the second factor. More precisely, as one study[5] demonstrates, a bond's sensitivity to credit risk can be effectively captured by its Duration Times Spread (DTS).

The two bond risk factors mentioned above are central in corporate bond investing. They are called term-structure risk (also called duration risk and interest rate risk) and credit risk. The sensitivities to these factors, measured by duration and DTS, are what the market betas are to equity investing. A corporate bond is an asset with two market betas, so to speak. If the betas of a bond are matched with those of the market index, its return is set to follow the market trend. If the betas are inferior, its return behavior will likely be defensive, or more precisely, both the interest rate and the credit component of the returns will be. And inversely, long duration and high DTS tend to lead to offensive returns, albeit that the terms *defensive* and *offensive* are less used in bond management than they are in equity management. The same additivity rule applies to equity market betas: the overall duration and DTS of a portfolio are the cap-weighted averages of those of its holdings.

Hence, in the sampling problem the active risk of a portfolio is effectively managed by matching its duration and DTS with those of the target market index, sample per sample. The two efforts that are required in the sampling approach, that is, defining the samples and then replicating them, are both challenging. In fact, defining samples can be regarded as a stylized version of risk modelling, whereby the risk factors that play are merely nominated, not fully estimated. Depending on the philosophy of the investment strategy at hand, the sample definition can recognize the importance of an economic sector effect for instance, or of a combination between country and currency effects. An experienced fund manager may agree that the impact of country and currency group effects on the co-movements of bond prices is, loosely speaking, comparable to those of equity prices.

Beyond the abovementioned habitual group effects on price movements, let us not forget certain pricing phenomena that are specific to corporate bonds. First, there is the phenomenon that credit rating categories affect bond prices at least as much as sectors, countries, and currencies do. Price-covariance levels are notably higher within rating categories than they are between them. Second, there is the phenomenon that firm-specific pricing effects group bonds together that are issued by the same firm. These issuer groupings constitute, an additional layer of covariance relationships compared to other asset classes. The covariance structure between corporate bond returns, which must be considered in the sample structure, consists of multiple layers, one on an individual issue level and one or several on an issuer level.

5. Arik Ben Dor, Lev Dynkin, Jay Hyman, Patrick Houweling, Erik van Leeuwen and Olaf Penninga, "Duration Times Spread" *Journal of Portfolio Management* 33(2), 2007, pp. 77–100.

The various pricing effects are all intertwined with each other into what one may rightfully call a Gordian knot. To get an idea of the complexity, consider the following. The U.S. firm General Electric, which has business activities in several economic sectors and in several countries, has about 100 bonds outstanding at any one time that are denominated in several currencies. Furthermore, bonds issued by the same firm do not necessarily belong to the same rating category in case one is subordinated over the other. At times it is not even trivial to establish whether bonds are issued by the same firm. In order to determine whether firms that are part of a same holding group are distinct risk-bearing entities or not, the 60% ownership rule is applied by convention, though that is only a convention and may not correspond to market reality.

Choosing the samples may be an art, but replicating them is another one. The task of building a portfolio for which the active risk is effectively controlled in the context of a multiple-layered framework of cells, each with a double matching criterion (i.e., duration and DTS) is a challenging combinatorial optimization problem. A bond portfolio manager once compared the task with solving sudoku puzzles. Up to a certain level of complexity, a trained manager can work the problem out without the help of sophisticated tools. Building a tracking portfolio takes about 40 minutes. However, the more considerations that come into play and the more granular the samples setting becomes, the more complex the optimization problem, and there inevitably comes a point where the computer outdoes the manager.

Staying with the base case of two bond risk factors, duration and credit risk, the sampling problem can be formulated in the following way with the relevant equations and notation shown in Exhibit 52-1. Let vector x^p contain the portfolio weights that are to be decided for the N bonds in a given investment universe; let vector x^b contain the N benchmark weights, vector d the N bond durations and vector S the N credit spreads. Introduce matrix Y that defines the sample structure consisting of J samples, as is done in (1) in Exhibit 52-1. In order to facilitate the notations, introduce an auxiliary matrix β that specifies the two matching criteria, duration and DTS, as in (2). For a portfolio x^p, pre-multiplying by matrix Y and post-multiplying by matrix β, as is done in (3), makes its two risk exposures apparent sample per sample. Applying the same operation onto the portfolio that is defined in difference with the benchmark, as is done in (4), makes the active risk exposures apparent, sample per sample.

In the sampling problem, the active exposures determine de facto the active risk, rather than the (active) return variance as by Markowitz' definition. But apart from that, the problem formulations can be very similar. The risk objective can be expressed in a quadratic form, as is done in (5), and the return objective in a linear form, as in (6), where the vector C stands for a given bond selection criterion. Vector C can contain a set of return forecasts, or more generally, it can contain any selection criterion. For the purpose of building index-tracking portfolios, C is simply set to zero. The complete objective function, specified in (7), is thus to maximize the return of the portfolio while minimizing risk, whereby the parameter λ expresses, as usual, the investor's aversion to risk.

Several implementation constraints are habitually imposed, four of which are specified below. Equation (8) imposes that portfolio holdings may not be negative, which makes sense since corporate bonds can in any event not be sold short. There is no such thing as primary brokerage in the bond markets. Equation (9) imposes the cardinality constraint, meaning that holdings must be few to keep trading costs down. Equation (10) imposes that the holdings must sum up to 1, or to any given leverage target. Equation (11) imposes the requirement that portfolio holdings must be exact multiples. The latter constraint addresses the situation in the corporate bond markets that securities are traded in lots of designated sizes; there is a fixed initial lot size and thereafter there are fixed increments, both of which may differ from security to security. Note that because of the lot sizes, the portfolio optimization problem is discrete rather than continuous, which adds importantly to the complexity of solving the problem.

On top of this set of constraints, additional ad hoc constraints tend to be imposed, which have to do with market liquidity. Liquidity problems are severe in the corporate bond markets, and there is no easy way of dealing with that. An extra hurdle is that there are no reliable data available on matters such as trading volumes, which can bring the problems to light. The most informative data at hand are the so-called bond liquidity scores, produced by data vendors since 2009, which are essentially proxies for trading costs. These scores reveal, in line with common perception, that trading costs vary significantly between bond issues, ranging from a few basis points for the most liquid bonds down to prohibitive amounts for the least liquid.

To limit trading costs, it therefore makes sense to integrate the liquidity cost scores, or some data equivalent, denoted L, into the portfolio optimization problem. A simple linear cost term as specified by (12) could be inserted into the objective function given by (7); however, note that such term would be valid only if the portfolio is to be built up from scratch. If not, if it concerns a rebalancing with respect to an existing portfolio, denoted by p', specifying a liquidity-cost objective becomes more complex. One way would be to introduce a cost term that takes a quadratic form, as the one given by (13). Optimizing with respect to this cost term has two positive effects, it zooms in on the most liquid bonds and, more importantly, it tends to reduce the portfolio turnover.

It would take a small step to convert the problem formulation given in Exhibit 52-1 into one that corresponds to the mean-variance optimization framework. It suffices to replace the identity matrix I in the objective function given by (7) by a 2×2 factor covariance matrix. The parameters, meaning the variance and covariance of the two risk factors, would need to be estimated since they are not directly observable. The minor modification translates the active risk exposures in effect into active return variances. The formulation that results is in its exact format not used much in practice; however, it does highlight the key features that are commonly present in portfolio optimization applications, namely the central role of the duration- and credit-risk factor, and the sample structure.

EXHIBIT 52-1

The Stratified Sampling Problem

Sample definition	$Y_{NxJ} : y_{ij} = \begin{cases} 1, \textit{ if bond i is in sample j} \\ 0, \textit{ otherwise} \end{cases}$	(1)
Matching criteria	$\beta_{Nx2} = [d \quad d \cdot S]$	(2)
Sample exposures	$Y \cdot x^p \cdot \beta$	(3)
Active exposures	$Y \cdot \mid x^p - x^b \mid \cdot \beta$	(4)
Active risk	$(Y \cdot (x^p - x^b) \cdot \beta)^T \cdot I \cdot (Y \cdot (x^p - x^b) \cdot \beta)$ where I is a two-dimensional identity matrix	(5)
Performance	$C^T \cdot x^p$	(6)
Objective	max. $C^T \cdot x^p - \lambda \cdot (Y \cdot (x^p - x^b) \cdot \beta)^T \cdot I \cdot$ $(Y \cdot (x^p - x^b) \cdot \beta)$ subject to	(7)
Positivity constraint	$\forall_i : x_i^p \geq 0$	(8)
Cardinality constraint	$\sum_i = {}_1^N \textit{ nonzero } (x_i^p) << N$	(9)
Leverage constraint	$\sum_i x_i^p = 1$	(10)
Lot-size constraint	$\forall_i : x_i^p \in \mathbb{N}$	(11)
Linear costs	$L^T \cdot x^p$	(12)
Quadratic costs	$(x^p - x^{p\prime})^T \cdot L \cdot (x^p - x^{p\prime})$	(13)
	$(C_1 \cdot x_1 - C_2 \cdot x_2) - \lambda \cdot \lvert d_1 \cdot S_1 \cdot x_1 - d_2 \cdot S_2 \cdot$ $x_2 - D_j \cdot S_j \rvert$	(14)

The risk model that underpins the problem specification displayed in the equation above for the objective function is, notionally, a linear factor model with two common factors and $J \times 2$ fixed effects. It is not trivial to estimate this model, or in general any risk model, for corporate bonds. What complicates matters is that bond returns are not stationary over time, while that is a precondition for time-regression models to be valid. Note that the return behavior of bonds is not stationary in principle, as the bonds' risk profiles fade in time as they approach the maturity date. The estimation procedures that are usually pursued for modelling asset risk, whereby sensitivities, or *betas*, of individual securities with respect to common risk factors are derived via time-series regressions, fatally fail.

Besides the purely mechanical reason for the nonstationarity issue that is mentioned above, the return behavior of corporate bonds is not time stationary by nature. When a bond loses value, and its credit spread widens, it tends to become more price-sensitive to credit events, to the extent that the amplitude of its price reactions increases. However, as one study[6] points out, since the increase in sensitivity is proportional to the widening of the spread, denoted S, scaling down the returns by dividing them by S, while scaling up the sensitivities, or betas, offsets this nonstationary effect and brings the returns back into the fold (i.e., into a linear framework). It is upon this market observation that the sampling and the mean-variance optimization framework crucially relies.

The observation made above underlines the fact that the credit betas of corporate bonds are not static over time. That has important repercussions for the risk budget of an investment portfolio that seeks to provide an indication of how much assets or asset groups contribute to the overall portfolio risk. As long as the portfolio contains corporate bonds only, the effect of time-varying bond betas is limited, but as soon as these bonds are mixed with other assets, the overall risk budget starts to vary over time depending on the prevailing credit spread levels. In times when corporate bonds are low valued, their contribution to the portfolio risk increases. This indeed has been observed to occur during crisis periods. It is a market phenomenon that is specific to corporate bonds that sets them somewhat apart from other asset classes.

Since it is not valid to run time-regressions on an individual security level, stationarity is usually sought on an aggregate level. On an economic sector level, for example, the characteristics that typify the overall risk profile of corporate bonds in the sector tend to be stationary. What is often ignored is that this is the case essentially because market-index providers deliberately make that happen. Bonds are purposely selected and rolled over in the index constituents so as to convey a stable and representative picture of the corporate bond market as a whole, sector by sector. The validity of the risk models that are estimated on an aggregate corporate bond level therefore relies a great deal on the diligence of the market-index providers.

The mean-variance optimization framework is less popular among bond managers than stratified sampling but is in use nevertheless for assessing corporate bond portfolios in some format or another. It serves for ex post reporting purposes predominantly, typically for regulatory bodies or for clients who are familiar with the mean-variance methodology and its terminology. However, apart from being a means of communication, it is not clear whether many fund managers build their corporate bond portfolios ex ante through mean-variance optimization. The hesitations stem from the fact that the method is less transparent and intuitive compared to sampling techniques.

Portfolio Construction

Even if the formulation of the corporate bond portfolio optimization problem is settled, stipulating which risk measures to use and how to combine them, it is not evident how to derive the optimal portfolio. Moreover, the question of

6. Ben Dor, Dynkin, Hyman, Houweling, van Leeuwen and Penninga, "Duration Times Spread."

constructing corporate bond portfolios has been, as elementary as it may seem, subject to fierce debate in recent years. The debate got going on the building of the so-called factor-investing portfolios. Since Asness, Moskowitz, and Pederson[7] have shown that factor investing makes sense, not only for equities, but for currencies, commodities, and government bonds as well, the attention turned to the one asset class that was left out, which is corporate bonds.

In the idea of carrying over a success story from one asset class to another, the same method of constructing factor portfolios has been proposed for corporate bonds as has been demonstrated to be efficient for equities. Researchers have proposed building bond factor portfolios through rankings.[8] This is done by constructing four bond factor portfolios corresponding to value, momentum, size, and low risk and by retaining the top deciles of bonds that are ranked by the respective criteria. This method has the merit of being transparent and giving full exposure to the factors in question; however, no consideration is given to risk. With reference to the mean-variance optimization framework, the portfolios that are built in this way correspond to the extreme case where the aversion to risk is nil, that is $\lambda = 0$.

Such extreme portfolios will not suit mainstream investment purposes, where risks must be managed. As soon as risk considerations come into play, formally $\lambda > 0$, the portfolio optimization problem underlying a factor-investing strategy becomes more complex. In fact, it corresponds to the problem that is formulated by the set of equations given by (7) to (11) in Exhibit 52-1, whereby the performance target, the vector C, contains the factor selection criterion. In that setting, simple bond rankings will no longer do. How to proceed then? How does a portfolio manager build risk-balanced factor portfolios? Israel, Palhares, and Richardson[9] give an interesting yet not very intuitive account. In their article they give a lengthy description of how they build bond factor portfolios that are adjusted for risk. What follows is a second account given by a fund manager who shall be identified simply as Manager X.

Manager X pursues a factor-investing strategy that is geared to mitigating climate risk. Manager X seeks to protect the invested capital against climate issues that are at play. To do so, Manager X introduces a tilt into the invested portfolio toward low-carbon enterprise. Thus, instead of introducing a value or a momentum tilt, Manager X introduces a carbon tilt, but apart from that the portfolio optimization problem is the same one. The vector C in the performance

objective contains carbon scores that are assigned to all bonds, which measure the tons of carbon dioxide emitted by the issuing firms during a given year divided by the firms' sales revenues over that year. Thanks to these scores, the efficiency of the production processes can be compared among firms, and that irrespective of the firm sizes. The idea is to invest in the best-in-class. To facilitate direct comparison, the scores are normalized, or z-scored, per sector.

Manager X invests in the global investment-grade corporate bond universe, which counts more than 7000 bonds. Manager X starts by reducing the vast universe down to more approachable numbers by applying two filters. First, a liquidity filter is run discarding the bottom third (least liquid bonds). Manager X can opt to apply liquidity cost scores for doing this, or alternatively simply screen on the bonds' debt sizes (which are actually a reasonably good proxy for liquidity). Incidentally, an argument for screening on size is that the carbon data quality is not great anyway for small firms. Manager X then runs an initial carbon filter, again discarding the bottom third of the bonds.

Note that since the carbon data are z-scored per sector, the bottom third will be weeded out within each sector more or less, leaving all sector groups sufficiently populated, which is a necessary condition for being able to control the risk of the portfolio. To generalize on the latter observation, running pre-screens is viable only for investment strategies that have a relative performance objective. In the case of the carbon investment, for example, if the best-in-class philosophy were replaced by an absolute view (in particular, if the goal were to minimize the absolute carbon footprint of the portfolio), the carbon screen would do more harm than good. In that case it would wipe out the carbon-intensive sectors entirely, leaving no possibility to straighten it out.

Among the bonds that remain, which take up a bit less than half of the universe at this point, Manager X starts selecting bonds proceeding in two consecutive steps. First, Manager X picks, among the bonds that are issued by the same firms, those that best represent the issuer groups, and then selects among the issuer groups that result. For most issuer groups, picking two bonds suffices, one with a DTS lower than the group average and the other higher, so that by weighing the two, the mutual DTS can be matched to the group average exactly. For large multinationals as for example for General Electric discussed earlier, it is wise to keep a few more bond issues. The debt structure of such large conglomerates cannot be captured effectively by two bonds. Given that there are around five issues per issuer on average in the global investment-grade universe, this selection procedure further thins out the bond population considerably.

Manager X will make one more short cut in order to make the task of optimizing the portfolio doable. After constructing the portfolio, Manager X will control the overall duration of the investment by installing a hedge using derivative instruments. Manager X will install an overlay of bond futures, one overlay per currency zone. Although keeping the futures matched with the portfolio holdings is a tedious exercise and is less precise than a real duration match via the bonds themselves, it has the advantage that it simplifies the portfolio optimization problem. This is because one of the two matching criteria is effectively removed. In this setting Manager X sets out to solve the core of the optimization problem. The task is then to select a limited number of issuers that concertedly reduce the carbon intensity while at the same time track the market index.

The bonds that have survived the various screens up to this point constitute an initial portfolio; it serves as a starting point for the local-search procedure that Manager X will apply next. But before being in a position to start the search, the sample structure must be defined. The samples should bring about the covariance structure underlying the bond price movements, as discussed earlier. Meanwhile it should agree with the philosophy of the investment strategy. For the strategy at hand the choice is straightforward. The notion of best-in-class it adheres to refers to economic sectors naturally; the intention is to purchase the assets of firms that have the most efficient production lines in terms of carbon emissions compared to their peers that operate in the same economic conditions, and thus in the same sector.

The sample choice is less obvious to make when designing a *quality* factor portfolio for example. Would it make sense to compare the creditworthiness of the issuing firms with peers in the same sector or rather with firms in the same credit rating category? The answer is not clear-cut. And besides, running pre-screens may not result in a pertinent *quality* factor portfolio either. Discarding the bottom third, the least creditworthy firms may wipe out the lowest rating category among the investment-grade bonds (i.e., the, BBB-rated bonds) entirely. In fact, the opposite may happen when trying to build a *value* factor. Screening on cheap-or-dearness would mechanically lead, if no care is taken, to discarding the highest rating categories (i.e., the AAA- or AA-rated bonds). Both such screens would introduce significant biases, which may lead to unintended tracking error.

Manager X decides to divide the bond world into three geographic zones: the United States plus Canada, Europe, and the rest of the world, and to divide each of them into 15 sectors. The third zone isn't actually very coherent and indeed turns out not to track very well; however, as long as the weight of this zone within the global bond index remains small, typically less than 15%, it does not weigh much on the overall performance. Hence, Manager X defines 3 × 15 samples and therefore has as many matching points for the portfolio to align in terms of DTS to the market index. The search procedure may then begin. The performance of the starting portfolio, obtained after the screening, can be quantified; its tracking capacity is measured by the scale of the mismatch in DTS summed over the matching points, and the tilt is measured in terms of relative carbon intensity.

Starting from the initial portfolio, issuer groups are eliminated in a way so as to move closer to the investment target. Manager X deploys an iterative selection procedure. The selection method relies on the same pairing principle that was used for replicating the issuer groups, namely that any two issuers, one having a low DTS and the other a high, can attain any DTS level together by adjusting their relative weights. The art is to find the pair among the many candidates that offers the best improvement, while siphoning weight from the one to the other.

Manager X chases up the winning pair, executes the optimal weight adjustment, and while doing so sees his portfolio improve step by step.

Pairs are sought within the sample groups of course. The improvement, or gain, a pair, x_1 and x_2, makes can be quantified as is done in equation (14) of Exhibit 52-1, where $D_j \cdot S_j$ is the target DTS of the sample j to which the pair belongs. At times, while executing a weight adjustment within a pair, the entire weight is siphoned away from one issuer. If that happens, the issuer is automatically eliminated from the portfolio. It may also happen that a small residual weight remains. Manager X decides to remove residual weights if they fall under a given threshold. The size of the threshold effectively controls how many portfolio holdings will eventually be retained.

This local-search procedure can be carried out by a computer algorithm. The advantage is that the search is exhaustive, as all combinations can be investigated in the space of a few microseconds. Also, nontrivial weight adjustments can be detected, which the eye does not spot, which do not necessarily lead to the elimination of an issuer but does sharpen up the portfolio. Moreover, the algorithm can be enhanced to deal with market liquidity as well. The liquidity scores can be inserted into the gain formula in a way as to give more chance to the most liquid bonds in a pair to survive. Or more importantly, if the optimization concerns a rebalancing of an already-invested portfolio, a penalty function can be introduced into the optimization objective that is geared to avoid excessive trading. Of course, to achieve that the gain formula must be calibrated carefully.

The optimization problem, which is the core of the sampling approach, is akin to the so-called knapsack problem.[10] This problem falls into the category of mixed-integer combinatorial optimization problems, which are NP-hard,[11] meaning that they are notoriously difficult to solve. Local-search computation algorithms are used habitually for solving this kind of problem, by which an initial solution is improved step by step until no more improvement is found.[12] The procedure that is described above can indeed be run by a computer algorithm programmed out. Interestingly, machine learning techniques appear to be effective for solving the bond portfolio optimization problem; in particular, the so-called genetic algorithms are successful.[13] In this method, not one but many solutions are tried simultaneously. They are locally improved, cross-fertilized

in a cunning way, and put into competition so that eventually the one with the strongest features survives.

The successes of such computer-powered solution techniques do not make the traditional bond manager redundant though. An important aspect of corporate bond investing is that the conditions keep changing, arguably more so than for other asset classes, and the problem setting should keep up with that. In particular, the market composition evolves relatively fast due to the continuous issuance and maturing of bonds, which can make the samples over- or undercrowded as a result. But also changes in the fund itself call for resets. While a fund grows, for example, more portfolio holdings can be afforded and with that a more granular sample setting, which eventually leads to better-optimized portfolios. Clearly, for dealing with such matters the versatile manager outdoes the subservient machine.

The bond management profession is facing a dilemma in this respect. It could be envisaged, going to one extreme, to develop powerful catch-all computer algorithms that are geared to solving the portfolio optimization problem in its most generic format. In that way, large quantities and a wide range of investment cases can be dealt with rapidly, albeit with little room for flexibility and customization. Or, going to the other extreme, the portfolio construction processes can remain ad hoc and largely manual, tailored to specific situations. This option may win based on quality but certainly loses out on quantity. It is not evident where the profession is going today, and the finance literature remains remarkably silent on this question. But overall, it is fair to say that automated algorithmic portfolio construction is gaining steam.

One market innovation that has stimulated the use of automated portfolio construction procedures over the last few years is the trading of what are referred to as "baskets in kind." These baskets are fictive stylized portfolios meant to represent the corresponding investment funds, which serve as reference points for handling the regular inflows and outflows of funds. Every morning for each fund, two baskets are produced and posted online, one for the subscriptions and one for the redemptions that may come in that day. The baskets facilitate the negotiations. In many cases, they are purchased or sold entirely; sometimes they are partly renegotiated. Considering that an average bond manager takes around 40 minutes to produce one in-kind basket manually, the interest of automating their construction is easy to understand.

KEY POINTS

- A unique aspect of corporate bonds is that they give access to a multiple of market exposures, all of which can be adjusted isolated and hedged out individually so as to fit precise investment purposes. Corporate bonds make it possible for investors to take a position on interest rate movements and on currency exchange rates, on top of firm-specific corporate credit risks.

- Corporate bonds are in effect utilized for a large spectrum of investment purposes, ranging from income-oriented strategies, such as liability-driven investing and long-term savings, to more price-driven strategies including pure alpha strategies.
- The risk of a corporate-bond portfolio is usually measured by means of directly observable characteristics; in particular, the duration measures the exposure to interest-rate risk and it is more and more popular to use the duration-times-spread for measuring the exposure to credit risk.
- There are basically two approaches to building corporate bond portfolios in use: the traditional mean-variance optimization method and the stratified sampling technique.
- As the daily management of corporate bond portfolios is becoming increasingly complex, especially since the handling of fund redemptions and subscriptions are taking place over baskets-in-kind, bond managers rely more on computer-powered portfolio-optimization algorithms.

CHAPTER
FIFTY-THREE

MANAGING THE SPREAD RISK OF CREDIT PORTFOLIOS USING THE DURATION TIMES SPREAD MEASURE

Arik Ben Dor, Ph.D.
Managing Director, Barclays

Lev Dynkin, Ph.D.
Managing Director, Barclays

Jay Hyman, Ph.D.
Managing Director, Barclays

The standard presentation of the asset allocation in a portfolio or a benchmark is in terms of percentage of market value. It is widely recognized that this is not sufficient for fixed income portfolios, where differences in duration can cause two portfolios with the same allocation of market weights to have extremely different exposures to macro-level risks. As a result, fixed income portfolio managers have become accustomed to expressing their allocations in terms of contributions to duration—the product of the percentage of portfolio market value represented by a given market cell and the average duration of securities comprising that cell. This represents the sensitivity of the portfolio to a parallel shift in yields across all securities within this market cell. For credit portfolios, the corresponding measure would be contributions to spread duration, measuring the sensitivity to a parallel shift in spreads. Determining the set of active spread duration bets (the differences between the exposures of the portfolio and the benchmark) from various market cells and/or issuers is one of the primary decisions taken by credit portfolio managers.

Yet all spread durations were not created equal. Just as one could create a portfolio that matches the benchmark exactly by market weights, but clearly takes more credit risk (e.g., by investing in the longest duration credits within each cell), one could match the benchmark exactly by spread duration contributions and still take more credit risk—by choosing the credits with the widest spreads within each cell. These credits presumably trade wider than their peer groups for a reason—that is, the market consensus has determined that they are more risky—and are often referred to as "high-beta" credits, because their spreads tend to react more strongly than the rest of the market to any systematic shock.

Based on this idea, and following an extensive analysis of corporate bonds' spread behavior, we have advocated since 2005 a new measure of risk sensitivity that utilizes spreads as a fundamental part of the credit portfolio management process. To reflect the view that higher spread credits represent greater exposures to sector-specific risks, we represent sector exposures by contributions to *Duration Times Spread* (DTS), computed as the product of market weight, spread duration, and spread. The shift from spread duration exposures to DTS exposures as the measure of market risk embraces a different paradigm for credit spread movement—in the form of relative spread changes rather than parallel shifts in spread.

The paradigm shift resulting from the DTS concept has many implications for portfolio managers, both in terms of the way they manage exposures to industry and quality factors (systematic risk) and in terms of their approach to issuer exposures (nonsystematic risk). First, modeling spread changes in relative rather than absolute terms generates improved forward-looking estimates of excess return volatility. Second, for computing the hedge ratios needed to form market-neutral credit trades, DTS is superior to "empirical betas" as a measure of market sensitivity. Third, for index replication, matching sector-quality allocations of a credit index in terms of contributions to DTS leads to improved tracking compared with matching the contributions to spread duration. This same way of viewing macro exposures can help to more accurately express active portfolio weights as well. Fourth, DTS-based issuer limits can be considered as an alternative to more standard caps on issuer market weight when imposing portfolio diversification constraints. Finally, the incorporation of the DTS approach into the design of multifactor risk models can help make such models more robust, more compact, and more accurate. In this chapter, we will explore each of these applications in turn, after a brief overview of the large body of evidence supporting the DTS concept.

THE NEED FOR A NEW MEASURE OF CREDIT SPREAD EXPOSURE

Two examples of market conditions when spread duration contributions do not suffice are shown in Exhibit 53-1. During the dot-com crisis, a relief rally in January 2001 led to a temporary tightening of spreads throughout the communications sector. However, that rally was not characterized by a purely parallel shift; rather, issuers with wider spreads tightened by more. Panel A displays the changes in spreads experienced in that month by the key issuers that made up the communications sector of the Bloomberg Barclays Corporate Index.[1] Panel

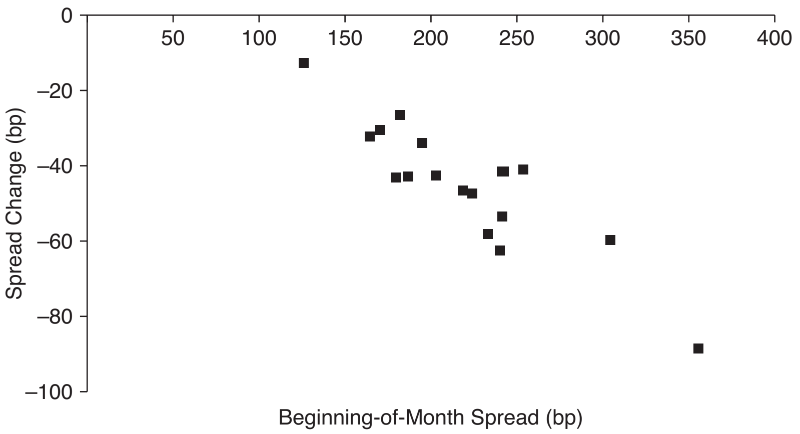
1. "Key issuers" refers to issuers that had outstanding issues with market value in excess of 1% of the sector aggregate market value. Panel A shows seventeen issuers that represented 216 outstanding issues; Panel B includes 19 issuers and 420 bonds.

B shows the spread tightening in the key issuers in the banking sector during the month of December 2010; a similar effect is seen in this industrywide rally.

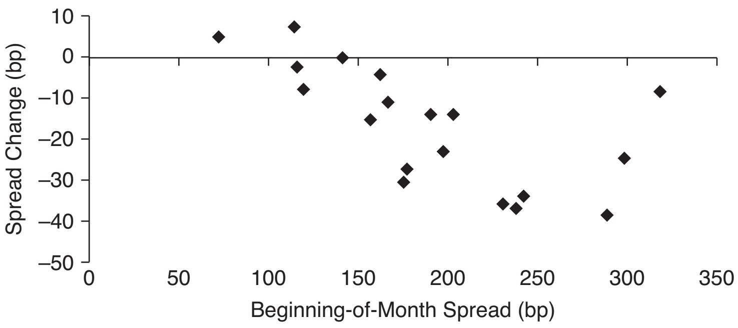
EXHIBIT 53-1

Spread Changes of Key Issuers in the Communications and Banking Sectors

Panel A. Communications Sector, January 2001



Panel B. Banking Sector, December 2010



Source: Barclays

Confronted with this reality, we conducted an extensive analysis of corporate bonds' spread behavior and developed a new measure of spread risk sensitivity. As higher spread credits have greater exposures to sector-specific risks, we represent sector exposures by contributions to DTS, computed as the product of market weight, spread duration, and spread. An overweight of 5% to a market cell implemented by purchasing bonds with a spread of 80 bps and spread duration of three years will be considered to be equivalent to an overweight of 3% using bonds with an average spread of 50 bps and spread duration of eight years ($0.05 \times 0.80 \times 3 = 0.03 \times 0.50 \times 8 = 0.12$).

How does this make sense? As mentioned above, a portfolio's contribution to spread duration within a given market cell is its sensitivity to a parallel shift in spreads across all bonds in that cell. What is the intuition behind this new measure?

In fact, the intuition is very simple. Let us look at a simple expression for the return of a given bond due strictly to change in spread R_{spread}. Let D denote the spread duration of the bond and s its spread; the spread change return is then given by

$$R_{spread} = -D \cdot \Delta s \tag{53-1}$$

It is quite easy to see that this equation is equivalent to

$$R_{spread} = -(D \cdot s) \cdot \frac{\Delta s}{s} \tag{53-2}$$

That is, just as spread duration is the sensitivity to an absolute change in spread (e.g., spreads widen by 5 bps), DTS is the sensitivity to a relative change in spread (e.g., spreads increase by 5% of their current levels). Note that this notion of relative spread change provides for a formal expression of the rough idea discussed above—that credits with wider spreads are riskier since they tend to experience greater spread changes in absolute terms.

Based on the absolute spread change approach (Equation 53-1), the volatility of excess returns can be approximated by

$$\sigma_{return} \cong D \cdot \sigma_{spread}^{absolute} \tag{53-3}$$

while in the relative spread change approach (Equation 53-2), excess return volatility follows

$$\sigma_{return} \cong D \cdot s \cdot \sigma_{spread}^{relative} \tag{53-4}$$

Given that the two representations above are equivalent, why should one of them be preferable to another? The key advantage of the DTS approach of Equation 53-4 is that relative spread volatilities are much more stable than absolute spread volatilities. We found extensive empirical evidence that the volatility of absolute spread changes of U.S. corporate bonds (both systematic and idiosyncratic) is linearly proportional to spread level, irrespective of sector, maturity, credit quality or time period.[2] This implies that the second approach, based on relative spread changes, should generate more accurate projections of spread volatility.

2. Arik Ben Dor, Lev Dynkin, Patrick Houweling, Jay Hyman, Erik van Leeuwen, and Olaf Penninga, "DTS (Duration Times Spread): A New Measure of Spread Exposure in Credit Portfolios," *Journal of Portfolio Management*, 33(Winter 2007), pp. 77–100.

SPREAD VOLATILITY AND DTS

The relation between the volatility of systematic spread changes and the average beginning-of-month spread level is plotted in Exhibit 53-2. The analysis was carried out using a large sample with over 560,000 monthly observations on all constituents of the Bloomberg Barclays Corporate and High Yield Indices rated B or higher between September 1989 and January 2005.[3] Bonds in each of the three main sectors (financials, industrials, and utilities) were divided into three equally populated duration buckets (short, medium, and long). Bonds in each duration bucket were then partitioned into pre-specified cells based on spread. Spread cell breakpoints varied across sector and duration to ensure that each spread cell was well populated monthly.[4] This procedure resulted in 66 distinct time series data sets; each consisted of a fairly homogeneous set of bonds with monthly data for their spreads and spread changes. The systematic spread change in a given cell each month was represented simply as the average spread change across all bonds that comprised that cell. We then calculated the time series volatility of these systematic spread changes and the average spread over time for each cell.

The results indicate an almost perfect linear relationship between spread volatility and the level of spread that can formally be expressed as

$$\sigma_{spread}^{absolute}(s) \cong \theta \cdot s \tag{53-5}$$

Estimating a simple regression based on Equation 53-5 provides an excellent fit to the data (R^2 in excess of 90%) with the slope coefficient θ equal to 9.1% using all observations and 9.4% if the three circled outliers are excluded.[5] Furthermore, for a given level of spread, the differences across sectors and maturity buckets are fairly small. Hence, the historical volatility of systematic spread movements can be expressed quite compactly, with only minor dependence on sector or maturity, in terms of a relative spread change volatility of about 9–10% per month. That is, spread volatility for a market segment trading at 50 bps should be about 4.5–5.0 bps/month, whereas that of a market segment at 200 bps should be about 18–20 bps/month.

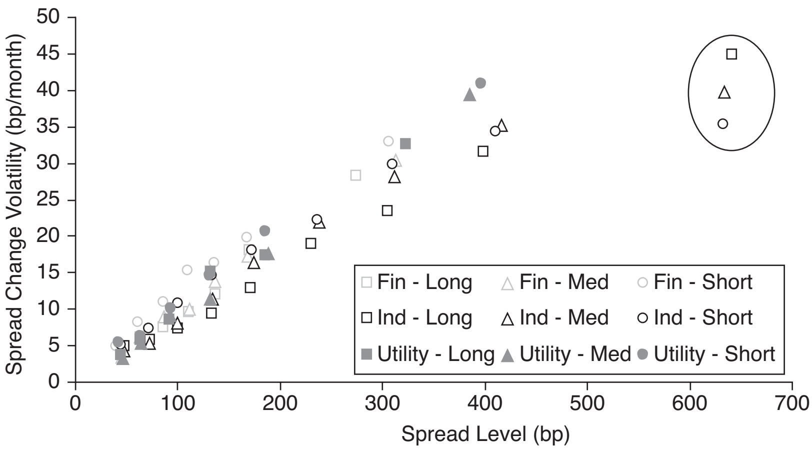
---

3. See Ben Dor, Dynkin, Houweling, Hyman, van Leeuwen, and Penninga, "DTS (Duration Times Spread): A New Measure of Spread Exposure in Credit Portfolios" for further detail regarding the analyses shown in Exhibits 53-2 and 53-3. In this section, we report our original results using data through 2005. In what follows, we use market data after this date as an extreme out-of-sample test of these relationships.
4. Bonds were assigned to one of 66 cells with breakpoints ranging from 100 bps to over 500 bps (the financial, industrial, and utility sectors had seven, nine, and six spread cells for each maturity bucket, respectively). To eliminate idiosyncratic effects, months in which a cell was populated by fewer than 20 bonds were excluded. Employing a weighted volatility estimate instead (where the number of observations in each month was used as the weighing factor) produced very similar results.
5. The population of the three highest spread cells (bonds trading at spreads above 500 bps) was very scarce for most of the study period. Consequently, most of their monthly spread realizations were excluded (due to the minimum bond population requirement). The statistical relevance of these most extreme data points is therefore questionable.

We also studied whether idiosyncratic spread volatility is similarly related to the level of spreads. We computed the standard deviation of the differences between all individual bonds' spread changes and the average spread change of their respective cell, pooled across all bonds and months. This pooled measure of idiosyncratic spread volatility per market cell was then plotted against the median spread of the cell. We again found a very strong linear relationship between spread and idiosyncratic spread volatility, with a slope similar to that estimated for systematic volatility.

EXHIBIT 53-2

Time Series Volatility of Systematic Spread Changes vs. Spread Level



Based on monthly observations for all constituents of the Bloomberg Barclays Corporate and High Yield Indices rated B or better, September 1989–January 2005.

Source: Barclays

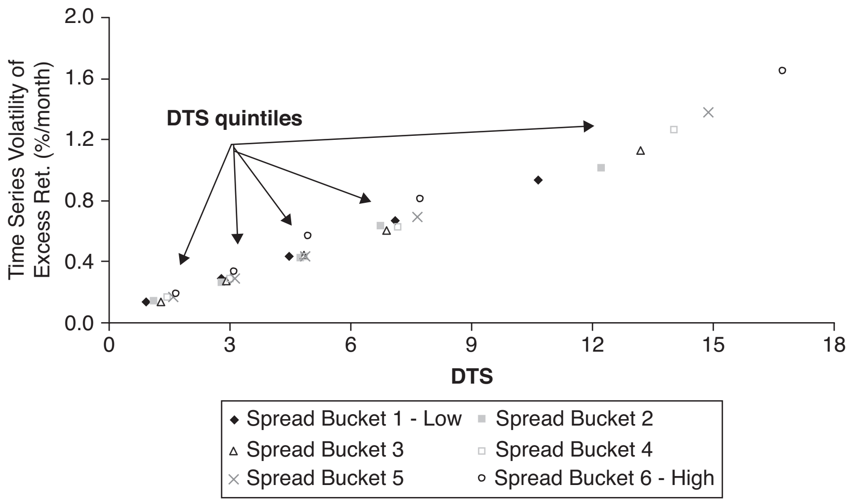
To corroborate these findings, we also investigated the relation between excess return volatility and DTS. If the volatility of systematic spread changes is proportional to the level of spread, then Equation 53-4 implies that a portfolio's excess return volatility should increase linearly with its DTS, with the slope equal to the volatility of relative spread changes. In addition, excess return volatility for portfolios with similar DTS should be approximately equal even if their spreads or spread durations differ.

To examine these predictions, bonds were assigned into DTS quintiles, which in turn were further subdivided into six equally populated buckets based on spread. The average excess returns and median DTS were calculated monthly for each bucket separately. These statistics were then used to compute the excess return volatility and average DTS for all time series.

The results of this analysis are presented in Exhibit 53-3, which plots the time series volatility of excess returns for each of the quintile-bucket combinations against its average DTS. First, it is clear that excess return volatility increases with the level of DTS and that a straight line through the origin provides an excellent fit. This is indeed confirmed by a regression of the excess return volatility against the average DTS, which finds a fit of 98% and an insignificant intercept. Furthermore, the estimate of the slope coefficient (8.8%) is in line with the volatility of relative spread changes found in Exhibit 53-2, as expected. Second, observations representing the same DTS quintile exhibit very similar excess return volatilities despite large difference in their spreads and durations.[6]

EXHIBIT 53-3

Excess Return Volatility vs. DTS



Based on monthly observations for all constituents of the Bloomberg Barclays Corporate Index, September 1989 to January 2005.

Source: Barclays

In 2009, we re-examined whether the key findings underlying the DTS concept remained valid through the credit crisis of 2007–2009.[7] We showed that the fundamental relationship between the level of spread and subsequent volatility persisted in a linear fashion across all sectors and credit ratings, although the proportionality factor increased from 10% to about 15%. While this implies that a long-term calibrated DTS model would not have fully captured spread risk during the crisis months, we demonstrated that it was far more effective than any other

6. The one exception to this is in the highest DTS quintile, where the subdivision by spread causes wide variations in DTS as well. As a result, the observations no longer form a tight cluster, but they continue to follow the same general relationship between DTS and excess return volatility.

7. Madhur Ambastha and Arik Ben Dor, "DTS (Duration Times Spread) in the Credit Crunch: Did It Live Up to Expectations?" *Barclays Research* (April 2009).

spread duration-based measure. The explicit use of spread in the DTS framework as a barometer of risk proved to be of paramount importance in managing credit portfolios during that volatile period.

The concept of spread proportionality and DTS are not limited only to U.S. corporate bonds. From a theoretical standpoint, we showed that structural credit risk models such as the Merton model imply a near-linear relationship between spread level and volatility.[8] Subsequent empirical studies indeed found that the applicability of DTS extends to other spread asset classes with a significant default risk. For example, we investigated the dynamics of CDS spreads[9] in both the U.S. dollar and euro markets using a different estimation approach, sample period and data frequency than those used in the original study of U.S. corporate bonds. Despite these differences in data and technique, we found clear evidence of a linear relation between spread volatility and spread level with a very similar slope.[10] Similar results were documented for European corporate and sovereign bonds and emerging market sovereign debt denominated in U.S. dollars.[11]

RISK PROJECTION: PREDICTING SPREAD VOLATILITY

Perhaps the most important requirement for managing a credit portfolio successfully is the ability to measure its risk accurately. A key benefit of DTS in the context of generating volatility forecasts is its use of current spread levels to quickly adapt to changing market conditions. In contrast, estimates based on past realized spread volatility can take longer to adapt, depending on the time window used for calibration. The selected time period is inherently subjective and may not perfectly reflect the current state of the market.

The credit crisis of 2007–2009 provides an excellent opportunity to examine the differences between forecasts based on DTS and traditional measures relying on historical realized spread changes for at least two reasons. First, the magnitude of the crisis was unprecedented. Spreads of U.S. investment-grade bonds widened to an all-time high of more than 6%, from lows of around 1% in the benign 2003–2006 period. Similarly, spreads of high-yield bonds rose to more

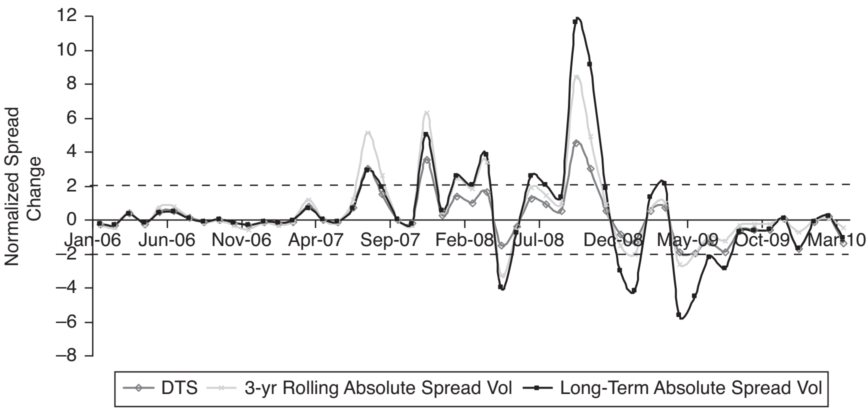
than 18% and credit default index swap (CDX) spreads increased by a factor of five. Not only the magnitude, but also the extraordinary speed at which spreads widened, caught many investors off guard, with risk estimates calibrated to the sustained "volatility drought" of the previous few years severely underestimating the spread risk of corporate bonds. Second, since the concept of DTS was first introduced in 2005, the crisis period presented a true out-of-sample test of its effectiveness.

Exhibit 53-4 shows the monthly spread changes of the Bloomberg Barclays U.S. Corporate Index normalized by several projections of spread volatility from January 2006, well before the first signs of the crisis were observed, through March 2010, when markets were already in recovery mode. The first forecast of volatility, based on DTS, is the product of the spread level at the beginning of the month and the (approximate) relative spread volatility (10%/month) estimated in our original study, based on the analysis shown in Exhibit 53-2. The plot also includes two estimates using the realized volatility over a trailing 36-month window or during the entire history (since September 1989) available as of the start of each month.

EXHIBIT 53-4

Comparison of Volatility Forecasts Based on DTS and Historical Absolute Spread Changes



Normalized spread changes are monthly changes in spreads divided by the forecast volatility based on DTS with a 10% slope, absolute spread volatility computed over the trailing 36 months or the entire available history since September 1989. The results are reported monthly between January 2006 and March 2010.

Source: Barclays

The exhibit illustrates that the forecast based on the trailing 36 months would have fit the low volatility level during the pre-crisis period quite well, but was susceptible to large sudden shocks such as in July 2007 and November 2007, which resulted in 5.1 and 6.3 standard deviation realizations, respectively.

Although the estimator gradually adjusted to the change in market conditions, it continued to understate the level of risk more than a year after the crisis began, with an 8.4 standard deviation realization in September 2008.

In contrast, the "long-term" forecast was better prepared at the beginning of the crisis since it incorporated information from previous extreme market events such as the 1998 and 2002 crisis periods. While its forecast of volatility for July 2007, for example, was higher than that of the "short-term" estimator, it generated grossly underestimated risk projections toward the end of 2008. Because adjustment to changing market conditions is slow, using the forecast generated by the long-term volatility measure the spread change in September 2008 would have corresponded to an 11.6-standard-deviation event! Similarly, the estimator underestimated the magnitude of the spread tightening beginning in early 2009 as market conditions started to improve.

The DTS volatility estimates over the period were consistently superior to both forecasts using realized volatilities. The DTS-based forecasts quickly (albeit not perfectly) reflected both the increased level of risk since the crisis erupted and the reversal in market conditions in 2009, with most spread change realizations corresponding to less than two standard deviations. A notable exception was September 2008. Despite the already heightened level of spreads, the combined effect of Lehman Brothers' and Washington Mutual's defaults and the bailout of AIG in that month resulted in a 4.5-standard-deviation event. However, as discussed above, the forecasts using realized absolute spread volatility underestimated the risk by a factor of between two and three times more than the DTS-based forecast.

The credit crisis that began in 2007 affected not only corporate but also sovereign issuers. The deteriorating economic conditions in several of the euro area economies with high deficits and/or debt ratios subsequently raised solvency concerns among many investors. As a result, spreads of countries such as Portugal, Ireland, Italy, Greece, and Spain widened significantly in 2010 relative to German treasuries, to the point where the risk contribution of sovereign spreads in investment grade bond indices grew larger than that of corporate bonds.[12] Many market participants had to suddenly re-evaluate their risk management practices. It was apparent that past volatilities of absolute spread changes could no longer serve as a basis for forward-looking risk projections in this market, as sovereign spreads had mostly been very tight and stable since the inception of the Euro in 1999. The DTS paradigm, keying on rising spread levels, does not require a long period of increased spread volatility to warrant an increase in forward-looking risk estimates. Furthermore, as we already mentioned earlier, theory suggests that DTS should apply to all securities with a credit component irrespective of the issuing entity, and earlier results indeed confirmed it is applicable to emerging market

12. See Jay Hyman, Antonio Baldaque da Silva, Yael Eisenthal-Berkovitz, Amine El Khanjar, Anando Maitra, and Simon Polbennikov, "Sovereign Risk Spillover into Euro Corporate Spreads," *Journal of Fixed Income* 24(1), 2014, pp. 51–74

countries. It is therefore interesting to see to what extent using the DTS paradigm to project the spread risk of Euro sovereign issuers could have helped investors in this asset class.

Exhibit 53-5 compares the daily spread volatility of several Euro countries over two distinct periods, which roughly span the time period of the crisis. Volatility between August 2008 and July 2009 is represented on the horizontal axis, whereas the vertical axis reflects the volatility in the period from August 2009 to July 2010. The time partition was selected such that both periods have about the same length but correspond to different stages of the sovereign debt crisis. Each observation represents either the absolute or relative spread volatility of a particular country. Observations along the diagonal line indicate that the volatilities are the same over the two time periods.

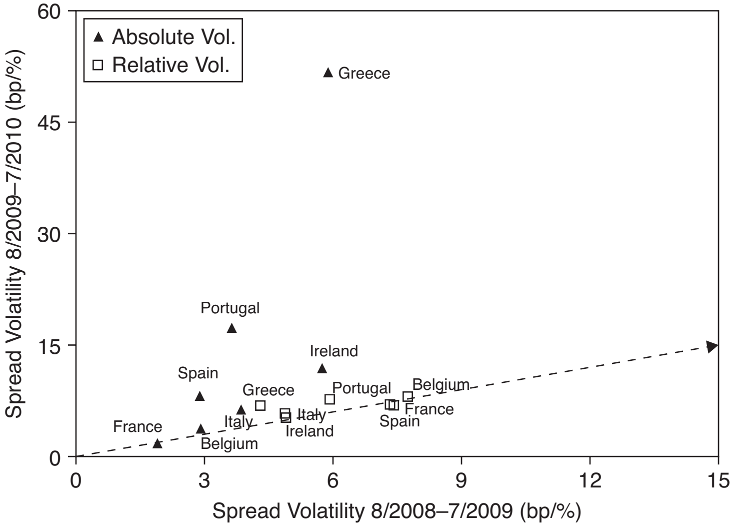
Two clear patterns can be observed in the plot. First, most of the observations representing absolute spread volatilities are located quite far above the line, pointing to a marked increase in volatility in the second period of the sample. In contrast, relative spread volatilities are quite stable, with almost all observations located near the straight line crossing the origin, which represents equal volatilities (absolute or proportional) in both periods. This is because the pick-up in volatility in the second period was accompanied by a similar increase in spreads. In particular, the daily volatility of absolute spread changes for Greece increased by a factor of almost 10 (from 5.9 bps to 51.6 bps), whereas in relative terms it only increased from 4.3% to 6.8%.

Second, the daily volatilities[13] of relative spread changes in various countries are quite tightly clustered, ranging from 4.5% to a bit over 8%, whereas the range of absolute volatilities is much wider, ranging from 1.6 bps to more than 17 bps for Portugal and even higher for Greece. Furthermore, spread proportionality seems to capture well not only the spread dynamics of the countries that were in the center of the crisis (Portugal, Greece, Spain, Ireland, and Italy), but also countries that were less affected such as Belgium and France. While the exhibit suggests that absolute spread volatility also remained essentially unchanged for these two countries, using relative spreads offers the advantage of similar volatilities across all sovereign issuers.

13. The results in this section are based on daily data due to the fairly short time period of relevance. The relative spread volatilities reported here thus seem to be much higher than those reported earlier for credit markets. Assuming that all daily spread changes are independent, and that a month contains about 20 business days, a 6% daily volatility would correspond to a monthly relative spread change volatility that is greater by a factor of $\sqrt{20}$, or over 26%. This apparent discrepancy reflects in part the fact that the analysis in this section directly examines the spread volatilities of individual issuers, without any attempt to separate systematic from issuer-specific effects. If we compute the total spread volatility for an issuer using our estimates of systematic and idiosyncratic spread volatility updated through the 2007–2008 credit crisis (15%/month), the implied *total* spread volatility of about 21%/month is not so different from the daily results (converted to a monthly frequency) shown here for euro sovereigns. It also underscores the approximate nature of this square root rule and the difficulty of comparing daily and monthly volatilities.

EXHIBIT 53-5

Absolute and Relative Volatility of Daily Spread Changes for Selected Sovereign European Issuers



Both absolute and relative spread volatilities are expressed in units with similar magnitudes. However, the interpretation is different: an absolute spread change of 10 represents a 10 bps widening in a country spread, while a relative spread change of 10 means that spreads changed by 10% of their current values (e.g., from 50 to 55, from 200 to 220).

Source: Barclays

Exhibits 53-4 and 53-5 provide an illustration of the advantage of the DTS approach compared with the risk estimated based on absolute spread changes. The DTS approach does not require a subjective selection of a historical calibration period, and allows for a rapid incorporation of market conditions as reflected in the level of spreads. This feature can be especially valuable in situations where market volatilities exceed any historical precedent, as illustrated in these two exhibits for the credit and sovereign crises of 2007–2010. It is also important to note that DTS-based risk forecasts can immediately adapt to changing conditions. Whereas models based on realized monthly volatility will only be updated at the end of a month, DTS estimates can be updated as soon as spread changes are marked—intra-month or even intra-day.

HEDGING: PREDICTING SENSITIVITIES TO MARKET SPREAD CHANGES

Another natural application of DTS is hedging. Consider an investor whose basic goal is to express a view favoring one issuer over another while taking as little directional market risk as possible. The primary driver of the performance of such a strategy should be the investor's skill at forming views on issuers, while any systematic risk is to be minimized. The success or failure in isolating issuer-specific risk lies in his ability to forecast the market beta of each security over the return horizon.

Suppose we are considering a trade as of the end of December, and plan to hold it in position for three months. The betas we would like to use for this hedge are the as-yet unknown ones that we will find ex post as we later review the returns realized from January through March. What is the best forecast we can make given the data that we have at our disposal? An obvious approach would be to use DTS. Since the DTS contribution of a position measures its systematic spread exposure, DTS neutrality should be the best way to hedge the market exposure of an issuer-specific trade that goes long one issuer and short another.

To examine this question, we conducted a study that compared two different methods for forecasting the market betas of individual CDS over a given period using only data available at the beginning of the period.[14] The first relied on the ratio of the DTS (in this case, risky PV01 times spread) of the individual CDS to that of the market as of the beginning of the period. The second approach was one commonly used by investors, based on the empirical beta of the individual CDS to the market from the prior period. We divided the data set, which contained roughly three years of weekly data, into nonoverlapping periods of equal length, either 26 weeks or 52 weeks each. For each period but the first, the beta of each security was estimated using the two methods: either by using the spread as of the start of the period or by using the security's beta from the prior period. We then regressed the realized beta during the period on each of these two candidate predictors. Since there were 84 issuers in each period, the regressions had 5×84 observations when a 26-week estimation period was used and 2×84 observations when a 52-week estimation period was used. The results of these regressions are shown in Exhibit 53-6.

Several things are apparent from Exhibit 53-6. First, we see that the DTS ratio provides a better prediction of next-period beta, with R-squared values approximately twice as high as those using the prior-period empirical betas. Second, the regression results tell a very different story for the two models. When using the DTS ratio, the intercept is not statistically significant, and the coefficient is very close to one; that is, the DTS ratio as of the start of the period is the best estimate of market beta in the coming period. For the empirical betas, this is not the case. The intercept plays nearly an equal role as the prior period beta, both in terms of the coefficients and the t-statistics. This means that if we want to forecast the next-period beta based on the empirical beta observed in the prior period, the best forecast would be to assume that the beta will be halfway between the prior observation and 1. That is, betas are mean-reverting. This observation dovetails nicely with the established literature on empirical betas in equity markets. For example, Grinold and Kahn make the following observations regarding equity betas:

DTS Ratio	52 weeks	0.5	Intercept	–0.04	–0.5
			DTS Ratio	1.05	12.86

Source: Barclays

> A stock with a high historical beta in one period will most likely have a lower (but still higher than 1.0) beta in the subsequent period. Similarly, a stock with a low beta in one period will most likely have a higher (but less than 1.0) beta in the following period. In addition, forecasts of betas based on the fundamental attributes of the company, rather than its returns over the past, say, 60 months, turn out to be much better forecasts of future betas.[15]

Rosenberg provides empirical evidence supporting this statement and shows how the predicted betas from Barra's E1 risk model do a much better job of forecasting next-period betas than just using historical betas.[16] His results indicate that a simple regression of the beta in one period on the historical beta from the prior period yield a coefficient of 0.58.

These results can perhaps help add another perspective to the DTS concept in general. Upon their first exposure to the DTS approach, some investors have noticed a striking similarity to the more familiar concept of beta-adjusted spread durations. Both of these approaches recognize that a systematic change in spreads throughout an industry does not tend to result in a parallel shift, but that some

16. Barr Rosenberg, "Prediction of Common Stock Betas," *Journal of Portfolio Management* (Winter 1985), pp. 5–14.

issuers will move by more than others. The difference between the two methods is that in one approach, the forward-looking market beta is estimated based on its past market beta, while in the other it is estimated based on its current spread level. Based on the head-on comparison of the two estimation methods shown in Exhibit 53-6, we can bring the two approaches into agreement. A portfolio's DTS exposure to a sector can now be seen to be equivalent to its beta-adjusted spread duration exposure, with the estimation of the betas provided by the market in the form of spreads.

After exploring the use of DTS to estimate hedge ratios of individual issuers relative to the market, we applied this approach to hedging paired long/short trades in CDS of two issuers from the same industry.[17] Selecting a pair of issuers *x* and *y* from a given industry at random, we would go long one unit of *x* (by selling protection) and hedge the systematic sector exposure by going short some amount of issuer *y* (by buying protection). A hedging strategy that used DTS ratios to determine the amount of issuer *y* to use was compared with one based on empirical betas. The details of this analysis are somewhat involved, and beyond the scope of this chapter, but they once again established the superiority of DTS-based hedge ratios over those based on empirical betas. The DTS-hedged trades were found to have lower P&L volatilities, more stable hedge ratios, and a smaller percentage of variance from systematic changes in sector spreads. Empirical betas proved to be more difficult to estimate, and prone to instability.

The DTS approach to hedge formation has several clear advantages. First, the calculation of the hedge ratio is simple and unambiguous and spares the investor some difficult decisions about how beta should be estimated (what frequency data? how long a window? Should recent data count more than older data?). Second, the DTS ratio has shown itself to be both a good predictor of market beta at the individual issuer level and a reliable mechanism for neutralizing the market exposure of long/short trades. Finally, when dealing with long/short trades in swaps of matched maturities, the DTS-neutral trade will be carry-neutral as well,[18] neatly avoiding the possibility of forming a portfolio with negative carry.

Although we restricted our investigation to the hedging of individual issuers and paired long/short trades in CDS, the results are applicable to a much broader portfolio context. Even portfolio managers who are able to take long/short positions in CDS do not necessarily hedge each trade on its own. Rather, long and short positions are established according to the manager's views, and the aggregate exposures of the portfolio are hedged to achieve the desired systematic exposures, either passive to the index or to actively reflect the manager's macro

17. For details, see Ben Dor, Hyman, Polbennikov, and Rosten, "Hedging Pairwise CDS Trades Using DTS."

18. If the duration is the same on both sides of the trade, then matching duration *x* notional *x* spread will be the same as matching notional *x* spread, which is exactly the way the monthly premium payments on the CDS are calculated. This means that the monthly premium flows on the two legs of the trade will exactly cancel each other out, and the total return of the trade will be entirely based on spread change.

views. We believe that the right way to manage spread risk, consistent with the hedging mechanism used here, is to measure industry exposures in terms of net DTS contributions. To maintain a neutral exposure, one would attempt to zero out the exposures in each industry. If a portfolio incorporates active industry exposures, the calculation of the overall risk should include correlations among relative spread movements in each sector. This approach is illustrated in the last section, which discusses how a risk model for spread asset classes can be constructed around the notion of DTS.

REPLICATION: CREATING INDEX TRACKING PORTFOLIOS

Portfolio managers often need to build portfolios that closely track the returns of the selected benchmark. Constructing a portfolio of cash instruments to replicate a target index can be accomplished using various methods, but the most commonly used approach is based on stratified sampling. It relies on partitioning the index into cells, which represent the manager's view of common risk factors affecting a given market (e.g., for credit, these might be sector and rating). Bonds are then selected from each "cell" based on certain criteria and weighted such that they match various characteristics of the cell, for example contribution to spread duration. The advantage of this approach is its simplicity and flexibility; its disadvantage is that it ignores the correlations among cells.[19]

In this section, we provide an illustration of the stratified sampling method using the Bloomberg Barclays U.S. Corporate Index, and matching only a single characteristic at a time: DTS or spread duration. Our intention is not to design the "optimal" replicating portfolio, but rather to focus on the relative efficacy of one characteristic relative to the other.

To construct the two replicating portfolios, we first partition the index into 24 cells (eight sectors × three credit ratings).[20] We then select 10 bonds to represent each cell in the portfolio.[21] This same set of 10 bonds is used in both variants of the replicating portfolio, to reduce noise from issuer selection and focus attention on the differences in systematic risk exposures. The key difference is in how we weight the bonds within each cell: in the DTS-based portfolio, we match the DTS exposure of the index in each cell, while in the spread-duration-based portfolio

19. A stratified sampling approach is "blind" to the relationships among cells. This can be remedied by complimenting a stratified sampling approach with the use of an optimizer that accounts for the correlations among cells.

20. The sector breakdown is as follows: Banking, Finance, Basic Industry, Consumer Cyclical, Consumer Non-Cyclical, Communications, Energy, and Utility.

21. The number of bonds selected from each cell is set to 10 since it strikes a good balance between having a realistic size for the replicating portfolio (240 bonds) and reducing idiosyncratic risk. If fewer bonds are used to represent each cell, the variation in tracking errors may reflect not only the difference between the two systematic risk measures (DTS and spread duration), but also the idiosyncratic performance of the set of bonds selected.

we match the index spread duration exposure.[22] For example, Exhibit 53-7 shows a market structure report of the Bloomberg Barclays U.S. Corporate Index along the sector/quality partition used for this replication exercise. For each cell of the partition, the report characterizes the exposure of the index to that market segment in three different ways: by market weight, contribution to option-adjusted spread duration (OASD), and contribution to DTS. The spread-duration-based replicating portfolio is constructed such that it matches the contributions to OASD in each of the index sectors (the second column from the right); the DTS-based replication matches the DTS contributions in the rightmost column.

EXHIBIT 53-7

Sector/Quality Profile of Bloomberg Barclays U.S. Corporate Bond Index, as of 12/31/2010

	Market Value [%]	OASD	OAS	DTS	OASD [cntr]	DTS [cntr]

(Continued)

22. The scheme used to weight the 10 bonds within each cell is fairly complex, involving a further subdivision of each cell into four quadrants, to ensure that we can match both market weight and the desired additional characteristic by a rule-based algorithm that always results in positive weights to all selected bonds. Details may be found in Ambastha and Ben Dor, "DTS (Duration Times Spread) in the Credit Crunch: Did It Live Up to Expectations?"

A key part of any index replication attempt is selecting the bonds that form the replicating portfolio. In a real-life portfolio management setting, security selection plays an important role in determining performance and several different criteria can be employed in the security selection process, depending on the portfolio setting. If minimizing tracking error is the primary goal, then the security weights within each cell should focus on the primary issuer exposures of the benchmark. Additionally, managers may aim to maximize liquidity, or to add value by choosing securities that they believe will outperform. Ideally, though, as long as the portfolio has matched the benchmark allocations on the macro level, it should track well in the event of any major industry rally or decline. The key is to match the right set of macro exposures.

For the purposes of this study, our interest is not in the issuer selection mechanism, but in checking which set of macro exposures is most important to match. The selection mechanism therefore does not need to be optimal in any sense (e.g., minimizing tracking error volatility or maximizing performance). Rather, we would like to test our replication methods using several different issuer selection mechanisms, to ensure that differences between the two replicating portfolios (DTS matched and spread duration matched) are independent of the specific bonds that were selected. One approach is simulation, where bonds in each cell would be randomly selected, the replication results recorded and the analysis repeated multiple times. Another approach, which we use instead, is to specify explicit selection criteria based on bond characteristics. While this approach leads to a single replicating portfolio (per criterion), it more closely mimics a realistic process of constructing replicating portfolios for index tracking purposes.

We analyze five potential bond selection criteria. The first criterion, based on market value, selects 10 of the largest bonds in each cell. Hence, it results in the most investible and liquid portfolios (as larger size is generally associated with increased liquidity). The remaining four criteria are designed primarily to maximize the ability of our study to distinguish between the two replication strategies. The second and third criteria rely on spread and select the bonds with the highest (lowest) level of spread. This represents a replication strategy that tries to maximize carry (minimize risk). The last two criteria use an algorithm designed to maximize the dispersion in either spread duration or DTS among the bonds selected within each cell. Selecting bonds with the maximum potential dispersion in the characteristics used to match the index should magnify the mismatch between the portfolio and the benchmark in terms of the exposures not being forced to match. This in turn would facilitate the comparison between the replication results of the two sensitivity measures.

Exhibit 53-8 presents the tracking error volatilities (TEV) of the replicating portfolios during the 24-month period beginning in January 2007, for the various bond selection criteria. Irrespective of the selection criteria, matching each cell's DTS achieves lower tracking error volatility than matching its spread duration, although the improvement varies widely, from 1.2 bps/month to almost 15 bps/

month. Looking at the difference in weight given to each bond under the two matching schemes (reported in the third column) suggests that the reduction in TEV is generally more meaningful as the weight differential increases (i.e., as the replicating portfolios are less similar to each other).[23]

For example, if the selection criterion is market value, the average (absolute) difference in the weight of each selected bond under the two replication schemes (in proportion to the total index market value) is 0.46%, and the TEV declines from 22.9 bps/month for matching spread-duration exposures to 21.4 bps/month when matching DTS exposures. If the maximum-spread criterion is used instead, the weight differential rises to 0.72%, and the decline in TEV when matching DTS rather than spread duration exposures is 14.7 bps/month.

It is important to mention that the superior tracking achieved by matching the index DTS does not come at the expense of performance. The last two columns in Exhibit 53-8 display the average tracking errors of the replicating portfolios. The results indicate that while our simple replication exercise tends to underperform the index for any bond selection criteria, the DTS-based approach gives better average tracking errors (with one exception) than the spread duration-based one.

EXHIBIT 53-8

Index Replication Using Stratified Sampling

Selection Criteria	*Tracking Error Vol. (bp/month)* SD Match	DTS Match	Weight Differential per Bond (as % of Total Index MV)	*Average Tracking Error (bp/month)* SD Match	DTS Match
Market Value (largest)	22.9	21.4	0.46%	–11.5	–8.0
Spread (lowest)	20.7	15.6	0.89%	–10.6	–14.0
Spread (highest)	33.0	18.3	0.72%	–11.7	–4.4
Spread Duration Dispersion	17.0	15.8	0.47%	1.9	5.8
DTS Dispersion	28.2	24.7	0.59%	–6.1	–1.5

Replication of the Bloomberg Barclays U.S. Corporate Index is performed through matching the spread duration (SD) or DTS characteristic of each of the 24 cells in the partition (8 sectors × 3 credit ratings). Based on monthly observations (January 2007 to December 2008).

Source: Barclays

23. For each selected bond, we calculate the difference in the weight (as a proportion of the index aggregate market value) it is assigned under the DTS and spread duration matching. The weight differential per bond in Exhibit 53-8 is computed as the average of the absolute value of the weight difference for all the bonds selected.

The use of DTS exposures to replicate an index by stratified sampling is far from a theoretical exercise. This approach has been used to form a highly liquid portfolio of bonds to track the Bloomberg Barclays U.S. Investment-Grade Credit Index.[24] A purely rules-driven sampling methodology ensures transparency. The replication methodology uses a partition of five sectors by five duration categories, with each cell represented by two bonds. The bonds are selected based on a proprietary measure of liquidity and are weighted such that the index DTS exposure in each cell is matched. Historical backtesting of this strategy indicates that it tracks the index much more closely than an alternative strategy based on liquid derivatives including Treasury futures, swaps, and CDX.

EXPRESSING MACRO VIEWS IN ACTIVE PORTFOLIOS

Attention to the DTS exposures of a portfolio is essential for active portfolio managers as well as passive ones. In many financial institutions, the management of a portfolio is a team effort with distinct tasks for different players. Often, one group forms a set of macro views and expresses them as a set of overweights and underweights to various market segments that the portfolio should adopt relative to the benchmark. A second group may be charged with the implementation of this plan in terms of individual securities, often following the issuer selection advice of yet a third group. Yet, in order to achieve the most accurate implementation of the macro views, they must be expressed in terms of the type of exposures that best reflect the way the market moves. Referring back to the index profile shown in Exhibit 53-7, we saw that the passive credit investor will most effectively replicate the macro exposures of the index by matching the DTS contributions in the far right column, not the market value weights or the contributions to OASD. Similarly, the active investor should express the desired overweights and underweights relative to the benchmark in terms of contributions to DTS.

PORTFOLIO CONSTRUCTION: OPTIMAL DIVERSIFICATION OF ISSUER RISK

In the management of all but the most passive credit portfolios, the sizing of credit exposures must find the right balance between two opposing needs. To control risk, it is important to avoid taking a position in any given issuer that is overly concentrated. Conversely, to generate alpha based on analyst recommendations, it is important that the recommended names have sufficient weight in the portfolio to drive outperformance; over-emphasis on diversification can dilute the value of issuer selection. As a result, investors often seek guidance on what the "correct" level of diversification should be for a given portfolio.

24. Ariel Edelstein, Siddhartha Dastidar, and Bruce Phelps, "Tradable Credit Portfolio (TCX) to Track the USD IG Credit Index," *Barclays Research* (April 2010).

In the traditional approach to portfolio diversification, a plan sponsor imposes constraints on the portfolio that specify the maximum percentage of the portfolio, by market weight, that may be invested in any single issuer. This issuer limit may be dependent on credit quality, allowing larger concentrations in higher-rated issuers. In the past, we have formulated an approach to optimally determine these quality-dependent limits, based on an empirical study of the performance impact of downgrades.[25] This analysis determined that the ratio of allowed position sizes should be based on the relative risks in different quality groups. If the sole concern is downgrade risk, then the ratio indicated based on credit market data gathered from 1988 through 2001 was approximately 9:4:1. This means that if we take the allowed portfolio weight in a Baa-rated issuer as our unit size, a position in a security rated A may be four times as large and positions in Aa–Aaa issuers may be nine times as large. If "natural" spread volatility, which occurs in the absence of a ratings transition, is included in the risk measure as well, the discrepancy between the different ratings categories is lessened, and the ratio becomes 4:3:1. A more recent update of this model found that the experience during the 2007–2009 crisis was not supportive of large concentrations even in higher-rated issuers. The same model, updated to include data through the end of 2010, found that the optimal position size ratios were 2.8:1.6:1 based purely on downgrade risk and 2.6:1.6:1 when including the effect of all nonsystematic risk, both from downgrades and from natural spread volatility.

How can we apply the DTS model to this problem? A first step to this end would be to retain the framework of ratings-dependent caps on issuer market weight, but compute the position size ratios based on the ratios of average DTS levels in each credit quality group. This approach gives ratios that change over time as spreads widen and tighten, responding quickly to changing market conditions rather than needing to wait for an ex post analysis of realized losses. For example, as of December 2001, the position size ratio from the DTS method was 4.3:1.7:1, similar to the result from the empirical approach including the risk of both downgrades and natural spread volatility. As market volatility (and spread) ground lower in the following years, these ratios increased, peaking in March 2005 at 6.6: 3.0:1. However, when spreads skyrocketed in 2008, the ratio of position sizes in September 2008 for example, declined to as low as 1.4:1:1 as all credit qualities were deemed highly risky. As of December 2010, the DTS-based ratio of 2.1:1.4:1 agreed well with that from the updated empirical study.[26]

However, the DTS paradigm shift suggests a completely different approach to controlling portfolio concentrations, not just a simple recalibration. Rather than imposing a limit on the portfolio market weight in a given issuer (with the size possibly dependent on quality), a limit on the DTS contribution of any

26. Lev Dynkin, Jay Hyman, and Vadim Konstantinovsky, "Sufficient Diversification in Credit Portfolios: Balancing Two Approaches," *Barclays Research* (January 2011).

issuer should be imposed regardless of credit quality. This would have the effect of allowing a portfolio to have large concentrations in low-spread issuers while enforcing stricter diversification constraints on high-spread issuers. While this idea is attractive in principle, its implementation encounters several practical problems, as we shall discuss.

This DTS-based approach is in some ways quite similar to the traditional approach, in which issuer caps are specified in terms of market weights that differ based on credit quality; yet there are some crucial differences. In both schemes, the fundamental principle is to allow greater concentrations to issuers perceived to be less risky, and require more diversification where risk is greater. The fundamental difference between the two methods is the source of the risk assessment: the quality assigned by the ratings agencies or the spread assigned by the market. There are advantages to each.

Market weight limits based on credit ratings are very well suited for specifying the investment policy for a particular mandate. A permitted position is easy to identify and not subject to debate. Furthermore, as ratings change rather slowly, the guidelines are stable, and the manager is not forced to churn the portfolio as markets move.

Conversely, spreads can react more quickly to market events. As a particular issuer deteriorates in credit quality, the spread-based indicator will typically register that risk has increased much faster than the ratings-based indicator. Nevertheless, while this may be a clear advantage as far as measuring risk, it is not so clear that it is desirable to require managers to transact on price gyrations; the cost of such a policy could be prohibitive. A strict cap on DTS exposure would have the disadvantage of making the limits dependent on pricing, and could lead to inefficient forced selling.

Consider, for example, a strict implementation of a policy that limits DTS contributions. Suppose we restrict the maximum DTS contribution to any issuer to be 3.0, and that the manager establishes a 0.5% position in issuer XYZ with a spread of 100 bps and a duration of five years, for a DTS contribution of $100 \times 5 \times 0.5\% = 2.5$. If the spread widens out to above 120 bps, the manager would then be required to sell off some of the position to stay within the limits. This simple example highlights a number of difficulties with this arrangement. First, pricing uncertainty can make it unclear whether a given position is within the guidelines or not. Second, the need to adjust positions as spreads change represents both an undue hardship for managers and an increase in transaction costs for investors.

Another difficulty with a policy based exclusively on DTS contributions is that it can potentially allow very large exposures to short-dated corporates. While the risk of such a position may not be large in terms of spread volatility or excess return volatility, it is clearly undesirable from a tail-risk point of view. A prudent approach to tail risk is to limit the overall portfolio exposure to any single event.

Nevertheless, it is hard to ignore the evidence that credit ratings do not always present the full picture. The broad-brush treatment that allows the same position size for all A-rated issuers, even while large differences in spreads exist across this peer group, clearly leaves room for improvement. There is no question that incorporating information on issuer DTS contributions gives an improvement in our ability to estimate issuer risk. The difficulty is in setting up rules or guidelines that can incorporate this information without requiring unreasonably high turnover. With some ingenuity, it might be possible to reap the benefits of DTS-based risk controls without imposing too much of an operational burden. For example, one could establish a two-tiered constraint with different thresholds for new and existing positions. For instance, in the above example, if the DTS contribution limits were set at 3.0 for new purchases and 4.0 for existing positions, the XYZ position would remain within the guidelines unless the spread widened out from 100 to beyond 160. Presumably, the requirement to reevaluate the exposure to an issuer after a spread move of this magnitude would not be perceived as overly intrusive.

A more difficult challenge for a system of limits on issuer DTS contributions would be a generic rise in corporate spreads as was seen in 2008. In this crisis environment, it is likely that virtually every issuer in the credit portfolio would exceed the previously established caps on issuer exposures. Would we want to force managers to massively rebalance the portfolio into a market with no liquidity?

In general, forced selling is undesirable, and should be avoided whenever possible. We have conducted empirical studies of the performance impact on corporate bond indices of the forced selling of bonds downgraded to below investment grade.[27] These studies show that investors would be better served by holding on to "fallen angels" well beyond the downgrade, as on average they tend to eventually recoup the overly large losses that they experience as IG managers are forced to sell all at once. How might these results apply to a policy of selling upon a spread widening, even without any change in ratings? This is not at all clear. One might argue that this could help reduce the losses from eventual downgrades, or, conversely, that this would just serve to lock in losses in many bonds that will recover immediately and never suffer a downgrade. Generally, a momentum strategy like this one will do well in trending markets and poorly in choppy markets.

Even when DTS limits are in place, one would probably want to include a hard limit on market value weights, to make sure that no truly large concentrations exist in the portfolio, even in very short-dated or low-spread securities.

---

27. Kwok Yuen Ng and Bruce Phelps, "Capturing Credit Spread Premium: Alternative Benchmarks for Credit Investors," *Barclays Research* (June 2010). This article traces the effect on credit index excess returns of rules that drop bonds immediately after downgrades to high yield. Indices and other forced sellers incur significant losses on such bonds but never enjoy the benefits of a subsequent recovery. Also see Arik Ben Dor and Zhe Xu, "Fallen Angels: Characteristics, Performance and Implications for Investors," *Journal of Fixed Income*, Spring 2011. This article studies the price dynamics of fallen angels over a three-year period around the downgrade date.

In short, we would recommend that for specifying hard limits on issuer exposures within a portfolio mandate, plan sponsors should retain the time-honored tradition of market-weight limits. However, we also believe that managers should track and control the DTS exposures to issuers, and ensure that no single exposure grows too large. Rather than implementing this rule via a hard cutoff beyond which sales would be mandated, managers should have a roughly defined upper limit for issuer DTS exposures and use their judgment in managing these exposures according to market conditions.

MODELING: CALIBRATING CREDIT RISK FACTORS

Many portfolio managers rely on multifactor risk models to help them measure and control portfolio risk, either in absolute terms or relative to a benchmark. The DTS approach is ideally suited to estimate spread risk in such models. For example, a risk model might contain modules for measuring exposures to three different types of adverse credit events: systematic changes in spreads, either market-wide or across a particular sector; issuer-specific spread changes; and defaults. The use of DTS can improve the modeling of the first two of these three types of credit risk.

Exposures to systematic changes in credit spreads in a particular market segment can be measured as the sum of the DTS contributions of all portfolio investments within that segment. The risk factor that relates to these exposures is a relative shift in spreads across the sector—for example, that all financial spreads increase by 10% of their current levels. The alternative to this, in a model not based on DTS, would be to assume that the risk factor is a parallel shift in spreads across a sector (e.g., all financials widen by 10 bps)—and that the exposures are therefore contributions to spread duration. Thus, in the DTS-based model, the key risk factor volatility for a particular sector would be its estimated volatility of relative spread changes, as shown in Equation 53-4 earlier in this chapter, while the alternative model would estimate the volatility of absolute spread changes as per Equation 53-3.

The DTS-based approach offers three distinct advantages. First, it offers a better assessment of the relative risks of different portfolios. If two portfolios have the same market weight and average spread duration in a given sector, but portfolio A implements this allocation with higher-spread assets than portfolio B, only the DTS-based model will correctly show that portfolio A has a greater exposure to a widening across this sector than does portfolio B. Second, the DTS-based approach improves the accuracy of the risk projection by reducing the uncertainty in the estimation of risk factor volatilities. As we have seen, relative spread volatilities are much more stable than absolute spread volatilities. Therefore, even if we do continually update our estimates of relative spread volatilities within each sector, we find that they change much more slowly than the corresponding estimates of absolute spread volatility and that they are less sensitive to the choice of the time window used in this estimation process.

The third advantage offered by DTS is perhaps more subtle, but it opens the door to the most profound change in the structure of the model. Up to this point, we have discussed the exposure to "a given segment of the market" in the abstract, without specifying exactly how the market is to be partitioned. However, choosing the partition along which to measure systematic exposures is one of the most critical elements of risk model design, involving careful trade-offs among various goals. It is desirable to limit the model to a small number of intuitive factors, both to maximize the clarity and practical applicability of the risk reports produced and to ensure that a sufficient number of bonds is available to accurately calibrate each risk factor. Conversely, it is important to include enough factors to achieve sufficient explanatory power. For example, a single risk factor that measures portfolio exposure to U.S. corporates would measure the effect on the portfolio of a potential rally or decline across the corporate bond universe, but not the effect of a relative widening of financials versus industrials. We would like to partition the universe finely enough to capture all major sector rotation effects.

When constructing a model of systematic spread risk for U.S. corporates prior to the introduction of the DTS model, we partitioned this universe into a sector/quality grid, using nine industry groups and three levels of credit ratings for a total of 27 risk factors.[28] The partitioning by quality was made absolutely necessary by the assumption that the systematic spread movement in a given market cell tends to take the form of a parallel shift in spreads. When we calibrated such a model to market data, we found that the volatility of absolute spread changes for Baa financials was much greater than that of Aa financials. Although the risk factors representing these two cells might be highly correlated, the substantial difference in volatilities precluded us from combining these cells.

If we instead assume that the spread change across an industry is a relative shift, we find that we no longer need to segregate our model by credit quality. The fact that Baa financials tend to have greater risk than Aa financials is reflected in the higher spreads; this will show up in the risk model as a larger exposure to the same risk factor based on relative spread volatility, rather than as an exposure to a different risk factor with greater (absolute spread) volatility. This puts the risk model designer at a great advantage with regard to the tradeoff between compactness and explanatory power. The model can be designed with roughly the same explanatory power as before using a much smaller number of risk factors, or we can use a finer industry breakdown to create a model with a similar number of factors but greater explanatory power. We have chosen the latter approach in our modeling efforts, increasing the level of sector detail to recognize 27 distinct industry groups.[29]

28. "The Global Risk Model: A Portfolio Manager's Guide," chapter 26 in Lev Dynkin, Anthony Gould, Jay Hyman, Vadim Konstantinovsky, and Bruce Phelps, *Quantitative Management of Bond Portfolios* (Princeton, NJ: Princeton University Press, 2007).

29. A detailed exposition of a multifactor risk model in which credit is modeled using the DTS approach may be found in Chapter 50 of this volume.

THE TERM STRUCTURE OF RELATIVE SPREAD VOLATILITY

We have shown conclusively that DTS is the best single metric available for measuring the overall exposure of a portfolio (or sector allocation) to systematic changes in credit spreads. We have further demonstrated that the success of the DTS paradigm is rooted in the stability of relative spread volatility compared to absolute spread volatility. However, mathematical models do not strictly govern the behavior of financial markets; they merely aim to establish a framework for guiding portfolio managers through whatever turbulence the next market swing may bring. Hence, if we directly measure the relative spread volatility of different segments of the corporate bond market over different time periods, we find that it varies—over time, across industries, and by maturity.

In a study focused on the dependence of relative spread volatility on bond maturity,[30] we found that relative spread volatility tends to be higher for shorter-maturity corporate bonds and lower for longer-maturity bonds. This effect was confirmed independently using data from both corporate bonds and from CDS in both U.S. and European markets. For example, using monthly data from 2006 through 2012, we found that compared with the relative spread volatilities of 5-year CDS, those of 10-year CDS are 20% lower, on average, and those of 3-year contracts are about 20% higher, on average. In bond markets, where a coarser approach to maturity partitioning is appropriate, we similarly find that relative spread volatilities in longer maturities (5–10 years) are about 20% lower than in shorter maturities (1–5 years).

One possible explanation that could be consistent with these observations is that the concept of relative spread shift applies more precisely in the cross-sectional dimension than along the term structure. A perception of increased risk in a sector is accompanied by a widening of spreads across the sector, with issuers at wider spreads widening by more. However, the issuer curve of any given issuer may move in a manner closer to a parallel shift. Thus, if issuer A trades at twice the spread of issuer B (at the same maturity), we should expect it to have twice the spread volatility as well; however, if the 10-year spread is double that of the 2-year spread within a single issuer curve, the implications for volatility may be different.

In a portfolio context, these conclusions are highly relevant for managers who take large active positions along the credit curve. In particular, if one seeks to match the sector exposures of a broad index by using only short-maturity bonds, leveraging the position to match the DTS contributions of the index, the resulting portfolio will tend to be over-hedged. For such a manager, a refinement of the DTS approach may help produce a more accurate hedge. We suggested several approaches to this problem, offering differing levels of accuracy and complexity.

30. Jay Hyman, Anando Maitra and Simon Polbennikov, "Term Structure Effects in Relative Credit Spread Volatility," *Barclays Research* (October 2012).

However, for managers who do not actively impose a maturity bias of this nature in their portfolios, we presented evidence that it should be sufficient to manage the net DTS contributions to each sector as long as the overall maturity profile of the portfolio remains in line with that of the index.

KEY POINTS

- Spread volatilities—both systematic and nonsystematic—tend to be proportional to spreads. This empirical observation, with theoretical backing, has many applications to credit portfolio management.
- Forecasts of spread volatility that combine long-term historical estimates of relative spread volatility with current spread levels are more accurate than historical estimates of absolute spread volatility, and quicker to adapt to changing market conditions.
- Estimates of market beta based on DTS ratios form better projections of future market beta than those based on past observations of empirical market beta.
- Matching index exposures to DTS is a better way to form index-replicating portfolios than matching exposures to market weight or contributions to spread duration. For active managers, credit sector overweights and underweights should be specified and implemented in terms of DTS exposures.
- Measuring and controlling DTS exposures to individual issuers can be viewed as an alternative or a supplement to issuer limits based on market weights and credit qualities.
- Portfolio risk models for fixed income can improve model accuracy and robustness by incorporating the DTS approach to project the risk entailed in both systematic sector overweights and in portfolio concentrations in individual issuers.
- DTS provides an excellent first-order risk estimate. However, direct measurement of relative spread volatilities reveals that these are somewhat higher for shorter maturities than for longer ones. This should represent a second-order effect in most portfolios, but must be considered when leverage is used to magnify term structure exposures.

CHAPTER
FIFTY-FOUR

CONSTRUCTING AND MANAGING HIGH-YIELD BOND PORTFOLIOS

Nicholas R. Sarchese, CFA
Senior Vice President
Portfolio Manager
Shenkman Capital Management, Inc.

Mark R. Shenkman
Founder and President
Shenkman Capital Management, Inc.

High-yield portfolio management involves the art and science of matching a portfolio's investments to its underlying objectives and overall risk profile. The focus is to balance risk against performance with the goal of achieving superior risk-adjusted returns over an entire credit cycle. From a portfolio management perspective, the high-yield market is a unique asset class due to the fact that high-yield securities exhibit the characteristics of both debt instruments and equities. Given the greater risk associated with highly levered companies, changes in the underlying fundamental credit profile are the primary driver of return over time as default loss is a key concern. However, as part of the fixed income asset class, debt attributes of the security, such as coupon, maturity, covenants, and ratings, also affect prices and performance.

High-yield bonds offer significant incremental return and income as compared to most other fixed income investments. However, it is essential to keep in mind their asymmetrical risk profile. That is, a bond's upside is generally limited to its face value at maturity or early redemption premium, while the downside could include an entire loss of principal in a default. In order to capture the attractive incremental returns and spreads offered by investing in high-yield bonds, minimizing default and credit loss are critical components to achieving this goal.

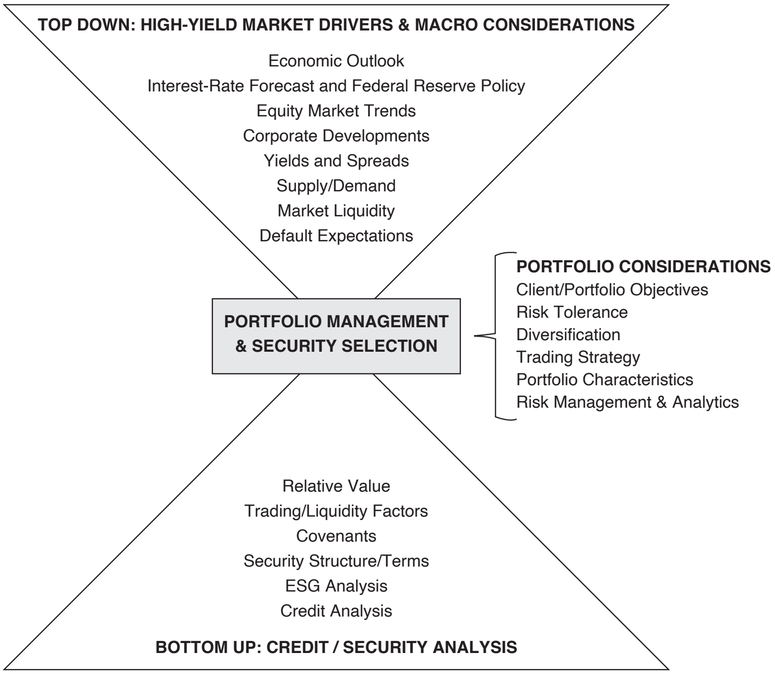
Properly assessing and managing risk is a critical element of managing a high-yield portfolio. Risk controls require developing insightful, comprehensive procedures to identify and control risk across the following three key areas:

1. Bottom-up credit/security analysis
2. Top-down high-yield market drivers and macro considerations
3. Portfolio considerations

Exhibit 54-1 identifies these three areas and highlights the elements to consider. The most successful portfolio managers have the ability to assimilate all three areas as the intersection point is the nexus of the portfolio decision-making process. Each of these areas and their elements are discussed in further detail below.

EXHIBIT 54-1

Constructing and Managing High-Yield Bond Portfolios



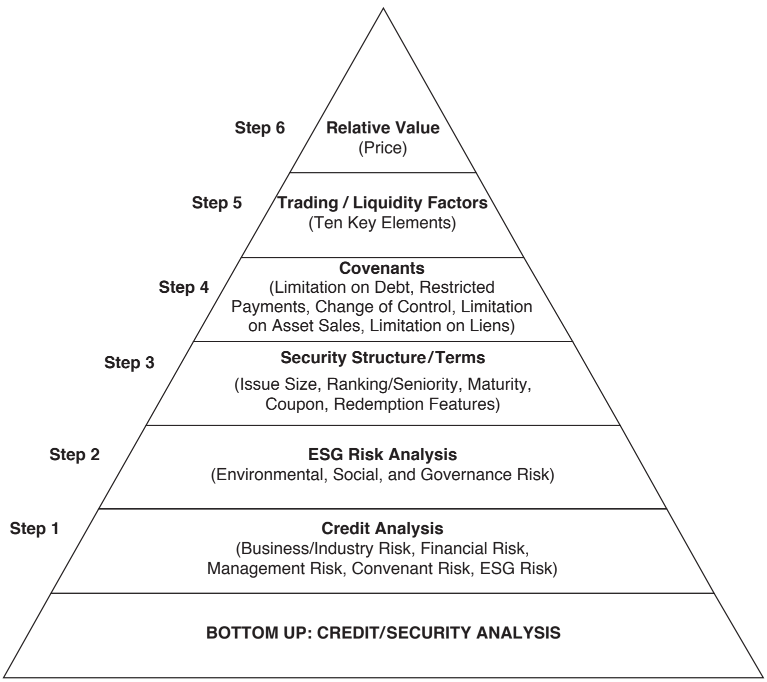
Over the long term (and through various economic cycles), portfolio managers who have avoided defaults and major trading losses have typically outperformed various high-yield benchmarks.

BOTTOM-UP CREDIT/SECURITY ANALYSIS[1]

While credit analysis is arguably the most important component of a bottom-up investment process, security structure/terms, covenants, trading liquidity factors, and relative value ultimately determine if a "good credit" will make a "good investment." Poor relative value or overpaying for a good credit could lead to underperformance. Weak trading liquidity factors can magnify the downside and disrupt the value equation in a negative surprise scenario. In executing a buy/sell decision, a step-by-step process is required to ensure consistent and disciplined decision-making. Exhibit 54-2 highlights the six steps in analyzing a high-yield credit. A checklist of positive and negative attributes should be utilized at each step. It is also important to emphasize that all of the bottom-up steps are significant in their own right. A favorable assessment on many of the steps may not necessarily outweigh an individual risk component that is identified in the process.

EXHIBIT 54-2

Six Steps in Bottom-Up Credit/Security Analysis



1. This section is adapted from Nicholas Sarchese and Amy Levine, "Credit Analysis and Analyzing a High-Yield Issuance," chapter 7 in William F. Maxwell and Mark R. Shenkman (eds.), *Leveraged Financial Markets: A Comprehensive Guide to High-Yield Bonds, Loans, and Other Instruments* (New York: McGraw-Hill, Inc., 2010).

Step One: Credit Analysis

Thorough credit analysis is ultimately the foundation for a successful high-yield investment. A greater investment risk is getting the credit analysis wrong as opposed to potentially overpaying for a sound credit. It is important to keep in perspective that the high-yield asset class involves highly levered companies that have disproportionately less margin for error. The asymmetrical upside/downside return profile of bonds also highlights the importance of avoiding meaningful downside credit risk. In practice, the underperformance related to overpaying for a good credit pales in comparison to the ultimate downside in holding the bonds of a credit that defaults. Remember that a bond's upside is limited to par (plus perhaps an early takeout premium), while the downside is theoretically zero. If a bond drops from par to 50, it would take 10 bonds to advance five points each in order to recoup the 50-point decline in just one credit! Equity portfolios do not have this similar dynamic because one investment can soar by 500%, thereby offsetting the losses in numerous other transactions. However, the number of bonds in a portfolio that can jump five points or more may be limited.

Credit analysis can be simply defined as determining the borrower's ability to meet its interest and principal obligations when due. It is often identified with financial ratio analysis. However, true credit analysis is much more comprehensive and encompasses greater in-depth review. For example, two credits with identical financial ratios may not represent the same credit risk. As outlined in Exhibit 54-3, credit analysis can be divided into five key areas: business risk; financial risk; management/ownership risk; covenant risk; and environmental, social, and governance (ESG) risk.

Thorough credit analysis is not complete without a detailed examination of all five risk factors. Weakness in any one of the five areas could offset the strength in the remaining four and result in high credit risk for a particular issuer (see Exhibit 54-4).

EXHIBIT 54-3

The Five Key Components of Credit Analysis

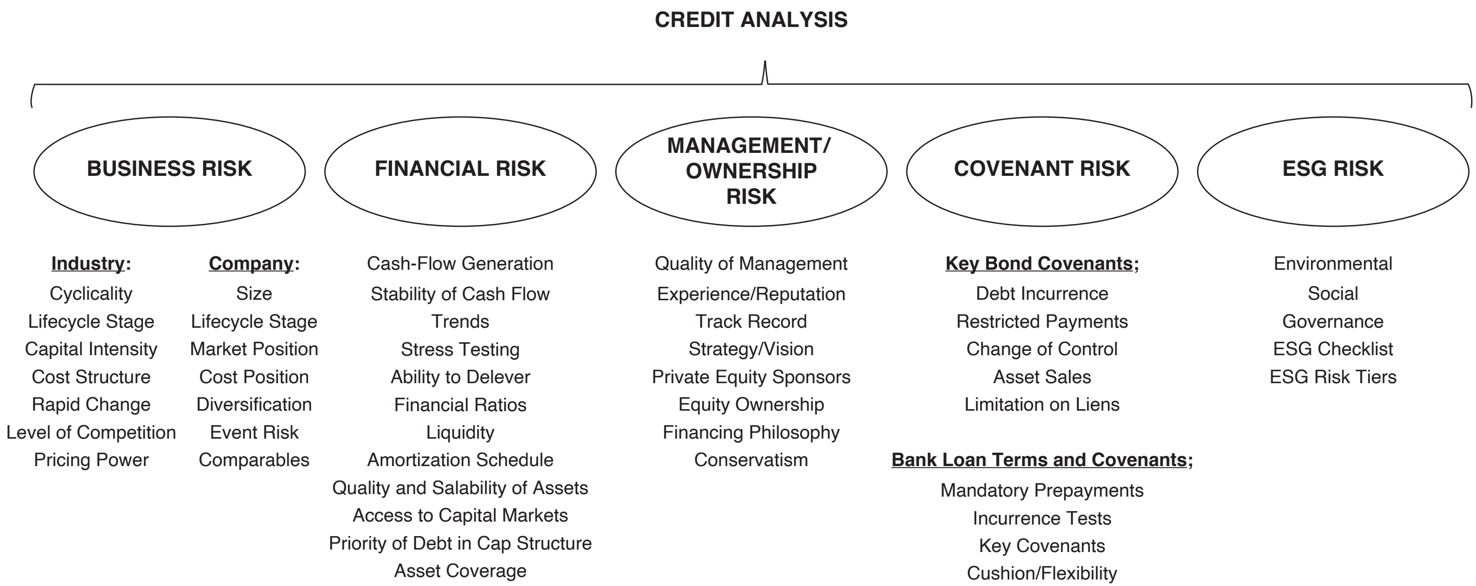


EXHIBIT 54-4

Credit Analysis Examples

Examples include:

Strong Financial Profile + Strong Management + Strong Covenant Protection + Strong ESG Profile

The issuer may not be able to offset a high business risk where the industry structure is unfavorable and the company is weakly positioned

Strong Business / Industry Fundamentals + Strong Financial Profile + Reasonable Covenant Protection + Strong ESG Profile

The strengths may not be able to offset the negative impacts of a weak management team with aggressive financial policy – OR – Bondholder unfriendly private equity sponsor

Strong Business / Industry Fundamentals + Strong Financial Profile + Strong Management + Strong ESG Profile

The strengths may not be able to offset the negative impact of a weak covenant package

Strong Business / Industry Fundamentals + Strong Management + Strong Covenant Protection + Strong ESG Profile

The strengths may not be able to offset the financial risk of a company that is overlevered

Strong Business / Industry Fundamentals + Strong Financial Profile + Strong Management + Strong Covenant Protection

The strengths may not be able to offset the ESG risk of a company with pollution concerns and potential for significant related liabilities and backlash.

Investors must focus their analysis on a "forward looking" view of all five risk areas. While historical results are important for perspective, ultimately it is the future credit trend that may dictate performance.

Business Risk

Analyzing the business risk of a particular credit involves an assessment of both the (1) industry risk and (2) company-specific risk from more of a strategic perspective. This analysis should involve not only determining whether the industry structure and fundamentals are favorable, but what is the company's strategic position within its industry. Even the best company in a given industry may not be able to withstand major structural or technological changes.

Industry Analysis. High levels of debt can be manageable and appropriate for certain industries but not others. Some industries are more conducive to leverage because their high operating margins, solid growth rates, and consistency of earnings enable the companies within the sector to service a higher degree of indebtedness. Factors used to assess an industry include stability of cash flows, stage in industry lifecycle, capital intensity, cost structure/operating leverage, degree of technical or demographic changes, competitive forces, regulation, and pricing power. In addition to providing an enhanced credit profile, industries that possess more favorable outlooks also tend to trade better because of positive macro considerations and investor support.

Company Analysis. In assessing an industry, it is imperative to dissect a company's specific strengths and weaknesses and determine how it fits into its industry. For example, a company can operate in a growing industry but possess obsolete technology. Conversely, a company can compete in a declining industry but have a leading market position and generate significant cash flow. There are several factors to consider:

- Size of the company
- Stage in company lifecycle
- Market position
- Diversification
- Potential for event risk

All of these factors can impact the creditworthiness of the borrower.

Financial Risk

After assessing an industry and company's business risk, the next step is to consider the overall financial risk and credit profile of the borrower. This consideration should take into account the company's capitalization and degree of leverage. The fundamental operating outlook and credit profile of a company are critical variables that should drive bond performance. Moreover, a thorough analysis must evaluate the past financial results to understand the drivers of the business.

Key variables to financial risk include:

- The stability of cash flows
- Recent and near-term projected performance trends
- Stress testing (how well a company's credit profile can withstand negative surprise)
- Analysis of free cash flow and the ability to de-lever
- Leverage and coverage statistics
- Cash and available liquidity
- Amortization/maturity schedule
- Quality and salability of assets
- Access to capital markets
- Asset coverage

Management/Ownership Risk

While factors relating to credit analysis are crucial, the owners and senior management of the company are responsible for establishing goals, objectives, and strategic vision for the business. In the end, a great management team can make a significant difference in the performance of a security.

Direct Communications. Portfolio managers or research analysts should have direct contact with senior management (i.e., one-on-one meetings or calls, company visits, etc.). Direct access is the best way to understand and evaluate management and can provide greater insight into the risk parameters for a specific issuer. Moreover, analysts should maintain an ongoing dialogue with company managements. During times of duress, if management is inaccessible, investor confidence in the company could be shaken, and the bonds may underperform.

Quality of Management. The quality of the senior management team is significant in making a sound investment. While successful companies must pursue effective strategies, development and execution of those strategies hinge on the management team in control. Although management assessment is somewhat subjective, and improves with experience, the best qualities to look for in a management team include: low turnover, tenure and reputation within the industry, strong track record, timeliness in filing financial statements, forthrightness in responding to questions, strategic vision, a deep bench, and successful completion of stated goals. Great business leaders are able to effectively communicate the company's strategy and vision, articulate the opportunities and risks confronting the company, and act decisively and proactively in times of change.

Private Equity Sponsors/Ownership. Oftentimes, a highly levered company may be owned by a private equity sponsor. In these cases, the equity sponsor drives the company's strategic direction and financial policies, while the operating senior management (i.e., CEO, COO, CFO) usually have less influence in the overall direction and financial risk tolerance of the company. It is always important to keep in mind that the interests of the private equity sponsor in many cases may not align with bondholders. For example, sponsors may declare a large cash dividend as quickly as possible to enhance their equity returns, although this action may lead to deterioration in the company's credit quality. If the sponsors have little capital at risk, they could try for a "swing for the fences" type strategy since they have little downside (having taken their invested capital out) but significant upside if the strategy pays off. This "no capital at risk" strategy is not ideal for bond investors as the company may have little capital cushion, particularly in a faltering economy. The sponsor's investment track record, default history, and record in paying down debt should be carefully examined. Another factor is the percentage of equity owned by the management team. If equity ownership is spread throughout management, they are more likely to be deeply engaged in the success of the overall enterprise.

Financing Philosophy. Investors must consider both the ownership's and management team's intentions regarding the company's balance sheet. Is management comfortable operating with high levels of debt and leverage, or are they more conservative and prefer to have more financial flexibility and lower leverage? Is management comfortable with the current amount of debt, or is debt pay down a key priority? How committed is management to paying down debt? Is management opportunistic in that they would consider making an attractive acquisition even if it involved meaningfully increasing the financial risk profile of the company? If the management team is comfortable with the current level of debt, they might focus on using cash flow toward paying dividends, share buybacks, or funding additional acquisitions. If debt pay down is a key priority, and the company generates a large amount of free cash flow, the issuer's credit metrics are likely to improve. Knowing management's philosophy toward debt is of vital importance in forecasting the company's credit profile as it will serve as a guide toward the application of free cash flow. Knowing management's philosophy is vitally important in order to judge their success in achieving previously stated goals as well as their credibility. For example, if the management team has stated its intention to de-lever and then initiates a large stock buyback, the bonds are likely to underperform as the "credit story" has not met expectations, and investors may have diminished confidence in senior management.

Covenant Risk

A detailed examination of covenants should be a critical focus of credit analysis. Although each tranche of debt may contain its own specific debt covenants, collectively they impact the borrower's overall credit risk profile and financial flexibility. Evaluating the collective impact of all of the company's covenants (bank loan as well as bond covenants) is important in understanding the overall credit risk of a company. The presence of a strong covenant package may have significant influence on bond performance. In certain cases, limited covenant flexibility may improve the overall credit profile of the company because it could create the opportunity for early redemption at a premium or limit increases in financial risk. Conversely, there are cases where limited covenant flexibility may prove to be a significant risk to a borrower's credit profile as it could force a liquidity event at an inopportune time in the credit cycle. Covenants are covered in further detail as part of step three, below, as the analysis of an individual security.

Environmental, Social, and Governance (ESG) Risk

Incorporating environmental, social, and governance factors into a thorough analysis strengthens the ability to assess the downside risk of credit investments. These issues are increasingly relevant because a growing portion of a firm's enterprise value lies in intangible assets, and many ESG factors relate to intangibles that are often not reflected in traditional financial statements and disclosures. Investors are increasingly applying these nonfinancial factors as part of their analytical process to identify material risks and growth opportunities.

While elements of ESG risks are already captured in the other previously outlined credit analysis components, including business risk (industry and company) and management/ownership risk, an ESG lens provides an extra tool for analysis. As stakeholders increasingly focus on these issues, ESG risks are increasingly becoming a more significant influence within a company's overall risk profile. Credit analysis is essentially incomplete if it ignores material ESG factors. ESG analysis is covered in further detail as part of step two, Environmental, Social and Governance (ESG) Risk Analysis.

Step Two: Environmental, Social, and Governance Risk Analysis

While environmental, social, and governance factors have always existed and percolated as more prominent risk factors for select companies and industries over time, collectively these risks have increasingly become a more visible and influential consideration for all companies and their overall fundamental risk profile. Managers that ignore these factors do so at their own peril as increased disclosure is demanded and investors, society, governments, and financial markets across the world continue to place greater emphasis on other important factors beyond near-term financial profitability and earnings trends. As part of a sound investment process and credit analysis, managers need to consider all meaningful risks, including those related to ESG, that may have an impact on a company's future prospects, operating performance, or valuation.

Defining ESG

ESG stands for Environmental, Social, and Governance and refers to the three key factors when measuring the ethical impact, hidden costs, and sustainability of a business or company. These factors are commonly used to evaluate the behavior of companies, as well as to help influence their future financial performance or valuation.

Environmental. Environmental criteria consider how a company performs as a steward of our natural environment as well as how climate change could impact the company.

Examples of environmental issues that should be considered include:

- Waste management and pollution
- Compliance with environmental regulations
- Greenhouse gas emission
- Resource depletion
- Climate change impacts
- Renewable energy

Social. Social criteria examine how a company treats people and manages relationships with employees, suppliers, customers, and the communities and local areas where it operates.

Examples of social issues that should be considered include:

- Employee relations & diversity/discrimination
- Workplace health and safety
- Labor standards across the supply chain
- Relations with local communities and customers
- Activities in conflict zones
- Data security and privacy

Governance. Governance deals with the company's leadership, how it polices itself, and how it is governed.

Examples of governance issues that should be considered include:

- Board composition and independence
- Audits and internal controls
- Stakeholder/shareholder relations
- Executive compensation
- Political contributions and lobbying
- Corruption and bribery

ESG Risk Analysis Integration

Formulating a formal ESG Policy is helpful to ensure that the investment process considers whether ESG factors are relevant to an investment, how to thoroughly assess these risks, and in what way to consider whether the factors could ultimately have a financial impact. Certain ESG issues can have a more direct impact on profitability, cash flow, and an issuer's ability to pay back debt in a timely manner and should already be a critical part of any investment analysis or research process as opposed to a "stand-alone" evaluation.

Examples of existing fundamental credit analysis that should already consider ESG variables include:

- An assessment of company and industry specific risk factors
- Proprietary financial models and stress tests to quantify impact of risk factors
- An assessment of company leadership and management track record

For example, an assessment of company and industry specific risk factors could focus on proposed environmental regulations that would have a detrimental impact on operations and model its impact on a company's credit profile. This could include considerations such as a material loss of revenues, a meaningful increase in cost structure, a significant increase in capital expenditures to meet compliance, or a substantial need for additional funding. As another example, an assessment of company leadership and management track record could focus on the private equity sponsor's pattern of aggressive and unfavorable actions toward bondholders.

Developing an ESG checklist with more specific factors for companies can be an invaluable risk assessment tool. Such checklists would not only highlight the more immediate and pressing ESG concerns already identified in traditional analysis, but can also serve as a vital screening tool to systematically identify and inventory a more comprehensive list of potential ESG risks. A comprehensive checklist of ESG considerations can include many of the examples mentioned in the section above defining each of the ESG factors. While managers may select outside vendors to aid in their ESG analysis, most services are heavily focused on companies with public equity. As a result, there is still incomplete data with the leveraged finance market and its private companies. Some observers have also noted inconsistency among different vendor results for the same issuer.

For those investors that choose to develop a proprietary approach, the analytical process should include a thorough review of the issuer using public information; financial statements; meetings with senior management; access to sell-side research; and, in some cases, discussions with competitors, vendors, customers, and industry contacts. It is the responsibility of credit analysts to identify and monitor ESG factors that may be impactful to a potential or existing investment. As part of the regular due-diligence process, the analyst should populate an ESG checklist that forms the basis for further analysis on key risks or opportunities related to specific ESG issues. Aside from specific ESG concerns considered, the resulting overall ESG risk tier can be an additional datapoint in assessing the risk and relative value of an investment.

Socially Responsible Investing (SRI)

No discussion of ESG is complete without mentioning the related concept of SRI. While ESG investing focuses on how environmental, social, and governance factors might affect the fundamentals, performance, or valuation of a particular company, SRI investing involves avoiding a particular investment in a company because it does not meet one's standards for making positive social impact. An example might be avoiding investments in companies that produce or sell addictive substances (e.g., alcohol, gambling, and tobacco). SRI investing can be implemented in various ways but is generally most commonly seen via custom-tailored, separately managed accounts with specific client-determined restrictions or a specially focused fund or portfolio with a socially responsible objective and investment restrictions.

Step Three: Security Structure and Terms

A key consideration of a particular bond investment is its terms and structure. Most investors tend to favor bonds that possess terms and structure that are in line or better than market standard. However, as terms evolve and change with market conditions, portfolio managers must understand the implications and risks associated with alternative structures, and if acceptable, ensure that they are compensated appropriately.

The following factors must be carefully evaluated:

- Issue size
- Ranking/seniority
- Maturity
- Coupon type
- Early redemption features

Issue Size

The issue size of a bond will influence its liquidity and general attractiveness to other constituents in the market. For example, an issue size that is less than $300 million will most likely have a smaller investor base and therefore less trading liquidity. To the extent there is a seller of this security, the downside impact to the market may be greater given the lower trading liquidity and a narrower universe of investors willing to purchase a small, less liquid security. Conversely, much larger issues (greater than $1 billion issue size) may experience greater price volatility. As they tend to be liquid "benchmark" issues in the high-yield market, they may exhibit higher beta during aggressive movements in the overall market as exchange-traded funds (ETFs) and institutional investors are able to more easily execute trades and express their market sentiment.

Ranking/Seniority

The ranking and seniority of a bond are vital factors in assessing the risk and attractiveness of a security. Ranking and seniority refers to the location of the bond within the issuer's capital structure as well as the priority of claim in the event of bankruptcy. The ranking and seniority range from and include senior secured, senior secured second-lien, senior unsecured, senior subordinated, subordinated, and structurally subordinated. The more senior securities in the capital structure are generally accompanied by lower relative yields. Additionally, investors must ascertain the level of guarantees provided and where the tranches of debt sit relative to the assets of the company as well as the ranking within the capital structure. Portfolio managers should properly identify the risk associated with the ranking/seniority terms of the specific security so that they can determine the appropriate yield.

Maturity

A bond's maturity involves both technical and credit considerations. From a top-down perspective, an investor may be concerned with a significant rise in interest rates and, therefore, favor a shorter maturity option within a given capital structure. From a bottom-up perspective, an investor may be comfortable with the short-term prospects and liquidity for a given credit, but much less comfortable with the longer-term viability of the company and, therefore, favor a shorter maturity option within a capital structure with multiple maturities. Demand for shorter maturities (five years or less) has grown due to the proliferation of dedicated short duration high-yield strategies. The short duration market has also led to a growing trend in primary issuance of bonds with final maturities of five years. High-yield bonds have most commonly been structured with final maturities of between 7 and 10 years, with 8-year maturities more recently being the most popular tenor. On occasion, issuers have also come to market with longer maturities of between 12 and 15 years to take advantage of the low-interest-rate environment. While these bonds can provide greater upside for improving credits and periods of yield compression, these longer maturity terms may sometimes lead to greater price volatility given the potentially smaller investor base interested in a "nonstandard" bond.

Coupon Type

While the high-yield market consists primarily of cash-pay bonds, alternative structures also exist, including zero coupon, pay-in-kind (PIK), or PIK toggle. While the alternative structures tend to offer higher yields as a result of the less investor-friendly repayment terms, they also typically possess greater trading liquidity risk as they tend to appeal to a much smaller investor base within the high-yield universe. Such bonds are generally indicative of higher risk companies that may require the flexibility to grow into their capital structure. Bonds with coupon-steps triggered by credit rating changes are also an alternative structure that can sometimes be seen in the high-yield market and are generally a result of fallen angel issuers that were originally investment-grade rated and subsequently downgraded to high yield. These coupon steps are triggered by a downgrade in credit ratings from the time or original issuance, providing a specified incremental coupon (e.g., 0.25% per rating notch) to help compensate investors for the deterioration in credit quality. While this feature can be an attractive offset in certain situations where credit ratings are deteriorating, they must also be carefully evaluated as the coupon-step will also adjust coupons lower when ratings are being upgraded, limiting the return and potential appreciation in bond price.

Early Redemption Features

Early redemption features are common within the high-yield market. For example, the most typical bond structures are eight-year, noncall 3. This type of security is not callable for the first three years of its life, but then is callable at the company's option and according to a schedule that pays a premium to face value that declines as it nears final maturity. There has also been a growing trend in issuers coming to market with less call protection in exchange for little-to-no additional premium. Portfolio managers must be careful in evaluating early redemption features that may have a significant impact on returns as they can limit a bond's potential upside. Conversely, having additional insight as to when a bond is most likely to be called can also present upside yield opportunities for more savvy investors. This concept is further explored in step six, Relative Value: Short Duration Callable Bond Analysis.

Step Four: Covenants

Contained within the indenture of all high-yield bond offerings are certain covenants (or agreements) between the issuing company and bondholders. Covenants are essentially restrictions on the borrower/issuer imposed by the lender/bondholder that require the company to do, or refrain from doing, certain activities. Covenants are primarily designed to protect bondholders by limiting the ability of the company to take actions that could lead to credit deterioration that would hinder the company's ability to service the interest and repay the obligations on a timely basis.

Covenants are often referred to as "tight/strong" or "loose/weak" depending on the specific terms and ultimate financial flexibility they provide the issuer. A weak covenant package can significantly increase the risk of a high-yield bond investment, even though the borrower's business and financial risk profiles can be strong. As a result, the covenant package may not protect the bondholders by prohibiting enough actions by the issuer that could be detrimental to its ability to repay the bonds and service the interest.

Covenant analysis is a crucial part of any high-yield bond investment process. While a strong covenant package cannot offset the risk of a weak credit, it may provide significant financial protection to the investor. A weak covenant package may not necessarily preclude investment in a particular issue; however, it may increase the return an investor demands due to the higher level of risk.

From an investment standpoint, there are six key covenant elements to analyze, as follows: Limitation on Indebtedness, Restricted Payments, Change of Control, Asset Sales, Limitation on Liens, and EBITDA Add-Backs.

Limitation on Indebtedness

The limitation on indebtedness covenant restricts the amount of additional indebtedness that an issuer can incur. Unless it is kept in proportion to operating cash flow and assets, additional indebtedness can ultimately dilute the claims of the existing bondholders and weaken the credit profile of the company due to the increased debt service requirements.

Restricted Payments

The restricted payments covenant protects bondholders' interests in the assets of the company by restricting the company's ability to distribute money or assets outside the company, thereby preserving the company's ability to repay its indebtedness. Undesirable distributions and asset transfers that are limited by this covenant include dividends, repurchases of equity, investments in unrestricted third parties, and retiring debt that is subordinate to the bonds before retiring the bonds.

It is important to recognize that the restricted payments covenant does not limit acquisitions and capital expenditures, both of which should result in incremental cash flow and return on investment. The test is ultimately backward looking in that it determines whether the company has earned the right to make a payment to benefit the equity of the company as opposed to the debt.

Change of Control

The change of control covenant requires the issuer to offer to purchase the notes at 101% of principal if a change of control occurs. It is the bondholder's option to accept or decline the offer. In effect, this covenant gives a put option to the bondholder upon certain events. The rationale behind the change of control covenant is that it protects bondholders against a change in controlling interest by an owner who may have a different financial strategy for the issuer that could ultimately lead to deterioration in credit quality.

Limitation on Asset Sales

In contrast to its title, the asset sale covenant does not necessarily limit the ability of the issuer to sell assets. Its true purpose is to define the acceptable use of proceeds from asset sales. The proceeds must be used to permanently repay debt or to reinvest in replacement assets. The rationale is that the assets sold usually generate earnings and cash flow to service debt and should be replaced with similar assets.

Limitation on Liens

The limitation on liens covenant is intended to protect the bondholder's seniority position relative to income producing assets and restricts a company's ability to secure future debt with company assets. It protects a bond's place in the capital structure and can support recoveries in the event of default. It is important to analyze and understand the definitions and carve-outs for the liens test given the potential for unexpected, additional secured debt. Unless it is kept in proportion to operating cash flow and assets, additional indebtedness can ultimately dilute the claims of the existing bondholders in recoveries and weaken the credit profile of the company due to the increased debt service requirements.

Addbacks

Addbacks are meant to reflect defined adjustments that are permitted to be added back to reported EBITDA or earnings-based calculations for covenant ratio and test purposes. Although addbacks are not a covenant in and of themselves, they impact the underlying calculations that are a key component for many of the earnings-based ratios and tests, including some described above. In most cases, addbacks are buried within defined covenant terms with the intention of portraying a more normalized earnings figure, exclusive of unusual negative one-time events, or inclusive of the benefit of implemented or expected cost savings. While the intention is constructive, investors must be extra careful of abuses in aggressive addback calculations that can sometimes represent as much as 50% or more of adjusted earnings and provide issuers materially more flexibility than warranted or expected. These aggressive adjustments can be overly generous in their portrayal of one-time events that in practice are more recurring in nature, or exceedingly liberal in anticipating prospective cost savings for which the realization is subject to significant execution risk and uncertainty.

Step Five: Trading/Liquidity Risk

While credit analysis is focused on assessing the financial risk of a particular bond issue, the analysis of trading and liquidity risk evaluates the additional volatility that may be experienced by a bond issue. Trading liquidity can hamper the performance of a bond issue that may possess a favorable credit risk profile, but the far more significant risk is that a poor trading liquidity profile could dramatically magnify the downside risk of a weak credit. It may be already difficult to garner investment interest and new buyers in a weak or deteriorating credit; however, it is considerably more challenging to develop new demand in a weak credit that also possesses poor trading liquidity. For example, a disappointing earnings announcement could result in a 2-point drop in bond price if the issue possesses favorable trading liquidity, whereas the same announcement could result in a 5-point (or greater) drop in price if the bond possesses thin trading liquidity. Portfolio managers should have extremely high conviction level in credits with limited liquidity and require higher returns in those situations.

Liquidity Risk [2]

Liquidity risk involves measuring the ability to sell a particular credit on a timely basis. While equities often trade on an organized stock exchange or electronically where buyers and sellers are matched, high-yield bonds trade over-the-counter. Bond investors are dependent on broker-dealers to make a market. Also, unlike equities, the majority of high-yield bonds do not trade on any given day. An interesting analogy is to think of the high-yield market as being like a lake that is one-mile wide, but only inches deep. If a particular high-yield bond has limited liquidity, portfolio managers may be unable to execute their buy/sell decisions.

Portfolio managers should take into consideration the following key elements to assess the liquidity risk of a particular bond.

1. *Public or private company:* Private companies may possess less liquidity than public companies because there is either not enough information about the company in the market or the information is as easily available to prospective investors. For example, an unregistered

2. This section is adapted from Mark R. Shenkman, "Principles of Managing High-Yield Assets," chapter 12 in *Leveraged Financial Markets: A Comprehensive Guide to High-Yield Bonds, Loans, and Other Instruments.*

bond (e.g., Rule 144A) issued by a private company may require potential investors to undergo a certification process before accessing reported financials, or prohibit sell-side research coverage and prevent them from publishing reports.

2. *Number of market-makers and number of analysts following the issuer:* The fewer professionals on Wall Street who trade or actively "follow" a bond, the less available information on a company. Bond issues that have only one market-maker and no analyst coverage may be so illiquid that they "trade by appointment" (meaning that a seller has to give an order to a broker-dealer who then tries to sell the bond over a period of time).

3. *Number of tranches of debt in the capital structure:* The more tranches, or issues, of debt that a company has outstanding, the higher the probability that more traders and analysts will follow a given credit. A large number of tranches provides more activity in an issuer because there are paired-trade possibilities, such as shorting senior bonds and going long subordinated bonds. The ability to trade across the capital structure in one credit increases the universe of investors interested in the bonds.

4. *Accessibility of management:* Bonds issued by companies with inaccessible management typically inhibit trading activity because investors lack sufficient information to give them comfort or conviction, particularly in volatile markets. If a management team is unwilling to talk when times are good, they are even more unlikely to talk when times are bad!

5. *CDX-listed issuer:* The CDX is a widely traded index of 100 credit default swaps (CDS) that mirrors the broader high-yield market. The CDX, the underlying CDS, and the underlying bonds are all linked by the arbitrage that exists if the CDX becomes too cheap compared to the CDS or the actual bonds. Therefore, underlying bonds of CDS in the CDX tend to trade more frequently because investors may be executing arbitrage trades. Moreover, the price of CDX-listed issues tends to be more volatile because they are the most liquid credits.

6. *Issuer is a major company within its industry:* Bonds of companies that have a real "presence" in their respective industries tend to have more liquidity for two reasons. First, if the underlying company is a major part of its industry, it becomes a proxy for the industry and allows investors to obtain exposure to a sector. Second, high-yield traders typically like to own and trade the largest credits in an industry sector.

7. *Size of issue:* The universe of potential buyers of a bond typically increases with the dollar size of the issue. The larger pool of potential

purchasers increases the ability of a bondholder to sell a particular issuer.

8. *Ratings of issuer and issue:* Higher-rated credits within the high-yield universe tend to trade more frequently because they are perceived as being more stable and have greater demand. Triple-C rated issues generally require more work and conviction to purchase, causing traders to be less willing to hold a bond with higher risk and a smaller universe of eligible investors.
9. *Crossover credits:* Bonds that generate demand from both investment-grade and high-yield buyers, such as utilities, offer greater liquidity. High-yield bonds that are considered crossover companies typically generate a new class of investment-grade purchasers who from time to time dip down and buy the high-yield bond tranche. With a larger universe of such buyers and sellers, liquidity often improves.
10. *Volume of trading activity according to TRACE:* Broker-dealers are required to timely report all high-yield bond trades to a self-regulating organization making post-trade price and volume details publicly available for all market participants to observe. This system is called TRACE (Trade Reporting and Compliance Engine). Providing market participants with timely information about transaction prices and quantities has dramatically increased transparency and visibility on liquidity and transaction costs. A bond's activity levels on TRACE will oftentimes be the most accurate measuring tool of its liquidity given its historical patterns and data points can be easily obtained and measured.

Based on these 10 criteria, with the greatest emphasis on TRACE activity, each credit should be designated as "L1," "L2," or "L3." L1 credits are traded by multiple market-makers on a daily basis and will typically exhibit the strongest liquidity characteristics and most consistent and frequent TRACE activity; L2 names are typically traded by two or more market-makers on a weekly basis and will typically exhibit reasonable liquidity characteristics and TRACE activity; and L3 credits trade a few times per month by one or more market-makers with limited TRACE activity, which can result in an inability to execute on a timely basis. In many cases, an L3 bond can become an "orphan" credit if the original underwriter no longer covers or makes a market in the credit.

The percentage of the portfolio represented by L1, L2, or L3 liquidity ratings should be calculated and monitored to determine the appropriate weighting in each category.

Step Six: Relative Value

Relative value is the final step in the bottom-up security analysis process. Once the credit and liquidity risks of an issue have been determined and evaluated, then the overall expected risk premium for the security can be appropriately established. Spread and yield analysis are typically the most appropriate metrics in determining if the security's return is commensurate with its overall credit and investment risk.

Risk/Reward

Determining relative value in the high-yield market is more an art than a science. The age-old maxim "Buyer Beware" rings loudly in high-yield as all risk is not created equal! For example, it is much easier to compare and value the risk of financial leverage across two credits than it is to determine how much incremental return or yield is required to compensate for the potential risk presented by significant covenant flexibility that can be utilized to the detriment of bondholders. Some investors use ratings (usually assigned by Moody's, S&P, and Fitch) to determine their credit risk and then evaluate the spreads on that basis. For example, a single-B-rated issue yielding 500 basis points over riskless U.S. Treasuries may be considered attractive relative to another single-B–rated issue yielding 350 basis points, or versus the current high-yield single-B index average spread of 400 basis points. However, in order to make this assessment, investors must assume that the credit ratings themselves are accurate, and that they are a "leading" indicator of credit risk. More importantly, investors should realize that credit ratings do not contemplate many of the investment risks discussed above, such as bond covenants, size of issue, quality of underwriter(s), number of market-makers, Wall Street sponsorship, and information flow, to list a few factors. Relying on the credit rating alone to determine risk will not give a complete picture and can be a perilous exercise during certain stages of the credit cycle.

Comparables

The basic formula for assessing relative value is to compare the yield and spread of the bond being evaluated to industry peers and other credits of similar risk. When evaluating yields and spreads on high-yield bonds, it is important to appropriately consider final maturities, optional redemptions, and workout dates. Given that the majority of bonds in the high-yield universe are callable, analysis of spreads and yields must consider multiple potential outcomes, with an emphasis on their yield-to-worst, spread-to-worst, effective workout dates, and option-adjusted spread. Option-adjusted spread (OAS) is the measurement of the spread that takes into account embedded redemption options. However, as OAS is calculated using historical data and volatility modeling, it is highly dependent on the model being used. Exhibit 54-5 is a typical "comp sheet" a portfolio manager should evaluate to assess the relative value of one bond versus another.

Analyzing the credit comparable above, it becomes apparent that Company C is a weaker credit. As compared to the other two companies, Company C has higher leverage, weak interest coverage, negative cash flow, and significant near-term amortization for which it does not appear to have ample liquidity to address.

OAS per unit of Net Leverage	**143**	**92**	**106**

Given the higher-risk credit profile, the spread on Company C's subordinated notes is meaningfully wider than its comparables, as one would expect. In contrast, Company A's stronger credit profile has resulted in a meaningfully tighter spread than its comparables. Although it also has substantial debt amortization in the current year, it appears to have ample liquidity (as measured by its cash and availability) to absorb the amortization. Ideally, credit comparables should include a snapshot of the trailing 12-month operating results as well as a forward-looking credit profile for the next 12 months.

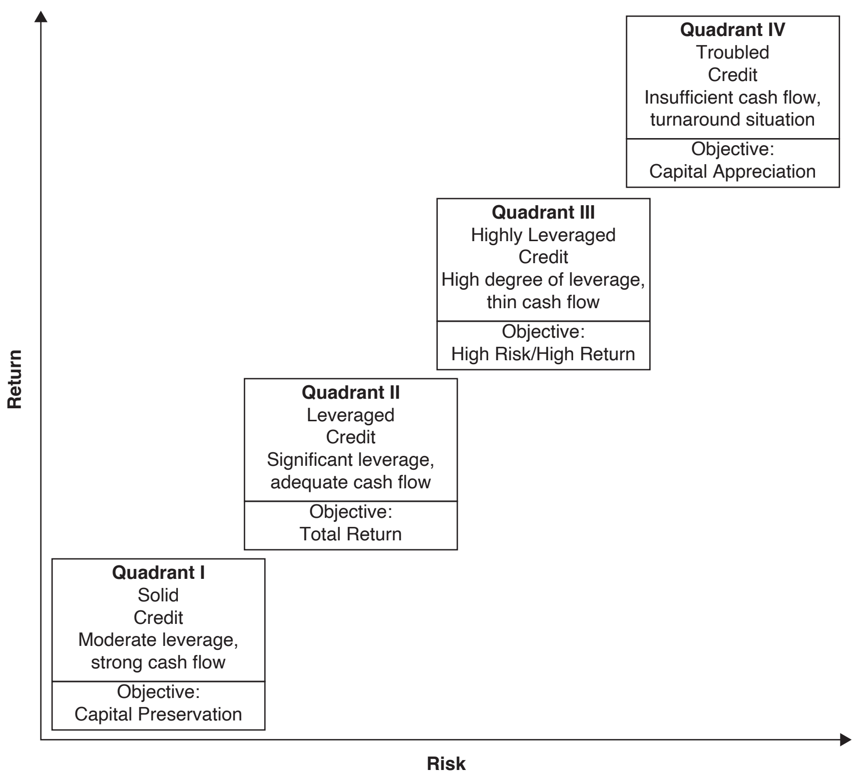
Quadrant Analysis

Many investors use credit ratings to determine risk and evaluate comparable spreads. Given the prevalence of ratings in the marketplace and their acceptance among market participants, portfolio managers cannot ignore these ratings but should not rely on them as a primary or ultimate assessment of creditworthiness. Rather, portfolio managers should construct a more comprehensive risk assessment that can be tailored to incorporate factors they deem appropriate.

Constructing a risk/return matrix can be helpful in determining a framework. Credits can be divided into quadrants as shown in Exhibit 54-6. A description of each of these quadrants is provided as follows:

EXHIBIT 54-6

Quadrant Matrix



Quadrant I: Solid credits with strong credit statistics, moderate leverage, and strong free cash flow. Typical characteristics would include companies with predictable and improving cash flows; deleveraging companies; and companies that have substantial assets well in excess of debt. Objective: capital preservation.

Quadrant II: Good credits with significant leverage that show stability and/or improvement in their credit profile via improved results and lower leverage. Quadrant II companies can appreciate or depreciate depending upon their ability to execute their business plans and ultimate credit trend. These companies typically possess above-average creditworthiness with adequate balance sheets and relatively weak asset value coverage of their total debt. Objective: capital preservation/total return.

Quadrant III: Weak credits with extremely high leverage and deteriorating or at-risk credit trends. These credits have a small margin for error and, therefore, require higher yields to compensate bondholders for the additional risk. Typical characteristics include minimal to negative free cash flow (best measured relative to total debt) and deteriorating credit statistics. They may also include start-up companies, companies with large capital requirements, and companies with aggressive capital structures that utilize zero coupon, PIK or PIK/toggle notes. Asset value coverage of total debt is typically weak. Objective: high risk/high return.

Quadrant IV: Troubled credits that are stressed or distressed and could be in actual or technical violation of covenants. Bonds are likely to be impaired and therefore should require much higher equity-like returns. Objective: capital appreciation.

When assigning quadrants to specific credits, they should be evaluated with an emphasis on the prospective, forward-looking view because the markets are more focused on where a credit is going rather than where it has been. Picking credits that may be transitioning from one quadrant to another can represent trading opportunities. Portfolio managers who are better able to correctly forecast credit trends should outperform their peers. Placing too much emphasis on past results could ultimately provide a myopic risk assessment and thereby limit the risk/reward equation and relative value analysis.

Within the quadrant concept, spreads can be analyzed relative to credits within the same quadrant. Given the potentially wide spectrum of credit quality within a specific quadrant, issuers may be further subdivided into lower and upper tiers for greater segmentation. Once quadrants have been assigned, portfolio managers should compare spreads of companies within the same quadrant that are most similar. When possible, comparisons should be to companies within the same industry and quadrant. Other relative considerations include trading history, stock, bank loan and CDS prices, and duration.

Scenario Analysis

Scenario analysis is another tool to better identify relative value and determine an appropriate investment recommendation. This analysis is particularly useful in circumstances with multiple outcomes or potential event risk.

In Exhibit 54-7, the subject company has just announced a significant acquisition, although financing has not yet been determined. After assessing the amount of flexibility provided by the company's existing covenants as well as taking into account current capital market conditions for debt and equity, the analyst can utilize a scenario analysis to determine a potential trading recommendation. Given management's prior comments and long-standing financial policy, the analyst has assigned a 75% probability to a debt-financed acquisition as opposed to a more balanced combination of debt and equity. Likely potential trading levels post the events are then assigned to each of the scenarios above based on relative value for the pro forma risk profile. This scenario analysis indicates that there are six points of potential downside on the higher probability outcome as opposed to one point of upside on the less likely outcome. Based on this analysis, the recommendation would likely be to sell or reduce the position if possible, or at least proceed with caution.

EXHIBIT 54-7

Scenario Analysis Example

	Probability	Bond Price	Yield	Spread	Leverage Ratio
Current Trading Level		97	6.8%	582 bps	5.0×
Scenario A	75%	92	7.6%	708 bps	6.3×
Scenario B	25%	99	6.4%	586 bps	4.7×

Assumptions:

Scenario A assumes 100% debt financed acquisition.

Scenario B assumes acquisition is financed with 60% equity and 40% debt.

Trading History

To the extent an issuer has had bonds outstanding for a period of time, portfolio managers should examine the trading history of those bonds. Exhibit 54-8 provides a list of some key trading history questions.

EXHIBIT 54-8

Key Trading History Questions

What is the issuer's bond price history? Has the bond been volatile in which case a higher risk premium may be more appropriate?

What is the issuer's bond spread history relative to the current spread? Is it at the tight end or wide end of its historical range? Is it aligned with credit profile?

What is the issuer's bond spread relative to its industry or the high-yield index? How has this relationship trended over time? Is it at the tight or wide end of its historical range? Where is the price relative to where the current credit profile warrants?

What is the current spread level relative to the spread at issuance? Has it widened or tightened dramatically? Were the moves associated with a change in credit profile as opposed to more technical factors?

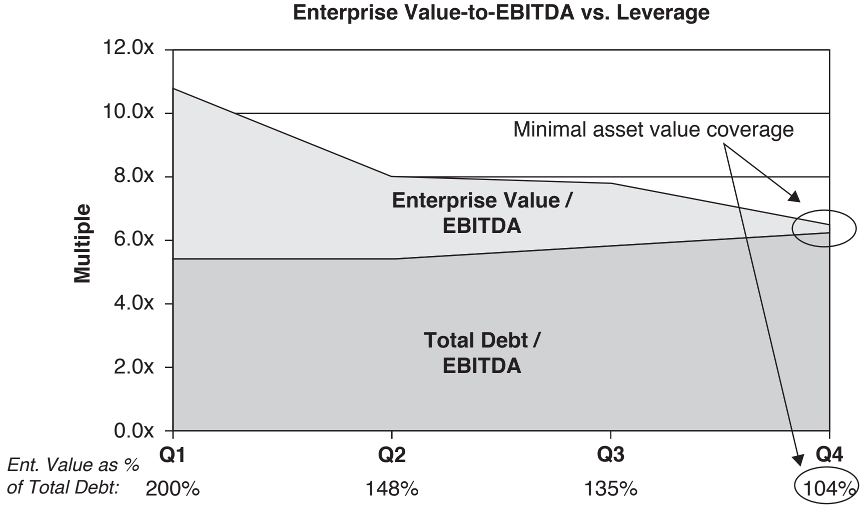
Stock Prices

Since many lower-rated companies are overlevered, their bond performance oftentimes is highly correlated to their stock prices. In some cases, equity prices may be a leading indicator and in other cases bond prices may lead the equity markets. In any event, equity prices (if it is public) of the specific credit, or its public peers and competitors, may have a significant impact on bond prices. As equity prices rise or fall, the equity valuation of the company changes, which essentially measures the degree of "equity cushion" on the specific credit. For example, a stock price that has declined 20% may signal that the implied asset value cushion relative to the bonds has also been dramatically reduced, thereby increasing the overall risk of the credit. If a portfolio manager is looking at two similar credits within the same industry and the same leverage ratios, they would rather own the company with the higher Enterprise Value-to-EBITDA valuation multiple because it ultimately implies greater asset value coverage and thereby less risk (all other things being equal). In Exhibit 54-9, a company's leverage has not changed dramatically over the last four quarters, but due to a severe decline in the stock price, the enterprise valuation of the company has fallen. As a result, the enterprise value coverage of total debt has declined dramatically, and the credit risk has increased. The equity cushion is the lightly shaded area in Exhibit 54-9.

Examples such as this illustration are an important reason why portfolio managers should not take comfort in high implied levels of asset coverage based on the stock price and enterprise value. If equity investors no longer have a favorable view on the company's growth prospects, multiples may contract. Thus, it is important for the credit analysis to include alternate independent methods of asset and enterprise valuation, while monitoring and considering movements in the current public equity value. Although credit metrics may not change dramatically in the near-term, a forward-looking viewpoint of the equity valuation may

EXHIBIT 54-9

Equity Cushion Example



be important in determining perceived enterprise value coverage and trading outlook. In Exhibit 54-9, the 104% enterprise value-to-total debt coverage in the fourth quarter (Q4) suggests that the bond requires equity-like returns as its implied asset coverage is weak.

Bank Loan Prices/CDS

Portfolio managers should monitor the price of the senior instruments in the capital structure as well as single-name CDS trends. Moreover, the lines between high-yield bonds and bank loans have blurred as the two markets and investor bases have converged with overlap. For example, if the yield on a company's term loan is too tight to the yield on its bonds, it may signify that one or both instruments are mispriced. In order to make an appropriate comparison, portfolio managers must evaluate both yields on an equivalent basis since the bank loan yield is a floating rate and based on LIBOR, SOFR, or an alternative benchmark, whereas the bonds are fixed-rate and based on comparable dated U.S. Treasuries. Monitoring CDS trends also provides a window into potential changes in market sentiment toward a particular issue. Depending on market conditions and trading in specific tranches, it can sometimes be easier for investors to express their credit opinion on a given issue by trading CDS as opposed to the underlying bond. As a result, market sentiment may sometimes be more quickly reflected in CDS price movement before it is evident in the bond. Evaluating and monitoring all securities within the capital structure is essential to good security selection.

Duration

Duration measures the price sensitivity to yield as well as the percentage change in price for a parallel shift in yield. The longer the duration, the more sensitive the price will be to interest rate fluctuations. Overall, bonds of equal maturity with higher yields will have shorter durations than lower-yielding issues.

Duration is an important consideration in assessing relative value apart from its sensitivity to changes in underlying Treasuries and determining the appropriate level of additional compensation for going further out on the curve. First, credit risk will naturally increase with longer-dated maturities as there are many factors that can change a company's credit profile over time and have a more profound impact on a levered issuer compared to an investment-grade issuer. Second, to the extent there is near-term potential for a negative surprise, a longer-duration bond should have more downside risk. As investors demand incremental yield to compensate for the risk, longer-duration bonds should generally experience more downside risk. Conversely, for issuers where the underlying credit profile is expected to improve meaningfully, longer-duration bonds will provide greater upside as credit spreads compress to reflect the lower risks, all other things being equal. Another important consideration in evaluating duration in high-yield bonds is adjusting analysis for callable bonds. As callable bonds are quoted at their yield-to-worst or most conservative yield outcome for a given price, the corresponding duration-to-worst metric may sometimes understate the duration of callable bond. As a result, it is important for managers to also consider the option-adjusted duration (OAD), final maturity, and the potential extension risk of duration being greater than expected should a bond's price drop below its call prices or par. The analysis of short duration callable bonds is further discussed below.

Short Duration Callable Bond Analysis

As the majority of bonds in the high-yield market are callable, it is important to consider the impact of their optional redemption features on a bond's potential return profile and duration. Before further exploring, it's important to note that market convention in pricing high-yield callable bonds is to quote the corresponding yield-to-worst and duration-to-worst for a given price. From a yield perspective, the resulting quoted yield will be the lower and more conservative outcome of the multiple redemption scenarios. This is to help investors ensure that specific income or yield requirements will still be met even in the worst scenarios. However, our experience has proven that yield-to-worst can oftentimes be an overly conservative metric, particularly when callable bonds are trading at premiums above their call prices. This is due to the fact that an issuer's decision to call its bonds is not soley based on refinance economics such as payback period and NPV, but more often driven by company specific motivations and circumstances. Some motivations beyond refinance economics can include the following:

- Issuer seeking to make a larger acquisition that may require additional debt financing and desiring to delay refinancing to occur in conjunction.

- Issuer is either in process or seeking to be acquired and not intending to refinance currently callable pre-payable debt with more onerous premiums or additional call protection.
- Issuer is intending to repay debt post filing an IPO, which can be an extended process.
- Issuer awaiting the benefit of improved operational trends over several quarters or expected/targeted credit rating improvement in anticipation of more favorable refinancing terms.
- Onerous covenant provisions that could incentivize issuers to redeem the bonds due to the additional financial flexibility advantages beyond the individual bond's payback economics.
- Issuer is awaiting conclusion of a strategic review that could result in sale, spinoff, or IPO of certain significant assets.
- An LBO sponsor is approaching its exit horizon and is unmotivated to call bonds as a refinancing would likely result in new call protection premiums that would be less appealing to potential suitors.
- Issuer seeking to coordinate redemption timing with other upcoming callable bonds or refinancing opportunities.

These are all just a few of the many company-specific circumstances that will ultimately drive the timing of refinancing and redemption decisions. As a result, yield-to-worst for bonds trading at a premium can oftentimes not be the best indicator of the likely yield, and investors may be able to capture greater yields and returns with more informed assumptions beyond the standard worst-case metric. Through in-depth research of catalysts driving the call and tender activity on each individual issue, a manager can add value and evaluate when bonds are most likely to be called to determine the yield to that more "likely" call date. Strong bottom-up fundamental research process can help a manager to understand issuers' financing needs and seize upon idiosyncrasies within the short duration high-yield universe. Exhibit 54-10 demonstrates a currently callable bond example. It highlights how quickly a bond's yield can ramp beyond the yield-to-worst if it remains outstanding as well as the meaningful incremental yield that can be captured when a manager's likely call date may differ with market expectations.

TOP-DOWN HIGH-YIELD MARKET DRIVERS AND MACRO CONSIDERATIONS

While the bottom-up component of portfolio management should be the primary driver of security selection, it is important to incorporate a view on key macro top-down factors that will influence the markets as well as individual industries and credits. Understanding these drivers is necessary in evaluating past performance

EXHIBIT 54-10

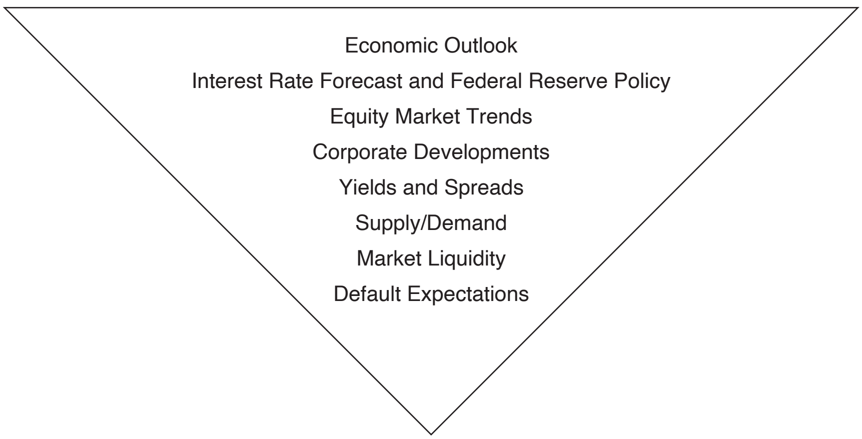
* Manager estimate.

and constructing individual portfolios. Furthermore, macro considerations are a key component to providing the proper context for individual industry and credit allocations. However, considerations must also be given to both global and local drivers and implications.

The high-yield market has eight primary drivers. The top-down (macro) component of the portfolio management process is further highlighted in Exhibit 54-11.

EXHIBIT 54-11

Top-Down High-Yield Market Drivers and Macro Considerations



Economic Outlook

All top-down macro views require some form of economic analysis. An assessment of current and expected future economic conditions is essential to portfolio management as the performance of the economy has a significant bearing on the performance and profitability of the companies that make up the high-yield market. All aspects of an economic analysis should consider both local and global drivers and implications. An analysis of the general economy usually begins with the business cycle. One determinant of industry allocation decisions is a forecast of whether the macro economy is improving or weakening. A forecast that differs from consensus can have a significant impact on strategy and performance. Economic indicators such as GDP, inflation, consumer sentiment, consumer spending, business investments, unemployment, housing, and ISM provide the necessary data to develop an informed viewpoint and forecast. Ideally, this data should be supplemented with primary research derived from direct management contact of portfolio holdings. Complementing economic data with primary research can provide a higher level of conviction in formulating an economic forecast. Furthermore, it may highlight risks in the consensus view and provide portfolio managers with an opportunity to add value and enhance returns. Once the economic outlook has been created, it is necessary to establish the impact of that forecast on specific industries as not all sectors are equally sensitive to the business cycle. For example, a negative economic outlook may warrant a higher weighting in defensive industries and credits. Conversely, a positive forecast would favor more economically sensitive industries and credits.

Interest-Rate Forecast and Federal Reserve Policy

Rising rates and tightening monetary policy tend to have a negative impact on fixed income investments. While high-yield bonds have historically shown a relatively low correlation to U.S. Treasuries as compared to many other fixed income asset classes such as investment-grade corporates, formulating an outlook on interest rates provides a framework for the construction of the portfolio. For example, if the interest-rate forecast calls for a significant increase in interest rates, it may be appropriate to reduce a portfolio's exposure to low coupon, longer maturities, and the most interest-sensitive lower-yielding credits. Additionally, from a credit perspective, certain industries that are highly sensitive to interest rates (such as financials) may face additional risk and technical pressure in a rising rate environment.

Equity Market Trends

Contrary to popular belief, the high-yield market has demonstrated a much higher correlation to the equity markets than to 10-year U.S. Treasuries. For the 20-year period ended May 2020, the high-yield market exhibited a –0.20 correlation to 10-year Treasuries versus a 0.69 correlation to large cap equity according to *eVestment*. Although high-yield is a fixed income vehicle, the meaningful risk premium over Treasuries absorbs much of the volatility in Treasuries to deliver more equity-like returns. As equity markets fluctuate, so does the ultimate equity cushion for debt investors. Stronger equity markets typically signify stronger outlooks and earnings momentum; however, they also signify stronger equity cushion and asset protection for bondholders. The opposite is true when equity markets are declining. These dynamics are amplified for highly levered companies. In the end, it is generally more difficult for high-yield bonds to perform well when the equity markets are declining. Portfolio managers should keep this dynamic in perspective when managing risk.

Corporate Developments

Just as corporate fundamentals drive returns on an individual issuer, broader trends in overall corporate developments influence the high-yield market as well.

To illustrate, a strong equity market may drive many private high-yield companies to go public and use the proceeds to pay down debt (a positive credit event). Conversely, an overabundance of available credit may incentivize private equity sponsors to raise debt in order to fund dividends to the equity holders at the expense of existing bondholders. To the extent corporate development trends are occurring on a broader scale, it may positively or negatively impact the high-yield market as investors anticipate other issuers that are likely to undertake similar positive or negative actions.

Market Yield and Spread: Relative to Historical Averages and Versus Other Asset Classes

In determining asset allocations for their larger, overall portfolio, investors will ultimately consider the relative yield and spread of high-yield bonds to historical averages as well as to other asset classes and investment alternatives. This consideration provides an important perspective for high-yield portfolio managers as it is a key influence that drives overall demand in the high-yield market as well as the market technicals. In developing a relative perspective, portfolio managers should consider the following reference points and how they compare to historical ranges and averages:

- High-yield market spread over Treasuries
- High-yield market absolute yield
- High-yield market spread vs. investment-grade corporates
- High-yield market spread vs. leveraged loans
- High-yield market yield vs. dividend yield on the S&P 500

For example, if high-yield spreads are at all-time wides, there should be strong technical pressure and ultimate demand to drive yields tighter as new buyers enter the market to take advantage of the opportunity. Additionally, if the incremental high-yield market spread over investment-grade corporates is at all-time historical tights, investors may decide that the incremental yield is insufficient, creating downside technical pressure.

High-Yield Market Supply/Demand

New issue supply and flow of funds play a meaningful role in the performance of the markets. While longer-term returns are more influenced by the overall corporate credit outlook and expected default rate, supply and demand characteristics may be difficult to forecast, but impossible to ignore. A record supply of new issuance can cause technical pressure on the secondary market in an otherwise fundamentally strong high-yield credit environment with low default expectations. Conversely, a lack of supply works to strengthen demand for existing issues in the secondary market and drive prices higher in a similar environment.

While new issue supply can easily be measured and monitored through multiple sources, demand is more difficult to ascertain. Although retail mutual fund flows are available on a daily basis, they provide only a limited picture of the overall high-yield market demand. High-yield retail mutual funds and ETFs account for less than 30% of the overall high-yield market. Additionally, these funds may not accurately represent the sentiment of the larger institutional investors, which account for a larger portion of the high-yield market. While retail fund flows provide a window into overall demand, the largest high-yield managers with significant institutional assets can better measure demand through their own level of marketing activity and internal subscriptions/redemptions. Demand can have a significant impact on market returns, particularly in periods where new issue supply is limited. Short-term demand considerations should also be evaluated. While retail mutual funds and ETFs represent a limited portion of the high-yield market, they can represent a significantly larger share of trading activity on given days where ETF activity is meaningful, causing them to have a greater technical impact on the market in certain circumstances.

Market Liquidity

Broker-dealers provide the liquidity needed to sustain active markets in high-yield securities. Over time, broader trends such as bank consolidation, increased regulations, and enhanced trade reporting have all had an impact on broker-dealers and market liquidity. Due to the consolidation among broker-dealers that was triggered by the financial crisis, smaller firms focused primarily on secondary trading entered the high-yield market to populate the void created in consolidation. Under global regulations known as Basel III, banks have had to use more capital to fund risky assets, while Dodd-Frank financial reform law in the United States imposed strict limits on how much of their own money banks are able to deploy across trading activities, adding pressure to market liquidity.

Additionally, TRACE reporting has required broker-dealers to report details of trades they execute within minutes. While the increased transparency has provided benefits to investors by reducing transaction costs, it has also impacted broker-dealer ability to take risk as a provider of liquidity and impacted their profitability. As a result, the broker-dealer's role has shifted from a vast majority of its trading volumes prior to the financial crisis being principal trades (involving their own inventory), to the majority being agency trades where it is simply linking up a buyer and seller. This has likely led to greater price volatility, particularly in downward markets, where levels must adjust lower until natural buyers are found. That said, overall liquidity has increased as trading volumes in high yield have grown meaningfully over the years to record levels and have largely kept pace with the robust growth in the size of the overall high-yield market. Additionally, growth in the popularity of ETFs, strong demand from foreign investors, and broader acceptance of the asset class have all had a positive impact on market liquidity. While electronic trading has captured a meaningful share of overall trading in investment-grade corporate bonds, its adoption in the high-yield market has remained more limited, as less than 12% of high-yield bonds were traded electronically on average in 2019, according to research by Greenwich Associates. Apart from the broader trends, the amount of capital provided to broker-dealer trading desks is a significant determinant of the ability to effectively trade in the high-yield market. For instance, a broker-dealer's senior management may decide (whether for macro concerns or company-specific circumstances) to "dial down" its risk exposure and hence limit the capital it allocates to its high-yield trading desk. As a result, investors may experience longer execution times, higher transaction costs, and greater price volatility before clearing levels are achieved. Market liquidity is also seasonal based on staffing and the new issue calendar. For example, late summer and periods surrounding holidays exhibit lower liquidity as broker-dealers operate skeleton crews and limit capital. Moreover, traders may be less willing to risk capital as they approach their fiscal year-end and thereby impact their year-to-date profit and loss. It is important for portfolio managers to understand both the secular and shorter-term trends that influence the ability to execute trades in the market.

Default Expectations

Since inception, the high-yield market's most important driver is default rates. In periods where default rate expectations are low, the high-yield market tends to perform well as the lower default expectations influence two important components of high-yield returns: risk premiums and default loss.

$$\text{Expected high-yield return} = \text{Risk-free rate} + \text{Risk premium} - \text{Default loss}$$

Many investors have become more tolerant of defaults and acceptance of losses due to defaults built into their performance expectations. In an environment of lower default expectations, risk premiums as measured through credit spreads should decline as investors are less concerned with default risk and willing to accept less yield, thereby driving bond prices up. Additionally, the lower expected default risk lowers the expected default loss, hence increasing the overall expected high-yield return. Portfolio managers can temper their portfolio risk tolerance based on their overall default expectations. For example, portfolio managers may be willing to assume more risk when the outlook for default rates are trending lower, whereas increasing default rates may warrant a more defensive posture.

PORTFOLIO CONSIDERATIONS

Portfolio considerations are the framework applied by the investment managers to ultimately decide which securities are most appropriate for inclusion in a given portfolio. They act as the filter to screen the potential investment universe utilizing the bottom-up and top-down considerations discussed in this chapter. These portfolio considerations include:

- Client/portfolio objectives
- Risk tolerance
- Diversification
- Trading strategy
- Portfolio characteristics
- Risk management and analytics

Client/Portfolio Objectives

Portfolio objectives are essential to providing the overall direction for portfolio construction and day-to-day investment decisions. A quote from poet Ella Wheeler Wilcox serves as a good analogy for the importance of these objectives: “One ship drives east and another drives west / With the selfsame winds that blow; / ‘Tis the set of sails / And not the gales / That tell us the way to go.”[3] With respect to portfolio management, investment objectives serve as the sails to guide the portfolio in the proper direction. The most vital portfolio objectives are return target and risk tolerance. The client or portfolio manager must decide what the primary investment objective is (i.e., income generation, total return, benchmark “hugger,” absolute return, or preservation of capital). Most portfolio managers have one primary objective and a secondary goal—for example, absolute total return as the primary objective and high current income as a secondary goal. The more clearly defined the objectives, the more likely the strategy will be effective and successful.

Risk Tolerance

In the universe of high-yield bonds, preserving capital, and controlling risks are paramount factors in generating superior returns over a full credit and economic cycle. Calibrating the portfolio’s risk tolerance goes hand in hand with the portfolio’s investment objective.

For example, a total return strategy will necessitate a higher-risk tolerance as managers must buy higher yielding issues with greater risk premiums or deeper discount paper in order to achieve the high return objective. However, these greater returns and higher risk premiums will likely result in greater volatility of returns as well a higher probability of default loss. Ultimately, portfolio managers must clearly define whether their core risk tolerance is conservative or aggressive and maintain an unwavering style in the face of changing markets.

3. Wilcox, Ella Wheeler, “The Winds of Fate,” in *World Voices* (New York: Hearst’s International Library Co., 1916).

Although it is feasible to beat the benchmark with a conservative strategy in a down market, or with an aggressive style in an up market, the combination of aggressive/conservative style outperforming in both bull and bear markets is extremely challenging and flawed. The lack of trading and the unavailability of many issues in the high-yield market inhibits the ability of portfolio managers to shift between styles in a short time frame. While a portfolio manager's core strategy and risk tolerance must remain intact in order to succeed over an entire market or credit cycle, this should not preclude portfolio managers from increasing or decreasing their risk tolerance within their core conservative or aggressive strategy as market conditions change. However, these changes in risk tolerance must remain incremental as opposed to radical. Success is measured by achieving the highest risk-adjusted returns over an entire market or credit cycle.

Diversification

A key factor in reducing risk and achieving return objectives is diversification. Diversification should not simply be measured by the number of investments held in a portfolio but must be evaluated on many critical levels in order to appropriately manage and lower the overall risk. One of the most common mistakes portfolio managers make is that they "fall in love" with an industry and/or a credit and fail to properly diversify their high-yield holdings.

Several key factors should be taken into account in assessing a portfolio's diversification. These include:

- Issuer concentration
- Industry concentration
- Credit and fundamental risk
- Liquidity
- Duration

Issuer Concentration

Diversification by issuer should be measured on several levels. Number of holdings and average position size are two of the most important diversification measures. Some investors may believe that a more concentrated "best ideas" approach to portfolio management (e.g., <35 issuers) will achieve the highest returns; however, it may do so at a much higher level of risk given that the most severe credit losses tend to be the unexpected ones. Conversely, some portfolio managers may believe that a large number of holdings (>400 issuers) provides greater protection against individual loss as well as smaller tracking error versus a given benchmark; however, this is typically more of an index fund approach and it is difficult to argue that a portfolio manager is adding much value in this scenario. Ultimately, a properly diversified portfolio should target position sizes of 1% to 1.5% on average per name in order to balance the benefits of diversification with the opportunity for greater value added. It is important to remember that larger portfolios will, by necessity, be forced to hold many more issues as their size limits the desired amount of a given issuer that can be held. Individual issuer weightings should also be managed with overall portfolio risk tolerance in mind. For example, higher-risk credits should at a minimum have lower average weightings in a conservative portfolio where higher-quality credits should be emphasized. In addition to the number of holdings and average position size, individual issuer limits, and top 10 concentrations should also be considered. In a properly diversified portfolio, most portfolio managers should maintain diversification percentages with limits of generally no more than 3% per issuer, and the portfolio's top 10 holdings should not exceed 25–30% of the portfolio. Portfolio managers must also make certain that their top 10 positions generate solid returns. If the top positions are underperforming, it is extremely difficult to achieve superior results.

Industry Concentration

Industry concentration levels should be held to no more than 15–20% and should be reserved for those industries with the strongest fundamental and technical characteristics. Additionally, the portfolio's five largest industry weightings should represent less than 50% of the total assets. Proper diversification should not only reduce a portfolio's volatility, but these weightings should help mitigate the effect of unexpected announcements by issuer or events that affect an industry in general. Industry allocations should also consider weightings based on more macro characteristics such as cyclicality and commodity exposure. While individual industry weightings may be diversified, there may be a higher concentration in cyclical exposure that could elevate portfolio risk if broader classification and monitoring is not also considered.

Credit and Fundamental Risk

Managing risk is a critical function for a high-yield portfolio manager. Most investors look to evaluate the ratings (e.g., Moody's/S&P/Fitch) distribution of the portfolio and monitor concentrations across ratings categories. However, portfolio managers should maintain their own proprietary framework and tools for evaluating and monitoring credit risk exposure and concentration. Managers who are able to utilize their own independent research and rankings have an advantage in capitalizing on inconsistencies or inefficiencies inherent in the agency credit ratings that are relied upon by the broader market. Geographic risk factors must also be considered, on the basis of country of domicile as well as source of profitability, demand, or supply. For example, in order to position a portfolio appropriately against potential trade concerns with a major economy such as China, a portfolio manager must be able to identify and manage their portfolio exposure to companies with meaningful supply/demand drivers tied to the country. Another important risk factor is to identify and monitor the percentage of holdings by the lead underwriter, senior lender, and private equity sponsor. Lead underwriters and senior lenders are important because not all underwriters and lenders are equally committed to the asset class. Some underwriter-brokers are active in high yield when there is a bull market and abandon their efforts when the market declines, leaving the purchaser holding an orphaned bond. Moreover, broker-dealers possess varying degrees of capital on their trading desks. Private equity sponsors, meanwhile, have track records that cannot be ignored. Some private sponsors are known for frequently taking major dividends out of their LBO companies, thus leaving the entities more leveraged with no benefit to the debt holders. ESG risk tiers are another important consideration in evaluating the potential downside risk to an overall portfolio. Overconcentration in any of these factors on a portfolio level could jeopardize performance over the long term.

Liquidity

Liquidity risk involves measuring the ability to sell a particular credit on a timely basis. If a particular high-yield bond has poor liquidity, a portfolio manager may be unable to execute a buy/sell decision. The percentage of the portfolio represented by L1, L2, or L3 liquidity ratings should be calculated and monitored. Concentration in L3 credits that trade sporadically should be a key focus and require strong conviction as the downside risk to these holdings is amplified by their illiquidity.

Duration

For the reasons discussed above, a bond's duration is an important driver of its volatility. Portfolio managers must consider their overall exposure to both longer and shorter duration bonds. Concentrations in either category can position the portfolio either more defensively (short-duration) or more offensively (long-duration). Barbell strategies where managers may emphasize shorter and longer duration extremes while avoiding mid-duration options may display a reasonable portfolio average duration, but ultimately exhibit greater risks given the longer concentration. Additionally, given the prevalence of callable bonds in the high-yield market, managing duration risk is more involved as it requires considering multiple redemption scenarios and metrics as opposed to a single duration measure. Duration-to-worst, option-adjusted duration, spread duration, duration-to-maturity, and average final maturity are all metrics to be managed and considered on both security and portfolio levels. Stress tests and scenario analysis are also helpful in quantifying variability and risk. It is important to evaluate exposures and concentrations across multiple measures to ensure that they are aligned with the portfolio manager's overall market outlook and portfolio objective.

Trading Strategy

Portfolio managers generally have trading styles that capture their bias toward generating short-term trading profits versus focusing on longer-term outperformance over an entire credit cycle. Given the significant transaction costs and liquidity limitations of the high-yield market, short-term trading can be costly.

Furthermore, it incorporates a greater degree of risk associated with attempting to time the market that can impact long-term performance. Regardless of the type of trading strategy, portfolio managers must develop and adhere to a buy and sell discipline that reflects their style and philosophy.

Buy Discipline

In executing a buy decision, a step-by-step process is required to ensure consistency and disciplined decision-making. It is critical for portfolio managers to employ a rigorous bottom-up credit/security selection process complemented by top-down macro considerations. Portfolio managers should not sacrifice this process in the name of expediency or believe they might miss a "hot" opportunity. If there is not sufficient time to complete adequate diligence on a particular issue, the investment should not be made. The optimal investment should exhibit positive characteristics across all six of the key security analysis steps discussed above and align with the overall investment objectives and risk tolerance of the portfolio. For example, portfolio managers should bifurcate the decision of whether the company is a sound credit from whether the credit's bonds are attractive on a relative value basis.

Sell Discipline

Having a disciplined sell process is crucial for high-yield investing. Knowing when to sell is many times more important than knowing what to buy because losses are typically greater than gains due to the call constrained feature inherent in most high-yield bonds. The ability to execute a sell decision can separate an average portfolio manager from an extraordinary one. The three primary reasons to sell a bond are:

- Credit deterioration
- Relative value (risk/reward imbalance)
- Management drift

Strong analysis and continuous in-depth monitoring are essential components of managing credit risk as the security analysis process does not end once a security is purchased.

Credit Deterioration. If a credit is undergoing (or forecasted to undergo) a decline in its fundamentals that may significantly increase the risk of default, the security should be sold. The more proactive a portfolio manager, the higher the overall portfolio return as default loss is minimized.

Relative Value. While fundamental reasons should always be the most significant sale criteria, relative value and managing the risk/reward balance are vital factors in driving long-term returns. For example, an issuer may not necessarily be at near-term risk for default, but if its risk profile has increased (or is forecasted to increase) materially, there may be a sale opportunity if yields have not yet reflected this concern. Conversely, if a credit's yield has increased well beyond the assessed risk, the bond should also be considered for sale. Lastly, credits that have shown significant improvement in their credit risk profile may no longer offer attractive yields. Although the credit profile may now be much stronger, an investment-grade credit profile may not be appropriate for a high-yield portfolio objective.

Management Drift. As discussed above, the quality of the management team is a significant factor in analyzing a company. The leadership and veracity of management is paramount in making this assessment. To that end, bonds of a company where the management team deviates from its previously stated goal(s) or misleads investors must be sold. These management teams present a higher level of risk that is difficult to assess or quantify.

Red Flags. An important complement to a strong sell discipline is to also have a process for uncovering potential risks that may not have been uncovered through traditional monitoring. Price drift and credit drift are two key elements to monitor. Bond prices should be monitored for declines and necessitate automatic reviews for declines of 10%. While ongoing credit analysis may not have uncovered a significant change in risk to justify the price movement, it is important discipline for the manager to appreciate and understand the reason for the movement. Credit drift is also an important element to monitor. For this purpose, the credit drift to monitor should be based on a systematically updated proprietary method by the portfolio manager as discussed above. Reacting to changes in the major rating agencies (e.g., Moody's, S&P, and Fitch) will invariably be a lagging indicator as the market is readily focused on these published credit ratings.

Portfolio Characteristics

A key element of portfolio management is monitoring and evaluating all of the portfolio's holdings and its resulting characteristics. Some of the characteristics to monitor include valuation metrics, risk metrics, and diversification/concentration metrics. A more comprehensive sample list is provided in Exhibit 54-12.

Each of the metrics should be evaluated both on an average portfolio level, but also further detailed in relevant buckets for deeper attention and analysis. For example, a portfolio's overall average yield may be in line with expectations and target, but a further analysis may uncover that the percentage weighting to bonds yielding above 10% is high and indicative of greater risk in the portfolio. Monitoring a portfolio's characteristics and its changes is an indispensable tool in portfolio management as it helps ensure a portfolio's holdings are in line with macro considerations and portfolio objectives as opposed to solely a result of bottom-up selection. Daily real-time review is necessary so that portfolio managers can make informed decisions based on actual facts that reflect changes in the market rather than "seat-of-the-pants" intuition. Organized, customized, and

EXHIBIT 54-12

Portfolio Characteristics

VALUATION	
Coupon	coupon
Price	price
Yield	current yield, yield-to-worst, yield-to-maturity, yield-to-custom
Spread	spread-to-worst, option adjusted spread, spread-to-custom, spread-to-maturity
Duration	duration-to-worst, option adjustd duration, spread duration, duration-to-maturity
Final Maturity	years-to-maturity
RISK	
Credit Ratings	Moody's, S&P, Fitch issue credit ratings
Proprietary Credit Rating	manager's custom independent rating/score to measure credit risk
ESG Risk Tier	manager's custom metric to measure ESG risk
Liquidity Risk Tiers	manager's custom metric to measure liquidity risk
DIVERSIFICATION/CONCENTRATION	
# of issuers	total number of issuers
% issuer weighting	individual issuer weightings
% top 10 issuers	% weighting to top 10 issuers
# of industries	total number of industries
% industry weighting	individual industry weightings
% top 5 industries	% weighting to top 5 industries
% cyclical	% weighting to cyclical industries
% heavy cyclical	% weighting to heavy cyclical industries
% energy	% weighting to energy
% non-U.S.	% weighting to non-U.S. domicile issuers

detailed analysis and reporting showing percentages and variance calculations are essential for critical decision-making.

Risk Management and Analytics

Risk management should be an integral part of the portfolio management process. This function is commonly performed by a group separate from the portfolio managers, although its members have frequent interactions with portfolio managers. Risk management typically involves portfolio monitoring, applying risk controls, performance attribution, and developing analytics.

Portfolio Monitoring

Both risk managers and portfolio managers are charged with monitoring a portfolio's characteristics and exposures on a more detailed and comprehensive level. This important function helps ensure a portfolio's holdings are aligned with portfolio objectives as well as consistent across multiple portfolios of similar strategy. Daily real-time review and analytics are vital to managing exposures and risk so that informed trade decisions are aligned with portfolio strategy and objectives. Interactive tools and analysis detailing exposures, weightings, and variance are important for decision-making and managing consistency.

Risk Controls

Risk controls should be present in the investment process, in pre-trade compliance, and in post-trade risk measurement and analysis. One of the keys to avoiding significant losses is to establish firmwide risk control procedures and to develop and maintain a formal credit review process that examines the key risk factors covered in this chapter, namely credit risk, liquidity risk, and portfolio/diversification risk. Implementing a pre-trade compliance system to monitor key parameters is a critical tool for controlling risk and helping to guide a portfolio's alignment with its objectives. A pre-trade compliance system typically involves an integrated portfolio management and trading system in which portfolio constraints and limitations are categorized and monitored in real time. As a result, a portfolio manager is unable to enter a trade order that does not comply with the portfolio's guidelines or risk tolerances. Post-trade risk measurement and analysis are useful for such things as monitoring portfolio concentrations and diversification as markets change. The analytics used for post-trade risk measurement can also be applied during portfolio construction exercises. For example, if a portfolio manager plans to increase duration and convexity in their portfolio, the post-trade risk measures can be used to forecast the impact of potential trades.

Performance Attribution

Performance attribution is another important tool that provides a feedback mechanism to portfolio and risk managers, serving as a helpful reference to better understand the results of investment decision as well as to guide future adjustments to the portfolio. The objective is to breakdown the variance between a portfolio's active returns and the returns of the passive market into various segmented detail for further analysis. This analysis serves to illuminate the portfolio manager's decision-making process and reveal factors that benefited or detracted from performance for a given period. It is important to identify the many flaws inherent in utilizing passive market indices as the benchmark, particularly in the high-yield market where the relative illiquidity of its underlying constituents makes an index very difficult to replicate in practice.

Analytics and Data Science

A successful risk management team can build and develop analytical tools that not only support the risk management process but also assist with portfolio construction. Common analytics include bond level valuation statistics such as yield-to-worst, option-adjusted spread, as well as other risk measures for both a portfolio and its associated index. The analytics could be available in reports or through business intelligence tools. Business intelligence tools have the added benefit of being dynamic, and thus are useful for scenario analysis. For example, a portfolio manager could examine the impact of spread widening or tightening across industries that are more or less sensitive to economic cycles. With good data and systems, analytics and data science can provide active tools to improve portfolio construction and understand where the risks exist relative to the potential rewards.

KEY POINTS

- High-yield bonds are a unique and dynamic asset class that combines the characteristics of both fixed income securities and equities. As such, the overall approach to managing a high-yield portfolio must involve an inherent underlying focus of the three key risks: credit, liquidity, and portfolio risks.
- High-yield portfolio management incorporates three key focus areas: (1) bottom-up credit/security analysis (2) top-down high-yield market drivers and macro considerations, and (3) portfolio considerations. All three elements are critical to effective portfolio management and the individual security selections occur at the intersection of these focus areas.
- The bottom-up credit/security analysis serves as the foundation for the investment decision. While credit analysis is arguably the most important component of the investment process, security structure/terms, covenants, trading liquidity factors, and relative value ultimately determine if a “good credit” will make for a “good investment.” It is important to emphasize that all of the bottom-up steps are significant in their own right, and that a favorable assessment on many of the steps may not necessarily outweigh an individual risk component that is identified in the process.
- Understanding and evaluating the top-down high-yield market drivers and macro considerations are another critical component of high-yield portfolio management. While the bottom-up component of portfolio management should be the primary driver of security selection, it is

important to incorporate a view on key macro top-down factors that will ultimately drive/influence the high-yield market as well as individual industries and credits.

- Portfolio considerations are the framework applied by the portfolio manager to ultimately decide which securities are most appropriate for inclusion in a given portfolio. They create the filter that is used to sceen the potential investment universe utilizing the bottom-up and top-down considerations.
- The high-yield market offers favorable return opportunities, but investors must also remember the old adage "The greater the return, the greater the risks!"

CHAPTER
FIFTY-FIVE

CORPORATE BONDS AND ESG

Gueorgui S. Konstantinov, Ph.D., CAIA, FDP
Senior Portfolio Manager
LBBW Asset Management

Christoph Gross
Senior Portfolio Manager
LBBW Asset Management

Corporate bond managers have enormous power in implementing Environmental, Social, Governance (ESG) criteria in their funds. The main source of influence they have might be transformed into strict engagement policy to pursue positive environmental and climate change policies. This chapter focuses on several topics and discusses the investment process of corporate bond managers and the possibility to invest in green bonds as promising tool to influence corporate management and achieve positive climate impact beneficial for future generations. It is important to note that corporate bond managers might be alpha seekers or environmentally motivated and provide examples of their investment processes.

Some economists believe that it is in the debt market that investors can have a greater impact on not only corporations but governments at all levels. The fixed income market represents one of the largest asset classes, with strong demand from pension funds, institutional investors, retail investors, and most importantly, dedicated ESG investors ranging from alpha seekers to environmental activists as noted by Branch, Goldberg, and Hand.[1] A way in which bond investors can have a greater impact than equity investors is by investing in green bonds and imposing carbon emission targets on corporations and governments.

Bonds do not have shareholder rights as equities; however, bond investors have indirect contact to companies that allows investors to exercise influence and attract management attention. "Engagement" reflects the specific type of involvement. An example of active engagement would be the influence of bond managers might make on senior management when issuing debt securities. More

---

The views expressed are those of the authors and do not necessarily reflect those of LBBW Asset Management.

precisely, commitment to participate in a new issuance if certain ESG criteria, or low-carbon norms, are met.

In Australia's mining sector, companies raise funds via bond issuance. Actions taken by investors in the debt market affect funding costs directly. For example, when companies approach the bond market with new issues, investors might have a big opportunity to scrutinize the issuer with respect to its carbon emission practices or critical ESG issues and charge an interest rate that penalizes issuers who have pursued adverse climate change practices. This reflects the traditionally polarized discussion between academics and practitioners regarding the cost-of-capital, which is observable at the market as noted by Blitz and Swinkels.[2]

Whereas Heinkel, Kraus, and Zechner, and Hong and Kasperczyk argued that the cost of capital should increase if corporate investors refrain from investing in socially irresponsible corporate bond issuers, Fabozzi, Lamba, Nishikawa, Rao, and Ma found that they experience lower financing costs.[3] Practical research by Blitz and Fabozzi found even that a specific premium does not exist.[4] Eichholtz, Holtermans, Kok, and Yonder investigated commercial mortgages and real estate investment trusts (REITs) and found that these green bonds have lower spreads on the secondary market.[5]

Partridge and Medda extensively analyzed the green bond premium called "*greenium*" in the U.S. municipal bond market.[6] This issue however reflects the negative and positive screenings bond managers might employ to classify "sin" versus "nonsin" issuers. Whereas this difference is highly important and deserves further investigation, we focus on the positive effects of applying both positive and negative screenings. More precisely, we argue that corporate bond managers might use such screenings to filter their investment universe. Of course, as Blitz and Swinkels argued: "Full exclusion of a firm sends the most credible signal that one will not finance future growth of this firm by any means."[7] Whereas, complete refrain from investors might send unmistakable signals to the management, we argue that corporate bond managers might take an active role influencing and

engaging corporate management in terms to improving the ESG utility for the public, investors, and future generations.

Dimson, Karakas, and Li[8] and Focardi and Fabozzi[9] argued that corporate bond managers might exercise even more powerful impact and to accomplish greater changes with companies than traditional equity methods. Madhavan and Sobczyk showed, however, that bond funds and equity funds diverge substantially in terms of investment process and approach to ESG.[10] Engagement might be the right policy to influence and change its practices. Furthermore, engagement might mitigate the impact of "greenwashing," which arises when underlying projects initially announced as green are unable to deliver the desired and stated green objectives, as noted by Benabou and Tirole,[11] and Deng, Tang, and Zhang.[12] This serious challenge has been documented by Lyon and Maxwell and refers to the adverse selection of bond issuers who are misleading the market participants.[13] The adverse selection gives the issuer the advantage to enjoy benefits and even recognition for participating in environmental issues in the rapidly growing green bond sector. As Baker, Bergstresser, Serafeim, and Wurgler argued, green bonds represent a successful instrument to environmental change.[14] Therefore, bond managers become a specific and important role when participating in the green bond market. They must act and enforce the change with engagement in every stage of the Green Bond Principles (GBP)—at the use of proceeds, during project evaluation, the management of proceeds, and the reporting phase. The GBP has been established as voluntary guidelines for green bond investing.[15]

This chapter investigates the ESG issues a corporate bond manager might face from several different angles. Whereas we identify the major issues, strategies, and investment processes, we highlight the role and potential of green bonds to help bond managers to engage and push establishing better procedures and policies regarding environmental issues and to influence corporate management. Bond managers become increasingly important role in identifying greenness,

robust and transparent implementation and management of bond proceeds, and exercising management control and engagement for improving environmental issues. How corporate bond managers might act as alpha seekers but also much more emphasize their role as social and environmental activists has been shown by Branch, Goldberg, and Hand.[16] However, Jacobsen, Lee, and Ma stressed that corporate financial performance might diverge from the goals of successful investment manager—to achieve higher returns and lower portfolio risk.[17] A major issue is that it is better to engage rather to divest in the sense of Chambers, Dimson, and Quigley.[18]

Chia, Goldberg, Owyong, Shepard, and Stoyanov argued that there is a green factor relevant to the companies engaged in climate change operations that are unrelated to the risk factors used to explain performance and behavior. Specifically, this factor is common for companies of lower size, which experience higher volatility. Corporate bond managers for example might influence management and engage in companies, which in turn would reduce volatility. Furthermore, this factor might be part of a quantitative investment process as showed recently by Chen and Mussalli.[19]

THE BOND MANAGER ROLE

The International Energy Agency estimated that more than \$50 trillion in total must be invested by 2035 to achieve the goal of limiting temperature rise to no more than 2°C. In addition, the World Economic Forum estimated that \$5.7 trillion per year in funding from public and private capital will be required to meet the carbon emission target of that scenario. What type of instruments can provide such tremendous amounts of capital?

Gyura argued that investor sentiment and the new generation worldwide is changing, focusing much more on environmental solutions, renewable resources, climate change, and responsible investing.[20] Thus, there will be costs and opportunities as a result of the transition to a low-carbon-emission economy, which also reflect the demand for financial market products that reflect future-related issues. Therefore, some industrial sectors—like the fossil fuel energy sector and

pollution-intensive sectors and services—will be penalized, but new sectors will be created. Moreover, a transition would be necessary, and this shift reflects the growing financial support by companies engaging in environmental projects either as disruptive change or as a transitory shift. These changes reflect of course the cost of capital as argued by Blitz and Swinkels.[21]

However, Partridge and Medda argued that assessing performance, demand, and supply of green bonds is challenging. Specifically, the green premium is available in the secondary market, but it is not observed in the primary market. Challenges arise from the lack of data, pricing, liquidity, and the long-term holding period of green bonds and the fiduciary duties of bond managers, among other reasons.

Both academics and practitioners have documented that new types of bonds and bond structures are needed to attract and allocate capital to the necessary public and private investments. The debt market offers several opportunities to impact carbon emissions via bond covenants and special borrowing arrangements such as green bonds.

The major vehicle is green bonds. Mark Carney, governor of the Bank of England and chair of the Financial Stability Board, stated that the development of green bonds is an opportunity to advance a low-carbon future while raising global investment and increasing global growth.[22] In many aspects of modern financial markets, we see a transitory shift form the public into private sources of capital.

MANAGING RISKS AND TAKING OPPORTUNITIES

Institutional investors' responsibility to manage and protect their beneficiaries' assets must consider the impacts of climate change. In addition, if we are all to avoid dangerous climate change outcomes, investors will play a crucial part in contributing the trillions of dollars needed to support the transition to a lower-carbon economy. Many investors are already taking action to manage the risks and capture the opportunities that climate change presents:

- Reducing exposure to high-carbon assets
- Engaging with companies and policy makers[23]
- Integrating climate change into investment strategies[24]

- Undertaking scenario analysis
- Improving disclosure and transparency
- Allocating capital to new, low-carbon, climate-resilient opportunities[25]

We investigate the possibilities to bond managers to influence and construct strategies to better cope with climate change. For bond portfolio managers, these strategies are based on negative and positive lists, avoiding specific investments, trading green bonds, and participating in the primary market by investing in green bonds or sustainability-linked bonds. First, we investigate the key strategies available for bond managers.

INTERNATIONAL NORM-BASED STRATEGIES

In the last 10 years several strategies have been established to reflect the growing "norm-based" strategies. For example, Fossil Fuel Free, UN SDGs, and UN Global Compact are the most important and widely accepted strategies. A brief explanation highlights the differences in these strategies. The UN Global Compact (Global Pact of United Nation) requires the consistent preservation of minimum social and ecological impact within organizations. Important principles referred to are human rights, diversity, child labor, bribery, and environmental protection.[26] However, as Amel-Zadeh and Serafeim argued, the lack of reporting standard makes the ESG criteria implementation a challenging task.[27]

What are green bonds, and why are green bonds a complementary tool to improve climate issues?

Green bonds are fixed income securities that have positive environmental and/or climate benefits. They are used to finance or refinance climate change undertakings. These bonds are issued via a special-purpose vehicles by supranational entities, central governments, government agencies, and corporations.[28] By definition, they follow the Green Bond Principles (GBP) stated by the International Capital Market Association (ICMA). The proceeds from the issuance are strictly used for pre-specified projects. The GBP are guidelines that recommend transparency and disclosure of information necessary to evaluate the environmental impact of a green bond.[29]

Under the *Green Use of Proceeds Bond*, the bond is full-recourse debt obligation. Under the *Green Use of Revenue Bond*, the bond is nonrecourse to the issuer and backed solely by the cash flow of the funded project. Fabozzi and

Nahlik stressed that under the third type, *Green Use of Proceeds Project Bond*, investors are fully exposed to the underlying project risk.[30] A further option is the *Green Use of Proceeds Securitized Bond*. This represent a structured product similar to plain vanilla covered bonds or asset-backed securities. There is a wide classification for green bond projects. In this respect, uniform guidelines are under development. Summarizing, we argue that the most green bonds have been issued for the purpose of financing or refinancing low-carbon-emission projects.

KEY STRATEGIES FOR MANAGING CLIMATE IMPACT OF BOND PORTFOLIOS

Amel-Zadeh and Serafeim stressed that performance, demand, and strategy and ethical considerations are highly important factors. More importantly, Branch argued that fund managers might act as alpha seekers or social activists with greater focus on their clients' needs and perceptions regarding environmental, social, and governance issues. There are several issues that reflect the engagement, decisions, and applications for corporate bond managers. And here an important distinction is necessary. Whereas companies dealing with renewable energies like solar, wind, and water are small newly founded enterprises dealing with environmental issues, large companies (blue chips) are focused on social and governance issues. The small and middle-size enterprises do not make new issues in large corporate debt. Moreover, the capital for such companies is provided by venture capitalists, private equity funds, and private placements. New corporate debt issues with a nominal size of $500 million is a privilege for large companies. Companies issuing debt in excess of $1 billion are primarily engaged in governance practices.

Alford argued that it is important to note that an ESG analysis does not differentiate between ESG and sustainability regarding equity or fixed income investing.[31] Moreover, the ultimate task is to assign a rating score based on the entire company structure. Therefore, conducting due diligence and research on companies includes analysis of the entire capital structure. However, the equity structure is much different than the debt capital. Whereas equity shareholders can directly participate and are involved in the long-term policy by their voting rights, debt owners have little influence on the company's activities. Corporate bond managers as debt holders can much less emphasize ESG factors unless they are dedicated to the principles and implement an active corporate bond strategy.

Bond Covenants

An alternative way available to corporate bond investors to influence corporate carbon emission practices is through covenants, as argued by Focardi and Fabozzi.[32] Covenants can specify a target emission level that, if violated by the corporate borrower, would result in a covenant default (as opposed to a payment default). Carbon policy performance bonds, also called index-linked carbon bonds, are bonds that specify carbon emission reduction targets. These bonds, which have been issued by governments, have a periodic interest rate that is linked to the carbon emission reduction the issuing entity must satisfy. Failure to satisfy the specified carbon emission reduction target for a period results in the imposition of a penalty in the form of a higher interest rates. Appropriate benchmarks are inevitable for measuring carbon emissions and to meet standardized reporting issues, regulation, and transparency. These tasks remain challenging, as stressed recently by Gyura.[33] The reporting issues reflect also the disclosure policy of green bond funds on projects and even more importantly on individual, very often heterogeneous, green bond reports, which make aggregation and standardization even harder to achieve.

Corporate Governance

Governance issues refer to management quality, culture, risk profile, and other related issues. Corporate governance incorporates the senior management responsibility to meet long-term obligations regarding strategic goals and socially responsible targets. Engagement with corporate governance would translate in better and efficient reporting and, in fact, a transparent management process that eliminates corruption and requires explicit management commitment to climate and environmental issues. These issues also reflect further problematic practices like management compensation, lobbying, board membership, and so on.

Screening of Investments

Investing in green bonds requires a setup that refers to the specific preselection and more precisely to the screening of criteria directly relevant to long-term portfolio investment. The screening of investments refers to the *negative* or *exclusionary* screening. Specifically, it refers to the exclusion from a portfolio of certain sectors, companies, or practices based on specific ESG criteria. Alternatively, bond managers apply *positive* or *best-in-class* screening. Positive screening refers to the analysis of sectors, companies, or projects selected for positive ESG performance relative to industry peers. A very specific activity involves *norms-based screening*. The primary task here is the screening of investments against

32. Focardi and Fabozzi, "Climate Change and Asset Management."
33. Gyura, "Green Bonds and Green Bond Funds."

minimum business practices based on international norms. Norms-based screening is split into two different techniques:

- Defining the green bond investment universe based on a company' performance on international norms related to responsible investment/ESG issues.
- Exclusion of companies from portfolios after investment if they are found following research, and sometimes engagement, to contravene these norms. Such norms include but are not limited to, for example, the UN Global Compact Principles, the UN Universal Declaration of Human Rights, the UN International Labour Organization, and so on.

Positive screenings help to investigate the different sectors and to make investment decisions in the most successful companies. Primary market investments refer to the low-carbon transition process and will play a critical role in aligning bond portfolios to support and accelerate the transition to a lower-carbon economy. Opportunities are clean energy infrastructure (wind and solar projects), storage infrastructure, grid technology, low-emission vehicles in the transportation sector, and energy efficiency in the built environment and companies issuing green bonds to finance these undertakings. Portfolio managers could invest in securitized green bonds. In general, bond managers look at the new issues in the primary market and premiums in the secondary market.

Negative screening refers to avoiding or selling of debt securities of companies heavily exposed to fossil fuels or environmental pollution. However, not only primary producer companies are of particular interest, but companies involved in the entire business-cycle of environmentally problematic industries in general.

Active Involvement and Implementation of ESG Strategy by Corporate Bond Managers

Active engagement in ESG strategy requires a close interaction with executives, board members, and portfolio managers in order to push the ESG themes and their implementation in an organization. This immediately highlights a chain process, in which the entire life cycle of a product and investment is involved. Specifically, not only the asset management company purchasing a bond is involved, but also all other related parties. From a bond portfolio management point of view, the returns, portfolio and policy constraints, asset allocation, liquidity, holding period, and risk management are significant parts of the process. We highlight specific issues related to the activities related to implementation of an ESG strategy:

- Management
- Stakeholders and investors
- Portfolio managers

Under the management approach, collaboration with board members, executives, and related parties aims at aligning return targets, risk and return metrics, and philosophy of investing. The alignment targets the future performance measurement and benchmarking. Within this framework, benchmarks, peer group analysis, and factor models for evaluation can produce meaningful results.

Portfolio managers pursuing an ESG strategy must invest a lot of resources in communication. The communication refers to performance and development presentations, reports on progress, results, targets including engagement, investment, and avoiding an investment in a company. For example, portfolio managers might present the recent increase of factor models and their success to explain the variance of ESG portfolio returns.

Portfolio managers are in the forefront of implementing ESG strategies. This is the most heterogeneous and broad way to actively implement the ESG strategy. Both active and passive strategies face wide acceptance. The tactic asset allocation and strategic portfolio are common issues. For example, a bond manager might implement passively low-carbon investments. Alternatively, the long-term structure of a current bond portfolio might shift to an ESG strategy.

The role of the portfolio managers can be split into three main categories. The first refers to *engagement*—the extent of involvement with regulators, policymakers, and board members to implement the principles. The second channel to implement the ESG strategy is *investment*. Investing in fixed income securities can be done in an asset class or on sector level. It can affect a part of the asset allocation or the entire portfolio. For example, a portfolio manager could invest the whole corporate bond exposure of a portfolio in sustainable bonds, but leave the allocation of a portfolio to government bonds unaffected by the ESG strategy.

Review and Monitoring

To utilize ESG initiatives and principles, and capitalize their effects, portfolio managers have to constantly monitor and review the implementation of the principles and policies—implementing a PRI reporting framework for example. Disclosing portfolio holdings and exposure is an increasingly important step toward transparency and wide acceptance of ESG in the asset management industry. Specifically, bond managers might disclose their holdings in certain sectors as part of their active strategies. Gyura identified the transparency and the disclosure of portfolio holdings as a challenging issue, as global official green bond register does not exist.[34] The focus might be to achieve a higher educational level for both investors and potential clients. For example, reduction of the bond portfolio exposure to an industrial sector toward green energy might send positive signals to regulators, clients, and the public.

34. Gyura, "Green Bonds and Green Bond Funds."

THE GREEN BOND DILEMMA AND FUTURE OUTLOOK

Despite the fact that the spreads are low and the yield pick up limited, the diversification advantage of green bonds from a quantitative asset management point of view should not be neglected. Even more, despite the fact that green bonds do not deliver significant returns, the impact that green bonds might have in the economy and on future generations should be considered carefully. This issue has been raised recently by Meziani.[35] The author showed that green bonds reduce systematic risk. Adding green bond exposure to a government bond portfolio or diversified bond fund would reduce volatility not only through the lower beta coefficients but also due to a low liquidity risk. More specifically, previous research stressed that green bonds outperform during financial turmoil but underperform during normal conditions. As Madhavan, Sobczyk, and Ang (2020)[36] argued, managers would be able to generate value-added returns, on average, by adding time-varying factor exposure for example. Renneboog, Horst, and Zhang argue that investors embrace the initiative of pursuing socially responsible investments.[37] Therefore, corporate bond managers should consider them within an investment process, engaging with management to encourage them and achieve a positive environmental impact. Last but not least, the issue size remains a barrier for bond managers to participate in new issues. Although, relatively small companies make new bond issuance, a positive trade-off might be the result of intensive dialog between fund managers and company management. Increasing issue size, covenants, and regulatory change might bring desired results. Involvement of endowments, sovereign wealth funds, pension funds, and governments might significantly change the environmental landscape.

Canfin and Grandjean[38] and Gyura[39] highlighted that there is a dilemma with green bonds that stems from the fact that green bond issuance does not immediately translate into green projects. Shislov, Morel, and Cochran even argued that green projects might be undertaken without green bond issuance.[40] However, the authors argue, decreasing the cost of capital might be a positive catalyst for green project utilization. Again, we argue that the role of corporate bond

managers in this case is important. Bond managers can exert influence in both the pre-issuance (as the use of bond proceeds are determined) and post-issuance (as the impact reporting is published). Further bond manager involvement would be the participation in scientific committees that would at least provide steps to translate target and desired tasks into investment procedures. A data-driven green bond investment process and the development of newest techniques in financial management might help managers with ratings, transparency, and evaluation issues. This important aspect has been recently addressed by Reed, Cort, and Yonavjak.[41]

The current stage of ETF development would be positive for bond trading and improving liquidity. Specifically, using electronic exchange, bond managers could enjoy higher liquidity in the market of green bonds for example. We remain confident that the future development in the industry, the rising worries highlighting the public interest on environmental issues, and the transition from small ESG-interested groups toward broader engagement of shareholders, regulators, investors, and asset managers will result in a positive overall impact. In our view, there should not be a discussion whether to divest or to engage. Moreover, the solution board members, institutional investors, regulators, and fund managers in particular should take is to engage.

In general, bond fund evaluation and asset class evaluation reveal that green bonds are still underdeveloped, do not automatically generate excess returns, and do not necessarily represent a *greenium* in the primary market, as argued by Zerbib.[42] Hachenberg and Schiereck[43] argued that green bonds do not even differ from normal bonds in terms of their spreads. However, a major issue remains that data on green bonds, green bond funds, and ESG in general is sparse. Zerbib argued that the entire primary market yield curve is slightly lower for green bonds than for plain vanilla bonds. However, Wulandari, Schäfer, Stephan, and Sun[44] found a significant premium in the secondary market. Rising bond prices in the secondary market might suggest higher liquidity, as most retail investors cannot approach the primary market and demand for exceeds the supply of green bonds. The influence the secondary market might have on the prime market that was initially suggested has not happened yet, thus it is up to bond managers to engage corporate management to improve the financial market for green bonds. Transparency, monitoring, and engagement would provide a better scope for

successful climate-related policy, which in turn would help not only investors but also society as a whole.

KEY POINTS

- We presented the challenges, current investment opportunities, and prospects for achieving positive environmental impact. Specifically, corporate bond managers should turn more attention to active engagement. We present both aspects of ESG management—alpha seeking fund managers and those who are environmentally and socially motivated to achieve returns and specific client goals.
- Green bonds offer several possibilities for influencing and achieving environmental benefits for future generations. Despite negative returns, they provide diversification, and, moreover, investors might be willing to opt for lower returns in order to achieve higher social and environmental objectives.
- The integration of the ESG and the principles of socially responsible investing on a broad level involving asset owners, corporate management, and fund managers might be beneficial for both current and future generations. Exercising control of the use of proceeds, higher transparency, and unified and standardized reporting are the promising fields on which investors and most of all portfolio managers might focus.
- Increasing issue size, covenants, and regulatory change might bring desired results. Involvement of endowments, sovereign wealth funds, pension funds, and governments might significantly change the environmental landscape.
- Portfolio managers are in the forefront in implementing ESG strategies. The most important role of the portfolio managers is to engage and not to divest.

CHAPTER

FIFTY-SIX

GLOBAL CREDIT BOND PORTFOLIO MANAGEMENT

Jack Malvey, CFA
Global Capital Market Consultant

Corporate bonds are the most demanding and fascinating subset of the global debt capital markets. The label, *corporate,* understates the scope of this burgeoning asset class. As commonly traded and administered within the context of an overall debt portfolio, the "corporate asset class" actually encompasses much more than pure corporate entities. Instead of the title, *corporate asset class,* this segment of the global bond market really should be classified as the *credit asset class,* including non-agency mortgage-backed securities (MBS), commercial mortgage-backed securities (CMBS), and asset-backed securities (ABS). Sovereigns and government-controlled entities with foreign currency debt issues thought to have more credit risk than the national government also should be included. In keeping with conventional practice in the debt market, however, the application of the term *credit asset class* in this chapter will pertain only to taxable corporate bonds, sovereigns, and government-controlled entities. U.S. tax-exempt issuers and issues for the separate U.S. municipal debt asset class are not covered in this chapter.

From six continents, thousands of organizations (corporations, government agencies, projects, and structured pools of debt securities) with different credit "stories" have sold debt to sustain their operations and to finance their expansion. These borrowers use dozens of different types of debt instruments (first mortgage bonds, debentures, equipment trust certificates, subordinated debentures, medium-term notes, floating-rate notes, private placements, preferred stock) in multiple currencies (dollars, yen, euros, sterling, Swiss francs, reals, renminbi) from maturities ranging from one year to even a thousand years. Sometimes, these debt structures carry embedded options, which may allow for full or partial redemption prior to maturity at the option of either the borrower or the investor. Sometimes, the coupon payment floats with short-term interest rates or resets to a higher rate after a fixed interval or a credit-rating change.

Investors buy credit assets because of the presumption of higher long-term returns despite the assumption of credit risk. Except immediately prior and during recessions, credit products usually outperform local government bond benchmarks like U.S. Treasury securities and other higher-quality "spread sectors" such as U.S. agency securities, mortgage-backed securities, and asset-backed securities.

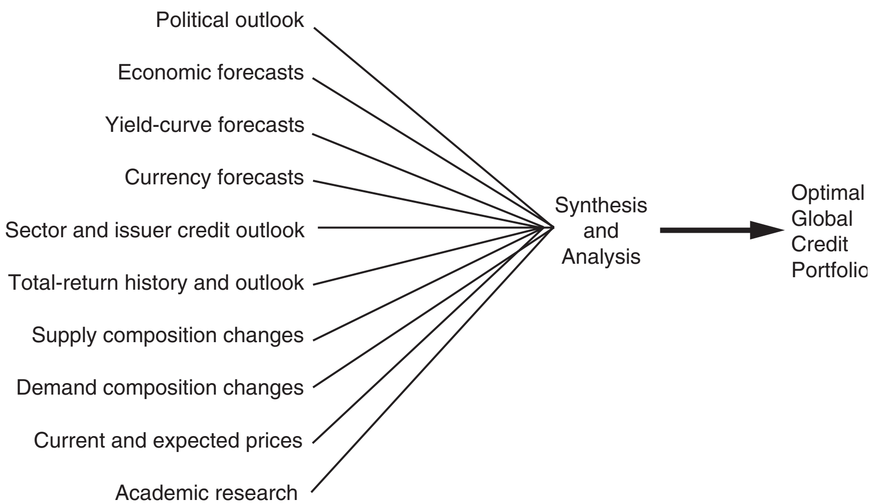
Global credit portfolio management presents a complex challenge. Each day hundreds of credit portfolio managers face thousands of choices in the primary (new issue) and secondary markets. In addition to tracking primary and secondary flows, investors have to keep tabs on ever-varying issuer fundamentals, creditworthiness, acquisitions, earnings, ratings, and prices cast in multiple gauges (bond price, nominal spread, interest-rate swap spread, and credit default swap spread). The task of global credit portfolio management is to process all this rapidly changing information about the credit markets (prices, issuers, issues, dealers, and competing managers) and construct the portfolio with the best return for a given risk tolerance. This discipline combines the qualitative tools of equity analysis with the quantitative precision of debt analysis.

Exhibit 56-1 illustrates the magnitude of this information-processing challenge. From a set of 5,000 different issuers, investors can assemble 4×10 (55) different combinations of 20-bond portfolios. The number of potential portfolio combinations of 20 bonds expands to the infinity neighborhood with the inclusion of additional variables such as rating (20 choices), issues (100,000), and currencies (at least 20). Incredibly, the number of potential combinations of this 20- bond credit portfolio exceeds the neutrons in the known universe. In turn, this begs the question of whether credit portfolio "optimization" is truly achievable given the current state of technology. Although perfect optimization may prove elusive, the optimization goal remains a worthy pursuit for asset managers.

Despite this apparent limitation on the perfection of credit portfolio optimization, broad demand exists for credit debt. Investors in credit debt consist of

EXHIBIT 56-1

Global Credit Sector Asset Allocation Methodology



individuals in the pursuit of incremental yields above government bonds, central banks aiming to extract a higher yield and return on their considerable holdings of fixed income assets, commercial banks arbitraging the difference between the greater yields on floating-rate notes and their lower cost of funding, mutual funds attempting to maximize both yield and total return, insurers and state pension funds seeking to fund their projected long-term liabilities, institutional total-return maximizers competing against each other on a monthly, quarterly, and annual basis to satisfy their clients (public or private pension fund plan sponsors) or risk their loss, and hedge funds staking out usually leveraged long or short positions in credits with short-term potential for major price movements. Portfolio investment choices are driven also by the existing security population of the credit market (sector, issuer, structure, and currency) and often the need to constrain tracking error deviations from broad corporate indices, by the psychology of portfolio managers (overall risk tolerance, shortfall risk aversion, and internal politics of the investment-management institution), and the state of market liquidity.

Borrowers and investors intersect mainly through dealers in both the classic telephone form and increasingly through "e-market techniques" such as electronic exchanges, websites, and emails. Each day a few dozen credit bond dealers convey information about secondary positions and new issue offerings from any of the thousands of credit borrowers to the hundreds of credit bond portfolio managers. Through their investment banking and syndicate operations, dealers also advise issuers on when and how to sell new debt. Through their debt research, sales, and trading arms, dealers relay investment recommendations to portfolio managers.

As shown in Exhibit 56-2, the task of global credit bond portfolio management is to process rapidly changing information about the credit bond market (cash and derivative prices, industry and issuers' fundamentals, ratings, issuance, demand, dealer market-making, and competing asset managers) and construct a portfolio with the best expected return for a given risk tolerance.

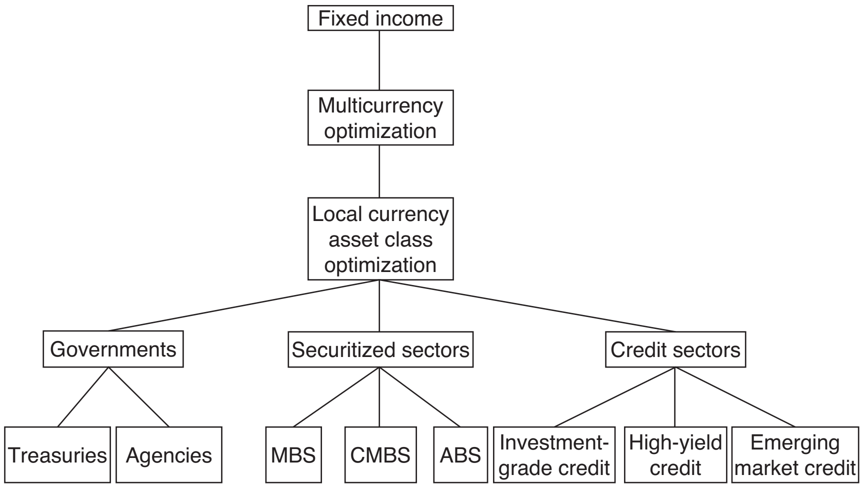
CREDIT RELATIVE-VALUE ANALYSIS

Credit portfolio management represents a major subset of the multi-asset global portfolio management process illustrated in Exhibit 56-2. After setting the currency allocation (in this case, dollars were selected for illustration convenience) and distribution among key debt asset classes (Treasuries, credit, agencies, asset-backed securities, commercial mortgage-backed securities, and mortgage-backed securities), bond managers are still left with a lengthy list of questions to construct an optimal credit portfolio. Some examples are:

- What stages are the global and local business cycles (peak, descending to recession, recession, ascending to peak)?
- How are overall capital market liquidity conditions and dealer receptiveness to trading?

EXHIBIT 56-2

Fixed Income Portfolio Management Process



- Will structural changes in broad market themes, geopolitical risk, regulation, rating agency philosophy, and portfolio management methodology affect valuations?
- Should U.S. investors add U.S. dollar–denominated bonds of non-U.S. issuers?
- Should central banks and sovereign wealth funds add high-quality euro-denominated corporate bonds or high-quality emerging market sovereigns to their reserve holdings?
- Should short-term money-market funded London-based portfolio managers buy fixed-rate U.S. industrial paper and swap into floating-rate notes?
- Should Japanese mutual funds own euro-denominated telecommunications debt swapped back into dollars or yen using currency swaps?
- Should U.S. insurers buy perpetual floaters (i.e., floaters without a maturity date) issued by British banks and swap back into fixed-rate coupons in dollars using a currency/interest rate swap?
- When should investors reduce their allocation to the credit sector and increase allocation to governments, pursue a "strategic upgrade trade" (sell Baa/BBB and buy higher-rated Aa/AA credit debt), rotate from industrials into utilities and/or financial institutions, switch from consumer cyclicals to noncyclicals, overweight airlines and underweight

telephones, or deploy a credit derivative (e.g., short the high-yield index or reduce a large exposure to a single issuer by selling an issuer-specific credit default swap) to hedge their portfolios?

To respond to such questions, managers need to begin with an analytical framework (relative-value analysis) and to develop a strategic outlook for the global credit markets.

Relative Value

Economists have long debated the concept and measurement of "value." But fixed income practitioners, perhaps because of the daily pragmatism enforced by the markets, have developed a consensus about the definition of value. In the bond market, *relative value* refers to the ranking of fixed income investments by geographic regions, sectors, structures (i.e., fixed versus floating rate), issuers, and issues in terms of their expected performance over some future period of time (horizon).

For a day trader, relative value may carry a maximum horizon of a few hours. For a dealer, relative value may extend from a few hours to a few months. For a total-return investor, the relative-value horizon typically runs from one to three months. For a large insurer, plan sponsor, and sovereign wealth fund, relative value usually spans a multiyear horizon. Accordingly, *relative-value analysis* refers to the methodologies used to generate such rankings of expected returns.

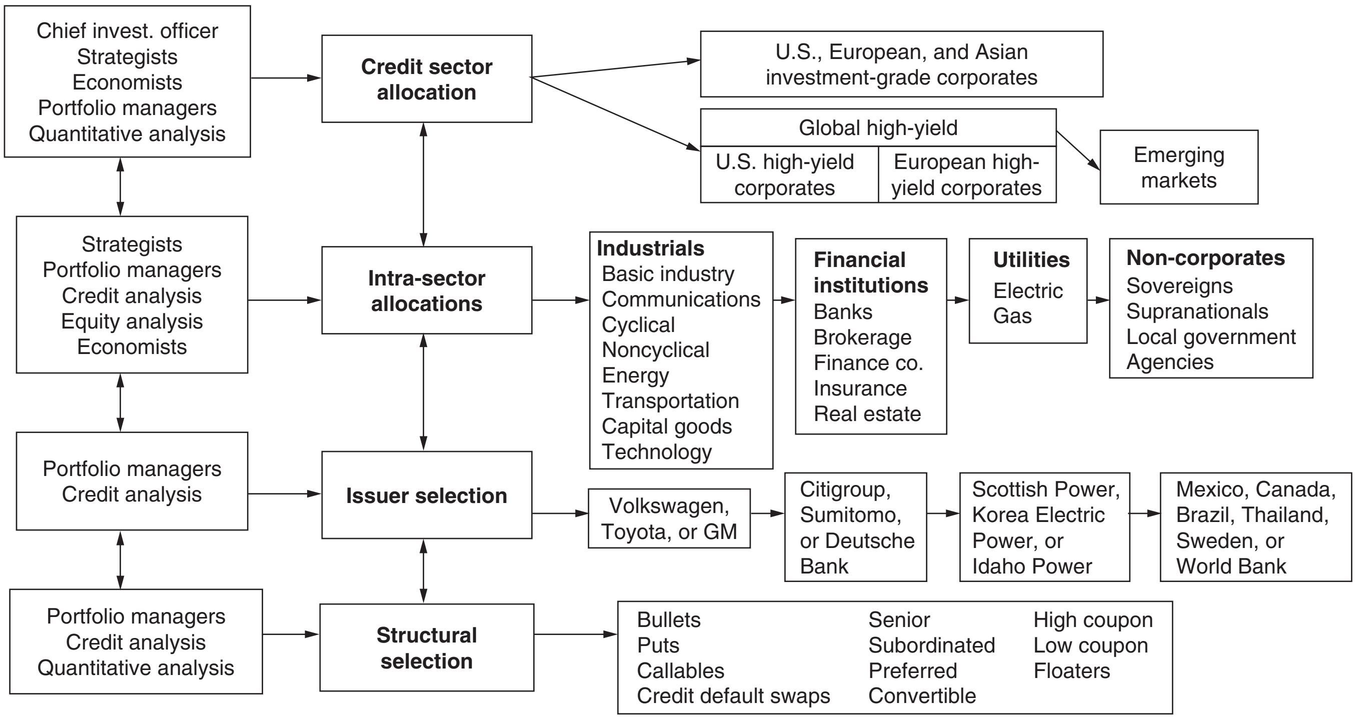
Classic Relative-Value Analysis

There are two basic approaches to global credit bond portfolio management—*top-down approach* and *bottom-up approach*. The top-down approach focuses on high-level allocations among broadly defined credit asset classes. The goal of top-down research is to form views on large-scale secular economic and industry developments like geopolitical risk, demographics, climate change, energy, global monetary and fiscal policies, global trade and capital flow imbalances, and plan sponsor investment philosophy. These views then drive asset allocation decisions (overweight certain sectors, underweight others). The bottom-up approach seeks to identify individual issuers and issues that will outperform their peer groups. Managers follow this approach hoping to outperform their benchmark owing to superior security selection while maintaining mainly neutral weightings to the sectors in the benchmark.

Classic relative-value analysis is a dialectic process combining the best of top-down and bottom-up approaches as shown in Exhibit 56-3. This process blends the macro input of chief investment officers, strategists, economists, and portfolio managers with the micro input of credit analysts, quantitative analysts, and portfolio managers. The goal of this methodology is to pick the sectors with the most potential upside, populate these favored sectors with the best

EXHIBIT 56-3

Credit-Sector Portfolio Management Process: Classic, Dialectic Relative-Value Analysis



representative issuers, and select the structures of the designated issuers at the yield-curve points that match the investor's overall portfolio duration target and perspective on the Treasury benchmark yield-curve.

For many credit investors, the use of classic relative-value analysis usually leads to portfolio management success. Although sector, issuer, and structural analyses remain the core of superior relative-value analysis, the increased availability of information and technology has transformed the analytical process into a complex discipline. Credit portfolio managers have far more data than ever on the total returns of sectors, issuers, and structures; quantity and composition of new-issue flows; investor product demand; aggregate credit-quality movements; multiple sources of fundamental and quantitative credit analyses on individual issuers; and yield-spread data to assist them in their relative-value analysis.

Relative-Value Methodologies

The main methodologies for credit relative-value maximization are

- Total-return analysis
- Primary market analysis
- Liquidity and trading analysis
- Secondary trading rationales and constraints analysis:
- Spread analysis
- Structure analysis
- Credit-curve analysis
- Green bonds, "ESG" compliant
- Credit analysis
- Asset allocation/sector analysis

In the sections that follow, we discuss each of these methodologies.

TOTAL-RETURN ANALYSIS

The goal of global credit portfolio management for most investors is to optimize the risk-adjusted total return of their credit portfolio. The best place to start is naturally total-return analysis. Accordingly, credit relative-value analysis begins with a detailed analysis of past returns and a projection of expected returns. For the entire asset class and major contributing subsectors (such as banks, utilities, natural gas pipelines, sovereigns, Baa/BBB, etc.), how have returns been generated? How much is attributed to credit-spread movements, changes in the fundamental fortunes of key issuers, and yield-curve dynamics? If there are macro determinants of credit returns (the total return of the credit asset class), then credit markets may display regular patterns. For instance, the macroeconomic cycle is the major driver of overall credit-spreads. With the approach of and during recessions, the escalation of default risk widens (raises) spreads (which are risk premiums over underlying, presumably default-free government securities—or swaps) and reduces credit returns relative to Treasuries. Conversely, economic prosperity reduces bankruptcies and enhances overall credit fundamentals of most issuers. Economic growth usually leads to tighter (lower) credit-spreads and boosts credit returns relative to Treasuries. For brief intervals, noncyclical technical factors can offset fundamentals.

Thanks to the development of total-return indexes for credit debt (databases of prices, spreads, issuer, and structure composition), analyses of monthly, annual, and multiyear total returns have uncovered numerous high-frequency patterns (i.e., large issue versus small issue performance variation, seasonality, election-cycle effects, and government benchmark auction effects) in the global credit market. Although they do not always recur, an awareness and understanding of these regular patterns is essential to optimizing portfolio performance.

PRIMARY MARKET ANALYSIS

The analysis of primary markets centers on new-issue supply and demand. Supply is often a misunderstood factor in tactical relative-value analysis. Prospective new supply induces many traders, analysts, and investors to advocate a defensive stance toward the overall credit market as well as toward individual sectors and issuers. Yet the premise, "supply will hurt spreads," which may apply to an individual issuer, does not generally hold up for the entire credit market. Credit spreads are governed by many factors; supply, although important, represents one of many determinants of spreads. During most years, increases in issuance (most notably during the first quarter of each year) are associated with market-spread contraction and strong relative returns for credit debt. In contrast, sharp supply declines are accompanied frequently by spread expansion and a major fall in both relative and absolute returns for credit securities. For example, this counterintuitive effect was most noticeable during August–October 1998. (Russian devaluation/default and Long-Term Capital Market implosion), August–December 2008 (fall of Lehman Brothers and onset of global financial panic), and March–May 2020 (initial peak of COVID-19 pandemic) when new issuance nearly disappeared temporarily in the face of a substantial increase in credit spreads.

In the investment-grade credit market, heavy supply is often associated with concurrent spread compression and boosts relative returns for credit assets as new primary valuations validate and enhance secondary valuations. When primary origination declines sharply, secondary traders lose reinforcement from the primary market and tend to reduce their bid. Contrary to the normal supply–price relationship, relative credit returns often perform best during periods of heavy supply.

The Effect of Market-Structure Dynamics

Given their immediate focus on the deals of the day and week, portfolio managers often overlook short- and long-term market-structure dynamics in making portfolio decisions. Because the pace of change in market structure is often gradual, market dynamics have less effect on short-term tactical investment decision making than on long-term strategy.

The composition of the global credit bond market shifted markedly over the last third of the twentieth century and continues in the twenty-first century. For example, medium-term notes (MTNs) dominated issuance in the front end of the credit yield-curve (1–7-year maturities) during the 1980s and 1990s. Structured notes and swap products heralded the introduction of derivative instruments into the mainstream of the credit market in the 1990s. The high-yield corporate sector became a widely accepted asset class in the 1980s, with emerging market debt following in the 1990s. Global origination became more popular since the early 1990s for U.S. government agencies, supranationals (e.g., World Bank), sovereigns, and large corporate borrowers.

Although the ascent of derivatives and high-yield instruments stood out during the 1990s, the quickening march toward full credit market globalization was the most important structural trend. The rapid development of the Eurobond market since 1975, the introduction of many non-U.S. issuers into the dollar markets during the 1990s, and the birth of the euro on January 1, 1999, led to the proliferation of truly transnational credit portfolios. The accelerating expansion of local-currency denominated debt origination, especially from Brazil, Russia, India, and China (the so-called BRICs), likely will be recalled as the most prominent evolutionary feature of early twenty-first-century global credit markets.

These long-term structural changes in the composition of the global credit asset class arise owing to the desire of issuers to minimize funding costs in different currencies, yield-curves, and yield spreads, as well as the needs of both active and asset/liability bond managers to satisfy their risk and return objectives. Portfolio managers will adapt their portfolios either in anticipation of or in reaction to these structural changes across the global credit markets.

The Effect of Product Structure

Partially offsetting the proliferation of issuers since the mid 1990s, the global credit market has become structurally more homogeneous. Specifically, bullet and intermediate-maturity structures have come to dominate the credit market. A *bullet maturity* means that the issue is not callable, putable, or sinkable prior to its scheduled final maturity. The trend toward bullet securities does not pertain to the high-yield market, in which callables remain the structure of choice. With the hope of credit-quality improvement, many high-yield issuers expect to refinance prior to maturity at lower rates.

There are three strategic portfolio implications for this structural evolution. First, the dominance of bullet structures translates into scarcity value for structures with embedded call and put features. That is, credit securities with embedded options have become rare and therefore demand a premium price. Typically, this premium (price) is not captured by option-valuation models. Yet, this "scarcity value" should be considered by managers in relative-value analysis of credit bonds.

Second, bonds with maturities beyond 20 years are a small share of outstanding credit debt. This shift reduced the effective duration of the credit asset class and cut aggregate sensitivity to interest-rate risk.

Third, the use of credit derivatives has skyrocketed since the early 1990s. The rapid maturation of the credit derivative market has led investors and issuers to develop new strategies to match desired exposures to credit sectors, issuers, and structures. In particular, many high-frequency traders (dealer desks, hedge funds, and active total return managers) prefer to execute their long and short credit positions in highly liquid portions of the credit derivative market rather than in conventional cash credit securities.

LIQUIDITY AND TRADING ANALYSIS

Short- and long-term liquidity needs influence portfolio management decisions. Citing lower expected liquidity, some investors are reluctant to purchase certain types of issues such as small-sized issues (less than $1 billion), private placements, MTNs, and nonlocal corporate issuers. Other investors gladly exchange a potential liquidity disadvantage for incremental yield. For investment-grade investors with even a medium-term horizon of more than six months, these liquidity concerns often are exaggerated.

The liquidity of credit debt changes over time. Specifically, liquidity varies with the economic cycle, credit cycle, shape of the yield-curve, supply, and the season. As in all markets, unknown shocks, such as a surprise wave of defaults or an eruption of geopolitical risk as in the immediate wake of 9/11, can reduce credit debt liquidity as investors become unwilling to purchase new issues at almost any spread and dealers become reluctant to position secondary issues except at very wide spreads. In reality, these transitory bouts of illiquidity mask an underlying trend toward heightened liquidity across the global credit asset class. With a gentle push from regulators, the global credit asset class is well along in converting from its historic "over-the-counter" domain to a fully transparent, equity/U.S. Treasury–style marketplace. In the late 1990s, new technology led to the creation of ECNs (electronic communication networks), essentially electronic trading exchanges. FINRA introduced the Trade Reporting and Compliance Engine (TRACE) to track publicly all institutional-sized trades of credit securities. In turn, credit bid/ask spreads generally have shifted lower for very large, well-known credit issues. This powerful combination of technological innovation and competition promises the rapid development of an even more liquid and efficient global credit market during the twenty-first century.

SECONDARY TRADE RATIONALES

Capital market expectations constantly change. Recessions may arrive sooner rather than later. The yield-curve may steepen rather than flatten in anticipation of monetary policy adjustments. Cyclical sectors, like auto and paper, may be moving down from their peaks. Higher oil and natural gas prices may enhance the credit quality of the energy sector. An industrial firm may have announced a large debt-financed acquisition, earning an immediate ratings rebuke from the rating agencies. A major firm may plan to repurchase 15% of its outstanding common stock (great for shareholders but leading to higher financial leverage for debt holders). In response to such daily information flows, portfolio managers amend their holdings. To understand trading flows and the real dynamics of the credit market, investors should consider the most common rationales of whether to trade and not to trade.

Popular Reasons for Trading

There are dozens of rationales to execute secondary trades when pursuing portfolio optimization. Several of the most popular are discussed below.

Yield-Spread Pickup Trades

Yield-spread pickup trades represent the most common secondary transactions across all sectors of the global credit market. Historically, at least half of all secondary swaps reflect investor intentions to add additional yield within the overall duration and credit-quality constraints of a portfolio.

This "yield-first psychology" reflects the institutional yield need of long-term asset/liability managers (plan sponsors and insurers). This investor bias toward yield maximization also may be a methodological relic left over from the era prior to the introduction and market acceptance of total-return indexes in the early 1970s.

Credit-Upside Trades

Credit-upside trades take place when the debt asset manager expects an upgrade in an issuer's credit quality that is not already reflected in the current market yield spread.

Credit-upside trades are particularly popular in the crossover sector—securities with ratings between Ba2/BB and Baa3/BBB– by two major rating agencies. In this case, the portfolio manager is expressing an expectation that an issue of the highest speculative-grade rating (Ba1/BB+) has sufficiently positive credit fundamentals to be upgraded to investment-grade (i.e., Baa3/BBB–). If this upgrade occurs, then not only would the issue's spread narrow based on the credit improvement (with an accompanying increase in total return, all else equal), but the issue also would benefit from improved liquidity because managers prohibited from buying high-yield bonds could then purchase that issue. Further, the manager would expect an improvement in the portfolio's overall risk profile.

Credit-Defense Trades

Credit-defense trades become more popular as geopolitical and economic uncertainty increase. Secular sector changes also often generate uncertainties and induce defensive positioning by investors. Unfortunately, because of yield-maximization needs and a general reluctance to realize losses by some institutions (i.e., insurers), many investors react more slowly to credit-defensive positioning. Ironically, once a credit is downgraded by the rating agencies, internal portfolio guidelines often dictate security liquidation immediately after the loss of single-A or investment-grade status. This is usually the worst possible time to sell a security and maximizes losses incurred by the portfolio.

New-Issue Swaps

New-issue swaps contribute to secondary turnover. Because of perceived superior liquidity, many portfolio managers prefer to rotate their portfolios gradually into more current and usually larger sized on-the-run issues. This disposition, reinforced by the usually superior market behavior of newer issues in the U.S. Treasury market (i.e., the on-the-run issues), has become a self-fulfilling prophecy for many credit issues. In addition, some managers use new-issue swaps to add exposure to a new issuer or a new issue structure.

Sector-Rotation Trades

Sector-rotation trades, within credit and among fixed income asset classes, have become more popular since the early 1990s. In this strategy, the manager shifts the portfolio from a sector or industry that is expected to underperform to a sector or industry that is believed will outperform on a total-return basis. With the general development of enhanced liquidity and lower trading transaction costs during non-crisis periods across the global bond market in the early twenty-first century, sector-rotation trades have become more prevalent in the credit asset class. Such intra-asset class trading has played a major role in differentiating performance among credit portfolio managers.

Curve-Adjustment Trades

Yield-curve-adjustment trades, or simply, *curve-adjustment trades,* are taken to reposition a portfolio's duration. For most credit investors striving for return maximization, their portfolio duration is typically within a range from 20% below to 20% above the duration of the benchmark index. Although most fixed income investors prefer to alter the duration of their aggregate portfolios in the more-liquid Treasury market, strategic portfolio duration tilts also can be implemented in the credit market. Such trades also are executed in anticipation of changes in the credit term structure or credit curve. For example, if portfolio managers believes that credit-spreads will tighten (either overall or in a particular sector), with rates in general remaining relatively stable, then they might shift the portfolio's exposure to longer-spread-duration credit issues in their preferred sectors.

Structure Trades

Within the set of investment-grade, fixed-rate credit securities, *structure trades* have become rarer as the global credit markets have become more homogeneous centered on intermediate bullets. Structure trades are swaps into structures (e.g., callable structures, bullet structures, and putable structures) that are expected to have better performance given expected movements in volatility and the shape of the underlying yield-curve. Structure trades also encompass swaps from less stringent issue indentures into stricter indentures that may afford bond investors greater protection should the issuer encounter financial difficulties. By expanding the choice set from fixed credit-only debt to include floating rate, preferred, preference, and even convertible securities, structural trades have become very common.

Basis Trades

Traders and asset managers regularly prowl the global credit asset class for discrepancies, even slight, among bond, nominal spread, Option-Adjusted Spread (OAS), interest-rate swap spread, and credit default swap spread values for the same and similar issues. These discrepancies may give rise to advantageous *basis trade* swaps.

Cash-Flow Reinvestment

Cash-flow reinvestment needs force credit investors into the market on a frequent basis. In some years, the sum of all cash flows from coupon, maturity, and partial redemptions (via tenders, sinking funds, and other issuer prepayments) can equal or exceed approximately 100% of all new gross issuance across the dollar bond market. Before the allocation of any net new investment in the bond market, investors have sufficient cash-flow reinvestment to absorb nearly all new bond supply. Some portfolio cash inflows occur during interludes in the primary market, or the composition of recent primary supply may not be compatible with portfolio objectives. In these periods, credit portfolio managers must shop the secondary market for investment opportunities to remain fully invested or temporarily replicate the corporate index by using ETFs, CDS, and financial futures. Portfolio managers who incorporate analysis of cash-flow reinvestment into their valuation of the credit market can position their portfolios to take advantage of the cash-flow reinvestment effect on spreads.

Trading Constraints

Portfolio managers also should review their main rationales for not trading. Some of the best investment decisions are not to trade. Conversely, some of the worst investment decisions emanate from stale views based on dated and anachronistic constraints (e.g., avoid investing in bonds rated below Aa/AA). The best portfolio managers retain very open minds, constantly self-critiquing both their successful and unsuccessful methodologies.

Portfolio Constraints

Collectively, portfolio constraints are the single biggest contributor to the persistence of market inefficiency across the global credit market. Here are some examples:

- Because many asset managers are limited to holding securities with investment-grade ratings, they are forced to sell immediately the debt of issuers who are downgraded to speculative ratings (Ba1/BB+ and below). In turn, this selling at the time of downgrade provides an opportunity for investors with more flexible constraints to buy such newly downgraded securities at a temporary discount (provided, of course, that the issuer's creditworthiness stabilizes after downgrade).
- Some sovereign wealth funds and U.S. state employee pension funds cannot purchase credit securities with ratings below A3/A– owing to administrative and legislative guidelines.
- Some U.S. pension funds also have limitations on their ownership of MTNs and non-U.S. corporate issues.
- Regulators have limited U.S. insurance companies' investment in high-yield corporates.
- Some European investors are restricted to issues rated at least single-A and sometimes Aa3/AA– and above, created originally in annual-pay Eurobond form.
- Some investors are confined to their local currency market—yen, sterling, euro, U.S. dollar. Often the same issuer will trade at different spreads in diverse local markets.

- Globally, many commercial banks must operate primarily in the floating-rate realm; this limits their use of all fixed-rate securities, unless converted into floating-rate cash-flows via an interest-rate swap.

"Story" Disagreement

"Story" disagreement can work to the advantage or disadvantage of a portfolio manager. Traders, salespersons, sell-side analysts and strategists, and buy-side credit researchers have dozens of potential trade rationales that supposedly will enhance portfolio performance. The proponents of a secondary trade may make a persuasive argument, but the portfolio manager may be unwilling to accept the "shortfall risk" if the investment recommendation does not provide its expected return. For example, in early 1998, analysts and investors alike were divided on short-term prospects for better valuations of Asian sovereign debt. After a very disappointing 1997 for Asian debt performance, Asia enthusiasts had little chance to persuade pessimists to buy Asian debt at the beginning of 1998. Technically, such lack of consensus in the credit market often signals an investment with great outperformance potential. Indeed, most Asian debt issues recorded exceptional outperformance over the full course of 1998 and 1999. After a difficult 2002, the same "rebound effect" was observed in U.S. electric utilities during 2003. Of course, "story" disagreement also can work in the other direction. For example, Enron and Lehman Brothers were long viewed as very solid credits before their sudden bankruptcies in late 2001 and September 2008, respectively. An asset manager wedded to this long-term view might have been reluctant to act on the emergence of less favorable information about Enron in the summer of 2001 and about Lehman during early 2008.

Buy-and-Hold

Although many long-term asset/liability managers claim to have become more absolute total-return-focused in the 1990s, accounting constraints (cannot sell positions at a loss compared with book cost or take too extravagant a gain compared with book cost) often limit the ability of these investors to trade. Effectively, these investors (mainly insurers) remain traditional buy-and-hold investors. Some active bond managers have converged to quasi-buy-and-hold investment programs at the behest of consultants to curb portfolio turnover. In the aftermath of the "Asian Contagion" in 1997–1998 and the Great Recession–induced financial panic of September 2008–March 2009, this disposition toward lower trading turnover was reinforced by the temporary reduction in market liquidity provided by wary bond dealers. At the first signs of a system-wide credit event (systemic risk) or credit trouble for an issuer (idiosyncratic risk), many credit portfolios would have improved returns by reducing their exposure to the overall credit asset class or to a deteriorating credit. And in the case of systemic-risk events, subsequent relative portfolio performance would have been greatly aided by adding solid issues temporarily caught up in the credit market's transitory general dislocation.

Seasonality

Lower-quality credits (Baa/BBB) tend to be more susceptible to underperformance during August–October as dealers and investors become more defensive with the approach of year-end. Conversely, lower-quality credits frequently outperform during the first quarter on optimistic hopes for strong economic, industry, issuer fundamentals for the full calendar year. Secondary trading slows at month end, more so at quarter end, and the most at the conclusion of calendar years. Dealers often prefer to reduce their balance sheets at fiscal year-end (December 31 or March 31 [Japan]). Also, portfolio managers take time to mark their portfolios, prepare reports for their clients, and chart strategy for the next investment period. During these intervals, even the most compelling secondary offerings can languish.

SPREAD ANALYSIS

By custom, some segments of the high-yield and emerging (EM) debt markets still prefer to measure value by bond price or bond yield rather than spread. But for the rest of the global credit market, nominal spread (the yield difference between corporate and government bonds of similar maturities) has been the basic unit of both price and relative-value analysis for more than two centuries.

Alternative Spread Measures

Many U.S. practitioners prefer to value investment-grade credit securities in terms of option-adjusted spreads (OAS) so that they can be compared more easily to the volatility ("vol") sectors (mortgage-backed securities and U.S. agencies).[1] But given the rapid reduction of credit structures with embedded options since 1990 (see structural discussion above), the use of OAS in primary and secondary pricing has diminished within the investment-grade credit asset class. Moreover, the standard one-factor binomial models[2] do not account for credit-spread volatility. And given the exclusion of default risk in OAS option-valuation models, OAS

1. These sectors are referred to as "vol" sectors because the value of the securities depends on expected interest rate volatility. These "vol" securities have embedded call options and the value of the options, and hence the value of the securities, depends on expected interest rate volatility.
2. The model is referred to as a "one-factor model" because only the short-term rate is the factor used to construct the tree.

valuation has seen only limited extension into the higher-risk markets of the quasi-equity, high-yield corporate, and EM-debt asset classes.

Starting in Europe during the early 1990s and gaining momentum during the late 1990s, interest-rate swap spreads emerged as the common denominator to measure relative value across fixed- and floating-rate note credit structures. The U.S. investment-grade and high-yield markets eventually may rely more heavily on such swap spreads to be consistent with Europe and Asia. But with the exponential growth of the credit-default swap (CDS) market since approximately 2000, CDS spreads have emerged as the standard gauge of relative pricing for large credit issuers.

The swaps framework allows managers (as well as issuers) to more easily compare securities across fixed-rate and floating-rate markets. The extension of the swap-spread framework may be less relevant for speculative-grade securities, in which default risk becomes more important. In contrast to professional money managers, individual investors are not comfortable using bond valuation couched in terms of swap spreads. The traditional nominal spread framework is well understood by individual investors, has the advantages of long-term market convention, and works across the entire credit-quality spectrum from Aaa to B. However, the nominal spread framework does not work very well for investors and issuers when comparing the relative attractiveness between the fixed-rate and floating-rate markets.

Spread Tools

Investors also should understand how best to evaluate spread levels in their decision making. Spread valuation includes mean-reversion analysis, quality-spread analysis, and percent yield-spread analysis.

Mean-Reversion Analysis

The most common technique for analyzing spreads among individual securities and across industry sectors is *mean-reversion analysis*. The *mean* is the average value of some variable over a defined interval (usually one economic cycle for the credit market). The term *mean reversion* refers to the tendency for some variables's value to revert (i.e., move toward) its average value. Mean-reversion analysis is a form of relative-value analysis based on the assumption that the spread between two sectors or two issuers will revert back to its historical average. This would lead investors to buy a sector or issuer identified as "cheap" because historically the spread has been tighter and will eventually revert back to that tighter spread. Also, this would lead investors to sell a sector or issuer identified as "rich" because the spread has been wider and is expected to widen in the future.

Mean-reversion analysis involves the use of statistical analysis to assess whether the current deviation from the mean spread is significant. For example, suppose that the mean spread for an issuer is 80 basis points over the past six months and the standard deviation is 12 basis points. Suppose that the current spread of the issuer is 98 basis points. The spread is 18 basis points over the mean spread or, equivalently, 1.5 standard deviations above the mean spread. The manager can use that information to determine whether or not the spread deviation is sufficient to purchase the issue. The same type of analysis can be used to rank a group of issuers in a sector.

Mean-reversion analysis can be instructive as well as misleading. The mean is highly dependent on the interval selected. There is no market consensus on the appropriate interval, and persistence frequents the credit market meaning that cheap securities, mainly a function of credit quality uncertainty, can remain cheap or become cheaper still.

Quality-Spread Analysis

Quality-spread analysis examines the spread differentials between low- and high-quality credits. For example, portfolio managers would be well advised to consider the "credit upgrade trade" when quality spreads collapse to cyclical troughs. The incremental yield advantage of lower-quality products may not compensate investors for lower-quality spread expansion under deteriorating economic conditions. Alternatively, credit portfolio managers have long profited from overweighting lower-quality debt at the outset of an upward turn in the economic cycle.

Percent Yield-Spread Analysis

Dating from the early twentieth century, *percent yield-spread analysis* (the ratio of credit yields to government yields for similar-duration securities) was another popular technical tool used by some investors. This methodology has serious drawbacks that undermine its usefulness. Percent yield spread is more a derivative than an explanatory or predictive variable. The usual expansion of credit percent yield spreads during low-rate periods overstates the risk as well as the comparative attractiveness of credit debt. And the typical contraction of credit percent yield-spreads during upward shifts of the benchmark yield-curve does not necessarily signal an imminent bout of underperformance for the credit asset class. Effectively, the absolute level of the underlying benchmark yield is merely a single factor among many factors (demand, supply, profitability, defaults, etc.) that determine the relative value of the credit asset class. These other factors can offset or reinforce any insights derived from percent yield-spread analysis.

STRUCTURAL ANALYSIS

As explained earlier in this chapter, there are bullet, callable, putable, and sinking fund structures. *Structural analysis* is simply analyzing the performance of the different structures discussed throughout this chapter. While evaluating bond structures was extremely important in the 1980s, it has become less influential in the credit bond market since the mid 1990s for several reasons. First, the European credit bond market almost exclusively features intermediate bullets. Second, the U.S. credit and the global bond markets have moved to embrace this structurally homogeneous European bullet standard. Plenty of structural diversity still resides within the U.S. high-yield and EM debt markets, but portfolio decisions in these speculative-grade sectors understandably hinge more on credit differentiation than the structural diversity of the issue-choice set.

Still, structural analysis can enhance risk-adjusted returns of credit portfolios. Leaving credit aside, issue-structure analysis and structural allocation decisions usually hinge on yield-curve and volatility forecasts, as well as interpretation of option-valuation model outputs (see the discussion below). This is also a key tool in making relative-value decisions among structured credit issues, mortgage-backed securities, and asset-backed securities. In the short run and assuming no change in the perceived creditworthiness of the issuer, yield-curve and volatility movements largely will influence structural performance. Investors also should take into account long-run market dynamics that affect the composition of the market and, in turn, credit index benchmarks.

Specifically, callable structures have become rarer in the U.S. investment-grade credit bond market. This is due to an almost continuously positively sloped U.S. term structure since 1990 and the yield-curve's intermittent declines to approximately multi-decade lows in 1993, 1997, 1998, 2002, 2008–2010, and 2020. As a result, the composition of the public U.S. corporate bond market converged toward the intermediate-bullet Eurobond and euro-denominated bond market. Sinking-fund structures, once the structural mainstay of U.S. natural-gas pipelines and many industrial sectors, are on the "structural extinct species list."

Callables

Typically after a 5- or 10-year wait (longer for some rare issues), credit structures are callable at the option of the issuer at any time. Call prices usually are set at a premium above par (par + the initial coupon) and decline linearly on an annual basis to par by 5 to 10 years prior to final scheduled maturity. The ability to refinance debt in a potentially lower-interest-rate environment is extremely valuable to issuers. Conversely, the risk of earlier-than-expected retirement of an above-current market coupon is bothersome to investors.

In issuing callables, issuers pay investors an annual spread premium (about 20–40 basis points for high-quality issuers) for being long (from an issuer's perspective) the call option. Like all security valuations, this call premium varies through time with capital market conditions. Given the higher chance of exercise, this call option becomes much more expensive during low-rate and high-volatility periods. Since 1990, this call premium has ranged from approximately 15–50 basis points for investment-grade issuers. Callables significantly underperform bullets when interest rates decline because of their negative convexity. When the bond market rallies, callable structures do not fully participate given the upper boundary imposed by call prices. Conversely, callable structures outperform bullets in bear bond markets as the probability of early call diminishes.

Sinking Funds

A sinking-fund structure allows an issuer to execute a series of partial calls (annually or semiannually) prior to maturity. Issuers also usually have an option to retire an additional portion of the issue on the sinking-fund date, typically ranging from one to two times the mandatory sinking-fund obligation. Historically, especially during the early 1980s, total-return investors favored the collection of sinking-fund structures at subpar prices. These discounted sinking funds retained price upside during interest-rate rallies (provided the indicated bond price remained below par), and given the issuers' requirement to retire at least annually some portion of the issue at par, the price of these sinking-fund structures did not fall as much compared with callables and bullets when interest rates rose. It should be noted that astute issuers with strong liability management skills sometimes can satisfy such annual sinking-fund obligations in whole or in part through prior open-market purchases at prices below par. Nonetheless, this annual sinking-fund purchase obligation by issuers limits bond price depreciation during periods of rising rates.

Putables

Conventional put structures are simpler than callables. Yet, in trading circles, put bond valuations often are the subject of debate. American-option callables grant issuers the right to call an issue at any time at the designated call price after expiration of the noncallable or nonredemption period. Put bonds typically provide investors with a onetime, one-date put option (European option) to demand full repayment at par. Less frequently, put bonds include a second or third put option date. A very limited number of put issues afford investors the privilege to put such structures back to the issuers at par in the case of rating downgrades (typically to below investment-grade status).

Thanks to falling interest rates, issuers shied away from new put structures as the 1990s progressed. Rather than incur the risk of refunding the put bond in 5 or 10 years at a higher cost, many issuers would prefer to pay an extra 10 to 20 basis points in order to issue a longer-term liability.

Put structures provide investors with a partial defense against sharp increases in interest rates. Assuming that the issuer still has the capability to meet its sudden obligation, put structures triggered by a credit event enable investors to escape from a deteriorating credit. Perhaps because of its comparative scarcity, the performance and valuation of put structures have been a challenge for many portfolio managers. Unlike callable structures, put prices have not conformed to expectations formed in a general volatility–valuation framework. Specifically, the implied yield volatility of an option can be computed from the option's price and a valuation model. In the case of a putable bond, the implied volatility can be obtained using a valuation model such as the binomial model. The implied volatility should be the same for both puts and calls, all factors constant. Yet, for putable structures, implied volatility ranged from 4% to 9% in the 1990s, well below the 10% to 20% volatility range associated with callable structures for the same time period. This divergence in implied volatility between callables (high) and putables (low) suggests that asset managers, often driven by a desire to boost portfolio yield, underpay issuers for the right to put a debt security back to the issuer under specified circumstances. In other words, the typical put bond should trade at a lower yield in the market than commonly the case.

Unless put origination increases sharply, allowing for greater liquidity and the creation of more standardized trading conventions for this rarer structural issue, this asymmetry in implied volatility between putable and corporate structures will persist. Meanwhile, this structure should be favored as an outperformance vehicle only by investors with a decidedly bearish outlook for interest rates.

CREDIT-CURVE ANALYSIS

The rapid growth of credit derivatives since the mid 1990s has inspired a groundswell of academic and practitioner interest in the development of more rigorous techniques to analyze the term structure (1–100 years) and credit structure (Aaa/AAA through B2/B) of credit-spread curves (higher-risk, higher-yield securities trade on a price rather than a spread basis).

Credit curves, both term structure and credit structure, are almost always positively sloped. In an effort to moderate portfolio risk, many portfolio managers take credit risk in short and intermediate maturities and substitute less-risky government securities in long-duration portfolio buckets. This strategy is called a *credit barbell strategy*. Accordingly, the application of this strategy diminishes demand for longer-dated credit risk debt instruments by many total-return, mutual fund, and bank portfolio bond managers. Fortunately for credit issuers who desire to issue long maturities, insurers and pension plan sponsors often meet long-term liability needs through the purchase of credit debt with maturities that range beyond 20 years.

Default risk increases nonlinearly as creditworthiness declines. The absolute risk of issuer default in any one year remains quite low through the investment-grade rating categories (Aaa/AAA to Baa3/BBB−). But investors constrained to high-quality investments often treat downgrades like quasi-defaults. In some cases, such as a downgrade from single-A to the Baa/BBB category, investors may be forced to sell securities under rigid portfolio guidelines. In turn, investors justifiably demand a spread premium for the increased likelihood of potential credit difficulty as rating quality descends through the investment-grade categories.

Credit-spreads increase sharply in the high-yield rating categories (Ba1/BB+ through D). Default, especially for weak single-B and CCC, becomes a major possibility. The credit market naturally assigns higher and higher risk premia (spreads) as credit and rating risk escalate.

In particular, the investment-grade credit market has a fascination with the slope of issuer credit curves between 10- and 30-year maturities. Like the underlying Treasury benchmark curve, credit-spread curves change shape over the course of economic cycles. Typically, spread curves steepen when the bond market becomes more wary of interest-rate and general credit risk. Spread curves also have displayed a minor propensity to steepen when the underlying benchmark curve flattens or inverts. This loose spread-curve/yield-curve linkage reflects the diminished appetite for investors to assume both curve and credit risk at the long end of the yield-curve when higher total yields may be available in short and intermediate-credit products.

CREDIT ANALYSIS

In the continuous quest to seek credit upgrades and contraction in issuer/issue spread resulting from possible upgrades and, more important, to avoid credit downgrades resulting in an increase in issuer/issue spread, superior credit analysis has been and will remain the most important determinant of credit bond portfolio relative performance. Credit screening tools tied to equity valuations, relative spread movements, and the Internet (information available tracking all related news on portfolio holdings) can provide helpful supplements to classic credit research and rating agency opinions. But self-characterized credit models, relying exclusively on variables such as interest-rate volatility and binomial processes imported from option-valuation techniques, are not especially helpful in ranking the expected credit performance of individual credits.

Credit analysis is both nonglamorous and arduous for many top-down portfolio managers and strategists, who focus primarily on macro variables. Genuine credit analysis encompasses actually studying issuers' financial statements and accounting techniques, interviewing issuers' managements, evaluating industry issues, reading indentures and charters, and developing an awareness of (not necessarily concurrence with) the views of the rating agencies about various industries and issuers.

GREEN BONDS/ESG COMPLIANT

The notion of "green bonds" began in the 1970s when some investors began to avoid buying the debt of electric utilities constructing nuclear power plants, especially after the accident at Three Mile Island in 1979. Through time, this reticence to invest in firms that were less rigorous in their adherence to pristine environmental, social, and governance (ESG) practices became more common and was often formally enshrined in investment guidelines. In response, green equity and debt indices were devised. A slew of green/ESG investment vehicles (particularly ETFs)were created by many mutual funds and institutional money managers. As a result, even in-house asset managers were obligated to consider the green/ESG status of existing and potential investments. At root, this well-intentioned practice created another rationale to either buy, hold, or sell a credit debt investment.

ASSET ALLOCATION/SECTOR ROTATION

Sector rotation strategies have long played a key role in equity portfolio management. In the credit bond market, "macro" sector rotations among industrials, utilities, financial institutions, sovereigns, and supranationals also have a long history. During the last quarter of the twentieth century, there were major variations in investor sentiment toward certain credit sectors like utilities, industrials, and financial institutions.

Beginning in the mid 1990s, "micro" sector rotation strategies in the credit asset class have become much more influential as portfolio managers gain a greater understanding of the relationships among intracredit sectors from these index statistics.

Exhibit 56-4 illustrates the main factors bearing on sector rotation and issuer selection strategies. For example, an actual or perceived change in rating agency philosophy toward a sector and a revision in profitability expectations for a particular industry represent just two of many factors that can influence relative sectoral performance.

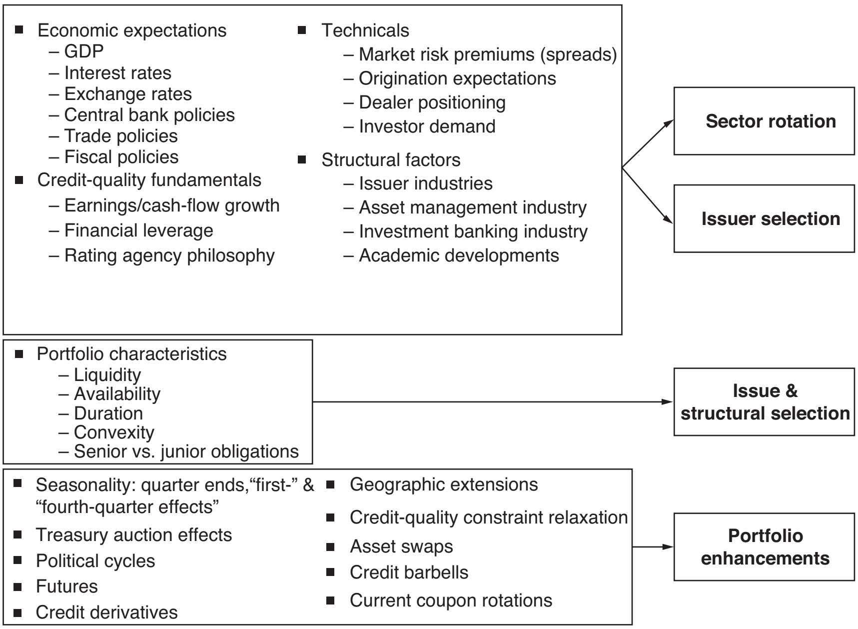
Common tactics to hopefully enhance credit portfolio performance are also highlighted in Exhibit 56-4. In particular, seasonality again warrants comment. The annual rotation toward risk aversion in the bond market during the second half of most years contributes to a "fourth-quarter effect;" that is, there is underperformance of lower-rated credits, B in high-yield and Baa in investment-grade, compared with higher-rated credits. A fresh spurt of market optimism greets nearly every new year. Lower-rated credit tends to outperform higher-quality credit. This is referred to as the "first-quarter effect." This pattern suggests a very simple and popular portfolio strategy: underweight low-quality credits and possibly even credit products altogether until the mid-third quarter of most years and then move to overweight lower-quality credits and all credit products in the fourth quarter of most years.

KEY POINTS

- As prescribed in capital market theory, investors should be rewarded for the assumption of incremental risk. Reality conforms to theory in the global credit market. Over the long run, credit products provide higher long-term returns than presumably risk-free government securities.

EXHIBIT 56-4

Some Outperformance Methodologies



- Credit returns and risk are viewed as "asymmetric." On occasion, asset managers may suffer large, transitory relative underperformance to Treasuries with the onset of systemic risk event. And the price of individual credit securities may tumble from the par vicinity to zero in the event of default.
- Credit bond portfolio management requires more work and asset management firm infrastructure than other debt asset classes. There are thousands of credit choices, dozens of security forms, and multiple structures, and the size of the global credit asset class will accelerate during the twenty-first century thanks to the entrance of new emerging market based issuers.
- Global bond management philosophy has evolved rapidly over the past two decades. Major portfolio-duration bets (more than 10% above or below the duration of an index benchmark) have become less common by asset managers because of frequent duration-timing disappointments. The use of CDS has expanded. New quantitative tools to assist in relative-value rankings and asset allocation (i.e., risk budgeting) have proliferated. And particularly at large asset management firms, credit portfolios have truly become globalized.

- In conjunction with the demonstrably higher long-term returns of corporates and an ongoing migration from “government-only index benchmarks” to “government plus corporate and securitized index benchmarks,” this reduction in currency and curve timing has propelled investor interest in global credit portfolio optimization as a path to more consistent overall portfolio outperformance in an increasingly competitive asset management industry.

CHAPTER
FIFTY-SEVEN

INTERNATIONAL BOND PORTFOLIO MANAGEMENT

Gueorgui S. Konstantinov, Ph.D., CAIA, FDP
Senior Portfolio Manager
LBBW Asset Management

Frank J. Fabozzi, Ph.D., CFA, CPA
Professor of Finance
EDHEC Business School

International bond portfolios invest in heterogeneous fixed income securities. Their focus is global, and compared to traditional bond funds, global bond funds try to gain different market premiums. Specifically, international bond funds focus on generating alpha investment in currencies and government bonds as liquid instruments and have exposure to corporate bonds, high-yield bonds, and financials both in local and hard currency. International unconstrained bond funds—that is, funds without restriction on which type of securities they have to invest in—use derivative instruments to generate excess returns.

Interest rates have been decreasing in the last 20 years, generating enormous bond market returns. However, the interest rates in different countries exhibit different dynamics in normal market environments and sometimes converge during times of financial distress. There are two main types of markets in which global bond funds invest: emerging markets and developed markets. In general, aggressively allocating bond funds prefer liquid instruments, countries with less political risk, and the major global currencies and asset classes, and use futures, options, and other derivatives. These funds invest in futures on interest rates, currencies, foreign exchange options, government bonds, and corporate bonds. They often undertake currency hedging, but in general implement active currency bets using options, forwards, and other derivatives.

Alternatively, some conservative bond funds prefer to invest in a large number of securities and to gain the liquidity premium—for example, investing in less liquid government and corporate bonds in both hard and local currencies—and have large numbers of portfolio holdings. However, these funds have less portfolio turnover.

In general, there are two currency universes that institutional investors prefer to invest in. The G10 currencies are the most liquid developed market currencies. The G10 include U.S. Dollar (USD), Euro (EUR), Canadian Dollar (CAD), British Pound (GBP), Swiss Franc (CHF), Japanese Yen (JPY), Swedish Krone (SEK), Norwegian Krone (NOK), Australian Dollar (AUD), and New Zealand Dollar (NZD).

The emerging markets (EM) group comprises the currencies of heterogeneous countries with different levels of liquidity. EM currencies include Mexican Peso (MXN), Brazilian Real (BRL), Chili Peso (CLP), Columbian Peso (COP), South African Rand (ZAR), Polish Zloty (PLN), Russian Rubble (RUB), Turkish Lira (TRY), Hungarian Forint (HUF), Thai Baht (THB), Malaysian Ringgit (MYR), Philippine Peso (PHP), and Indonesian Rupiah (IDR), among others.[1]

A third group is the *frontier markets* group, consisting of Nigeria, Romania, Bangladesh, Jordan, Oman, Argentina, Bulgaria, Kazakhstan, and Sri Lanka, among others, which offer high yields but suffer from extremely low liquidity and are beyond the primary focus of international bond portfolio managers.

It is important to note that international bond funds are classified according to their emerging market exposure. Funds with large weights in EM are considered by database providers to be EM funds. This distinction is less important from a management perspective unless the manager desires explicitly to change its category in a specific category. Database providers for global bond funds include Mercer Insight, Morningstar, and Lipper, among others.

The objective of the chapter is to provide a detailed analysis of a yield curve–based quantitative approach to management of international bond portfolios. A central issue is how to deal with risks associated with international bond portfolios, to derive expected bond returns for multiple currencies, and to optimize portfolio allocation and fixed income security selection in a multiple-stage procedure. Finally, the monitoring and the performance attribution using multiple spot curves that is an integral part of the management process is described.

RISKS AND RETURNS IN INTERNATIONAL BOND PORTFOLIOS

International bond portfolios involve a complex number of risks. Some of these risks are common for traditional fixed income portfolios. However, these risks interact, and their interconnectedness increases with time. Exhibit 57-1 summarizes six main risks of international bond portfolios.[2]

For globally invested portfolios there is a specific, heavy risk factor, which is the currency risk. Anson argued that currencies have an expected return of zero, and thus investments in local currency fixed income securities expose the

1. The classification changes with time. The current classification refers to FTSE, MSCI, S&P, and Russell: https://en.wikipedia.org/wiki/Frontier_markets.

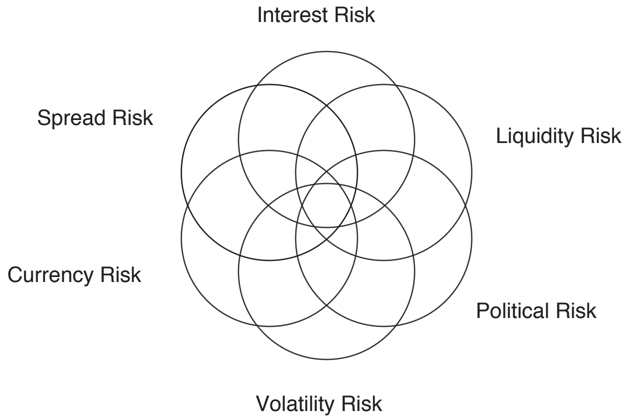
EXHIBIT 57-1

Interacting Common Risks for International Bond Portfolios



portfolio to a certain amount of volatility.[3] This underlines the short-term necessity of actively managing international bond portfolios. Controlling for the currency volatility and exposure becomes a central part of international fixed income portfolios. Currency risk, interest rate risk, and spread risk are directly related to liquidity and political risks. The latter become increasingly relevant for EM and less capitalized financial markets—e.g., Sub-Sahara, Asia, and LatAm.

In addition, the liquidity risk is in the normal market environment contradictory to the currency and interest rate risk, as liquidity premium requires a long-term holding period. Bond portfolios with short-term views focus on interest rate risk, currency risk, and spread risk. A major issue is the weekly currency and rate volatilities, which had a correlation of 0.69 in the period from 2005 to 2019. The monthly correlation coefficient is 0.62. The high correlation between rates and currencies requires approaches and tools that deal with the dynamic of the two asset classes.

Thus, the main focus turns to international bond portfolios dealing with currency, interest rate, and spread risk, as managers apply multiple approaches to asset allocation and securities selection. We show that volatility risk is a primary risk in international bond portfolios.

A YIELD CURVE–BASED APPROACH FOR INTERNATIONAL BOND PORTFOLIOS

Decomposing the price of a fixed income security provides valuable information for portfolio managers. Considering the discrete price change of a fixed income security in a small change in time-to-maturity shows the relationship clearly. It is easy to decompose the total return of a bond into a price change due to the passage of time and a change of bond price due to a change in yield:

$$R_t = \frac{P_t - P_{t-1}}{P_{t-1}} = \frac{\Delta P(t,y)}{P} = \frac{\partial P}{\partial t}\frac{1}{P}\Delta t + \frac{\partial P}{\partial y}\frac{1}{P}\Delta y$$

To derive expected returns, the focus remains on the passage of time component. Building the total differential shows the effects on the expected returns:

$$\begin{aligned}\left[\frac{\partial P}{\partial t}\frac{1}{P}\Delta t\right] &= \sum\nolimits_{i=1}^{n} CFe^{-yt}\left(-t\frac{\partial y}{\partial t} - y\frac{\partial t}{\partial t}\right)\frac{1}{P}\Delta t \\ &= -t\sum\nolimits_{i=1}^{n} CFe^{-yt}\,\frac{1}{P}\frac{\partial y}{\partial t}\Delta t - \sum\nolimits_{i=1}^{n} CFe^{-yt}\,\frac{1}{P}y\Delta t = MD\frac{\partial y}{\partial t}\Delta t - P\frac{1}{P}y\Delta t\end{aligned}$$

If we assume that there are small changes in time $\frac{\partial y}{\partial t} \approx \frac{\Delta y}{\Delta t}$, and a bond is approaching time-to-maturity as Δy rolls down or up the yield curve, then the passage of time, or roll down, is a sum of a vertical component attracting yield-curve volatility as measured by the modified duration, ($MD\Delta y$), and an initial yield adjusted by the change in time $(y\Delta t)$:

$$\left[\frac{\partial P}{\partial t}\frac{1}{P}\Delta t\right] = MD\frac{\partial y}{\partial t}\Delta t - P\frac{1}{P}y\Delta t = MD\frac{\Delta y}{\Delta t}\Delta t - P\frac{1}{P}y\Delta t = MD\,\Delta y - y\Delta t$$

Modified duration (MD) is a measure of the interest sensitivity of a bond price to interest rate changes multiplied by the yield changes Δy.

Finally, extending the MD to the spread duration incorporates the spread factor. However, interest rate dynamics are related to currency movements. Thus, bond yield changes ultimately reflect currency dynamics, since the uncovered interest parity (UIP) does not hold in the short term. This is consistent with the short holding periods applied for the roll downs. The UIP states that the interest rate differential between two countries should be equal to the projected change in exchange rate between the respective currencies. If the UIP holds, the interest rate movements would offset currency movements, and vice versa. Put differently, in an unhedged Australian dollar (AUD) bet against the U.S. dollar (USD) with positive pay-off, fixed income instruments would generate loss. The rising yield on an Australian government bond would neutralize the appreciation, and thus the gain, of the AUD–USD position. Again, the fact that the UIP does not hold in the short term allows for the modeling of currency investing and fixed income investing in international bond portfolios with short-term rebalancing.

In an international bond portfolio, to integrate the entire yield curve, we move from discrete to continuous bond pricing. Consequently, parsimonious yield-curve models apply to bond pricing. The theoretical price of a bond $T(t,s)$ at time *t* using the spot curve *s* is

$$T(t,s)=\sum_{t=1}^{n}\frac{CF}{\left(1+s_t\right)^t}=\sum_{t=1}^{n}\frac{CF}{\left(1+\frac{s_t}{n}\right)^{n.t}}=\sum_{t=1}^{n}\frac{CF}{\left(e^{s_t}\right)^t}=\sum_{t=1}^{n}CF.e^{-t.s_t}\text{, with}\lim_{n\to\infty}\left(1+\frac{1}{n}\right)^n=e$$

Now, we can use the spot rates instead of yields and apply the roll downs derived by the corresponding yield curve.

There are two models to fit a yield curve from the observed bond prices. These are the parsimonious Nelson-Siegel and the Svensson approaches.[4] Parsimonious means that a handful number of parameters explain the interest rate dynamics. The Nelson-Siegel polynomial is expressed as follows:

$$s_t\left(\beta_i,m,\tau\right)=\beta_0+\beta_1\left[\frac{1-e^{-\frac{m}{\tau}}}{\frac{m}{\tau}}\right]+\beta_2\left[\frac{1-e^{-\frac{m}{\tau}}}{\frac{m}{\tau}}-e^{-\frac{m}{\tau}}\right]$$

The Nelson-Siegel approach is suitable for sectors, countries, and asset classes with a lower number of fixed income securities available for regression. The local currency spot curves derived from government bonds in Hungary, Poland, the Czech Republic, New Zealand, Norway, Sweden, South Africa, and Mexico are good examples of the suitability of this parsimonious approach.

Formally, the Svensson model is similar to the Nelson-Siegel. The difference is in the additional curvature component β_3 and a decay parameter τ_2 suitable for explaining short-term bond yields. This model is preferred for countries, industry segments, or general sectors with a large number of bonds. The Svensson approach is widely applied to some European government bonds, U.S. Treasury bonds, and Japanese bonds.

$$s_t\left(\beta_i,m,\tau_1,\tau_2\right)=\beta_0+\beta_1\left[\frac{1-e^{-\frac{m}{\tau_1}}}{\frac{m}{\tau_1}}\right]+\beta_2\left[\frac{1-e^{-\frac{m}{\tau_1}}}{\frac{m}{\tau_1}}-e^{-\frac{m}{\tau_1}}\right]+\beta_3\left[\frac{1-e^{-\frac{m}{\tau_2}}}{\frac{m}{\tau_2}}-e^{-\frac{m}{\tau_2}}\right]$$

The shape of local currency spot curves varies substantially between countries. Nelson-Siegel and Svensson polynomials are a good choice for modeling local currency spot curves that behave like real curves and are also a good choice to use for attribution analysis. Exhibit 57-2 contains possible spot curves.

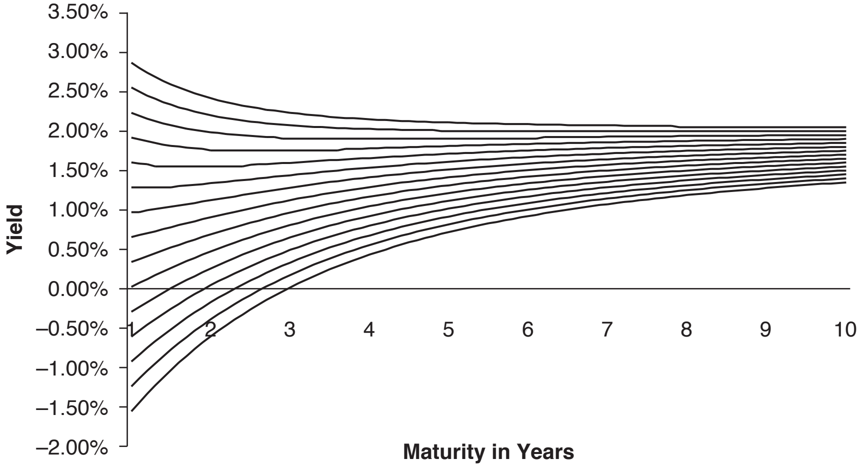
EXHIBIT 57-2

Nelson-Siegel Polynomial for Various Beta-Parameters in a Low-Interest-Level Environment—Simulation



Having fitted the spot curves, a quantitative bond management approach focuses on expected returns. The price (P) of a fixed income security at time *t* is equal to the theoretical price (T) using the underlying spot curve and the option-adjusted spread (OAS):[5]

$$P(t) = T(t, s_t + OAS_t) = \sum_{t=1}^{n} CF.e^{-t(s_t + OAS_t)}$$

The OAS is the spread of a fixed income security that is added to the underlying spot curve in order to estimate the theoretical price of a bond. The OAS is a sum of the z-spread, or zero-volatility spread, or the spread to the spot-rate curve (ZS) and the option component (OC) of a bond with embedded option. Thus, for fixed income securities without embedded options, the OAS is equal to the ZS, which is true for most government bonds, for example.

$$OAS_t = ZS_t + OC_t$$

Thus, the roll-down return of a fixed income security, and thus its expected return, is estimated using the yield curve at the beginning of the period:

$$E(R)_t = T(t_1, s_0 + OAS_0) - T(t_0, s_0 + OAS_0)$$

5. William Burns and Wensong Chu, “An OAS Framework for Portfolio Attribution Analysis,” *Journal of Performance Measurement* (Summer 2005), pp. 8–20, and Phil Galdi, “Bond Index, Rules and Definition: General Calculation Methodology & Classification Scheme,” Merrill Lynch Bond Indices, October 12, 2000, and ICE “Bond Index Methodologies,” July 31, 2018.

Furthermore, the assumption holds that the option-adjusted spread is constant. As spreads and interest rates change with time, choosing an appropriate holding period is an important issue. Otherwise explained, a holding period of three months and estimating roll downs under the assumptions of constant yield curve and constant spread bear significant risk, magnified by the natural strong volatility of currencies. As already noted, foreign exchange volatility impacts the roll downs. Thus, long holding periods are simply unrealistic to lead to robust and trustworthy investment processes.

The expected roll down applies to all fixed income securities in an international bond portfolio and is the building block for the portfolio construction and optimization, and then for spot curve–based performance attribution. In Exhibit 57-3, we apply the analysis to a sample portfolio using fitted spot curves:

CURRENCY ALLOCATION AND BOND SELECTION: PORTFOLIO CONSTRUCTION

Absolute Return Bond Portfolios

Within this setup, the optimization would produce reasonable weights for a portfolio: an allocation to U.S. dollar (USD) might be 25%, an exposure to the Mexican peso (MXN) 10%, to the Australian dollar (AUD) with 5%, and a 15% weight in the New Zealand dollar (NZD), and so on. A long/short portfolio allocation is possible and often desired. Size and side models for allocation are usually in place. Bond managers with currency management skills prefer short currencies with low interest rates and build long positions in currencies with high interest rates. This approach, simply categorized as a carry strategy adapted to bond portfolios, requires strong risk management.

Benchmark Portfolios

Absolute return bond portfolios are the exception. According to Morningstar, most of the international bond portfolios have a benchmark. The following are widely used benchmarks for international bond portfolios focused on government bonds:

- ICE BofA World Sovereign Bond Index
- ICE BofA Global Government Index
- J. P. Morgan GBI Broad Unhedged Index

The country/currency allocation in these indices is similar, with the largest weight in U.S. dollar and U.S. Treasuries of roughly 35%. The second and third largest weights are European government bonds in euro (EUR), with roughly 27%, and Japanese government bonds in Japanese yen (JPY), with roughly 25%. Thus, the three major currencies/countries comprise roughly 75% of the index.

Widely used indices for international bond portfolios that include corporate, quasi-sovereign, and government bonds are the following indices:

- Bloomberg Barclays Global Aggregate Total Return Index Value Unhedged
- Bloomberg Barclays Multiverse Total Return Index Value Unhedged
- ICE BofA Global Fixed Income Markets Index
- ICE BofA Global Broad Market Index

Benchmark portfolios require additional constraints in the allocation process. However, active managers are tempted to allocate aggressively in order to outperform the benchmark. High active share—as a measure of the difference of the absolute sum of weights relative to benchmark—is an integral part of the optimization. However, tracking error can increase substantially. Therefore, currency allocation should take this into account. Additional risk of increasing tracking error results from the number of single fixed income securities in a portfolio. A large number of securities reduces the tracking error. Whereas global government bond indexes comprise roughly 2,000 bonds, global aggregate benchmarks comprise more than 20,000 single issues. In the case of liquid government bonds, a large number of portfolio holdings allows for frequent turnover. However, a large number of less liquid bonds reduces the possibility of frequent turnover, thus decreasing the short-term gains of a currency premium but increasing the liquidity premium in a portfolio. In general, for benchmark portfolios there is a much higher trade-off between the currency risk, liquidity risk, interest rate and spread risk than for absolute return portfolios.

A General Framework for Currencies and Countries

As the complexity of multicurrency international bond portfolios grows, a separation between portfolio allocation and selection is a natural consequence. Considering the newest developments in finance, Marcos López de Prado showed that integrated models dealing with buying or selling fixed income instruments (the *side* decision), and decisions degrading the size of particular exposure (the *size* decision, or risk management decision), present problems for fund managers.[6]

This issue is present and represents a serious concern in international bond portfolios. The reason lies in the different setups for deriving expected returns and considering risks of currencies and fixed income instruments. Whereas currencies have an expected return of zero, the local currency yield curves in different sectors—government, corporate, financial, high-yield, and so on—help to derive expected returns of fixed income securities.

In practice, it is better to build two models, one to allocate in currencies and another to allocate and/or select in bonds. Currency decisions (size) and fixed income decisions (side), or vice versa, of international bond portfolios require different techniques. Let us consider the currency exposure decision as a risk management decision and the bond exposure as a buying or selling decision.

Since currencies represent risk for fixed income portfolios, the minimum variance optimization (MVO) suggested by Nobel prize–winning economist Harry Markowitz (1952) suits the purpose very well to minimize the risks associated with foreign exchange (FX).[7] In this line of thought, currency exposure is an allocation decision. However, following different setups is possible, and a convenient choice between them determines the risk of an international bond portfolio. Nevertheless, multiple decisions may employ two-step MVO optimization:

- Country-Country Allocation
- Country-Currency Allocation
- Currency-Country Allocation

6. Marcos López de Prado, "The 10 Reasons Most Machine Learning Funds Fail," *Journal of Portfolio Management* 44(6), 2018, pp. 120–133.
7. Harry Markowitz, "Portfolio Selection," *Journal of Finance* 7(1), 1952, pp. 77–91.

- Currency-Currency Allocation

Within the *Country-Currency* setup, the manager allocates to the country (e.g., 30% in Japan) and then allocates to different currencies (e.g., JPY-denominated bonds, EUR-denominated bonds, or even USD-denominated bonds). Within this setup, the portfolio asset allocation is not determined by a single factor (e.g., the U.S. dollar). Thus, the analysis is focused on country-specific economic drivers and valuations.

In a *Currency-Country* setup, the portfolio construction has the primary task of determining the currency exposure risk as portfolio allocation and then of making a country decision; for example, an MVO optimization allocated 30% to the Japanese yen (JPY) as a consequence of a risk-off scenario or expectation of market turmoil, and after further optimization, allocates to different countries of risk—European government bonds in JPY of 10% and 20% of U.S. bonds in JPY.

In a *Country-Country* setup, the decision is much more driven by two types of currency debt issuance: hard currency and local currency debt. Within this rare situation, a management decision is spread between a small number of countries issuing debt in hard and in local currencies. An MVO optimization to track the benchmark exposure of the ICE BofA Emerging Markets External Sovereign Index (EMGB Index) is a good example. Specifically, the allocation would be to invest in Bulgarian EUR- or USD-denominated debt.

The *Currency-Currency* allocation is widely applied in international bond portfolios, due to its suitability to reflect the benchmark exposure, both the currency and country allocation, and the liquidity risk in a single step. Specifically, one of the most widely used international bond portfolio benchmarks is the ICE BofA World Sovereign Bond Index, which comprises roughly 35% in USD-, 23% in JPY-, and 30% roughly in EUR-denominated government bonds. Funds that compare their performance against this benchmark in fact manage two of the risks associated with international bond portfolios—interest rate risk and currency risk. Applying currency-currency allocation is the same as country-country allocation, since both risks are identical.

The next natural step in a top-down portfolio management process is to derive portfolio selection. To remain consistent with the previous step, the selection deals with expected risks and returns within the portfolio allocation. Put differently, an allocation of 15% in the British pound requires selection and optimization of weights to the fixed income instruments to fit within this allocation.

OPTIMIZATION TECHNIQUE FOR MULTICURRENCY BOND PORTFOLIOS

Optimizing the Portfolio Allocation

Regarding portfolio allocation, the focus is on optimal currency allocation. The variance of currency movements in a portfolio accounts for a large proportion of portfolio risk, and long time series in all currencies are available for this purpose.

A successful optimization technique for FX risk in a portfolio is the minimum variance optimization (MVO), and a good example is the currency-currency optimization. However, a necessary adjustment to the currency time series is inevitable in order to properly run the optimization and to derive allocation.

A currency pair is given in the notation EUR-USD for example. The first part of the notation means the currency in which the pair is long and the second refers to the short position. Some currency pairs are expressed in unit notations and not in price notations. Put differently, it is essential to convert all unit notations into prices in order to derive returns. In the above example, this notation differs from the base currency of the fund or the currency in which the fund's net asset value (NAV) is denominated. Specifically, the EUR-USD notation and the time series suits a USD-based fund. However, an international bond fund with a euro base currency has to convert the unit notation into a price notation. A similar technique applies to all currencies:

$$\frac{\text{EUR}}{\text{USD}} = 1.083 \rightarrow \text{USDEUR} = 0.9233$$

The EUR-USD notation of 1.083 corresponds to the price notation for a European investor of 0.9233. As a rule of thumb, the base currency should always take the second part of the notation. For funds with base currency in USD, the currency pairs might be: EUR-USD, CAD-USD, AUD-USD, NZD-USD, JPY-USD, CHF-USD, GBP-USD, PLN-USD, HUF-USD, and so on.

This makes clear that the currency allocation of an international bond portfolio depends on a proper formulation of currency risk. Specifically, from the above notation, it is clear that the foreign exchange risk depends on the base currency of a portfolio. Computing the global foreign exchange volatility shows the different volatility magnitude for USD-, EUR-, JPY-, and GBP-based investors. The observant reader can recognize the different magnitude of foreign exchange volatility from different investors' perspectives. As shown in Exhibit 57-5, the currency volatility for JPY-based investors is higher compared with that of EUR-based investors.

Formally, the MVO optimization under consideration of the variance-covariance matrix of currency returns has the following form:

$$\sigma_{PF}^2 = \left(w_1^{FX}, \ldots, w_k^{FX}\right) \begin{pmatrix} \sigma_1^2 & \cdots & \rho_{1k}\sigma_1\sigma_k \\ \vdots & \ddots & \vdots \\ \rho_{k1}\sigma_k\sigma_1 & \cdots & \sigma_k^2 \end{pmatrix} \begin{pmatrix} w_1^{FX} \\ \vdots \\ w_k^{FX} \end{pmatrix}$$

Of course, country weights $w_1^{Country}$ can replace the currency weights w_i^{FX} depending on the management approach, preferences, and constraints.

Optimizing the Portfolio Selection

The complexity of international multicurrency bond portfolios requires appropriate optimization techniques. An appropriate technique should be capable of incorporating a possibly extremely high number of restrictions, for example. However, specific needs might expand the list and thus the matrix equation:

- Multiple modified durations—the portfolio MD as the sum of segment MD
- Maturity buckets—for example, 1–3 years, 3–5 years, 5–7 years, 7–10 years, and more than 10 years in every single currency/country in the portfolio
- Single bond min/max weights—for example, constraints on single fixed income securities in a portfolio
- Sectors and countries—for example, Germany, South Africa, Mexico, Chile, Thailand, Poland
- Currency exposure—for example, USD, GBP, HUF, NZD, EUR, and so on
- Spreads—threshold spread levels as rich/cheap indicators—for example, a maximum of 0.2% spread on U.S. Treasuries above the spot curve is acceptable

- Specific factor sensitivity—specific curve factor exposure
- Interactive exposure—for example, USD- and EUR-denominated corporate bonds, but no GBP-denominated corporates. Alternatively, Australian covered bonds in EUR, but not in local currency.

Linear equations help to model the complex constraints and exposure of an international bond portfolio. A simple estimation would include the desired portfolio allocation expressed as a vector of the portfolio weights. However, fund managers often desire to see the differences between the current portfolio and the new portfolio allocation and selection and thus to estimate the differences as vectors of sell and buy orders. Thus, a more holistic model incorporates the current portfolio in the optimization. The additional add-in allows adjustments for transaction costs (*tc*) and a specific threshold level for the overall portfolio turnover, for example.

Formally, the optimization problem is expressed as follows:

$$Arg \max_{w} w'r = \left(w_1, \ldots, w_n, b_1, \ldots, b_n, s_1, \ldots, s_n\right) \begin{pmatrix} r_1 \\ \vdots \\ r_n \\ tc \\ \vdots \\ tc \end{pmatrix}$$

where w' is the transposed vector of portfolio weights including the buy and sell securities, and r is the vector of expected returns, including a uniform transaction cost penalty parameter tc. Transaction costs can be split into two categories: explicit (such as bid-ask spreads, brokerage fees, and trade and custodian commotions) and implicit (such as market impact and price movement costs). Market impact costs result during the execution of trades and as markets are volatile. In general, large international bond funds have an advantage on the explicit costs; however, too-large bond funds have a strong market impact and might move markets if engaged in specific currencies or fixed income securities. For example, the relatively low spot liquidity and daily average turnover volume of 5,017 million U.S. dollars of the Polish zloty (PLN) against the U.S. dollar might be challenging for a multibillion international bond fund taking a spot 10% bet of its volume in USD-PLN.[8] Additionally, uniform tc is problematic for heterogeneous bond portfolios, since the transaction costs in the different currencies, sectors, sub-asset-classes, and so on, cannot be uniform. For example, the transaction costs for U.S. Treasuries cannot be the same as for trading Indonesian government bonds in Indonesian rupiah (IDR), or Turkish sovereign bonds in EUR, Turkish

8. Bank of International Settlements, "Triennial Central Bank Survey: Global Foreign Exchange Market Turnover in 2019," Monetary and Economic Department, 2019.

lira (TRY), or even in U.S. dollars (USD), for example. However, the purpose of *tc* is to act as a penalty function in an optimization process.

In general, a matrix enhanced by slack variables helps to model the portfolio constraints.[9] The slack variables are necessary to capture possible restrictions in a portfolio. Every bond is assigned 1 if it is denominated in U.S. dollars and 0 otherwise. For example, if a desired restriction to the MD of a bond in Hungarian forints (HUF) is not to exceed 6%, the slack variable takes a value of 1, and zero otherwise. Modeling these restrictions is central in international bond portfolio management due to the lack of liquidity in specific markets. For example, U.K. gilts or U.S. Treasuries have very different liquidity than emerging market bonds. This issue becomes relevant in times of financial stress, as liquidity dries out, typically emerging market currencies depreciate heavily, interest rates soar due to bond sell-offs, and low-yielding currencies appreciate as investors seek to shelter their capital in large economies and liquid markets. Examples of such markets are U.S. Treasuries and U.S. dollar, Japanese yen (JPY) and Japanese government bonds, and Swiss franc (CHF) and Swiss government bonds.

Within matrix $\acute{A}^*$, a manager can capture all possible exposures in the portfolio: modified duration, currency, sector, asset class—covered bond, government bond, financial, corporates, high-yield bonds, and so on—in addition to the yield-curve factor exposures, country of issuance, country of risk, maturity buckets, and so on. The portfolio constraints matrix can be expanded according to a vast set of quantified criteria. Let us explain the complexity of this technique in matrix solution form.

Specifically, the upper left matrix comprises the four constraints on currencies (FX), maturity buckets (M), sectors (S), and countries (C). Of particular interest are the matrixes in the middle. They control for the portfolio holdings and the buying and selling of securities. The lower part of the portfolio constraints matrix refers to the turnover constraints. In general, the matrix increases in dimension as more constraints or variables and parameters are added. This is a major advantage of portfolio optimization in heterogeneous bond funds.

9. Dessislava A. Pachamanova and Frank J. Fabozzi, *Simulation and Optimization in Finance: Modeling with MATLAB, @Risk, or VBA.* (Wiley, 2010), p.157 discuss the inclusion of slack variables.

In fact, the upper-left matrix is a $m \times n$ country-maturity-allocation matrix (alternatively, currency-maturity-allocation matrix, sector-maturity-allocation matrix, etc.) that captures a very large amount of information. This matrix provides fund managers of international bond portfolios with unique opportunities to manage their funds. Specifically, they can adjust for multiple duration constraints and manage both the overall allocation and selection toward sectors and maturity buckets in particular. For example, the matrix view allows for a bullet maturity allocation in Hungarian government bonds, but at the same time to allocate using a barbell strategy in European debt, or alternatively using a ladder strategy in U.S. Treasuries. Furthermore, short modified duration in South Africa and long duration in U.K. gilts are possible solutions as subtargets in the optimization. However, managers must be vigilant, as the dimension of the matrix can cause serious estimation problems if the constraints and input information increase. To summarize, a fund manager can increase the degree of flexibility of the portfolio selection and allocate in global corporate bonds, covered bonds, government bonds, countries, maturity buckets, or durations, and above all adjust for interactions according to certain constraints. Exhibit 57-6 illustrates a sample portfolio with its currency and maturity allocation as a result of an allocation and selection optimization.

RISK MANAGEMENT AND ADDITIONAL TOOLS

Risk management for international bond portfolios is a challenging and sophisticated task, which involves the risk management division and front office. Specifically, fund managers employ complex techniques to monitor and analyze the exposure to risk. This is the main idea of this section.

To this end, risk management refers to duration management and stop-loss discipline, carrying out stress-test scenarios of curve shifts, currency simulations, and calculating break-even rates for the roll down returns, and so on. We highlight some important topics:

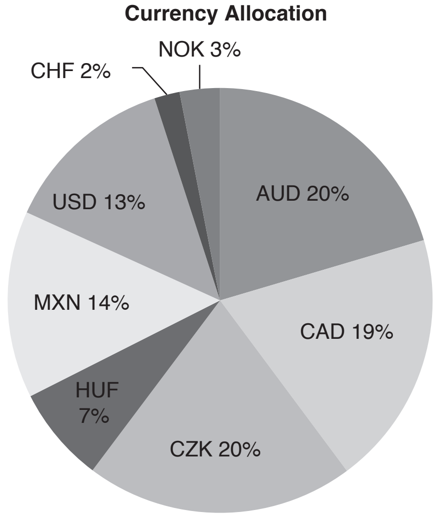
- Duration management
- Factor models
- Currency hedge and overlay management
- Simulations

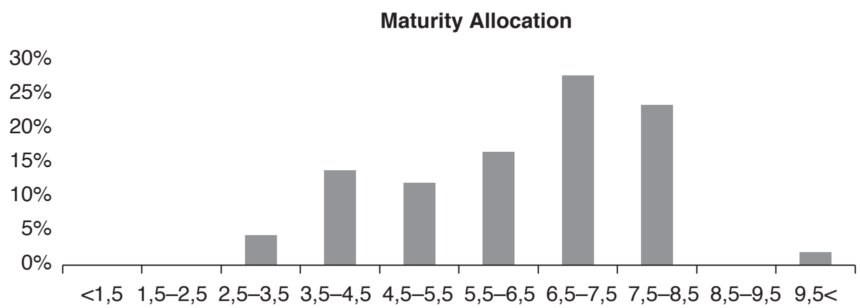
Duration Management

Duration management as a risk management tool for managing interest rate risk has a much more complex role for international portfolios than for traditional portfolios. Specifically, the systematic risks of international portfolios comprising multiple currencies and fixed income securities in multiple currencies mean a heterogeneous duration metric. More precisely, in an international portfolio

EXHIBIT 57-6

Currency, Country, and Maturity Allocation of an International Bond Portfolio





exposure to 10 currencies, the manager faces 10 different duration measurements. This would be the natural step of the allocation and selection process to different yield curves. In this example, a manager allocates to U.S. dollars and considers the U.S. Treasury curve. International bond portfolios allow tremendous possibilities for duration management. A helpful approach is to show the durations using country-maturity matrices or currency-maturity matrices.

Factor Models

A further enhancement to the risk management tool is the incorporation of risk factor models. Factor investing has gained great momentum in recent decades.

The portfolio systematic risk can be decomposed into factors and managers can monitor their risk factor exposure. A serious advantage for factor models is that they are suitable to evaluate both benchmark and absolute return portfolios.

Further enhancements consist of incorporating active monitoring of factor bets and actively managing a bond portfolio according to the factor exposure. This represents an important technique applied to more passively managed products. A novel risk approach is to actively monitor the risk factor bets of other fund managers. The terms "crowded trades" and "factor crowdedness" measure the exposure of other fund managers to the same underlying factors. Specifically, within the optimization process, exposure to the factors shift, slope, and butterfly is a reasonable and desirable solution, and applying a factor model as a risk management tool and measuring the factor crowdedness allows for constant monitoring of herding behavior. It is an important source of information, since it would reveal, for example, strong bets on decreasing interest rates globally. Furthermore, factor models allow for the control of currency risk exposure.

Specifically, style factors capturing the main currency strategies—carry, value, and trend—allow an explanation of which style reflects the current management approach. A general factor model can have the following form:

$$R_{i,t} = \alpha_i + \sum_{i=1} \beta_i F_{j,t} + \varepsilon_t$$

where $R_{i,t}$ is the total return generated by the fund, α is the intercept, β is a coefficient that measures the sensitivity of a fund's return to the factor, F is the beta factor that requires a systematic risk premium in the market, and ε is the random error term.

Possible factors to include in a factor model for international bond portfolios are:[10]

- Level factor, or bond carry factor
- Structure factor, or bond value factor
- Curvature factor
- Currency carry
- Currency value
- Currency momentum

10. For extensive analysis on factors for international bond portfolios, see Gueorgui Konstantinov, "On the Dynamics of EMU Bond Portfolios: From Diversification of Risk Factors to Convergence of Fund Exposure," *Journal of Investing* 27(2), 2017, pp. 91–101 (the author provides information on constructing curve-based factors); Gueorgui Konstantinov, "Capturing Short-Term and Long-Term Alpha of Global Bond Portfolios: Evidence from EUR-Investors' Perspective," *Financial Markets and Portfolio Management* 30(3), 2016, pp. 33–365; Clifford S. Asness, Tobias Moskowitz, and Lasse. H. Pedersen, "Value and Momentum Everywhere," *Journal of Finance* 68(3), 2013, pp. 929–985; Jean Michel Maeso, Lionel. Martellini, and Riccardo Rebonato, "Factor Investing in U.S. Sovereign Bond Markets: A New Generation of Conditional Carry Strategies with Applications in Asset-Only and Asset-Liability Management," *Journal of Portfolio Management* 46(2), 2020, pp. 121–140.

- Default risk premium
- Fama-French-Carhart global equity factors
- Currency and rate volatility

An overview of the factors provides information on their relevance for international portfolios:

The *level factor*, comprising international bond level as denoted by the long-term bond yields of liquid bonds: corporate, government, covered, financials. The factor can be modeled as the change of the long-term bond yield level: $\left(\Delta 10Y\right)$.

The *structure factor* refers to a factor capturing the slope of international fixed income securities as measured by the rate of change of the differences in the corresponding long-term and short-term bond yields $\left(\Delta 10Y - 2Y\right)$.

The *curvature factor* might capture the bond dynamics to residual curve movements.

The currency *carry* represents the borrowing in low-yielding currencies and investing in high-yielding ones. The index consists of long positions in the top high-yielding currencies and short positions in the low-yielding ones. Deutsche Bank Currency Harvest Index represents a currency carry factor.

The *currency value* factor represents the under- or overvalued currencies that an investor may consider—this factor is typical for currency investors and was established to explain the fundamental currency valuation. A systematic process considers the ranking of the three currencies with the highest average spot market return adjusted for the purchase power parity exchange rate, published by the OECD. Thus, the index consists of the long position in the three undervalued and short positions in the three overvalued currencies. An example is the Deutsche Bank Currency Value Index.

The *currency momentum* describes the short-term or some of the mid-term tendencies in the price movements. This factor captures the often-used technical analysis in the markets. The Deutsche Bank Trend Index is an example of such a factor.

The *default risk premium* is the spread of Baa bond yield minus the 10-year U.S. Treasury yield and is a widely accepted measure for corporate bond risk premium.

The *Fama-French-Carhart factors* for global equities are suitable for international bond portfolios. Recent research found that the Fama-French equity factors explain a large percentage of corporate bond returns. Specifically, these factors are relevant for fixed income instruments with more equity-like properties—for example, high-yield securities and corporate bonds with lower ratings. These factors are the equity premium (Mkt-Rf), value (HML), size (SMB), profitability (RMW), investment (CMA), and the momentum factor (MOM).

The *currency and rate volatility* are important factors in international bond portfolios both from management and risk management perspectives. Investment banks provide data on the currency and rate volatilities. Implied volatility time series are inputs for option prices, thus monitoring them allows an impression of risk to be gained in both asset classes. Furthermore, volatility simulations can provide valuable information of possible tail risks for a portfolio.

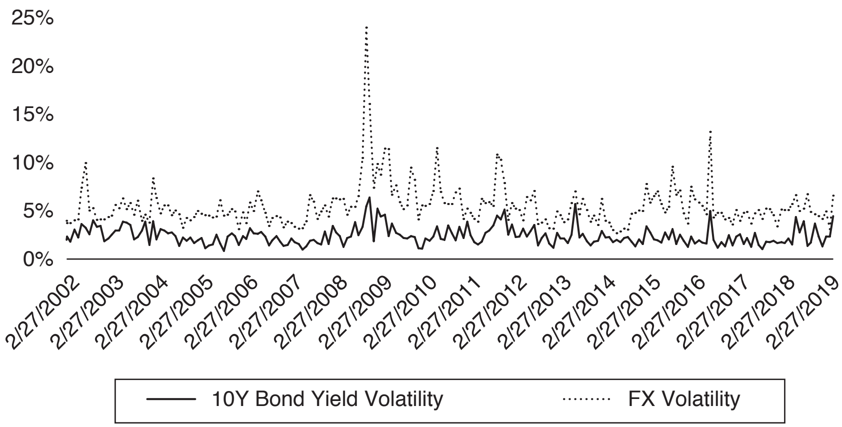
We measure the daily absolute changes q for a set of currencies (EUR, CAD, CHF, JPY, GBP, AUD, NZD, SEK, NOK, PLN, HUF, ZAR, MXN, THB, MYR, IDR, PHP, CLP, BRL) on each day τ in our sample. We then average over all currency return available on any given day, and average daily values up to the weekly frequency. Thus, our foreign exchange and global 10-year (10Y) bond volatility proxy in month t is given by[11]

$$\sigma^{FX} = \frac{1}{T_t}\sum_{\tau\in T_t}\left[\sum_{n\in N_\tau}\left(\frac{\left|\Delta FX_\tau^q\right|}{N_\tau}\right)\right] \text{and}\, \sigma^{10Y} = \frac{1}{T_t}\sum_{\tau\in T_t}\left[\sum_{n\in N_\tau}\left(\frac{\left|\Delta 10Y_\tau^q\right|}{N_\tau}\right)\right]$$

Thus, we can compute the 10-year bond volatility and the foreign exchange volatility and compare them. These factors, contained in Exhibit 57-7, can be used in both the management optimization approach and as explanatory variables in a factor model.

EXHIBIT 57-7

Monthly 10Y Government Bond and Global Foreign Exchange Volatility



Source: Constructed by the author from data obtained from Bloomberg, LLC.

Computing historical volatilities reveals information regarding foreign exchange and bond risks. Appropriate models for predicting volatilities exist and are widely accepted for both fixed income and foreign exchange investments.

11. Lukas Menkhoff, Lucio Sarno, Maik Schmeling, and Andreas Schrimpf, "Carry Trades and Global Foreign Exchange Volatility," *Journal of Finance* 67(2), 2012, pp. 681–718.

For example, one of the most widely used models is the General Autoregressive Conditional Heteroscedasticity model (GARCH).

Currency Hedge and Currency Overlay Management

Currency depreciations during financial market turmoil cause a rise in correlations of multiple assets. In particular, emerging markets are vulnerable to capital outflows and rising bond yields and thus currency depreciation. Although the exact mechanism flows through different channels, abrupt spikes harm bond investments. Investors prefer currency-hedged international investments; however, the nature of the benchmark and the underlying exposure is one of the variables to consider. The next component refers to the amount of base currency exposure in the benchmark—that is, the amount of U.S. dollar exposure of a U.S.-based investor, or the EUR-bond-exposure for a Euro-based investor. A further, perhaps the most important, component of currency hedge is the cost of hedging, which depends on the level of short-term or money market yields.

Currency overlay management techniques serve as an add-on to the existing fixed income portfolio. This topic has attracted a great deal of attention, since currency risk poses a serious threat to fixed income portfolios. Currency overlay strategies consider the actual weights, and thus the current currency exposure, of a bond portfolio and apply momentum strategies to hedge the exposure to risk.[12] Other techniques refer to the base currency risk of a fixed income portfolio. Gueorgui Konstantinov and Frank J. Fabozzi showed the direct relationship between currency strategies and fixed income investments.[13]

Simulations

These are convenient tools to model complex relationships and to compute different scenarios of the underlying variables. Simulations in international bond portfolios allow for the following:

- Computation of probability of different scenarios—for example, positive (upward) shift in U.S. Treasuries, negative parallel movement of the spot curve in Emerging Markets Asia (Thailand, Indonesia, Philippines, Malaysia, China, for example) following a risk-off scenario and financial turmoil in this region
- Interaction-based scenario analysis—combined-stress-test-based or correlation-based scenarios with multiple effects on portfolio—for example, a global shift in the bond yields and combined effects with

12. Momthchil T. Pojarliev, "Some Like It Hedged," CFA Research Foundation, 2018 provides a comprehensive overview and arguments of currency hedging, how it is created, and what the important differences are between Canadian, European, U.S., and Japanese investors.

the U.S. dollar, and possible effects on the option-adjusted spreads as a consequence of rising interest volatility

- A cheap and efficient method of scenario analysis for portfolio managers

PERFORMANCE MEASUREMENT AND ATTRIBUTION

Within this section, we refer to the performance evaluation and attribution of international bond portfolios, which defer to a large extent compared to the overall performance measurement. The main difference, and thus the most important source of management information, is yield-curve management.

Performance Measurement

The Sharpe ratio is widely applied in performance measurement. The ratio is a sample statistic calculated using the sample mean and the standard deviation of a manager's returns over a period of time. The Sharpe ratio has a significant advantage, measuring the reward of a unit of taken risk, and is expressed in the following way:

$$SR = \frac{E\left(R_{PF}\right) - R_f}{\sigma_{PF}}$$

However, the simple Sharpe ratio considers only the first and the second moments of the return distribution and fails to account for non-normal returns of international bond portfolios caused in particular by currency exposure. The Adjusted Sharpe Ratio (ASR) suggested by Jacques Pezier and Anthony White (2008) considers the skewness (s) and the kurtosis (k) of the original Sharpe Ratio:[14]

$$ASR = SR\left[1 + \frac{s}{6}SR - \frac{(k-3)}{24}SR^2\right]$$

Yield Curve–Based Attribution

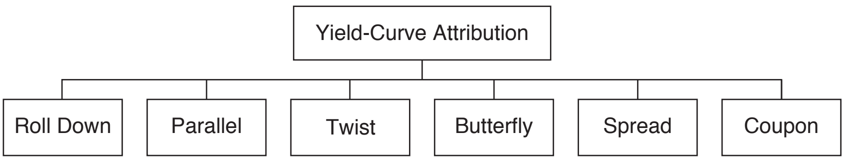
Decomposing the drivers of portfolio return ex post is inevitable for multicurrency bond portfolios. As a natural consequence of a multi-curve-based management approach, the performance attribution should properly reflect portfolio results. A yield curve–based attribution model allows information to be gained regarding

14. Jacques Pezier and Anthony White, "The Relative Merits of Alternative Investments in Passive Portfolios," *Journal of Alternative Investments* 10(4) 2008, pp. 37–39.

the different curve dynamics in the underlying currency exposure and different interest rate regimes. Specifically, the curve dynamics of the U.S. Treasuries differs from the yield-curve changes in Hungary, for example. The specific business cycle causes these changes to differ substantially, as well. In general, the factors level, slope, and curvature explain roughly 95% of the volatility of interest rates.[15] As a natural consequence, the changes of these factors explain the curve dynamics. At a portfolio level, quantifying the factors in the different currency exposures reveals the underlying complex dynamic of both currency and fixed income securities.[16] The return attribution of a portfolio can be decomposed by the following five factors in addition to the local currency returns shown in Exhibit 57-8:[17]

EXHIBIT 57-8

Yield-Curve Attribution Factors



Whereas the roll down and the coupon factors are return effects resulting from the passage of time, the remaining three factors—parallel, twist and butterfly, and spread—are yield curve–based. Measuring the effects in local currency in every sector, country, or asset class allows identification of the source of return by taking different bets on the yield curves. The currency effects reveal the magnitude of currency depreciation or appreciation as a result of the curve management. The price change from t_0 to t_1 is decomposed in separate steps using the underlying spot curve to evaluate the impact of the five factors—shown formally as follows:

$$R_t = \frac{T\left(t_1, s_1 + OAS_1\right) - T\left(t_0, s_0 + OAS_0\right)}{T\left(t_0, s_0 + OAS_0\right)}$$

The spot curve–based attribution model then needs to estimate the following factors and put them in relation to the dirty prices—that is, including the accrued interest on the clean price at $t_0\left(P_0 + AI_0\right)$.

A necessary step is to estimate the spot curves at the beginning and at the end of the desired period.

For simplicity, the curve dynamics are explained only by the shift component. The difference in the β_0 parameter of the Nelson-Siegel or the Svensson curve gives the shift of a particular spot curve:

$$shift = \beta_0\left(t_1\right) - \beta_0\left(t_0\right)$$

The *roll down* is the pure effect of the passage of time and results from the difference of a bond price discounted with the same spot curve and option-adjusted spread OAS_0 at time t_1 and t_0:

$$\text{Roll down} = \frac{T\left(t_1, s_0 + OAS_0\right) - T\left(t_0, s_0 + OAS_0\right)}{P_0 + AI_0}$$

The *parallel* effect results as a consequence of a sole shift in the initial spot curve at time t_1. More precisely, the bond price at t_1 is discounted using the spot curve at s_0 with the option-adjusted spread OAS_0. The shift is added to the bond price at t_1, using the spot curve s_0, and the OAS_0:

$$\text{Parallel} = \frac{T\left(t_1, s_0 + OAS_0 + shift\right) - T\left(t_1, s_0 + OAS_0\right)}{P_0 + AI_0}$$

The *twist* and butterfly effects add up to a structure effect, which reflects the change in the yield curve shape. The structure effect is shown as

$$\text{Structure} = \frac{T\left(t_1, s_1 + OAS_0\right) - T\left(t_1, s_0 + OAS_0 + shift\right)}{P_0 + AI_0}$$

However, a split of the structure effect is necessary to evaluate the returns from changes in steepness (twist) and curvature (butterfly). Within this framework, we start where we stopped with the parallel effect. Specifically, after adding a shift to the old spot curve at t_0, we now measure the effect on bond prices between that price and the completely new price resulting from the spot curve at t_1:

$$\text{Twist} = \frac{T\left(t_1, s_1 + OAS_0 + shift\right) - T\left(t_1, s_0 + OAS_0 + shift\right)}{P_0 + AI_0}$$

The *butterfly* can be shown as a residual effect of the entire curve movement. Perhaps in an intuitive manner, the butterfly captures the residual effect in excess curve shift between s_0 and s_1 spot curves:

$$\text{Butterfly} = \frac{T\left(t_1, s_1 + OAS_0\right) - T\left(t_1, s_1 + OAS_0 + shift\right)}{P_0 + AI_0}$$

Mathematically, adding the twist and the butterfly effects, the term $T\left(t_1, s_1 + OAS_0 + shift\right)$ cancels out, to result in a structure effect. An alternative way to show the twist and butterfly effects is to gage them by the spot curve parameters.

The *spread* attribution effect is simply the bond price change at t_1 using the spot curve s_1 due to a change in the option-adjusted spread between OAS_0 and OAS_1.

$$\text{Spread} = \frac{T\left(t_1, s_1 + OAS_1\right) - T\left(t_1, s_1 + OAS_0\right)}{P_0 + AI_0}$$

The *coupon* effect measures the amount of accrued interest during the holding period.

$$\text{Coupon} = \frac{AI(t_1) - AI(t_0)}{P_0 + AI_0}$$

This sum of these effects shows the local curve return effect. Yield-curve attribution is essential in international bond portfolios. The advantage lies in the possibility of using different types of spot curves—local currency, country, sector and asset classes—corporates, financials, covered, etc., with different ratings fitted from the bulk of fixed income securities available in the investment universe.

Exhibit 57-9 shows the spot curve–based attribution for an international bond portfolio. One of the biggest advantages of the separation of local currency bond returns and the foreign exchange impact is that the vector of FX returns always reflects the base currency. In general, this attribution approach explains on average 97% of local currency bond returns.

To compute the contribution to portfolio return in that month, it is necessary to multiply the portfolio weights w_i with the corresponding return components—roll down, parallel, and so on:

$$R_t^{C_k} = \sum_{i=1}^{n} r_n^c w_n$$

The total portfolio return of 1.77% is the sum of the local currency bond returns of 0.63%—estimated using the underlying spot curves and the foreign exchange impact of 1.14%. The local currency bond returns (0.63%) are mainly driven by positive contribution of roll-down returns of 0.25%, and a twist effect of 0.21%. The spread effect contributed 0.17%. The residual effect shows how much performance is not explained by the model. Exhibit 57-10 contains the cumulative results for the yield-curve factor attribution.

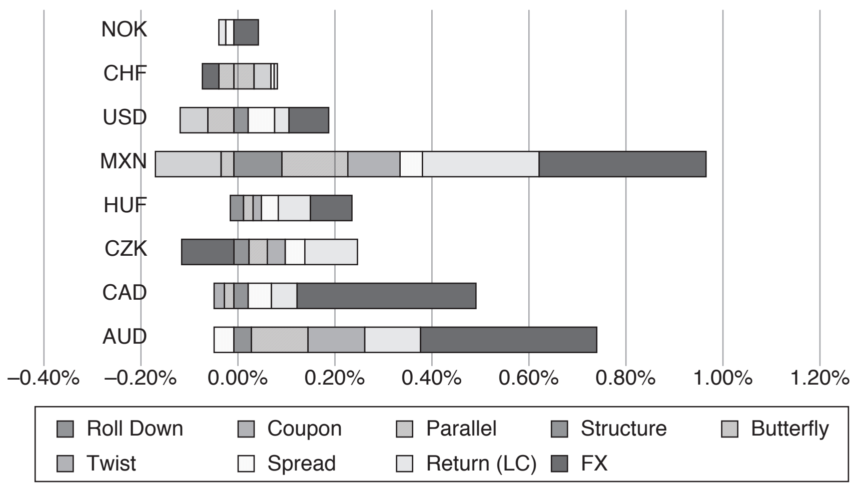
EXHIBIT 57-11

Currency Spot Curve–Based Effects



The same procedure applies to a benchmark. In this case, the active decisions are the differences between portfolio and benchmark components, both in currency and factor exposure.

Backtest Evaluation

Portfolio managers are always interested in improving their strategies, models, and tools. Therefore, over the years, backtesting of portfolio strategies has been an integral part of fund managers' activities. In this line of thought, multiple tests using the Svensson instead of the Nelson-Siegel polynomial, or cubic spline models, or the Vasicek approach for yield-curve fitting, are examples of different tests. International bond portfolios have the unique advantage that they can be expanded or shrunk in respect of the number of currencies, countries, sectors, and types of fixed income securities. Further examples are modification to the optimization techniques, the inclusion of machine-learning approaches, factor models, and so on. Simple comparison of the tests with corresponding performance metrics, such as the Sharpe ratio, the Treynor ratio, the information ratio, and so on, would produce a biased estimation. Put differently, a strategy might be profitable in backtest but would produce undesirable results in real conditions. Given the complexity of international multicurrency bond portfolios, adjusting for multiple testing is the cornerstone of modern finance, the finance of the twenty-first century.

KEY POINTS

- Expected returns can be decomposed into two components—horizon and vertical effects. These effects show that fixed income securities absorb currency and interest rate movements.
- Estimating the specific spot curves allows currency allocation, bond selection, and performance yield curve–based attribution.
- Currency risks can be minimized using minimum variance optimization, since currencies are financial assets but not real assets, and thus have zero expected return.
- Bond portfolio optimization, or portfolio selection, can be easily modeled using local currency yield curves and modeling the entire portfolio, incorporating portfolio constraints—for example, duration, factor exposure, currency exposure, spreads, turnover, and specific portfolio holdings constraints.
- Spot curve–based attribution provides insightful information for past performance. However, the yield curve–based factor exposure is a valuable input for portfolio construction.
- Developing new models and techniques is inevitable for modern bond portfolio management. Adjusting the results for multiple tests, transparency in result presentation and successful implementation of a new strategy are issues both investors and regulators should focus on in the future.

The abundance of theoretical and empirical research on factor investing in the equity universe stands in sharp contrast to the relative scarcity of research on risk premia in bond markets. From the investment practice standpoint, a similar contrast exists between factor investing in the equity space, which is a relatively mature subject, and factor investing in bond markets, which still is in its infancy. That relatively little is known about the out-of-sample performance of factor investing in fixed income is perhaps surprising, given the importance of bond holdings in investors' portfolios, and given that a number of concerns have been expressed about the shortcomings of traditional sovereign bond benchmarks.

This chapter describes the theoretical, empirical, and implementation challenges related to factor investing in a credit-risk-free issuer universe. In such a universe, neither time-series nor cross-sectional differences in risk and performance can be explained by differences in creditworthiness, as they could be in the case of a multi-issuer universe. The key message is that it is possible to identify economically justifiable strategies that, after accounting for transaction costs and other forms of trading frictions, generate excess returns from investing in a relatively homogenous set of highly correlated securities. The profitability of these strategies can be due to a reward from factor exposure, systematic predictability resulting from market inefficiencies, behavioral biases, or a combination of the above.

PROBLEMS WITH EXISTING BOND BENCHMARKS

One of the major problems with bond benchmarks that simply weight the debt issues by their market value has been referred to by Laurence Siegel as the "bums' problem."[1] Given the large share of the total debt market accounted for by issuers with large amounts of outstanding debt, market-value-weighted corporate bond indices will have a tendency to overweight bonds with large amounts of outstanding debt. It is often argued that such indices will thus give too much weight to riskier assets. It is debatable whether debt weighting really leads to the riskiest securities being overweighted.[2] However, it is clear that market-value debt weighting leads to concentrated, and hence poorly diversified, portfolios. A similar problem has been documented for cap-weighted equity benchmarks.[3]

In addition to the problem of concentration, fluctuations in risk exposures (such as duration or credit risk in existing indices) are another source of concern.[4] Such uncontrolled time variation in risk exposures is incompatible with the requirements of investors that these risk exposures be relatively stable so that allocation decisions are not compromised by implicit choices made by an unstable index. For example, an asset–liability mismatch would be generated by changes in the duration of the bond index if the latter were used as a benchmark for a pension fund bond portfolio.

BENEFITS AND PITFALLS OF FACTOR INVESTING IN FIXED-INCOME MARKETS

The modern approach to factor investing first requires the identification of robust and economically motivated sources of risk in fixed income markets.[5] An economic motivation is not just an academic nice-to-have. Understanding the reason for the cross-section differential returns matters a lot from the point of view of a robust benchmark creation. If the excess returns are due to a behavioral "irrationality," it

1. Laurence B. Siegel, *Benchmarks and Investment Management,* technical report, the Research Foundation of the Association for Investment Management and Research (Charlottesville, Virginia, 2003).

2. A higher weight for an issuer with a high market value of debt does not necessarily mean that the index is overweighting issuers with a high face value of debt. An issuer with a high amount of par value debt outstanding will only get a high weight if the market value is relatively close to par value, which implies that the issuer is not perceived to be very risky. It is therefore not clear why the market-value-weighted index should become riskier. In addition, loading onto riskier issuers should not be a problem if this risk is rewarded by higher expected returns.

3. See, for example, Noel Amenc, Felix Goltz, and Véronique Le Sourd, "Assessing the Quality of Stock Market Indices." EDHEC Publication, 2006.

4. For more details, see Carlos Heitor Campani and Felix Goltz, "A Review of Corporate Bond Indices: Construction Principles, Return Heterogeneity, and Fluctuations in Risk Exposures," EDHEC-Risk Institute Publication, 2011.

5. See, for example, Lionel Martellini and Vincent Milhau, "Factor Investing: A Welfare-Improving New Investment Paradigm or Yet Another Marketing Fad," EDHEC-Risk Institute Publication, 2015.

could in principle be arbitraged away by rational investors. Revealing the behavioral anomaly could therefore be the first step toward its disappearance. However, its persistence or otherwise may be linked to the availability or scarcity of "arbitrage capital."[6] Finally, if the excess returns are due to institutional frictions, they can be an easy source of profitability for investors who are not affected by the regulatory or institutional constraints. However, they can disappear at the stroke of a regulatory pen. And if the excess returns are truly due to an anomaly, then they are likely to disappear after its discovery as it becomes exploited.

Matters are different if the origin of the excess returns can be traced to a source of rewarded systematic risk. In this case, the attending compensation (the corresponding "market price of risk") will not disappear by discovering it, as it is just a compensation for being paid well or poorly in good and bad states of the world, respectively. This compensation may well decrease or increase in size over time with the investors' risk aversion, but, at any point in time, it simply reflects "fair pricing."

For the sake of brevity, we refer in what follows to all types and sources of differential cross-sectional returns as "generalized factors," but it should be kept in mind that, from the perspective of the creation and long-term profitability of investable factor benchmarks, the underlying causes for the excess returns can be very important.

Unfortunately, the recent discovery that "traditional" equity factors such as value or momentum seem to be effective also in the fixed income area and other asset classes does create an embarrassing explanation problem. As Asness, Moskowitz, and Pedersen eloquently put it, "the strong correlation structure among value and momentum strategies across such diverse asset classes is difficult to reconcile under existing behavioral theories, while the high Sharpe ratio of a global across-asset-class diversified value and momentum portfolio presents an even more daunting hurdle for rational risk-based models."[7] So, we seem to find more and more factors and to observe that the "old" factors seem to work even where they were not expected (or even supposed) to; however, we are further and further away from a unified understanding of why they do. As argued above, unfortunately this imperfect understanding does matter when it comes to building robust and stable investable portfolios.

Modern "generalized factor discovery" in the fixed income area is also made more difficult by the problem of proxies. Very often a candidate factor (such as liquidity or value) is difficult to measure, or even to define, precisely. Furthermore, as recognized as early as 1993 by Fama and French, a straightforward transposition to the fixed income arena of the factors that are most popular

6. This clear distinction between "irrationality"-based and institutional-based source of differential cross-sectional returns can easily become blurred: the availability of the speculative capital that should arbitrage irrationalities away, for instance, may become greatly reduced because of regulatory initiatives such as the Volker rule in the United States or the Likanen proposal in the EUR area.
7. Clifford S. Asness, Tobias J. Moskowitz, and Lars H. Pedersen, "Value and Momentum Everywhere," *Journal of Finance* 68(3), 2013, 929–985.

in the equity space (such as value, momentum, or low volatility) is not straightforward.[8] This has led to the proliferation of proxies and, sometimes, to the creation of proxies of proxies. For instance, Asness, Moskowitz, and Pedersen investigate value and momentum in fixed income, and circumvent the problem of defining value for bonds (a concept that, according to Fama and French, "has no obvious meaning for . . . bonds")[9] by arguing that "individual stock portfolios formed from the negative of past 5-year returns are highly correlated with those formed on BE/ME ratios in our sample. . . . Hence, using past 5-year returns to measure value seems reasonable." The logic here is to use as proxy (the 5-year returns) to stand in for another proxy (value) for an unspecified latent factor. In itself, the choice may well be reasonable, but the link to the desired proxy (value), let alone to the latent factor, is neither transparent, nor unique: indeed, in the literature a number of additional measures of value for bonds have been proposed.

This concern is of relevance for the construction of robust benchmarks. After all, if a factor proxy is associated with a true risk premium, the attending "excess" return is simply a compensation for receiving good or bad payoffs in periods of high or low consumption, respectively. High or low consumption, in turn, can be parsed in terms of a relatively small number of (often highly correlated) economic configurations, such as low growth or high unemployment. A principled and parsimonious approach to proxy analysis is therefore essential, especially in the nascent field of fixed-income factor investing.

TAXONOMY OF FIXED INCOME FACTORS

All these qualifications should be clearly kept in mind as we review the generalized fixed-income cross-sectional factors that have been identified most consistently in the modern literature. Despite of the aforementioned difficulties, value[10] and momentum[11] remain among the best documented fixed income generalized factors.

9. Footnote 5 in Asness, Moskowitz, and Pedersen, "Value and Momentum Everywhere."

10. For U.S. Treasuries, see Asness, Moskowitz, and Pedersen, "Value and Momentum Everywhere." For corporate bonds, see Mathieu L'Hoir and Mustafa Boulhabel, "A Bond-Picking Model for Corporate Bond Allocation," *Journal of Portfolio Management* 36(3), 2010, 131–139.

11. For U.S. Treasuries, see Asness, Moskowitz, and Pedersen, "Value and Momentum Everywhere." For investment-grade bonds, see the following two studies that find a reversal: Kenneth Khang and Tao-Hsien King, "Return Reversals In The Bond Market: Evidence And Causes," *Journal of Banking & Finance* 28(3), 2004, 569–593 and William S. Gebhardt, Seren Hvidkjaer, and Bhaskaran Swaminathan, "Stock and Bond Market Interaction: Does Momentum Spill Over?" *Journal of Financial Economics* 75(3), 2005, 651–690. Gebhardt, Hvidkjaer, and Swaminathan also find reversal, while no momentum is found in the study by Gergana Jostova, Nikolova, Alexander Philipov, and Christo Stahel, "Momentum in Corporate Bond Returns," *Review of Financial Studies* 26(7), 2013, 1649–1693. Jostova, Nikolova, Philipov, and W. Stahel also find evidence of momentum in the corporate high-yield market, as did Libor Pospisil and Jing Zhang, "Momentum and Reversal Effects in Corporate Bond Prices and Credit Cycles," *Journal of Fixed Income* 20(2), 2010, 101–115.

Beyond value and momentum, liquidity has also been found to be a relevant factor. Rebonato and Sherwin focus on the establishment of a robust liquidity proxy for fixed income.[12] They show that this measure of liquidity is closely linked to measures such as "liquidity and noise"[13] and to funding liquidity. They also argue that a large part of the yield premium provided by TIPS over U.S. nominal Treasuries can be explained as a compensation for the liquidity risk factor. Using a variety of visible market proxies (but without trying to combine them as in Rebonato and Sherwin), Rebonato and Naik also document the impact of liquidity on the pricing of TIPS relative to nominal Treasury bonds.[14] Finally, low risk has been found relevant both in corporate bonds and in Treasuries.[15] Indeed, in the case of Treasuries, it is well known[16] from time-series studies that low-maturity bonds offer a higher Sharpe ratio in virtually every economic environment.[17]

These factors (in particular, value and momentum) have direct counterparts in the equity universe. In addition, one also needs to analyze the well-known factors that explain time-series changes in returns. Wherever there is a risk, and to the extent that this risk covaries positively with consumption, asset-pricing theory tells us to look for a possible reward. Ever since the 1990s, it has been well known that a principal component analysis of the returns on bonds with different maturity from a sovereign issuer suggests that three main factors, namely, changes in level, slope, and curvature of a yield curve,[18] explain a very large

Pedersen, "Betting against Beta," *Journal of Financial Economics* 111(1), 2014, 1–25; and Patrick Houweling and Jean van Zundert, "Factor Investing In The Corporate Bond Market," *Financial Analysts Journal* 73(2) 2017, 100–115.

16. See, for example, Rebonato and Naik, "Can Liquidity Explain the Recent Fall in Breakeven Inflation?"

17. While these results are statistically very robust, their economic significance is not obvious in the presence of realistic implementation constraints: especially for Treasuries and high-yield corporate bonds, the recent very-low-yield environment has made equity-like returns only obtainable with unfeasibly high leverage. The following study documents a required leverage of 50 for the lowest-risk (and highest Sharpe ratios) bonds: De Carvalho, Dugnolle, Lu, and Moulin, "Low-Risk Anomalies in Global Fixed Income: Evidence from Major Broad Markets."

18. Crump and Gospodinov have recently challenged this received wisdom by arguing that only the first (level) factor has economic meaning, and that the slope and curvature features are artefacts of the orthogonalization of the eigenvectors. Whatever the merit of their observation, the traditional decomposition remains valid from a statistical point of view. For a discussion, see R.K. Crump and N. Gospodinov, "Deconstructing the Yield Curve," Federal Reserve Bank of New York Staff Reports, Staff Report No. 884, April 2019, revised May 2019.

portion of returns over time.[19] In this context, it is therefore natural to ask whether the risks associated with changes in interest rate levels, and also possible in slope and curvature, are rewarded.

In what follows, we focus on the level and slope factors, which explain the largest percentage of bond return variations, before turning our attention to value and momentum.

LEVEL AND SLOPE FACTORS IN SOVEREIGN BOND MARKETS

Excess return studies in Treasuries have concentrated to date on the profitability of "carry" strategies, that is, strategies where the investment on a N-maturity bond is held for a holding period (typically of one year) and is funded by the sale of a short bond expiring at the end of the investment period. The returns are given by

$$xret_{t\to t+1} = p_{t+1}^{N-1} - p_t^N - y_t^1 = \left(y_t^N - y_{t+1}^{N-1}\right)\left(N-1\right) + \left(y_t^N - y_t^1\right) \qquad (58\text{-}1)$$

where p_t^N denotes by time-t log price of a T-maturity bond, and y_t^N its yield.

These strategies have been unconditionally profitable, as Exhibit 58-1 shows for data spanning the 1971–2017 period. The most commonly adduced explanation for this profitability is the existence of a positive risk premium associated with bearing "duration" risk. These performance results become more interesting when analyzed during expansion and recession periods, as shown in Exhibit 58-2. When this business-cycle decomposition is made, it becomes apparent that the carry strategies have been profitable during recessions, unprofitable during expansions, and particularly unprofitable in the second half of the recorded expansions. If an explanation of the excess returns in terms of a risk premium is to be valid, the market price of risk must therefore change sign, and must do so with the expansionary/contraction phases of the business cycle. The same exhibit also shows that the unconditional profitability of the carry strategy strongly depends on the exact period under study: even for a period as long as 1955–1986 (over 30 years) the excess return from holding Treasuries has been at best indistinguishable from zero, and perhaps even negative.

19. See Robert B. Litterman and Jose Scheinkman, "Common Factors Affecting Bond Returns," *Journal of Fixed Income* 1(1) 1991, 54–61.

EXHIBIT 58-1

Zero-Coupon Carry Strategies Main Statistics

Maturity	2	3	4	5	6	7	8	9	10
Average	0.53%	0.96%	1.32%	1.63%	1.90%	2.13%	2.32%	2.48%	2.62%
Standard Deviation	1.73%	3.15%	4.38%	5.51%	6.58%	7.61%	8.61%	9.60%	10.58%
Sharpe Ratio	0.30	0.30	0.30	0.30	0.29	0.28	0.27	0.26	0.25

This exhibit reports the average returns, standard deviations and Sharpe ratios from the carry strategies (1-year investment period) in equation (1) for U.S. Treasuries from 1971 to 2017. Zero-coupon bond prices are from Refet S. Gürkaynak, Brian Sack, and Jonathan H. Wright, "The U.S. Treasury Yield Curve: 1961 to the Present," *Journal of Monetary Economics* 54 (8), 2007, 2291–2304.

EXHIBIT 58-2

Zero-Coupon Carry Strategies Sharpe Ratios Under Different Economic Periods

	2-Year	5-Year	10-Year
Full Sample	0.20	0.20	0.16
1955–1986	0.04	–0.01	–0.07
1987–2014	0.59	0.56	0.49
Recession	0.82	0.72	0.59
Expansion	0.01	0.06	0.05
First-Half Expansion	0.52	0.50	0.45
Second-Half Expansion	–0.61	–0.50	–0.48
Tightening Cycles			
1979:Q3–1981:Q2	–1.06	–1.13	–1.23
1993:Q3–1995:Q1	–0.79	–0.86	–0.86
2004:Q2–2006:Q2	–1.52	–0.90	–0.50

This exhibit gives the Sharpe ratios of the 2-, 5- and 10-year carry strategies during different time periods.

Overall these empirical facts show that (1) if the excess returns are due to risk premia, the market price of risk must be time-varying and depend on state variables linked to the business cycle and (2) even over extended periods of time, the profitability of the unconditional carry strategy stems from averaging the positive excess returns made during recessions and the negative excess returns incurred in expansionary periods.

These two findings suggest that additional performance can be generated from a time-varying exposure to the level factors, embedded within so-called *conditional* carry strategies, with suitably defined time-varying exposures to the level factor. The set of dynamic fixed income factor investing strategies also includes conditional flattener/steepener strategies, with suitably defined time-varying exposures to the slope factor.[20] Slope-based strategies ("flatteners" and "steepeners") require long/short positions. In a long-only mandate portfolio, they can therefore only be implemented as on overlay. Since the variability associated with the level mode of deformation is much higher than the volatility of slope or curvature, slope-based strategies require precise immunization against level (duration) risk. These slope-based strategies also have to be made self-funding. As they are built from long and short duration-neutral positions, they entail leverage, which must be controlled.

20. One can also mention curvature-based strategies are based on the exploitation of convexity and require level and slope immunization. For more details, see Riccardo Rebonato and Vladislav Putyatin, "The Value of Convexity: A Theoretical and Empirical Investigation," *Quantitative Finance* 18(1), 2017, 11–30.

Strategies Based on the Prediction of the Level

As Equation (58-1) shows, the success of level-based ("carry") strategies is totally predicated on the ability to predict the future *level* of rates. Curve steepening or flattening does not contribute to their profitability. In practice, level-based strategies are implemented by being longer or shorter duration than a given benchmark (with no leverage and after funding). As their profitability is linked to the first mode of deformation, which is by far the most volatile, in general they give rise to the largest potential profits. It must be stressed, however, that in the current market conditions of extremely low rates, long-only carry strategies have very limited potential upside. Indeed, if their profitability is to be explained in terms of risk premia, most estimate currently suggest zero or negative risk compensation.

The literature on the predictability of level-based returns is large and has witnessed a true blossoming after the 2005 paper by Cochrane and Piazzesi, who discovered the "tent" factor.[21] Ludvigson and Ng[22] have shown that non-yield-curve factors greatly improve the predictability of returns, and Cieslak and Povala[23] employ a mixed yield-curve/macro-financial set of variables to obtain even greater predictability of returns. Rebonato and Hatano[24] extend the Cieslak-Povala approach and show how to build a whole class of parsimonious return-predicting factors with similarly high out-of-sample predicting power.

Given a set of factors, in order to establish when an investor should be longer or shorter duration than a benchmark, the excess returns calculated using Equation (58-1) are first regressed against a vector, $\mathbf{x}_t$, of yield-curve or macro-financial variables, denoted by

$$\boldsymbol{x}_t = \left[1; x_t^1, \ldots, x_t^k\right] \; :$$

$$xret_t = (\gamma^{(n)})^T \quad \boldsymbol{x}_t + \varepsilon_t \tag{58-2}$$

The quantities $(\gamma^{(n)})^T \quad \boldsymbol{x}_t$ are referred to as the *return-predicting factors*. We mainly work in what follows with the factors identified in the studies by Cochrane and Piazzesi, Cieslak and Povala, Fama and Bliss (slope), and Campbell and Shiller factors. In all cases, the factors are built from yield-curve variables (with the addition of macrofinancial information for the Cieslak-Povala model). More precisely, for the slope the single regressor is taken to be the difference between the 10-year and the 2-year yield; in the case of the Cochrane-Piazzesi factor the

regressors are five forward rates[25]; for the Cieslak-Povala model, the factors are given by cycles, which, in turn, are built by regressing yields against a slow-moving average of inflation, τ_t:

$$y_t^{(n)} = a + b\tau_t + \varepsilon_t \tag{58-3}$$

and then using the residual, ε_t, as the maturity-depedent cycle:

$$cycle_t^{(n)} = y_t^{(n)} - a - b\tau_t \tag{58-4}$$

As Rebonato and Hatano[26] discuss, the quantity $a - b\tau_t$ can be interpreted as "where the yield should be" given the inflation expectation (proxies by the estimated long-term inflation trend). These cycles then become the right-hand variables in regression (58-2).

The Sharpe ratios and descriptive statistics of the unconditional carry strategy have already been shown in Exhibit 58-1. Exhibit 58-3 details the substantial improvement in Sharpe Ratios when conditional strategies based on the Cieslak-Povala (*CiP*) or Cochrane-Piazzesi (*CP*) return-predicting factors are employed. All the returns were calculated using one-year investment periods, monthly overlapping.

Strategies Based on the Prediction of the Slope

Turning to slope-based strategies, one may define a *flattener* strategy as the trade consisting of buying one unit of a 10-year zero-coupon bond and selling *R* units of the 2-year zero-coupon bond, where *R* is chosen so as to duration-neutralize the portfolio. The whole portfolio is cash positive, and the cash is invested in a zero-duration discount bond maturing at the end of the investment horizon.[27] After duration hedging, an unconditional flattener strategy has a (positive) Sharpe ratio that is barely statistically different from zero. However, one can again create a return-predicting factor, $(\beta^{(n)})^T \boldsymbol{x}_t$, using the regression

$$xret_t^{flattener} = (\beta^{(n)})^T \boldsymbol{x}_t + \varepsilon_t \tag{58-5}$$

where $xret_t^{flattener}$ are now the excess return from the unconditional duration-hedged flattener strategy, and the vector $\boldsymbol{x}_t$ contains either the level or the slope of the yield curve, or both. Maeso, Martellini, and Rebonato find that both slope and

25. In the original paper by Cochrane and Piazzesi, yearly returns for maturities out to five years were analyzed, and therefore the five forward rates exactly covered the maturity spectrum. When more return maturities than factors are used, as in our case, we retain the same number of regressors, and the five forward rates are evenly spaced along the maturity spectrum. The following study shows that the precise location of the forward rates makes little difference: Riccardo Rebonato, "Are Non-Level Factors Rewarded in The Treasury Yield Curve? EDHEC-Risk Institute Working Paper.

EXHIBIT 58-3

Conditional Carry Strategies Sharpe Ratios

Maturity	**2**	**3**	**4**	**5**	**6**	**7**	**8**	**9**	**10**
Cielsak-Povala	0.522	0.533	0.544	0.554	0.561	0.566	0.569	0.571	0.571
Cochrane-Piazessi	0.408	0.427	0.441	0.45	0.457	0.461	0.464	0.466	0.467
Unconditional	0.359	0.357	0.354	0.348	0.34	0.331	0.32	0.308	0.297

This exhibit reports the Sharpe ratios of the conditional carry strategies with the notional proportional to the Cieslak-Povala (*CiP*) or Cochrane-Piazzesi (*CP*) return-predicting factors (first two rows), and of the unconditional carry strategy (third row) for maturities from 2 to 10 years.

level are statistically significant predictors of profitability for the flattener/steepener strategy.[28] They also find that the sign of the slope coefficient in Equation (58-5) for the slope factor is positive both in the univariate and the bivariate regression. When the slope is high, the investor should enter a flattener strategy; when the slope is low, or the yield curve inverted, investors should engage in a steepener strategy. Additionally, the sign of the level coefficient is negative in the univariate regression and positive in the bivariate regression. Also the slope and level regressors are strongly negatively correlated, and therefore the significant increase in R^2 achieved by adding an explanatory variable that, on a stand-alone basis, has a negligible stand-alone R^2 that can be explained in terms of cooperative suppression[29] or reciprocal suppression.[30,31]

In sum, conditional flattener/steepener strategies present attractive and simple strategies; investors should enter flatteners when the yield levels are high and the curve is steeply sloped, and steepeners when yields are low and the yield curve inverted.

VALUE FACTOR

Value has been recognized as one of the most important factors for equities at least since the pioneering work by Fama and McBeth.[32] In equities, the ratio of book to market value has traditionally been used as a proxy for the value factor. Natural as this choice is for this asset class, it is difficult to translate the concept of value to the fixed income domain, and, for this reason, Fama and French[33] have argued that value does not apply to fixed income instruments in general, and to Treasury bonds in particular.[34] This seems to be at odds with recent literature, which claims to have found value (and momentum) "everywhere."

The "problem with value in bonds" is rendered more acute by the rather ad hoc definitions of value used for fixed income instruments. As discussed earlier

31. Intuitively, the increase in explanatory power stems from the fact that, owing to the negative correlation, both independent variables achieve higher explanatory power than in stand-alone regressions because when used together each independent variable is adjusted for the other.

32. Eugene F. Fama and James D. MacBeth, "Risk, Return, and Equilibrium: Empirical Tests," *Journal of Political Economy* 81(3), 1973, 607–636.

33. Eugene F. Fama and Kenneth R. French, "Common Risk Factors in the Returns on Stocks and Bonds," *Journal of Financial Economics* 33(1), 1993, 3–56.

34. Fama and French note that "explanatory variables like size and book-to-market equity have no obvious meaning for government and corporate bonds."

in this chapter, Asness, Moskowitz, and Pedersen have defined value for bonds as the (negative of the) five-year bond returns—a choice motivated by the observation that, in equities, this difference in returns is found to be positively correlated with the book-to-market ratio.[35] The factor thus defined may well predict future bond returns, but its interpretation as "value" seems at least stretched, and one, if not two, steps removed from the true latent underlying factor. As a result, the labeling of the chosen measure as "value" becomes rather arbitrary.

An Economically Motivated Definition for Value

Rebonato, Maeso, and Martellini[36] provide an arguably more satisfactory definition of value in U.S. Treasury bonds and show that the value quantity thus defined has very strong predictive power of future cross-sectional Treasury returns. More precisely, they identify "cheap" ("valuable") and "expensive" bonds using a dynamic Gaussian term structure models, and show that a systematic, no-peek-ahead strategy of investing in the cheap and shorting the expensive bonds has a strongly positive Sharpe ratio.

The affine model Rebonato, Maeso, and Martellini employ is written under the physical P measure as

$$dr_t = \kappa_t^P \left(\theta_t^P - r_t\right) dt + \sigma_t dw_t \tag{58-6}$$

$$d\theta_t = \kappa_\theta^P \left(\theta_\theta^P - \theta_t\right) dt + \sigma_\theta dw_\theta \tag{58-7}$$

$$E\left[dw_t dw_\theta\right] = \rho dt \tag{58-8}$$

The model can be interpreted as describing the actions of the monetary authorities who respond to deviations of the inflation and/or output gap from their desired target levels by adjusting the Fed Funds rate (in our model, the "short rate") toward the long-term NAIRU-compatible[37] nominal rate (the ultimate reversion level θ_θ^P). They do so, however, with a degree of urgency (of "aggressiveness") that depends on the economic conditions of the moment; the adjustment is therefore achieved by letting the short rate revert to a time-dependent reversion level, which in turn reverts toward the unchanging NAIRU-compatible long-term nominal rate, θ_θ.[38]

After the calibration procedure has been carried out, for each bond one can generate a time series of pricing errors by comparing the model price to the

35. "Value and Momentum Everywhere." They show "that individual stock portfolios formed from the negative of past 5-year returns are highly correlated with those formed on BE/ME ratios in our sample. . . . Hence, using past 5-year returns to measure value seems reasonable."

36. Riccardo Rebonato, Jean Michel Maeso, and Lionel Martellini, "Defining and Exploiting Value in U.S. Treasury Bonds," *Journal of Fixed Income* 29(2), 2019, 6–25.

37. The NAIRU is defined as the nonaccelerating inflation rate of unemployment, i.e., the unemployment rate which produces neither inflationary nor deflationary pressures.

38. More details on the model formulation, on the connection between the real world and the pricing measure and on model calibration can be found in the study by Rebonato, Maeso, and Martellini.

market price. As for the signal, it can be formed for each bond by taking the difference between a slow-moving average and an adjusted fast-moving average of price errors. To establish a trading strategy, one may set the notional of the position in each bond to be proportional to the strength of the signal for that bond on that day.

Typical patterns for the two moving averages and the resulting signal are shown in Exhibit 58-4. As the exhibit shows, the trading signals tend to display a clear mean-reverting behavior, with reversion speeds implying half-lives of several weeks to a few months. This observation is important because it suggests that the signal is practically exploitable, in that it requires neither excessively long investment horizons nor overly frequent rebalancing.

On any given day, a trading strategy will consist of long positions in cheap bonds and short positions in expensive bonds. The resulting portfolio will not have a systematic long or short bias but, on any given day, it will not have exactly zero cost and will not be exactly duration neutral. To neutralize for the impact of systematically decreasing (or increasing) yields, one may control for a possible residual duration exposure in the portfolio by calculating the net portfolio duration, and by subtracting the hypothetical profit (or loss) that a portfolio with that residual duration would make given the change in average yield from one day to the next.

Profitability of the Strategy

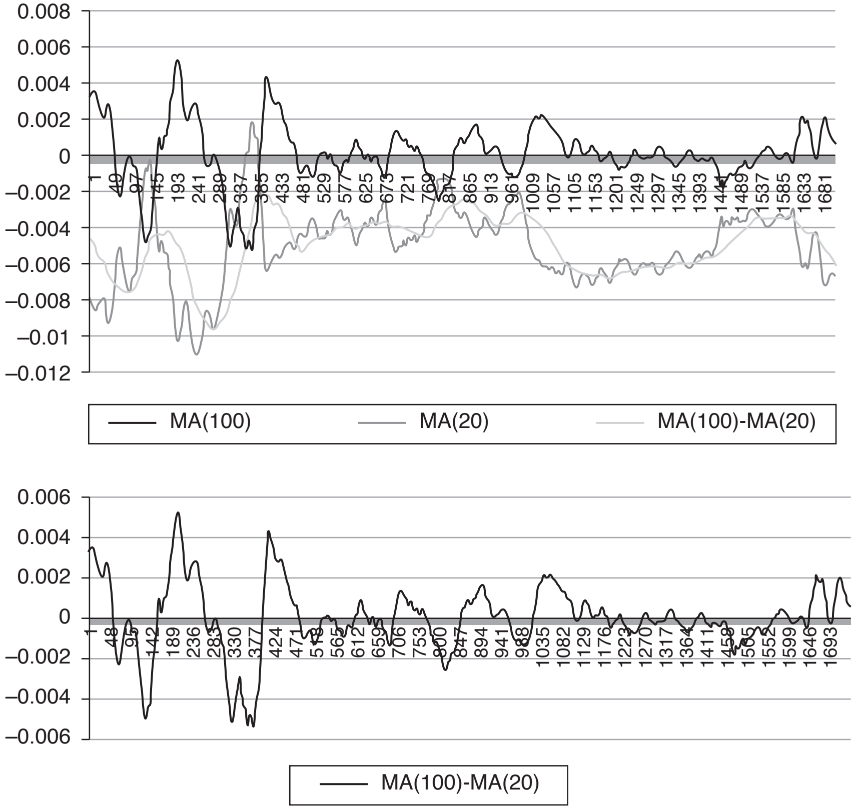
Implementing a version of this strategy, Rebonato, Maeso, and Martellini[39] obtain results shown in Exhibit 58-5, which displays the ratio of the strategy returns and volatility, that is, the Sharpe ratio of the funded, duration-neutralized strategy. They find that the Sharpe ratio is positive in 14 out of 15 of the three-year blocks under study, has tended to decline over time but is often very high, is never significantly negative, and is significantly greater than zero at the 99.9% confidence level in 12 out of 15 blocks.

They also note that the strategy tends to produce high returns (but not necessarily high Sharpe ratios!) when the market volatility is high: in these periods, the volatility of the strategy is also high, and therefore the Sharpe ratios do not display this link with the market volatility. This finding is significant because it suggests a clear indication of the origin of the profitability of the strategy. These results can, in fact, be reconciled with the findings by Hu, Pan, and Wang,[40] who establish a link between price errors ("noise" in their terminology [p. 2341]) for Treasury bonds and a general decrease in market liquidity. The explanation they offer is that the greater the decrease in liquidity, the greater the difficulty encountered by pseudo-arbitrageurs in carrying out the trades that should bring Treasury prices in line with fundamentals. To the extent that an increase in volatility can be

39. "Defining and Exploiting Value in U.S. Treasury Bonds."
40. "Noise as Information for Illiquidity."

EXHIBIT 58-4

20-Day and 5-Day Moving Averages for CUSIP 912810CU and Their Difference (Top Panel), and the Associated Trading Signal (Bottom Panel)



associated with a decrease in market liquidity, the findings of our study are consistent with the interpretation in Hu, Pan, and Wang and provide a rationale for the source of profitability of the strategy. And if, indeed, high returns are reaped in periods of high market volatility, it is not surprising that in these periods also the volatility of the strategy should be high, as the deviations from fundamentals may well increase (giving rise to temporary losses) before eventually reverting toward their reversion level.

Rebonato, Maeso, and Martellini also explore a long-only version of the strategy, which at any point in time only invests an equal amount in those bonds that, according to the model, are underpriced (cheap). They find that the long-only strategy outperforms, in terms of Sharpe ratio, the market portfolio in 14 out of the 15 three-year periods. These results are very important for the practical applicability of the strategy for many institutional investors, who often have long-only constraints.

EXHIBIT 58-5

Sharpe Ratios for the Strategy in the Three-Year Block in the Left Column for 2 and 20 Days in the Short and Long Moving Averages

Date	Sharpe Ratio
1975–1977	0.565
1978–1980	0.573
1981–1983	1.348
1984–1986	1.820

2017–2018	1.121

MOMENTUM FACTOR

Momentum strategies have been found to be profitable in a wide number of asset classes. In equity markets, a well-known early example of academic research in this area is the study by Jegadeesh and Titman,[41] who find over the period 1965–1989 a statistically significant positive performance for dollar-neutral cross-sectional momentum strategies that purchase best performing U.S. stocks over the past 3 to 12 months, sell the losers, and hold the position for 3 to 12 months. Cross-sectional momentum strategies have also been studied in the U.S.

41. Narasimhan Jegadeesh and Sheridan Titman, "Returns to Buying Winners and Selling Losers: Implications for Stock Market Efficiency," *Journal of Finance* 48(1), 1993, 65–91.

equity market by Moskowitz and Grinblatt,[42] and in European stock markets by Rouwenhorst.[43] Similar cross-sectional strategies have then been found profitable in currencies.[44] All these cross-sectional strategies consist of buying (selling) securities that recently outperformed (underperformed) their peers over the past 3 to 12 months.[45]

Rebonato, Maeso, and Martellini[46] complement this strand of the literature by presenting a systematic empirical investigation of the profitability of cross-sectional momentum and reversal strategies in U.S. Treasuries, using more than 40 years of daily data at the individual security level. Looking at the security level is very important, because studies that instead employ "synthetic" zero-coupon bonds can be vitiated by the well-known serial autocorrelation of pricing errors, which can masquerade as a momentum effect.[47]
Rebonato, Maeso, and Martellini apply the following empirical methodology[48] to build a zero-cost cross-sectional momentum strategy:

1. Fix a lookback period of L months and a holding (investment) period of H months; for example, take (L, H): (3, 3), (6, 6), (9, 9) and (12, 12).
2. At end of month date t, consider all the N_t bonds that (i) are in the universe at date t, (ii) were in the universe at date $t-L$, and (iii) that will be in the universe at date $t+H$.
3. At date t, compute for each bond i its relative L-month past excess return with respect to the market: $\left(r_{i,t}^{L} - r_{m,t}^{L}\right)$. $r_{i,t}^{L}$ is the bond i L-month past performance and $r_{m,t}^{L}$ is the market L-month past performance.
4. At date t, assign to each bond i the weight: $w_{i,t} = \frac{1}{\mathrm{N_t}}\left(r_{i,t} - r_{m,t}\right)$. Note that we have $\sum_{i=1}^{N_t} w_{i,t} = 0$.

42. Tobias Moskowitz and Mark Grinblatt, "Do Industries Explain Momentum?" *Journal of Finance* 54(4), 1999, 1249–1290.
43. Geert Rowenhorst, "International Momentum Strategies," *Journal of Finance*, 53 (1998), 267–284.
44. See, for example, Lukas Menkhoff, Lucio Sarno, Mark Schmeling, and Andreas Schrimpf, "Currency Momentum Strategies," *Journal of Financial Economics* 106(3), 2012, 660–684.
45. One can also define time-series momentum, namely, the strategy of looking at the past performance of each security over the last 3 to 12 months, and of buying (selling) those with positive (negative) past performance over a certain investment period.
46. Riccardo Rebonato, Jean Michel Maeso, and Lionel Martellini, "Factor Investing in Sovereign Bond Markets: Cross-Sectional and Time-Series Momentum in U.S. Sovereign Bond Market," EDHEC-Risk Institute Working Paper, 2019.
47. For instance, the widely used zero-coupon bond prices was used by Refet S. Gürkaynak, Brian Sack, and Jonathan H. Wright, "The U.S. Treasury Yield Curve: 1961 to the Present," *Journal of Monetary Economics* 54(8), 2007, 2291–2304. They are obtained by fitting the Nelson-Siegel model to the market prices of coupon-bearing bonds. (Charles R. Nelson and Andrew F. Siegel, "Parsimonious Modeling of Yield Curves," *Journal of Business* 60(4), 1987, 473–489.) As the authors recognize, these fitted prices suffer from serially correlated pricing errors.
48. This methodology was first suggested in Jonathan Lewellen, "Momentum and Autocorrelation in Stock Returns," *Review of Financial Studies* 15(2), 2002, 533–563.

5. Normalize the weights so as to have a cross-sectional zero-cost momentum portfolio, that is, to be 1$ long and 1$ short at the beginning of the investment period:

$$w_{i,t}^{norm} = \frac{w_{i,t}}{\sum_{i=1}^{N_t} w_{i,t}^{+}} \text{ where } w_{i,t}^{+} = w_{i,t} \text{ if } w_{i,t} > 0 \text{ and } w_{i,t}^{+} = 0 \text{ otherwise.}$$

Finally, applying a duration-adjustment to the notional of the short and long positions by dividing the returns of each bond by their duration, and the duration-adjusted market return is the cross-sectional average of the duration-adjusted bond returns. Duration adjustment, *which does not imply duration neutralization*, is performed so as to achieve an approximate risk parity (volatility parity) among the various constituent bonds.

When they do so, Rebonato, Maeso, and Martellini[49] find significant profitability for all the duration-adjusted *reversal* (as opposed to momentum) strategies, and significant results for three out of the four lookback/investment periods (6, 9, and 12 months). Exhibit 58-6 displays some of these results, which show that the annualized mean return of the 6-, 9-, and 12-month duration-adjusted reversal strategies are 0.9%, 1.1%, and 1.3%, respectively, over their sample period.

EXHIBIT 58-6

Descriptive Statistics of Duration-Adjusted Long-Short Cross-Sectional Momentum Strategies

Look-Back and Holding Periods (months)	**3M**	**6M**	**9M**	**12M**
Mean return (annualized)	–0.5%	–0.9%	–1.1%	–1.3%
Volatility (annualized)	3.8%	3.8%	3.9%	3.8%
Sharpe ratio	–0.14	–0.23	–0.29	–0.34
t-stat (Newey-West)	–1.16	–2.21	–3.13	–4.11

This exhibit reports the main descriptive statistics (annualized mean total return, annualized volatility and Sharpe ratio) of the long-short cross-sectional momentum strategies with duration-adjustment. The row labelled “t-stat (Newey-West)” reports the *t*-statistic for the rejection of the hypothesis that the mean in the first row is zero.

From the perspective of important classes of institutional investors with investment constraints, long-only portfolios are particularly relevant, and the strategy presented above can be implemented in such a way as to meet long-only constraints. More specifically, one can naturally compare the returns from giving each bond in the universe an equal duration-adjusted notional with the returns from the strategies of giving equal duration-adjusted weights to the previous

49. “Factor Investing in Sovereign Bond Markets: Cross-Sectional and Time-Series Momentum in U.S. Sovereign Bond Market.”

period winners and losers. The results obtained in a long-only context also suggest that the reversal ("losers") portfolio outperforms the momentum ("winners") portfolio and the market portfolio in term of mean return.

KEY POINTS

- Factor investing in equities has traditionally been focused on identifying securities with positive and negative exposure to rewarded factors and building long-short portfolios to exploit this difference in exposure via cross-sectional strategies.
- The prevailing academic approach for equity factor strategies has been to assume a constant premium.
- Return studies in the fixed income area have taken the complementary view of focusing on the state dependence of the factor, invariably assumed to be associated with the level ("duration") risk, and of constructing unleveraged, time-series strategies.
- Recent empirical evidence suggests that slope-based strategies are profitable, and that their profitability may arise from a residual degree of predictability in the mean-reversion properties of the yield-curve slope once business-cycle components have been accounted for.
- The empirical evidence suggests that value-based cross-sectional strategies are not only statistically significant but also economically profitable.
- Profitability of reversal (as opposed to momentum) strategies over a wide range of look-back and investment periods have been found to be profitable.
- Overall, empirical findings suggest that both time-series and cross-sectional factor investing in the fixed income market are a vibrant field of research and fruitful sources of practically implementable strategies.

CHAPTER
FIFTY-NINE

HEDGE FUND FIXED INCOME STRATEGIES

Ellen Rachlin
Partner
Blue Leaf Ventures

Chris P. Dialynas
Managing Director
PIMCO

Vineer Bhansali, Ph.D.
Chief Investment Officer
LongTail Alpha, LLC

In this chapter, we discuss several common hedge fund fixed income investment strategies, including macro, asset-backed credit, capital structure arbitrage, long/short credit, distressed, basis trading, volatility trading, and cross-currency arbitrage. We believe that a solid understanding of macro-economic conditions, the economic environment, and the influence of policymakers and participants is critical for any robust investment strategy, including fixed income hedge fund investment strategies. Therefore, we begin with a discussion of macro investing fixed income strategies, focused on interest rates and currencies, and then move into further discussion of other strategies that are relative value arbitrage ones, as well as long-biased ones. The performance of all of these strategies is dependent upon the portfolio manager's ability to take advantage of deviations in asset prices from their fair values. This process requires having analytical tools and a historical context within which to gauge asset price deviations and their potential for corrections. Relative value, asset-backed, and arbitrage strategies require more sophisticated valuation tools for the computation of the expected value of security cash flows.

MACRO INVESTING

All elements of fixed income investing require an understanding of the macroeconomic framework and the macro-political economic environment. The macro initial condition will dictate a growth and price stability bias. The macro policy bias will determine the set of policy choices appropriate to achieve the policy bias objective. The philosophical bias of policymakers influences the analytical framework within which initial conditions are diagnosed. The elements of macro economies include by country or region: political framework, economic biases, banking system management, central bank growth and political biases, government balance sheet conditions, initial macro credit conditions, political decision-making process, and currency management, among others.

The complex dynamics of the interaction of these considerations will result in a directional bias for many (if not all) of the risk parameters that concern portfolio managers. The interest-rate direction, yield-curve shape, volatility of interest rates, risk spreads, and currency valuation depicted in Exhibit 59-1, along with the corresponding second derivatives of each, are dominated by the dynamics of the macro system.

Many attributes define the macro-political economic environment. The institutional architecture is certainly very important. This is defined by political, banking, and legal systems. While these systems may be easily understood conceptually, they morph over time as the political/philosophical bias of the people in charge change as well as changes in the attitude of the general population occur, which can happen much more slowly.

Understanding the philosophical economic bias of each region is vital to anticipating policy and changes in policy. The primary objectives are simple and straightforward. In the United States, the stated objectives are a stable rate of inflation and full employment. The Europeans concern themselves most with price stability. The Chinese have traditionally seemed more concerned with internal industrial development via a mercantilist export policy. Each country will have a particular objective at any particular time, and over time the importance of any particular objective will change as conditions change. Moreover, the philosophical bias evolves as a country evolves. In his *Republic,* Plato describes a very plausible evolution of political rule. Among those considered include democracy, aristocracy, oligarchy, philosopher kings, monarchy, socialism, totalitarianism, and dictatorship. The implications of each are quite important to investment decisions, as are the migration of regime one to another.

In a 1968 article, Milton Friedman elaborates on public policy priorities, potential policy choices, and the difficulty of effective implementation:

> To state the general conclusion still differently, the monetary authority controls nominal quantities—directly, the quantity of its own liabilities. In principle, it can use this control to peg a nominal quantity—an exchange-rate, the price level, the nominal level of national income, the quantity of money by one or another definition—or to peg the rate of change in a nominal quantity—the rate of inflation or deflation, the rate of growth or decline in nominal national income, the rate of growth of the quantity of money. It cannot use its control over nominal quantities to peg a real quantity—the real rate of interest, the rate of unemployment, the level of real national income, the real quantity of money, the rate of growth of real national income, or the rate of growth of the real quantity of money.

EXHIBIT 59-1

Expected Changes in Market Variables Relative to Changes in Economic Growth

	Early Growth	Mid-Growth	Late Growth	Recession
Rates	Stable	Increasing	Increasing	Falling
Yield Curve	Positive	Flattening	Inverting	Steepening
Volatility	Low	Moderate	High	High
Risk Spreads	Narrowing	Narrowing	Narrowing	Widening
Currency	Appreciate	Appreciate	Appreciate	Depreciate

UNDERSTANDING THE COMPONENTS OF THE STATISTICS

With an eye to dissecting aggregated statistics, the investor should analyze key economic data such as debt-to-GDP ratio, exports and imports as a percentage of GDP, banking system leverage, aggregate bank assets, nominal government spending, personal savings rates, net national savings, expected changes in FX rates, inflation rates, GDP nominal and real rates, and unemployment rates, among others.

Understanding the trend of any particular statistic is insufficient. Understanding the distribution of components of the statistic is vital. In this regard, it is most important to distinguish between the distribution of debt formation, both public and private, directed to consumption and that associated with investments. It is important to understand the distribution of prices associated with inflation. It is important to understand the components of trade, both exports and imports, associated with consumption and investments. The implications of the distributions are vitally important to predictions of the future and to an inferential understanding of the motivations of policymakers and the public at large. Also vital to the process is an understanding of when policy end points are near and the implications thereof. A microscopic understanding of the data will enable the investor to decide what coefficients to assign to each statistic and to change the coefficients when appropriate.

Armed with data that may differ somewhat across sources, the portfolio manager's challenge is to forecast various risk parameters, knowing there is more to economic behavior than statistics. The portfolio manager must also account for regulatory changes, sociological conditions, political risk, and the psychology of the participants. One looks to the markets for inferential valuations that presumably synthesize all of these criteria. After all, money-making is a bet against forward prices. So, forward rates, yield curves, and currency values are all requisite inputs to the portfolio manager's decisions after an assessment of all of the statistics and after an evaluation of all of the political/economic/philosophical judgments.

BIG CHANGES ARE VERY IMPORTANT

The price of an asset is simply the intersection of supply and demand. Activist policy institutions such as the U.S. Federal Reserve Bank, the European Central Bank (ECB), the Bank of England, and the Bank of Japan have decided to change their status from referee to both player and referee and to engage directly in the markets in such a way that they become price setters. ZIRP (zero interest rate policy) and NIRP (negative interest rate policy) across much of the non-U.S. developed market have created significant changes in the pricing of all assets, and of course of the global bond markets. This is a most important fundamental change to capitalism. Direct government interference in capital markets means that prices are less subject to fundamental macro valuations described herein and more a function of the "social" desire of policymakers. This is a gigantic change and during such a change the portfolio manager must consider placing political, sociological, and philosophical forecasts ahead of the traditional economic forecasts associated with a "capitalist" system.

THE YIELD CURVE

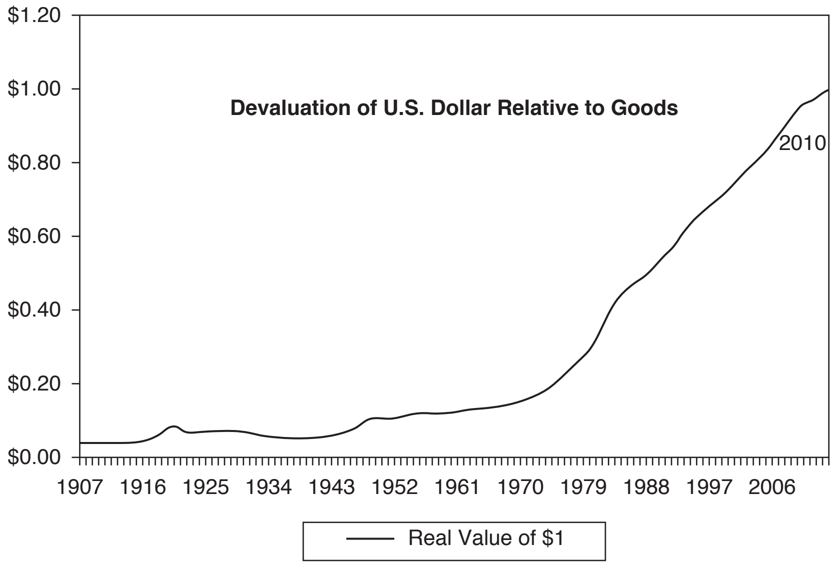
The yield curve is a mapping of interest rates for various lending periods for a particular issuer. The yield-curve shape can vary substantially, and changes in the shape of the yield curve can be an important source of return to the investor. Longer maturities typically yield more because there is more pro-inflation risk and credit risk embedded within them and they are less liquid than shorter maturities. Absent credit risk considerations, longer-maturity securities' yields are lowered because of their higher convexity, which takes on greater value when interest rates become more volatile. In addition, we observe an example of the pro-inflation tendency of policy in the United States from 1907 to 2011 in Exhibit 59-2.

Creditors generally cannot foreclose on a sovereign issuer. Defaults on sovereign issuers result in "restructuring," in which creditors receive a fraction of their principal back. So, in anticipation of a potential restructuring, rates increase on the sovereign to reflect increased credit risk. The increase in rates further impairs the sovereign's credit, thereby increasing default probabilities because the interest rate itself is higher than the rate of sovereign growth, growth that itself is reduced by the higher interest rate. Moreover, over very long periods, demographic trends become an increasingly important variable if there is a large outstanding debt. Reductions in population growth translate into fewer workers to contribute to debt servicing and increases in the forward population relieve the debt burden.

The sovereign credit default swap (CDS) market is yet another check on the creditworthiness of the sovereign and the change in credit status. The CDS market is one in which investors can buy and sell insurance on sovereign credit.

EXHIBIT 59-2

U.S. Inflation Policy



A policy is triggered, and the insurance collected if and only if a default occurs or a restructuring, if the CDS contract so specifies. The CDS spread is relative to a standardized LIBOR term and should map closely to the yield spread on that sovereign's bond to the same term rate. Technical contract specifications and potential for regulatory interference cause the two spreads to be unequal. However, the direction of the spreads should be consistent most of the time.

Economic inferences and dynamics, forecasts for interest rates and currencies are, as discussed, much more complex in a highly globalized world economy. Traditionally, currency forecasting was a function of interest-rate differentials, growth and inflation, trade and capital flows, differentials and purchasing-power parity. Post the 2008 financial crisis, there has been an increasing focus on the growth in relative factor productivity and net trade flows. The military strength of a nation is always a very important consideration.

Many financial economists and investors believe the output gap is an important determinant of inflation. The output gap and inflation are inversely related as the output gap measures the degree of abundance of resources in the economy. The output gap theory relies on empirical Phillips curve analysis, which measures the historical relationship between labor and inflation.

Currency debasement, inflation, and taxation are all substitute expropriating vehicles in addition to regulatory tools, such as capital controls, the sovereign has at its disposal. The selection of vehicles is made in consideration of prevailing conditions paramount to an investor in sovereign bonds and currencies relative to forward values. Exhibit 59-3 is a crude mapping of currency and bond strategy given a particular policy circumstance.

In regard to the valuation of currencies in the spot and forward markets, any differences between U.S. and another country's interest rates implied by forward over prevailing rates represents the speculative motive in that market or is indicative of high transaction costs.

EXHIBIT 59-3

Implications of Policy Choices

	Capital Controls	Increase Taxes	Reduce Taxes	Inflate	Deflate	Increase Spending	Decrease Spending
Bonds	–	+	–	–	+	–	+
Currency	–	Amb	Amb	–	+	Amb	Amb

+ Buy, – Sell, *Amb* ambiguous.

POLITICAL SELF-INTEREST VERSUS INTEREST OF THE SOVEREIGN

Politicians and policymakers can be predisposed to do what is in their best interest as opposed to the national interest. The national interest is, as discussed in the beginning of this chapter, a function of one's underlying political/philosophical/economic beliefs. To the extent that politicians get re-elected by providing benefits to the population through spending programs, we will observe an accumulation of debt and a generalized inflation over time. This has certainly been the case for the United States. Exhibit 59-4 provides inferential support for the thesis that politics in democratic nations are incentivized to increase debt for the purpose of providing greater benefits to its constituents with the hope of re-election.

Investors in bonds and currencies must consider the psychological impact on policymakers' behavior when legacies are in the making. The period from the 2008 financial crisis through 2011 is an example of a period when legacies are at risk and monumental global financial and social change is proceeding. It is a time for bond and currency investors to evaluate the efficiency and sustainability of policies, as well as realistic alternatives to prevailing policies and the implications thereof. Investors should heed the council of notable economists of the past. Specifically, Keynes' policy prescription to a financial crisis might result in "euthanasia of the rentier,"[1] as well as Robert Triffin's concern about the

responsibility of the custodians of the reserve currency: "We should be as averse as foreign countries—or more so—to incurring again the awesome political responsibilities and inflationary temptations inseparable from the exorbitant privilege of having our national currency used as the main international currency of the world."[2]

Macro fixed income hedge fund investment is one significant hedge fund style of investing. The rest of this chapter is devoted to other styles ,including asset-backed credit, capital structure arbitrage, long/short credit, distressed, basis and volatility trading, and cross-currency arbitrage.

ASSET-BACKED CREDIT STRATEGY

The asset-backed credit strategy is a long/short style of portfolio management that focuses on investing in securitized debt obligations, which may encompass a wide variety of types of debt from residential and commercial mortgages to leases and credit cards. The portfolio manager seeks to identify asset-backed securities that they believe are mispriced relative to the value of the supporting loan collateral for long or short investments. This strategy is focused, generally, on higher-yielding securities backed by loans to riskier borrowers, but not exclusively so.

The best opportunities to purchase mispriced asset-backed securities generally occur during significant dislocations in the credit markets. Practitioners of this strategy will often develop complex proprietary models to value collateral referencing a given security with the goal of ascertaining whether that security may or may not have a greater liquidation value and principal and interest payment stream than is built into the current pricing. These valuation models will include current information such as payment delinquencies as well as payment projections over the expected life of the security. These models will have the ability to analyze loan level data. Hedging or shorting in this strategy may tend to focus on hedging macro risk factors such as general market declines as well as use derivatives on specific vintage or year and seniority in the payment of a securitized obligation.

The types of asset-backed credit collateral considered as a potential investment set for the credit strategy includes agency and agency-issued residential mortgage securities, primarily, as well as consumer credit asset-backed securities, commercial mortgage securities, and commercial nonmortgage-asset-backed securities, among others. The largest asset-backed credit group, residential mortgages, consists of securities backed by the differing mortgage loan types.

These loans are not only securitized into pooled obligations but are further divided into tranches tiered by payment priority loss. The lower the payment priority, the higher the default risk, but also the higher the current yield. Part of this investment strategy is for the portfolio manager to not only identify misvalued

2. Robert Triffin, "The International Role and Fate of the Dollar," *Foreign Affairs* 57(2), 1978/79, Council on Foreign Relations.

securities but misvalued tranches. At times, the cheapest security may be the first loss and in other instances it may be the top of the structure. The portfolio manager may also choose to allow their impression of the market environment determine where they are most comfortable in the tranche structure with the view that defaults have a cyclical component.

A portfolio manager may also choose to purchase securities that are "seasoned," meaning that they are older. Borrowers that have been current on their payments, historically, tend to continue to pay. However, seasoned securities tend to be more fully priced and are less likely to be cheap. Short strategies tend to be hedges designed to protect from systematic risks such as against general deterioration in all asset prices. Less security specific, these hedges might include both stocks and bonds or their derivatives due to limited ability to short or borrow cash securities particular to the asset type of the long positions.

Some of the underlying collateral trends monitored by the portfolio manager include home and commercial property price appreciation, cumulative default rates, delinquency trends, cumulative loss rates, loss severity from sale, loan-to-value rates, loan modification levels, liquidation rates, geographic REO levels, commercial sector demand, and unemployment rates, among others. Because default rates are the primary risk factor in this asset class, the asset-backed credit portfolio manager will monitor the performance of the underlying loans behind the asset-backed securities held and the ones under consideration for possible inclusion in their portfolio. Some details include the number of reference loans that are delinquent, length of time delinquent, nonperforming, in foreclosure and liquidated, as well as restructured and re-performing.

Hedging techniques and possibilities have greatly expanded in scope and potential for this hedge fund strategy over time. At one time, one could only primarily think in terms of hedging systematic or cyclical risk. One would choose broad-based credit, interest-rate, or even equity indices to provide downside protection. However, during the beginning stages of the housing debt market crisis a proliferation of derivative products that referenced asset-backed securities and tranches of asset-backed securities by type were developed that offered ways to more directly hedge or short sell residential and, later, commercial asset-backed securities. These derivatives are tranched, allowing for a more specific type of asset-backed hedge or short sale instrument.

CAPITAL STRUCTURE ARBITRAGE

Capital structure arbitrage is an investment strategy that is typically focused on stressed or distressed companies. These are ones with high balance sheet leverage. A capital structure arbitrage portfolio manager considers all securities of a company (debt and equity) for possible mispricing or relative mispricing. They view the securities by payment priority against current cash and future earnings potential. They assess value by ascertaining probabilistic ability to pay debt obligations as well as potential realized equity valuation. Capital structure arbitrage is an investment strategy that is flexible and broad enough in scope to accommodate opportunities that arise throughout the credit cycle. For example, the portfolio manager may be more constructive on holding equity that appears cheap versus a senior debt short hedge during an economic recovery and shorting equity while holding senior secured debt during economic contraction. Other times, the financial merit of a company's outstanding securities may hold a case independent of economic times. The portfolio manager will likely identify a specific catalyst event that will correct the senior versus junior security relative value mispricing. This catalyst could be an upcoming refinancing or a business specific event. This strategy tends to use low levels of leverage as the companies invested in have high levels of balance sheet leverage.

The layers of securities within a company can be quite varied from senior secured bank debt with strong covenants to the most junior security or equity-based ones. Each of these securities can be expected to have unique volatility characteristics. The more junior a security, the more likely it will be relatively more volatile. The portfolio manager must consider this volatility when positioning long and short as this will affect the overall P&L volatility exposure to their portfolio.

The portfolio manager must evaluate the covenants of outstanding debt and ascertain payment priority, which can be complicated. The most difficult layer of complication comes from companies with multiple subsidiaries. Subsidiaries and holding companies may have cross-liabilities and not be entirely self-reliant. The portfolio manager must also factor in debt maturity schedules as an important element of valuation against their prediction of future ability to make interest and principal payments. Often the clarification of payment priority and asset rights are resolved in a court of law. The portfolio manager must have a thoughtful way of assessing the likely bankruptcy proceeding outcomes in regard to the various debt instruments outstanding. This process can be fairly long and the outcomes uncertain. However, these securities are usually ones that can be sold or traded long before final legal decisions are reached.

A capital structure arbitrage portfolio is likely to contain multiple positions in various securities within the capital structures of many companies. Each of these companies is likely to be or anticipated to be experiencing some form of structural change as a result of meaningful current or prospective corporate events. The events may not only include a changing capital structure specific to one company but may represent changing financial fortunes inflicted by the larger macroeconomic environment on many sectors of the economy. Often the capital structure arbitrage portfolio can be concentrated by sector as industry dynamics can affect multiple companies at once in a way that creates opportunity unique to that sector. The portfolio manager thinks in terms of various scenarios with probabilistic outcomes. The long and short security weightings will reflect their probabilistic assessments. Longs may hold a larger weight if stronger economic fortunes are expected ahead, for example. Events have varying time frames and the portfolio manager is also likely to assess the attractiveness of an opportunity based on the present value of the expected price change of the securities positioned.

Hedging in this strategy tends to be company specific, whether on a junior or senior security basis. However, it is usual to see industry-level hedges or even index-based ones in this strategy. Capital structure arbitrage portfolios can tend to be net long for the company specific positions. Other more generalized hedging techniques may often make sense to deploy in order to mitigate overall market beta exposures.

LONG/SHORT CREDIT STRATEGY

The long/short credit strategy is also referred to as a relative value strategy or a fixed income arbitrage strategy. Within any of these descriptions are multiple substrategies or investment approaches. Some of these substrategies may have very specific tightly hedged arbitrages while others have more systemic or generalized hedging approaches. Long/short credit strategies can include debt securities within the entire credit spectrum from investment-grade to high-yield and distressed. All approaches depend upon a bottom-up analysis of a given company's ability to pay its debt obligations based on its business model and its revenue prospects. Similarly, portfolio managers are focused on economic and leverage cycles, which affect companies' abilities to meet their debt obligations. A long/short credit portfolio can consist simply of diverse bond positions both long and short of companies that the portfolio manager feels are worthy of taking a positive or negative view based on current default probability versus current price. A portfolio manager can be expected to hold overall exposure ranging from net long to closer to market neutral. Practically speaking, it is unusual for a portfolio to be consistently net short.

Cash corporate debt (loans, bonds, and preferreds) and derivatives, both single company reference as well as index and tranches of indices, are the main instruments used, in addition to sovereign debt instruments. However, interest-rate and equity instruments are used to hedge or emphasize certain desired exposures. Specifically, cash corporate debt obligations are ones that have some claim or payment priority in the event of corporate default. Derivative instruments, credit default swaps, are generally bi-lateral payment agreements between two contractual parties based upon the financial fortunes of a referenced entity. These instruments represent no direct obligation of the referenced company in the event of default. These instruments will be assessed based on a given entities' prospective cash flows, asset quality, covenant protection, possible catalysts that may alter an entity's future earnings capabilities, industry trends, overall default rates, credit conditions, industry, and broad economic factors, among others.

The long/short credit portfolio manager may take several different approaches toward building their portfolio. They may construct a credit long book and a credit short book with the net and gross exposures reflecting some macro point of view regarding underlying market volatility and near-term direction. In general, the gross market value of the aggregated positions versus assets under management can be expected to be larger for higher-rated, lower-spread debt than lower-rated, wider-spread debt. Such construction reflects a risk attitude that the latter is likely more volatile in price.

Directional longs may include the debt or credit derivatives of out of favor, stressed, distressed companies; debt whose prices seem to be below their fair price as assessed by the portfolio manager or of companies undergoing positive changes. Directional shorts may include the debt of or credit derivatives of companies that are experiencing a cyclical decline, whose prices seem to be above their fair price given future earnings potential as assessed by the portfolio manager or provide opportunity to profit from the part of the leverage cycle in which all corporate bond spreads are widening. The portfolio manager can be expected to use leverage but hold some reasonable portion of unencumbered or excess cash over their margin requirements. The amount of unencumbered cash held will rise and fall depending on the overall conditions of the markets, both by cyclicality and opportunity. Depending on the risk appetite of the portfolio manager, their portfolio may be highly diversified with hundreds of positions or be more concentrated. Generally, over time the more concentrated a portfolio, the more volatile that portfolio's valuation can be expected to be. Concentration can refer to position size, ownership percentage of a particular debt issue, geography, industry, and credit quality, among others.

Of a given debt issue, the higher its investment rating, the lower the probability of its default; however, the return distribution of such a debt issue will be negatively asymmetrically skewed with more downside potential than upside. This is what makes hedging interesting in this strategy. Hedging can be company specific in such a way that overlaps with capital structure arbitrage and involve other debt in the same company as well as reference credit default swaps. Hedging or shorting can be used to express a negative view on a company or a sector as well as to maintain a net short position during times of market turmoil. Hedging can also be as broad in nature to include generalized equity, credit, and interest-rate hedges. The more tightly hedged, market neutral, or investment-grade focused a given portfolio is, the greater the likelihood leverage will be higher than otherwise. Concentrated or net long portfolios can be expected to be commensurately less leveraged, as this type of portfolio will be more volatile than a market neutral one.

DISTRESSED DEBT

The distressed investing strategy is one that focuses on investing in the securities of companies experiencing financial stress. They may or not be in default. The investment situations may be ones that are meant to focus on improving corporate balance sheets, others may be liquidation investments in which a company's securities may represent a claim on valuable assets, including cash, some liquidity investments in which refinancing will provide the necessary time for a company to recover, or litigation investments in which the portfolio manager may participate on creditor committees and the value of certain securities will be determined in a court of law. As well, some positions may be short ones in deteriorating companies that are losing market share or are cyclical in nature. All positions will generally be constructed with an identifiable catalyst or some event, usually corporate specific, that will unlock the value potential of securities held in the portfolio.

The securities held in the portfolio of a distressed strategy can include all parts of the capital structure of a company, holding company, or subsidiary as well as aggregated debt securities as described in the asset-backed security strategy section. Securities range from senior secured debt (such as bank loans) to subordinated debt (such as second lien debt) down to more junior secured securities (such as busted convertibles trading well below the convertible price and equities). Other types of debt securities exist only with companies experiencing financial distress, such as debtor in possession (DIP) or rescue financing. The lower the debt in the capital structure or payment priority, the lower the dollar price can expect to be.

The distressed portfolio manager may take several approaches to building their portfolio. This strategy is primarily long biased, and the characteristics of the securities held in a sensibly constructed portfolio will include ones that are the debt or equity of companies that are industry leaders or have strategic importance, ones that are cheap relative to not only current valuation but have a cushion to protect during a downturn or market volatility, and ones that are well-priced for the industry and region in which the company does business. The portfolio manager may use other companies' valuations in a similar industry to ascertain value of a target company as a way of affirming the total valuation of the securities they are holding. It is worth noting that one aspect of this strategy overlaps with the asset-backed credit strategy in that impaired structured credit such as collateralized debt obligations (CDOs) and collateralized loan obligations (CLOs), which are bundled multiple corporate debt obligations are often part of a distressed portfolio manager's investment set. These securities can be disaggregated to the loan or bond level and valued against current market pricing for the debt obligations of the underlying companies. The portfolio manager will value the sum of the collateralized obligation against the parts and attempt to profit if there is a suitable mismatch. Overall, the distressed portfolio will be likely constructed of multiple positions in multiple companies but can be concentrated, as when the securities of the top 10 companies represent a majority of the invested assets under management.

Hedging for this strategy will span from other parts of the capital structure in which strategic long positions exist to index or interest-rate hedges. Hedges may also include the debt and equity of other companies within the same or similar industries as strategic long positions. This strategy may also encompass short positions for companies whose fortunes are declining given industry trends and economic outlook. However, in this situation, which can be fairly cyclical by nature, portfolio managers may tend to restrict capital inflows, or even return money to investors if opportunities are scarce. Tactically, portfolio managers can move "up or down" in the capital structure, buying senior secured positions during the weaker part of the economic or industry cycle and taking more junior security positions, unsecured or equity, during growth phases of the cycle. While not necessarily a hedging technique, it is a risk mitigation one.

BASIS TRADING

Basis trading involves the simultaneous purchase and sale of two closely related securities to take advantage of relative mispricing.

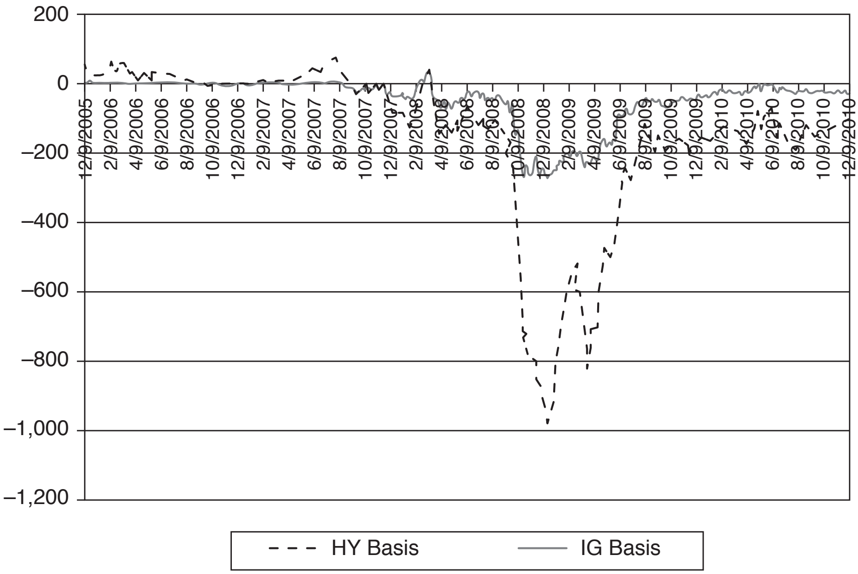
In the classic futures basis trade, an investor can buy a cash U.S. Treasury security and sell a futures contract. In a credit basis trade, an investor purchases or sells a cash corporate bond and hedges the credit risk by the purchase or sale of credit default swaps. Other versions, such as the LIBOR-fed funds or its longer-maturity counterpart, the swap-spread trade, as well as the cross-currency basis swap, which involves funding in one currency and swapping via the currency forward exchange-rate market, are also popular.

The hallmark of all basis trades is the isolation of a factor that is not present in one side of the trade but is present in the other side. In the futures basis trade, the important factor is the presence of a delivery option. The gross basis of each bond in the delivery basket is computed by computing the difference in its forward price versus the converted price of the futures contract (the delivery price, which equals the futures price times a conversion factor specified by the exchange). To obtain the net basis, the gross basis is adjusted by the net carry, which is the coupon income and re-investment income minus the funding cost or repo rate of the bond. When the net basis is positive, a long cash/short futures basis trade has a negative expected loss equal to the basis. For example, if the net basis is 2/32nds, the long-cash, short futures position is expected to lose 2/32nds if held to the futures expiration date. The reason for negative expected return is that the person who is short the futures contract has an option to deliver one of the bonds in the delivery basket, and the price of the option is equal to the value of the net basis. The short effectively pays the long futures holder for this option. Since all option values are positively correlated to a rise in volatility, the value of the option can rise if interest-rate volatility rises. In the case of the futures basis trade, the probability of another bond switching to become the cheapest to deliver rises as volatility rises. An investor with the short futures position will have the value of the delivery option rise in an environment of rising volatility. Futures basis trading is really an option trading enterprise.

In a cash-CDS basis trades, an investor prefers to purchase a cash corporate bond and buy protection against it using credit default swaps contracts. If cash bond yields are higher than the price of protection, then the investor can take out risk-free profits. Following the history of the cash-CDS trade (below depicted at an aggregate level), illustrates some important insights into the fundamental driving factors. Before the Global Financial Crisis (GFC) of 2008, the cash-CDS basis traded within a small range around zero. However, the GFC created a substantial widening of the spread, and the basis went negative; that is, cash bonds traded substantially wider than CDS. In other words, at the height of the GFC an investor who had cash could purchase a cash corporate bond and buy protection on the credit risk and still be ahead by hundreds of basis points from those who did not have the CDS and were forced to liquidate the cash bonds. In other words, the cash-CDS corporate basis trade is driven by the important risk-factor of liquidity. When liquidity is ample (as illustrated by the convergence of the basis trade after the infusion of liquidity from the Fed), the spread between cash and CDS quickly falls, as shown in Exhibit 59-5.

EXHIBIT 59-5

Sample Spreads Between Cash and CDS



VOLATILITY TRADING

Volatility trading focuses on the purchase and sale of implied volatility in the market. In its most direct form, volatility trading attempts to benefit from opportunities and perceived mispricing in the fixed income options markets. Since options prices are primarily determined by the implied volatility of the underlying reference security, a portfolio manager can analyze the opportunity from many different angles.

The first approach is to buy or sell options when the implied volatility is rich or cheap compared with some metric of long-term levels. To do so, portfolio managers use various estimation techniques to measure and forecast realized volatilities. If implied volatilities are higher than the forecast of realized volatilities, options are sold and the risk to the underlying is delta-hedged based on some model. Typically, option prices reflect a risk premium since sellers of options require compensation over and above the fair value of the options in order to sell them. Over long periods of time, the average return from selling fixed income options and holding them to maturity, in particular, has been positive since yields are naturally mean reverting (high rates slow the economy down and hence cause yields to fall). Many portfolio managers follow the ratio of implied to realized volatilities to wait to initiate these trades. For those who do not want to hedge the risk to the underlying by delta hedging, instruments such as variance and volatility swaps are available where a direct bet on the level of volatility levels can be made in relation to a volatility strike. Of course, this strategy is very directional in both the level of volatility and in the level of rates since the profit or loss is driven by both movements in the level of uncertainty as well as the demand for options from hedgers.

Another approach to trading volatility is to look at the volatility surface and find opportunities from mispricing of particular strikes, expiries, and maturities. The swaption volatility "cube" is specified in terms of swaption expirations, as well as the swap "tails" that these swaptions exercise into the different strikes given the option expirations and underlying forward swaps. For instance, with low rates and the short-end of the yield curve pegged to zero rates, a portfolio manager might take the view that the implied volatility for a payer swaptions (one that gives the right to pay fixed) at a higher strike than current forward is pricing in too much volatility. They can sell that swaption and pick both the volatility premium and the payer skew (currently, payer swaption volatilities are higher than receiver swaptions due to inflation hedging demand for high strike payer swaptions).

Many portfolio managers also look at implied optionality across various fixed income securities. For instance, a mortgage-backed agency pass-through is sensitive to the change in volatilities since rising volatilities increase prepayment probabilities. A mortgage pass-through buyer is naturally short the prepayment option to the homeowner and is compensated for the option in terms of extra spread. If the level of swaptions volatilities is low compared with the option volatility implicit in the mortgage security, a portfolio manager can position a volatility arbitrage by buying the MBS and buying the swaption.

A further extension of volatility trading is to execute the trades across markets. One might take the view that fixed income option volatility in the United States is higher than Europe and sell options in one market versus purchase in another. Or that the volatility expressed in the fixed income options market is higher or lower than the volatility expressed in the longer dated currency options markets. The two are related because currency forwards are driven by both the spot exchange–rate and interest-rate differentials, and for longer-dated forwards the volatility and correlation of the longer rates becomes a dominant relative value factor.

CROSS-CURRENCY ARBITRAGE

Cross-currency arbitrage is a strategy where bonds in one country are purchased and then hedged with cross-currency swaps to take out the currency risk. Typically, the currency hedging is done using shorter maturity currency hedging contracts than the maturity of the bonds. For instance, a USD-denominated fund might purchase Japanese government bonds (JGBs) or German bunds at close to or even below zero yields. Hedging out the currency risk using a one-month forward would require selling the Japanese yen forward and buying the USD forward for one month. As discussed in the macro section earlier, different global central banks are pursuing different monetary policies, so as of this writing, the short-term interest rates in Japan or in Europe are much lower than in the United States. If the interest rate differential between U.S. short-term rates and the foreign rates is large, this adds to the yield of the foreign bond purchased over the horizon of the currency hedge (note that there is no guarantee that the currency hedge can be "rolled" at its maturity, which is a risk of this strategy).

By buying low-yielding foreign bonds and leveraging up the positions and then overlaying a currency hedge, investors are then able to increase the yield on their portfolios, primarily as a function of short interest-rate differentials. The risk of this strategy can emanate from three areas: first, there is a significant duration risk of the underlying bonds with their long maturities; second, there is currency hedging risk if the forwards cannot be rolled; finally, there is the risk that the underlying bond has credit risk that can result in spread widening or perhaps even default. Foreign buyers have bought large quantities of peripheral European bonds such as Italian bonds on a currency-hedged basis and taken on the credit risk of Italy. One impact of the cross-currency strategy has been that even though foreign bonds have a much lower yield than U.S. bonds as of this writing, on a currency hedged basis their yield is higher than U.S. bond yields, so for a short-term investor, there is better carry in such foreign bonds than in U.S. bonds.

KEY POINTS

- All elements of fixed income investing require an understanding of the macroeconomic framework and the macro-political economic environment at any point in time, present and future, for any country or region within which the investment is derived. The complex dynamics of the interactions of these considerations result in a directional bias for many (if not all) of the risk parameters that concern portfolio managers. The interest-rate direction and volatility, yield-curve shape, risk spreads, and currency valuations as well as the second derivatives of each of these are all dominated by the dynamics of this macro system.

- The asset-based credit strategy is a long/short style of portfolio management that focuses on investing in securitized debt obligations, which may encompass a wide variety of types of debt from residential and commercial mortgages to leases and credit cards, among others.
- Capital structure arbitrage is an investment strategy that is typically focused on stressed or distressed companies, ones with high balance sheet leverage.
- The long/short credit strategy contains multiple substrategies or investment approaches. Some of these substrategies can have very specific, tightly hedged arbitrages, while others have more systemic or generalized hedging approaches. For example, such a portfolio could hold diverse bond positions, both long and short of companies that the portfolio manager feels are worthy of taking a positive or negative view on based on expected default probability versus current price. The hedges could be quite similar to the long positions or just an index hedge.
- The distressed investing strategy is one that focuses on investing in the securities of companies experiencing financial stress. They could be in default or close. The investment situations could be ones that are meant to focus on improving corporate balance sheets; others could be liquidation investments in which a company's securities may represent a claim on valuable assets including cash, some liquidity investments where refinancing will provide the necessary time for a company to recover, or litigations investments where the portfolio manager may participate on creditor committees and the value of certain securities will be determined in a court of law.
- Basis trading involves the simultaneous purchase and sale of two closely related securities to take advantage of relative mispricing. For example, in the classic futures basis trade, an investor buys a cash Treasury security and sells its futures contract.
- Volatility trading focuses on the purchase and sale of implied volatility in the market. In its most direct form, volatility trading attempts to benefit from opportunities and perceived mispricing in the fixed income options markets.
- Cross-currency arbitrage involves the purchase of bonds in one country that are then hedged with cross-currency swaps to remove currency risk. Typically, the currency hedging is done using shorter maturity currency hedging contracts than the maturity of the bonds. This strategy can add to the yield of the bonds.

CHAPTER
SIXTY

FINANCING POSITIONS IN THE BOND MARKET

Frank J. Fabozzi, Ph.D., CFA, CPA
Professor of Finance
EDHEC Business School

Steven V. Mann, Ph.D.
DIstinguished Professor Emeritus
Moore School of Business
University of South Carolina

Leveraging strategies require that an investor borrow funds. There are several well-established arrangements in the bond market for borrowing funds. The most common practice is to use the securities as collateral for a loan. In such instances, the transaction is referred to as a *collateralized loan*. In this chapter we will look at the four types of collateralized loans in which the collateral is a bond: repurchase agreement, dollar roll, securities lending, and margin buying.

A collateralized loan is not the only mechanism available to an investor for creating leverage. Derivative contracts are instruments that allow an investor to synthetically create leverage. This is so because a derivative contract allows an investor to obtain greater exposure to a specific bond issuer per dollar invested than the same dollar amount invested in the cash-market instrument. For example, the initial futures margin that an investor must make to obtain a long position in a Treasury bond futures contract creates an exposure to Treasury bonds much greater than the exposure if that initial futures margin were used to purchase Treasury bonds. In the case of an interest-rate swap, consider the fixed-rate receiver's position. This party is effectively borrowing on a floating-rate basis to obtain exposure to a fixed-rate bond position where the par value of that bond position is equal to the swap's notional amount. Similarly, there are cash-market instruments that have embedded leverage. For example, an inverse floater position is equivalent to borrowing funds on a floating-rate basis in order to obtain a fixed rate.

REPURCHASE AGREEMENT

A *repurchase agreement*, or simply *repo agreement* or *repo*, is the sale of a security with a commitment by the seller to buy the same security back from the purchaser at a specified price at a designated future date. The price at which the seller subsequently must repurchase the security is called the *repurchase price*, and the date that the security must be repurchased is called the *repurchase date*. Basically, a repurchase agreement is a collateralized loan where the collateral is the security sold and subsequently repurchased. The difference between the purchase (repurchase) price and the sale price is the loan's dollar interest cost. The interest rate a borrower agrees to pay is called the *repo rate*. When the term of a repo is one day, it is called an *overnight repo*; a repo for more than one day is called a *term repo*.

To illustrate a repo, suppose that a portfolio manager owns a five-year Treasury note with a par value of \$10 million and a full value of \$10,015,455. Suppose further that the portfolio wants to borrow funds for 10 days using the Treasury note as collateral for a repo. Since the repo is for more than one day, it is a term repo. On the day the repo is initiated, the portfolio manager would agree to deliver ("sell") \$10,015,455 it is holding of the Treasury note to a third party, say a government dealer firm, and repurchase the same Treasury note from the government dealer firm 10 days later for an amount determined by the repo rate. Suppose that the repo rate in this transaction is 0.08%. Then, as will be explained below, the portfolio manager would agree to deliver the Treasury note for \$10,015,455 and repurchase the same securities for \$10,015,677.57 10 days later. The \$222.57 difference between the "sale" price of \$10,015,455 and the repurchase price of \$10,015,677.57 is the dollar interest on the financing.

The following formula is used to calculate the dollar interest on a repo transaction:

$$\text{Dollar interest} = (\text{dollar principal}) \times (\text{repo rate}) \times (\text{repo term}/360)$$

Notice that the interest is computed using a day-count convention of actual/360 like most money market instruments. In our illustration, using a repo rate of 0.08% and a repo term of 10 days, the dollar interest is \$222.57, as shown below:

$$\$10{,}015{,}455 \times 0.0008 \times (10/360) = \$222.57$$

The advantage to the dealer of using the repo market for borrowing on a short-term basis is that the borrowing rate (i.e., the repo rate) is less than the cost of bank financing. (The reason for this is explained below.) From the perspective of the entity lending the funds, the repo market offers an attractive yield on a short-term secured transaction that is highly liquid.

The repo market can be used not only to finance a position in the market but also to cover a short position. For example, suppose that a dealer shorted a bond issue two weeks ago and must now cover the position—that is, deliver the bond issue. The dealer can do a *reverse repo* (i.e., agree to buy the bond issue and sell it back). Of course, the dealer eventually would have to buy the bond issue in the market in order to cover its short position. In this case, the dealer is actually making a collateralized loan to the counterparty.

Any security can be used as collateral for a repo. When a Treasury security is used with an overnight maturity, the repo rate is referred to as the *Secured Overnight Funding Rate.*

Credit Risks

Repos should be structured carefully to reduce credit risk exposure. The amount lent should be less than the market value of the security used as collateral, thereby providing the lender with some cushion should the market value of the security decline. The amount by which the market value of the security used as collateral exceeds the value of the loan is called *repo margin* or, simply, *margin*. Margin is also referred to as the "haircut." Repo margin is generally between 1% and 3%. For borrowers of lower creditworthiness and/or when less liquid securities are used as collateral, the repo margin can be 10% or more.

To illustrate the role of a haircut in a repurchase agreement let us once again return to the portfolio manager who wants to use $10 million of the Treasury note as collateral for 10-day borrowing using a repo. Recall that the par value of the position is $10 million, and the note's full price is $10,015,455. When a haircut is included, the amount the customer is willing to lend is reduced by a given percentage of the security's market value. In this case, the collateral is 102% of the amount being lent. Accordingly, to determine the amount being lent, we divide the note's full price of $10,015,455 by 1.02 to obtain $9,819,073.53. Suppose that the repo rate in this transaction is 0.08%. Then the portfolio manager would agree to deliver the Treasury note for $9,819,073.53 and pay interest of $218.20 as shown below:

$$\$9{,}819{,}073.53 \times 0.0008 \times (10/360) = \$218.20$$

The repurchase price is then $9,819,291.73 (= $9,819,073.53 + $218.20).

Another practice to limit credit risk is to mark the collateral to market on a regular basis. (Marking a position to market means recording the value of a position at its market value.) When the market value changes by a certain percentage, the repo position is adjusted accordingly. The decline in market value below a specified amount will result in a margin deficit. The Master Repurchase Agreement (MRA)[1] gives the borrower the option to cure the margin deficit by either providing additional cash or by transferring additional securities that are reasonably acceptable to the lender. Suppose instead that the market value rises above the amount required for margin. This results in a margin excess. In such instances, the MRA grants the lender of funds the option to give the borrower cash equal to the amount of the margin excess or to transfer purchased securities to the borrower.

1. In the United States, the MRA is the standardized repo agreement used for repo transactions. The latest version of the MRA, published by Securities Industry and Financial Markets Association (SIFMA) can be found on its SIFMA website.

Since the MRA covers all transactions where a party is on one side of the transaction, the margin maintenance is not looked at from an individual transaction or security perspective but as all repo transactions with the same counterparty.

The price to be used to mark positions to market is defined in the agreement. The market value is defined as one "obtained from a generally recognized source agreed to by the parties or the most recent closing bid quotation from such a source."

One concern in structuring a repo is delivery of the collateral to the lender. The most obvious procedure is for the borrower to deliver the collateral to the lender or to the cash lender's clearing agent. In such instances, the collateral is said to be "delivered out." At the end of the repo term, the lender returns the collateral to the borrower in exchange for the principal and interest payment. This procedure may be too expensive, though, particularly for short-term repos, because of the costs associated with delivering the collateral. The cost of delivery would be factored into the transaction by a lower repo rate that the borrower would be willing to pay. The risk of the lender not taking possession of the collateral is that the borrower may sell the security or use the same security as collateral for a repo with another party.

As an alternative to delivering out the collateral, the lender may agree to allow the borrower to hold the security in a segregated customer account. Of course, the lender still faces the risk that the borrower may use the collateral fraudulently by offering it as collateral for another repo transaction. If the borrower of the cash does not deliver out the collateral but instead holds it, then the transaction is called a *hold-in-custody repo* (HIC repo). Despite the credit risk associated with an HIC repo, it is used in some transactions when the collateral is difficult to deliver (such as in whole loans) or the transaction amount is small and the lender of funds is comfortable with the reputation of the borrower of the cash.

Another method is for the borrower to deliver the collateral to the lender's custodial account at the borrower's clearing bank. The custodian then has possession of the collateral that it holds on behalf of the lender. This practice reduces the cost of delivery because it is merely a transfer within the borrower's clearing bank. If, for example, a dealer enters into an overnight repo with customer A, the next day the collateral is transferred back to the dealer. The dealer can then enter into a repo with customer B for, say, five days without having to redeliver the collateral. The clearing bank simply establishes a custodian account for customer B and holds the collateral in that account. This specialized type of repo arrangement is called a *triparty repo*. In fact, for some regulated institutions, for example, federally chartered credit unions, this is the only type of repo arrangement permitted.

The agreement covers the events that will trigger a default of one of the parties (i.e., "events of default") and the options available to the nondefaulting party. In the case of a bankruptcy by the borrower, the bankruptcy code in the United States affords the lender of funds in a qualified repo transaction a special status. It does so by exempting certain types of repos from the stay provisions of the bankruptcy law. This means that the lender of funds can liquidate the collateral immediately to obtain cash.

Determinants of the Repo Rate

Just as there is no single interest rate, there is no unique repo rate. Repo rates vary from transaction to transaction and across time due to a number of factors. These factors include the following: (1) quality of the collateral; (2) term of the repo; (3) delivery of the collateral; (4) availability of the collateral; and (5) the prevailing federal funds rate.

DOLLAR ROLLS

In the mortgage-backed securities (MBS) market, a special type of collateralized loan has developed because of the characteristics of these securities and the need of dealers to borrow these securities to cover short positions. This arrangement is called a *dollar roll*, so-called because the dealer is said to "roll in" securities borrowed and "roll out" securities when returning the securities to the investor.

As with a repo agreement, it is a collateralized loan that calls for the sale and repurchase of a security. Unlike a repo agreement, the dealer who borrows the securities need not return the identical securities. Specifically, the dealer need only return "substantially identical securities." This means that the security returned by the dealer that borrows the security must match the coupon rate and security type (i.e., issuer and mortgage collateral). This provides flexibility to the dealer. In exchange for this flexibility, the dealer provides 100% financing. That is, there is no overcollateralization or overmargin required. Moreover, the financing cost may be cheaper than in a repo because of this flexibility. Finally, unlike in a repo, the dealer keeps the coupon and any principal paid during the period of the loan.

Determination of the Financing Cost

Determination of the financing cost is not as simple as in a repo. The key elements in determining the financing cost, assuming that the dealer is borrowing securities/lending cash, are

1. The sale price and the repurchase price
2. The amount of the coupon payment
3. The amount of the principal payments due to scheduled principal payments
4. The projected prepayments of the security sold (i.e., rolled in to the dealer)
5. The attributes of the substantially identical security that is returned (i.e., rolled out by the dealer)
6. The amount of under- or overdelivery permitted

Let's look at these elements. In a repo agreement, the repurchase price is greater than the sale price; the difference represents interest and is called the *drop*. In the case of a dollar roll, the repurchase price need not be greater than the sale price. In fact, in a positively sloped yield-curve environment (i.e., long-term rates exceed short-term rates), the repurchase price will be less than the purchase price. The reason for this is the second element, the coupon payment. The dealer keeps the coupon payment.

The third and fourth elements involve principal repayments—scheduled principal and prepayments. As with the coupon payments, the dealer retains the principal payments during the period of the agreement. A gain will be realized by the dealer on any principal repayments if the security is purchased by the dealer at a discount and a loss if purchased at a premium. Because of prepayments, the principal that will be paid is unknown and represents a risk in determination of the financing cost.

The fifth element is another risk because the effective financing cost will depend on the attributes of the substantially identical security that the dealer will roll out (i.e., the security it will return to the lender of the securities) at the end of the agreement. Finally, delivery tolerances allowing for a small amount of under- or overdelivery are permitted.

MARGIN BUYING

Investors can borrow cash to buy securities and use the securities themselves as collateral in a standard margin agreement with a brokerage firm. The funds borrowed to buy the additional securities will be provided by the broker, and the broker gets the money from a bank. The interest rate that banks charge brokers for these transactions is known as the *call money rate* (also called the *broker loan rate*). The broker charges the investor the call money rate plus a service charge.

The broker is not free to lend as much as it wishes to the investor to buy securities. The Securities and Exchange Act of 1934 prohibits brokers from lending more than a specified percentage of the market value of the securities. The initial margin requirement is the proportion of the total market value of the securities that the investor must pay for in cash. The 1934 act gives the Board of Governors of the Federal Reserve the responsibility to *set initial margin requirements*, which it does under Regulations T and U. The initial margin requirement varies for stocks and nongovernment/nonagency bonds and is currently 50%, although it has been below 40%. There are no restrictions on government and government agency securities.

The Fed also establishes a *maintenance margin requirement*. This is the minimum amount of equity needed in the investor's margin account as compared with the total market value. If the investor's margin account falls below the minimum maintenance margin, the investor is required to put up additional cash. The investor receives a margin call from the broker specifying the additional cash to be put into the investor's margin account. If the investor fails to put up the additional cash, the securities are sold.

SECURITIES LENDING

A security lending transaction involves two parties. The first is the owner of a security who agrees to lend that security to another party. This party is called the *security lender* or the *beneficial owner*. The second party is the entity that agrees to borrow the security, called the *security borrower*. A *security lending transaction* is one in which the security lender loans the requested security to the security borrower at the outset, and the security borrower agrees to return the identical security to the security lender at some time in the future. The loan may be terminated by the security lender on notice to the security borrower, typically of not more than five business days.

To protect against credit risk, the security lender will require that the security borrower provide collateral. Collateral can take the form of (1) cash, (2) a letter of credit, or (3) a security whose value is at least equal in value to the securities loaned. In the United States, the most common form of collateral is cash. Outside the United States, all types of securities have been used as collateral, including common stock and convertible securities. Typically, if the collateral is a security, it is marked-to-market on a daily basis.

When cash is the collateral, the proceeds are reinvested by the security lender. The security lender faces the risks associated with reinvesting the cash. The income generated from reinvesting the cash is given to the security borrower less an amount retained by the security lender for loaning the security because the fee earned by the security lender is then the difference between the income earned from reinvesting the cash and the amount the security lender agrees to pay the security borrower. The security lender's fee is called an *embedded fee* when there is cash collateral. The agreed-on amount that the security lender pays to the security borrower is called a *rebate*. The security lender only earns a fee if the amount earned on reinvesting the cash collateral exceeds the rebate. In fact, if the amount earned is less than the rebate, the security lender incurs this cost.

When the collateral is a letter of credit or a security, the security borrower compensates the security lender by a predetermined fee. This fee is called a *borrow fee*, and it is based on the value of the security borrowed. Notice that while the security lender knows what the fee will be in the case of noncash collateral, this is not the case when there is cash collateral. The fee is a function of the performance of the portfolio or security in which the cash collateral is reinvested.

During the period in which the security is loaned to the borrower, there may be an interest payment (dividend payment in the case of stock). The security lender is entitled to a payment from the security borrower equal in amount to any such payment. The payment made by the security borrower to the security lender for this purpose is called a *substitute payment* or *in-lieu-of payment*.

A party with a portfolio of securities to lend can either (1) lend directly to counterparties that need securities, (2) use the services of an intermediary, or (3) employ a combination of the first two. If a party decides to lend directly, it must have the in-house capability of assessing counterparty risk. When an intermediary is engaged, the intermediary receives a fee for its services. The intermediary could be an agent (i.e., acts on behalf of a security lender but does not take a principal risk position) or a principal (i.e., takes a principal risk position). Possible agents include the current domestic/global custodian of the securities or a third-party specialist in securities lending.

When cash collateral must be reinvested, a securities lender must decide on whether it will reinvest the cash or use the services of an external money manager. As noted earlier, securities lenders may realize a return on the cash collateral that is less than the rebate.

Comparison to Repurchase Agreements

It is worthwhile to compare a security lending transaction in which the collateral is cash to a repurchase agreement because both transactions represent a secured borrowing. We will do this with an illustration. The parties are as follows:

- Manager X, who is the beneficial owner of security A
- Manager Y, who needs security A to cover a short position

Also suppose that security A is a debt instrument that pays coupon interest.

The following agreement is entered into by manager X and manager Y:

1. Manager X agrees to transfer security A to manager Y.
2. Manager Y agrees to give cash to manager X.
3. At some future date, manager Y agrees to return security A to manager X.
4. Manager X agrees to return the cash to manager Y when manager Y returns security A to manager X.

The economics of this transaction are simple: it is a secured loan of cash with the lender of cash being manager Y and the borrower of cash being manager X. The collateral for this loan is security A. This transaction can be structured as a security lending or a repurchase agreement. No matter what it is called, the economics are unchanged.

If this transaction is structured as a security lending agreement, then

1. Manager X is the security lender (beneficial owner).
2. Manager Y is the security borrower.
3. Manager X invests the cash received from manager Y and at the end of the transaction rebates part of the income earned to manager Y.
4. The amount earned by manager X from security lending is uncertain and, in fact, can be negative.
5. Manager Y pays manager X any interest income that manager X would have received from the issuer of the security.

6. At some future time, manager X requests the return of security A and returns the cash collateral to manager Y.

If this transaction is structured as a repurchase agreement, then

1. Manager X is the seller of collateral or, equivalently, the borrower of funds using security A as collateral.
2. Manager Y is the buyer of collateral or, equivalently, the lender of funds.
3. Manager X invests the cash received from manager Y and at the repurchase date pays interest to manager Y based on the repo rate.
4. The amount earned by manager X from the repurchase agreement is uncertain and, in fact, can be negative.
5. Manager Y pays manager X any interest income that manager X would have received from the issuer of the security.
6. At the repurchase date, manager X buys back security A from manager Y at the repurchase price (which includes interest).

Whether the transaction is a repo or reverse repo depends on the perspective of the parties, as discussed earlier in this chapter. Notice that unlike a repurchase agreement, which has a repurchase date—which can be rolled over—there is no repurchase price in a security lending transaction.

KEY POINTS

- A repurchase agreement is the sale of a security with a commitment by the seller to buy the security back from the purchaser at a specified price on a designated future date.
- Repo margin, or haircut, is the amount by which the security's value exceeds the loan amount.
- A dollar roll is a specialized type of collateralized loan particular to the MBS market.
- Investors can borrow cash to buy securities and use the securities themselves as collateral with a standard margin agreement with a brokerage firm.
- A securities lending transaction involves one party lending a security and accepting collateral while another party borrows a security and provides collateral.
- In order to induce the security borrower to provide cash as collateral as opposed to some other form (e.g., another security or letter of credit), the security lender pays the security borrower a prespecified fee called the rebate rate.

Adam Kobor, Ph.D. CFA
Managing Director of Investments
New York University

Interest-rate derivatives give bond portfolio managers a vehicle for altering the interest-rate sensitivity of a fixed income portfolio economically and quickly. *Derivative contracts,* known as such because they derive their value from an underlying instrument, offer portfolio managers and traders risk and return profiles that are difficult to attain in their absence. Interest rate derivatives include futures, forwards, options, swaps, caps, and floors. Our focus in this chapter is on futures, forwards, and options. Swaps are covered in Chapter 64, and caps and floors in Chapter 67.

The purpose of this chapter is twofold. First, we explain the basic characteristics of futures, forward contracts, and options Second, we review the most actively traded and most representative over the counter (OTC) and listed contracts. We omit from our discussion the use of futures for controlling interest rate risk; this topic will be explained in more detail in Chapter 62.

BASIC CHARACTERISTICS OF FUTURES CONTRACTS

A *futures contract* is an agreement between a buyer (seller) and an established futures exchange or its clearinghouse in which the buyer (seller) agrees to take (make) delivery of a specific amount of a valued item such as a commodity, stock, or bond at a specified price during a designated time. For some futures contracts, settlement at expiration is in cash rather than actual delivery.

When an investor takes a position in the market by buying a futures contract, the investor is said to be *long the futures* or have a *long position in the futures*. If, instead, the investor's opening position is the sale of a futures contract, the investor is said to be *short the futures* or have a *short position in the futures.*

Futures contracts based on a financial instrument or a financial index are known as *financial futures.* Financial futures can be classified as interest-rate futures, stock index futures, or currency futures. This chapter focuses on interest-rate futures and includes a description of the most important interest-rate futures contracts currently traded.

To illustrate how financial futures work, suppose that X buys a futures contract and Y sells a futures contract on a 6% five-year Treasury note for settlement one year from now. Suppose also that the price at which X and Y agree to transact one year from now is $100. This is the futures price. This means that one year from now Y must deliver a 6% five-year Treasury note and will receive $100. X will take delivery of a 6% five-year Treasury note and will pay $100.

The profit or loss realized by the buyer or seller of a futures contract depends on the price and interest rate on the delivery date. For example, if the market price of a 6% five-year Treasury note at the settlement date is $110, because rates have declined, the buyer profits, paying $100 for a security that is worth $110. In contrast, the seller loses, because an instrument worth $110 must be delivered in exchange for $100. If interest rates rise on 6% five-year Treasury notes so that the market price is $90, the seller of the futures contract profits and the buyer loses.

When the investor first takes a position in a futures contract, he must deposit a minimum dollar amount per contract as specified by the exchange. As the price of the futures contract fluctuates, the value of the investor's equity in the position changes. At the close of each trading day, any market gain results in an increase in the investor's equity, whereas any market loss results in a decrease. This process is referred to as *marking to market.* Should an investor's equity position fall below an amount determined by the exchange, he must provide additional margin. On the other hand, if an investor's equity increases, he may withdraw funds. Consequently, a futures position may require substantial cash flows before the delivery date. Margin is described in more detail later in this chapter.

BASIC CHARACTERISTICS OF FORWARD CONTRACTS

A *forward contract* is much like a futures contract. A forward contract is an agreement for the future delivery of some amount of a valued item at a specified price at a designated time. Futures contracts are standardized agreements that define the delivery date (or month) and quality and quantity of the deliverable. Futures contracts are traded on organized exchanges. A forward contract is, in contrast, usually nonstandardized and is traded over the counter by direct contact between buyer and seller.

Although both futures and forward contracts set forth terms of delivery, futures contracts are not intended to be settled by delivery. In fact, generally only a small percentage of outstanding futures contracts are delivered or go to final settlement. However, forward contracts *are* intended to be held to final settlement. Many of the most popular forward contracts, however, settle in cash rather than actual delivery.

Forward contracts may or may not be marked to market. Consequently, there is no interim cash flow on forwards that are not marked to market.

Finally, both parties in a forward contract are exposed to credit risk because either party may default on its obligation. In contrast, credit risk for futures contracts is minimal because the clearing corporation associated with the exchange guarantees the other side of each transaction.

BASIC CHARACTERISTICS OF OPTION CONTRACTS

An *option* is a contract in which the seller of the option grants the buyer of the option the right to purchase from, or sell to, the contract seller a designated instrument at a specified price within a specified period of time. The seller (or *writer*) grants this right to the buyer in exchange for a certain sum of money, called the *option price* or *option premium.*

The price at which the instrument may be bought or sold is called the *exercise* or *strike price.* The date after which an option is void is called the *expiration date.* An *American option* may be exercised any time up to and including the expiration date. A *European option* may be exercised only on the expiration date. A *Bermudan option* can be exercise only on predetermined dates.

When an option writer grants the buyer the right to purchase the designated instrument, it is called a *call option.* When the option buyer has the right to sell the designated instrument to the writer, the option is called a *put option.* The buyer of an option is said to be *long the option;* the writer is said to be *short the option.*

Consider, for example, an option on a 6% five-year Treasury note with one year to expiration and an exercise price of \$100. Suppose that the option price is \$2 and the current price of the Treasury note is \$100 with a yield of 6%. If the option is a call option, then the buyer of the option has the right to purchase a 6% five-year Treasury note for \$100 within one year. The writer of the option must sell the Treasury note for \$100 to the buyer if he or she exercises the option. Suppose that the interest rate on the Treasury note declines and its price rises to \$110. By exercising the call option, the buyer realizes a profit, paying \$100 for a Treasury note that is worth \$110. After considering the cost of buying the option, \$2, the net profit is \$8. The writer of the option loses \$8. If, instead, the market interest rate rises and the price of the Treasury note falls below \$100, the call option buyer will not exercise the option, losing the option price of \$2. The writer will realize a profit of \$2. Therefore, the buyer of a call option benefits from a decline in interest rates (a rise in the price of the underlying fixed income instrument) and the writer loses.

If the option is a put rather than a call and the interest rate on Treasury notes declines and the price rises above $100, the option buyer will not exercise the option. The buyer will lose the entire option price. If, on the other hand, the interest rate on Treasury notes rises and the note's price falls below $100, the option buyer will benefit by exercising the put option. In the case of a put option, the option buyer benefits from a rise in interest rates (a decline in the price of the underlying fixed income instrument) and the option seller loses.

The maximum amount that an option buyer can lose is the option price. The maximum profit that the option writer (seller) can realize is the option price. The option buyer has substantial potential upside return, whereas the option writer has substantial downside risk. The risk/reward relationships for option positions are investigated in Chapter 66.

Options can be written on cash instruments or futures. The latter are called *futures options* and are traded only on exchanges. Options on cash instruments are also traded on exchanges but have been traded much more successfully over the counter. These *OTC,* or *dealer, options* are tailor-made options on specific Treasury issues, mortgage securities, or interest-rate indexes. Option contracts are reviewed later in this chapter.

DIFFERENCES BETWEEN OPTIONS AND FUTURES (FORWARD) CONTRACTS

Unlike a futures or forward contract, an option gives the buyer the *right* but not the *obligation* to perform. The option seller has the obligation to perform. In the case of a futures or forward contact, both the buyer and seller are obligated to perform. In addition, the buyer of a futures or forward contract does not pay the seller to accept the obligation, whereas in the case of an option, the buyer pays the seller an option premium.

Consequently, the risk/reward characteristics of the two contracts also differ. In a futures or forward contract, the long position realizes a dollar-for-dollar gain when the price of the futures or forward increases and suffers a dollar-for-dollar loss when the price of the futures or forward decreases. The opposite holds for a short position. Options do not provide such a symmetric risk/reward relationship. The most a long position may lose is the option premium, yet the long retains all the upside potential. However, the gain is always reduced by the price of the option. The maximum profit the short position may realize is the option price, but the short position has substantial downside risk.

REPRESENTATIVE EXCHANGE-TRADED INTEREST-RATE FUTURES CONTRACTS

Interest-rate futures contracts can be classified by the maturity of their underlying security. Short-term interest-rate futures contracts have an underlying security that matures in less than one year or a short-term reference interest rate. The maturity of the underlying security of long-term futures exceed one year. Exhibit 61-1 displays most interest-rate futures contracts traded in the United States. The contracts are arranged along the yield curve from short-term interest rates through the Ultra Long Bond contract. Notice that some of the contracts have physical settlement. Other contracts are cash settled. The success of cash-settled contracts depends on having the price or yield in the calculation not be subject to manipulation. Below we describe the specifications of the long-term futures contracts (Treasury bond futures and Treasury notes futures) and short-term futures contracts (Treasury bill futures, Eurodollar futures, interest-rate swap futures, and federal funds futures).

Treasury Bond Futures Contract

The Treasury bond (T-bond) futures contract is the most successful interest-rate (or commodity) futures contract. Prices and yields on the T-bond futures contract are quoted in terms of a (fictitious) 20-year 6% Treasury bond, but the exchange where the contract is traded, the Chicago Mercantile Exchange (CME), allows many different bonds to be delivered in satisfaction of a short position in the contract. Specifically, any Treasury bond with a remaining maturity of at least 15 years, but less than 25 years, from the first day of the delivery month is acceptable for delivery. There is an Ultra Long Treasury futures contract that differs only in that it is based on Treasury bonds with at least 25 years to maturity.

The T-bond futures contract calls for the short (i.e., the seller) to deliver \$100,000 face value of any one of the qualifying Treasury bonds. However, because the coupons and maturities vary widely, the price that the buyer pays the seller depends on which bond the seller chooses to deliver. The rule used by the CME is one that adjusts the futures price by a conversion factor that reflects the price the bond would sell for at the beginning of the delivery month if it were yielding 6%. Using such a rule, the conversion factor for a given bond and a given delivery month is constant through time and is not affected by changes in the price of the bond or the price of the futures contract.

The seller has the right to choose which qualifying bond to deliver and when during the delivery month delivery will take place. When the bond is delivered, the buyer is obligated to pay the seller the futures price multiplied by the appropriate conversion factor, plus accrued interest on the delivered bond. It is important to emphasize that while the underlying Treasury bond for this contract is a hypothetical issue and therefore cannot itself be delivered into the futures contract, the bond futures contract is not a cash settlement contract. To close out a Treasury bond futures contract, one can either initiate an offsetting futures position or deliver a qualifying issue.

Paradoxically, the success of the CME Treasury bond contract can in part be attributed to the fact that the delivery mechanism is not as simple as it may first appear. There are several options implicit in a position in bond futures. First, the seller chooses which bond to deliver. Thus, the seller has an option to swap between bonds. If the seller is holding bond A for delivery, but bond B becomes

EXHIBIT 61-1

Representative Exchange-Traded Interest-Rate Futures Contracts

Contract	Form	Contract Size	Contract Months	Settlement
Eurodollar 1-month	Futures	$3,000,000	First 12 consecutive calendar months	Cash
SOFR 1-month	Futures	$5,000,000	First 12 consecutive calendar months	Cash (average daily SOFR interest during contract delivery month)
Fed Funds 30-day	Futures	$5,000,000	First 24 calendar months	Cash
Eurodollar 3-month	Futures	$1,000,000	Mar/Jun/Sep/Dec 40 contracts = 10 years	Cash
SOFR 3-month	Futures	$1,000,000	Mar/Jun/Sep/Dec 40 contracts = 10 years	Cash (compounded daily SOFR interest during contract reference quarter)
Overnight Index Swap 3-months	Futures	$1,000,000	First eight months in the March quarterly cycle (i.e., White and Red expiry years)	Cash
Treasury 2-year	Futures	$200,000	First five consecutive contracts in the March, June, September, and December quarterly cycle	Physical
OTR 2-year	Futures	$100,000	Corresponds to 2-year Treasury notes auctions. Final Settlement Date is the morning of the following new Treasury note auction (in the named expiry month).	Cash

Representative Exchange-Traded Interest-Rate Futures Contracts (*Continued*)

Contract	Form	Contract Size	Contract Months	Settlement
Swap 10-year	Futures	$100,000	The first three consecutive contracts in the March, June, September, and December quarterly cycle	Cash
Treasury Bond	Futures	$100,000	The first five consecutive contracts in the March, June, September, and December quarterly cycle	Physical/Maturity at last 15 years from first day of delivery month, but less than 25 years, from first day of delivery month
Treasury Ultra Bond	Futures	$100,000	The first five consecutive contracts in the March, June, September, and December quarterly cycle	Physical/ Remaining maturity of not less that 25 years from the first day of delivery month
Swap 30-year	Futures	$100,000	The first three consecutive contracts in the March, June, September, and December quarterly cycle	Cash
Barclay's U.S. Index	Futures	$100 × Index Value of Barclays Capital Aggregate Bond Index	March, June, September, and December (March quarterly cycle)	Cash

cheaper to deliver, she can swap bond B for bond A and make a more profitable delivery. Second, within some guidelines set by the CME, the seller decides when during the delivery month delivery will take place. She thus has a timing option that can be used to her advantage. Finally, the short retains the possibility of making the wildcard play. This potentially profitable situation arises from the fact that the seller can give notice of intent to deliver for several hours after the exchange has closed and the futures settlement price has been fixed. In a falling market, the seller can use the wildcard option to profit from the fixed delivery price.

The seller's options tend to make a contract a bit more difficult to understand, but at the same time they make the contract more attractive to speculators, arbitrageurs, dealers, and anyone else who understands the contract better than other market participants. Thus, in the case of the Treasury bond futures contract, complexity has helped provide liquidity.

Treasury Note Futures

There are seven Treasury note futures contracts: 10-year on the run, 10-year, the Ultra 10-year, 5-year on-the-run, 5-year, 2-year on-the-run, and 2-year. Four of the seven contracts are modeled after the Treasury bond futures contract and are traded on the CME. The on-the-run contracts are also traded on the CME, but they are cash settled. The underlying instrument for the 10-year Treasury note futures contract is $100,000 par value of a hypothetical 10-year 6% Treasury note. There are several acceptable Treasury issues that may be delivered by the short. A note is acceptable if the maturity is not less than 6.5 years and not greater than 10 years from the first day of the delivery month. The delivery options granted to the short position are the same as for the Treasury bond futures contract.

For the five-year Treasury note futures contract, the underlying is $100,000 par value of a U.S. Treasury note that satisfies the following conditions: an original maturity of not more than five years and three months and a remaining maturity of not less than four years and two months as of the first day of the delivery month.

The underlying for the two-year Treasury note futures contract is $200,000 par value of a U.S. Treasury note with a remaining maturity of not more than two years and not less than one year and nine months. Moreover, the original maturity of the note delivered to satisfy the two-year futures cannot be more than five years and three months.

As mentioned earlier, there are several Treasury securities that are eligible for delivery by the seller of the futures contract. Consider the 10-year Treasury Note futures: the underlying security of 10-year Treasury Note with 6% coupon is a hypothetical security. In fact, the 6% coupon is very far from the yield levels after the Great Financial Crisis of 2008–2009; it was defined many years earlier, when a 6% coupon or yield was typical for a 10-year Treasury note. Over recent years, when 10-year Treasury yield has been in the range of 0.5% to 3.3%, the futures contract price has been inflated due to this high 6% hypothetical coupon relative to the much lower yield levels. However, once the actual bonds that are eligible for delivery get "converted" to the theoretical 6% security, the invoice price will get adjusted to the current market conditions. To make an informed decision which security to deliver, the seller has to calculate the actual price she would receive when the futures contract settles:

Invoice Price = Futures Settlement Price ×
Conversion Factor + Accrued Interest

The conversion factor brings all eligible securities to the "common denominator" (i.e., it is the present value of the cash flow of a deliverable bond, discounted by a 6% yield). The cheapest-to-deliver security would be a deliverable bond with the lowest converted futures price.

To illustrate this, let us take a look at the 2020 September 10-year Treasury futures contract as of June 10, 2020. The futures price is 138-05+, optically quite high, given the gap between the 6% theoretical coupon and the below 1% 10-year yield these days. The following table shows three of the many eligible securities:

Security	Price	Conversion Factor	Gross Basis
T 2 3/8 05/15/27	112-05 ¼	0.8072	20.215
T 2 ¼ 08/15/27	111-18 ¾	0.7943	58.753
T 0 5/8 03/31/27	100-09	0.7142	51.165

The *gross basis* would indicate that the first bond in the above table would be the cheapest-to-deliver. The seller would buy this bond today at 112-05¼ price (112.1641 in decimal terms), and would receive 0.8072 × 138-05+ (111.5352 in decimal terms) from the futures contract buyer (paid and received accrued interest would net each other out). The net difference is –\$0.6317, or 20.215 ticks (0.6317 × 32).

When yields are below 6%, the cheapest-to-deliver bond is typically one of the lower duration eligible bonds, and when yields are higher than 6%, the cheapest-to-deliver would typically be a longer-duration bond.

Treasury Bill Futures Contract

The futures contract on Treasury bills was the first contract on a short-term debt instrument and has been the model for most subsequent contracts on short-term debt. The contract traded on the International Money Market (a division of the CME) is based on three-month Treasury bills with a face value of \$1 million.
The contract is quoted and traded in terms of a futures "price," but the futures price is, in fact, just a different way of quoting the futures interest rate. Specifically, the futures price is the annualized futures rate subtracted from 100. For example, a futures price of 97.50 means that Treasury bills are trading in the

futures market at a rate of 2.50%. The actual price that the buyer pays the seller is calculated using the usual formula for Treasury bills:

$$\text{Invoice price} = \$1{,}000{,}000 \times [1 - \text{rate} \times (\text{days to maturity}/360)]$$

where the rate is expressed in decimal form. As this formula shows, each basis point change in the interest rate (or each 0.01 change in the futures price) leads to a $25 change in the invoice price for a 90-day bill. Consequently, the value of a 0.01 change in the futures contract is always $25.

The Treasury bill futures contract is considerably simpler than the T-bond and T-note futures contracts. First, because all Treasury bills of the same maturity are economically equivalent, there is effectively only one deliverable issue, namely, Treasury bills with three months to maturity. Three months may have 90, 91, or 92 days depending on the month in which the contract is initiated. The fact that the three-month bills may be either new three-month bills or older bills that currently have three months of remaining life makes little difference because the new and old issues will trade the same in the cash market. Thus, all the subtleties surrounding conversion factors and most deliverable issues are absent from the Treasury bill futures market. Furthermore, there is little uncertainty or choice involved in the delivery date because delivery must take place during a very narrow time frame, usually a three-day period. The rules of the exchange make clear well in advance the exact dates on which delivery will take place. Finally, because there are no conversion factors, there is no wildcard play in the Treasury bill futures market.

Although the Treasury bill futures contract is simple and thus may not provide as many speculative and arbitrage opportunities as the more complex long- and intermediate-term futures contracts, it does provide a straightforward means of hedging or speculating on the short end of the yield curve. Because the Treasury bill rate is a benchmark off which other short-term rates may be priced, the bill contract fills a well-defined need of many market participants.

Eurodollar Futures Contract

Eurodollar CDs are U.S. dollar–denominated CDs issued primarily in London by U.S., Canadian, European, and Japanese banks. These CDs earn a fixed rate of interest related to dollar LIBOR. The term LIBOR comes from the London Interbank Offered Rate and is the interest rate at which one London bank offers funds to another London bank of acceptable credit quality in the form of a cash deposit. The rate is "fixed" by the British Bankers Association every business morning by the average of the rates supplied by member banks. After December 2021, LIBOR will be phased out as a reference rate.

Three-month LIBOR is the underlying instrument for the Eurodollar futures contract. The contracts are traded on the International Monetary Market of the CME and the Eurex International Financial Futures Exchange (LIFFE). This contract has a $1 million face value and is traded on an index price basis. The index price basis in which the contract is quoted is equal to 100 minus the annualized futures LIBOR. For example, a Eurodollar futures price of 97.50 means a futures three-month LIBOR of 2.50%.

For illustration, assume that an investor buys one contract of Eurodollar futures at \$98.00 price, or equivalently, the underlying rate is 2.0%. One week later, the underlying rate goes up by 20 basis points. This means that the futures price would decline to 97.80, and the investor would face a loss of \$1 million × 0.2% × 90/360 = \$500. Note that the value of one contract of Eurodollar futures responds \$25 to 1 basis point in yield change, since \$1 million × 0.01% × 90/360 = \$25. Thus, given that buyers of Eurodollar futures benefit from declining rates, and sellers benefit from rates rising, we can also calculate the profit/loss of this for the example in this simple way: –1 × –20 bps × \$25 = –\$500. The –1 is because the buyer of futures loses when rates increase.

The minimum price fluctuation or tick for this contract is 0.005 or 1/2 basis point. Accordingly, the tick value for this contract is \$12.50 as determined by the following expression:

$$\text{Tick value} = \$1{,}000{,}000 \times (0.005 \times 90/360) = \$12.50$$

The Eurodollar futures contract is a cash settlement contract. There are Eurodollar futures contracts available to trade with quarterly expiration dates (March, June, September, and December) that extend out 10 years. Accordingly, it is possible for market participants to hedge or speculate on the level of three-month LIBOR for the next decade. The Eurodollar futures contract is used frequently to trade the short end of the yield curve and many hedgers believe this is the ideal contract for a wide range of hedging situations. Moreover, the Eurodollar futures market and interest rate swaps are intensely interconnected. When valuing swaps at their inception, the future path of floating rates is derived from positions in Eurodollar futures contracts.

In practice, it is common that investors, traders, and hedgers do not simply trade a single contract of Eurodollar futures, but buy or sell a series of contracts to get a somewhat broader exposure to the front end of the yield curve. "Packs" are groups of Eurodollar contracts that can be traded together with a single quote, making the trader's job easier by eliminating the need to enter multiple orders for each Eurodollar contract. The "white" pack contains the first four quarterly contracts (e.g., as of June 10, 2020, the Jun 20/Sep 20/Dec 20/Mar 21 contracts). The "red" pack would mingle the next four quarterly contracts (e.g., those of Jun 21/Sep 21/Dec 21/Mar 22). The "white" and "red" packs would be followed by the "green," "blue," "gold," "purple," "orange," "pink," "silver," and "copper" packs, by following the same logic. Given that each of these packs mingle four contracts, the value of 1 basis point would be \$100 for each of them (4 × \$25). However, trading packs of different colors would provide key rate exposures at distinct segments of the yield curve.

"Bundles" would mingle "packs" together: the "red" bundle would consist of the "white" and the "red" packs, and the "green" would contain all the first 12 quarterly Eurodollar contracts. Thus, the value of 1 basis point would differ by bundles: the "white" bundle has \$100, the "red" has \$200, and the "green" has

$300 value of 1 basis point, and the same logic applies to the full list of various colors, with the "copper" bundle having $1000 value of 1 basis point.

The 90-day sterling LIBOR interest-rate futures contract trades on the main London Futures Exchange, LIFFE. The contract is structured similarly to the Eurodollar futures contract described above. Prices are quoted as 100 minus the interest rate and the expiration months are March, June, September, and December. The contract size is £500,000. A tick is 0.01 or 1 basis point and the tick value is £12.5.

The LIFFE also trades short-term interest-rate futures for other major currencies including euros, yen, and Swiss francs. Short-term interest-rate futures contracts in other currencies are similar to the 90-day sterling LIBOR contract and trade on exchanges such as Deutsche Terminbourse in Frankfurt and MATIF (Marché à Terme International de France) in Paris.

Swap Futures Contracts

Interest-rate swaps are discussed in Chapter 64. The underlying instrument for the swaps futures contract is the notional price of the fixed-rate side of a 10-year interest-rate swap that has a notional principal equal to $100,000 and that exchanges semiannual interest payments at a fixed annual rate of 6% for floating interest-rate payments based on three-month LIBOR.

This swap futures contract is cash-settled, with a settlement price determined by the International Swap and Derivatives Association (ISDA) benchmark 10-year swap rate on the last day of trading before the contract expires. This benchmark rate is published with a one-day lag in the Federal Reserve Board's statistical release H.15. Contracts have settlement months of March, June, September, and December, just like the other CME interest-rate futures contracts that we have discussed.

LIFFE introduced the first swap futures contract called Swapnote, which is referenced to the euro interest-rate swap curve. Swapnotes are available in 2-, 5-, and 10-year maturities.

SOFR Interest Rate Futures Contract

The SOFR is the secured overnight financing rate and serves as a benchmark interest rate for repurchase agreements. With the demise of LIBOR, SOFR represents the heir apparent to be used as a reference rate for various interest rate contracts from interest rate swaps to forward rate agreements. The Federal Reserve publishes the SOFR every business day at 8:00 am. SOFR is calculated as the transaction-weighted median repo rate based on transaction data collected by the Federal Reserve.

There are two futures contracts that trade on the CME derived from the SOFR—the three-month SOFR futures contract and the one-month SOFR futures contract. The underlying price is the compounded daily SOFR interest during the reference quarter such that each basis point per annum of interest is equal to $25 per contract. Price is computed as (100 – R) where R is the compounded daily SOFR interest during the reference quarter. Both contracts have cash settlement.

Fed Funds Futures Contracts

The 30-day federal funds futures contract is designed for financial institutions and businesses who want to control their exposure to movements in the federal funds rate. These contracts have a notional amount of $5 million, and the contract can be written for the current month up to 24 months in the future. Underlying this contract is the simple average overnight federal funds rate (i.e., the effective rate) for the delivery month. As such, this contract is settled in cash on the last business day of the month. Just as the other short-term interest-rate futures contracts discussed earlier, prices are quoted on the basis of 100 minus the overnight federal funds rate for the delivery month. These contracts are marked to market using the effective daily federal funds rate as reported by the Federal Reserve Bank of New York.

Other Futures Contracts

If the yield curve were flat and moved in parallel shifts, a single futures contract would be sufficient for all fixed income hedging and speculative purposes. Different note or bond positions would differ only in the number of contracts needed for a hedge. For example, with perfectly correlated interest-rate changes, one could hedge long bonds with Treasury bill futures. It would require many multiples of the bond's par value in Treasury bills futures for the hedge, but it would work perfectly. The only challenge would be to get the scale of the hedges right.

Historically, the yield curve shifts parallel to itself, steepens or flattens, and becomes more or less curved. Consequently, multiple kinds of contracts are needed to hedge bonds of varying maturity. In addition, because credit spreads widen and narrow, at least one contract with credit risk embedded is needed to allow complete hedging.

The on-the-run (OTR) U.S. Treasury futures contracts are based on prices derived from the yields of on-the-run (most recently auctioned) 2-year, 5-year, and 10-year Treasury notes. These contracts are designed to give users synthetic exposure to the most liquid benchmark maturities on the U.S. Treasury yield curve.

Unlike traditional Treasury futures, OTR Treasury futures have cash settlement. The notional underlying is a U.S. Treasury note with a face value of $100,000 paying a 4% coupon rate per annum on a semiannual basis.

As noted above, credit-spreads widen and narrow and are not perfectly correlated to shifts in the yield curve. This fact suggests there should be a futures contract derived from bonds with exposure to credit risk. Consider the Barclays Capital U.S. Aggregate Bond Index futures contract that trades on the CME. The underlying instrument is the index value multiplied by $100. The index includes all of the sectors of the bond market: Treasury, agency, corporate, agency mortgage-backed, asset-backed, and commercial mortgage-backed.

MECHANICS OF FUTURES TRADING

Types of Orders

When a trader wants to buy or sell a futures contract, the price and conditions under which the order is to be executed must be communicated to a futures broker. The simplest type of order, yet potentially the most perilous from the trader's perspective, is the *market order*. When a market order is placed, it is executed at the best price available as soon as the order reaches the trading pit, the area on the floor of a futures exchange where all transactions for a specific contract are made. The danger of market orders is that an adverse move may take place between the time the trader places the order and the time the order reaches the trading pit.

To avoid the dangers associated with market orders, the trader can place a *limit order* (or *resting order*) that designates a price limit for the execution of the transaction. A *buy limit order* indicates that the futures contract may be purchased only at the designated price or lower. A *sell limit order* indicates that the futures contract may be sold only at the designated price or higher.

The danger of a limit order is that there is no guarantee that it will be executed at all. The designated price may simply not be obtainable. Even if the contract trades at the specified price, the order may not be filled because the market does not trade long enough at the specified price (or better) to fill all outstanding orders. Nevertheless, a limit order may be less risky than a market order. The trader has more control with a limit order because the price designated in the limit order can be revised based on prevailing market prices as long as the order has not already been filled.

The limit order is a conditional order: It is executed only if the limit price or a better price can be obtained. Another type of conditional order is the *stop order*. A stop order specifies that the order is not to be executed until the market reaches a designated price, at which time it becomes a market order. A *buy stop order* specifies that the order is not to be executed until the market rises to a designated price (i.e., trades at or above, or is bid at or above, the designated price). A *sell stop order* specifies that the order is not to be executed until the market price falls below a designated price (i.e., trades at or below, or is offered at or below, the designated price). A stop order is useful when a futures trader already has a position on but cannot watch the market constantly. Traders can preserve profits or minimize losses on open positions by allowing market movements to trigger a closing trade. In a sell (buy) stop order, the designated price is less (greater) than the current market price of the futures contract. In a sell (buy) limit order the designated price is greater (less) than the current market price of the futures contract.

There are two dangers associated with stop orders. Because futures markets sometimes exhibit abrupt price changes, the direction of the change in the futures price may be very temporary, resulting in the premature closing of a position. Also, once the designated price is reached, the stop order becomes a market order and is subject to the uncertainty of the execution price noted earlier for market orders.

A *stop-limit order,* a hybrid of a stop order and a limit order, is a stop order that designates a price limit. Thus, in contrast to the stop order, which becomes a market order if the stop is reached, the stop-limit order becomes a limit order if the stop is reached. The order can be used to cushion the market impact of a stop order. The trader may limit the possible execution price after the activation of a stop. As with a limit order, the limit price might never be reached after the order is activated, and therefore the order might not be executed. This, of course, defeats one purpose of the stop order—to protect a profit or limit a loss.

A trader also may enter a *market-if-touched order.* A market-if-touched is like a stop order in that it becomes a market order if a designated price is reached. However, a market-if-touched order to buy would become a market order if the market *falls* to a given price, whereas a stop order to buy becomes a market order if the market *rises* to a given price. Similarly, a market-if-touched order to sell becomes a market order if the market rises to a specified price, whereas the stop order to sell becomes a market order if the market falls to a given price. One may think of the stop order as an order designed to exit an existing position at an acceptable price (without specifying the exact price), and the market-if-touched order as an order designed to enter a position at an acceptable price (also without specifying the exact price).

Orders may be placed to buy or sell at the open or the close of trading for the day. An *opening order* indicates that a trade is to be executed only in the opening range for the day, and a *closing order* indicates that the trade is to be executed only within the closing range for the day.

Futures brokers may be allowed to try to get the best possible price for their clients. The *discretionary order* gives the broker a specified price range in which to fill the order. For example, a discretionary order might be a limit order that gives the broker a one-tick (i.e., 1 basis point or 1/32) discretion to try to do better than the limit price. Thus, even if the limit price is reached and the order could be filled at that limit, the broker can wait for a better price. However, if it turns out that the market goes in the wrong direction, the broker must fill the order but at no worse than one tick from the limit price. A *not held order* gives the broker virtually full discretion over the order. The not held order may be placed as any of the orders mentioned so far (market, stop, limit, etc.), but if the broker believes that filling the orders is not advisable, he or she need not fill them.

A client may enter orders that contain order cancellation provisions. A *fill-or-kill* order must be executed as soon as it reaches the trading floor, or it is canceled immediately. A *one-cancels-other order* is a pair of orders that are worked simultaneously, but as soon as one order is filled, the other is canceled automatically.

Orders may designate the time period for which the order is effective—a day, week, or month, or perhaps by a given time within the day. An *open order,* or *good-til-canceled order* is good until the order is specifically canceled. If the time period is not specified, it is usually assumed to be good only until the end of the day. For some orders, like the market order, a specific time period is not relevant, because they are executed immediately.

On execution of an order, the futures broker is required to provide confirmation of the trade. The confirmation indicates all the essential information about the trade. When the order involves the liquidation of a position, the confirmation shows the profit or loss on the position and the commission costs.

Taking and Liquidating a Position

Once an account has been opened with a broker, the futures trader may take a position in the market. If the trader buys a futures contract, she is said to have a long position. If the trader's opening position is the sale of the futures contract, she is said to have a short position.

The futures trader has two ways to liquidate a position. To liquidate a position before the delivery date, she must take an offsetting position in the same contract. For a long position, this means selling an identical number of contracts; for a short position, this means buying an identical number of contracts.

The alternative is to wait until the delivery date. At that time, the investor liquidates a long position by accepting the delivery of the underlying instrument at the agreed-on price or liquidates a short position by delivering the instrument at the agreed-on price. For interest-rate futures contracts that do not call for actual delivery (e.g., Eurodollar futures), settlement is in cash at the settlement price on the delivery date.

The Role of the Clearing Corporation

When an investor takes a position in the futures market, there is always another party taking the opposite position and agreeing to satisfy the terms set forth in the contract. Because of the *clearing corporation* associated with each exchange, the investor need not worry about the financial strength and integrity of the party taking the opposite side of the contract. After an order is executed, the relationship between the two parties is severed. The clearing corporation interposes itself as the buyer for every sale and the seller for every purchase. Thus, the investor is free to liquidate a position without involving the other party to the original transaction and without worry that the other party may default. However, the investor *is* exposed to default on the part of the futures broker through which the trade is placed. Thus, each institution should make sure that the futures broker (and specifically the *subsidiary* that trades futures) has adequate capital to ensure that there is little danger of default.

Margin Requirements

When first taking a position in a futures contract, an investor must deposit a minimum dollar amount per contract as specified by the exchange. (A broker may ask for more than the exchange minimum but may not require less than the exchange minimum.) This amount is called the *initial margin* and constitutes a good faith deposit. The initial margin may be in the form of Treasury bills. As the price of the futures contract fluctuates, the value of equity in the position changes. At the close of each trading day, the position is marked to market, so that any gain or loss from the position is reflected in the equity of the account. The price used to mark the position to market is the settlement price for the day.

Maintenance margin is the minimum level to which an equity position may fall as a result of an unfavorable price movement before additional margin is required. The additional margin deposited, also called *variation margin,* is simply the amount that will bring the equity in the account back to its initial margin level. Unlike original margin, variation margin must be in cash. If there is excess margin in the account, that amount may be withdrawn.[1]

If a variation margin is required, the party is contacted by the brokerage firm and informed of the additional amount that must be deposited. A margin notice is sent as well. Even if futures prices subsequently move in favor of the institution such that the equity increases above the maintenance margin, the variation margin must still be supplied. Failure to meet a request for variation margin within a reasonable time will result in the closing out of a position.

Margin requirements vary by futures contract and by the type of transaction—that is, whether the position is an outright long or short or a spread (a long together with a short), and whether the trade is put on as a speculative position or as a hedge. Margins are higher for speculative positions than for hedging positions and higher for outright positions than for spreads. Margin requirements also vary between futures brokers. Exchanges and brokerage firms change their margin requirements as contracts are deemed to be more or less risky, or as it is felt that certain types of positions (usually speculative positions) should be discouraged.

REPRESENTATIVE EXCHANGE-TRADED FUTURES OPTIONS CONTRACTS

Although futures contracts are relatively straightforward financial instruments, options on futures (or *futures options,* as they are commonly called) deserve extra explanation. Options on futures are very similar to other options contracts.

Like options on cash (or spot) fixed income securities, both put and call options are traded on fixed income futures. The buyer of a call has the right to buy

1. Although there are initial and maintenance margin requirements for buying stocks and bonds on margin, the concept of margin differs for futures. When securities are bought on margin, the difference between the price of the security and the initial margin is borrowed from the broker. The security purchased serves as collateral for the loan and interest is paid by the investor. For futures contracts, the initial margin, in effect, serves as good-faith money, indicating that the investor will satisfy the obligation of the contract. No money is borrowed by the purchaser. Similarly, the seller of futures borrows neither money nor securities.

the underlying futures contract at a specific price. The buyer of a put has the right to sell the underlying futures contract at a specific price. If the buyer chooses to exercise the option, the option seller is obligated to sell the futures in the case of the call or buy the futures in the case of the put.

An option on the futures contract differs from more traditional options in only one essential way: the underlying instrument is not a spot security, but a futures contract on a security. Thus, for instance, if a call option buyer exercises her option, she acquires a long position in futures instead of a long position in a cash security. The seller of the call will be assigned the corresponding short position in the same futures contract. For put options the situation is reversed. A put option buyer exercising the option acquires a short position in futures, and the seller of the put is assigned a long position in the same futures contract. The resulting long and short futures positions are like any other futures positions and are subject to daily marking to market.

An investor acquiring a position in futures does so at the current futures price. However, if the strike price on the option does not equal the futures price at the time of exercise, the option seller must compensate the option buyer for the discrepancy. Thus, when a call option is exercised, the seller of the call must pay the buyer of the call the current futures price minus the strike price. On the other hand, the seller of the put must pay the buyer of the put the strike price minus the current futures price. (These transactions are actually accomplished by establishing the futures positions at the strike price, then immediately marking to market.) Note that, unlike options on spot securities, the amount of money that changes hands at exercise is only the difference between the strike price and the current futures price, not the whole strike price. Of course, an option need not be exercised for the owner to take her gains; she can simply sell the option instead of exercising it.

We now turn to the options contracts themselves. We describe two of the most important contracts, the CME's options on the long-term bond futures contract and on the Eurodollar contract. There are also options on the 5- and 10-year note futures contracts, but because they are both very similar in structure to options on Treasury bond futures, they are not included in this section.

Options on Treasury Bond Futures

Options on CME Treasury bond futures are in many respects simpler than the underlying futures contracts. Usually, conversion factors, most deliverables, wildcard plays, and other subtleties of the Treasury bond futures contract need not concern the buyer or seller of options on Treasury bond futures. Although these factors affect the fair price of the futures contract, their impact is already reflected in the futures price. Consequently, they need not be reconsidered when buying or selling an option on the futures.

The option on the Treasury bond futures contract is in many respects an option on an index; the "index" is the futures price itself, that is, the price of the fictitious 20-year 6% Treasury bond. As for the futures contract, the nominal size of the contract is \$100,000. Thus, for example, with futures prices at 95, a call option struck at 94 has an intrinsic value of \$1000 and a put struck at 100 has an intrinsic value of \$5000.

In an attempt to compete with the OTC option market, *flexible Treasury futures options* were introduced. These futures options allow counterparties to customize options within certain limits. Specifically, the strike price, expiration date, and type of exercise (American or European) can be customized subject to CME constraints. One key constraint is that the expiration date of a flexible contract cannot exceed that of the longest standard option traded on the CME. Unlike an OTC option, where the option buyer is exposed to counterparty risk, a flexible Treasury futures option is guaranteed by the clearinghouse. The minimum size requirement for the launching of a flexible futures option is 100 contracts.

The premiums for options on Treasury bond futures are quoted in terms of points and 64ths of a point. An option premium of 1-10 therefore implies a price of $1^{10}/64\%$ of face value, or \$1156.25 (from \$100,000 × 1.15625%). Minimum price fluctuations are also 1/64 of 1%.

Although an option on the Treasury bond futures contract is hardly identical to an option on a Treasury bond, it serves much the same purpose. Because spot and futures prices for Treasury bonds are highly correlated, hedgers and speculators frequently find that options on bond futures provide the essential characteristics needed in an options contract on a long-term fixed income instrument.

Options on Eurodollar Futures

Options on Eurodollar futures fill a unique place among exchange-traded hedging products. These options are currently the only liquid listed option contracts based on a short-term interest rate.

Options on Eurodollar futures (traded on the CME) are based on the quoted Eurodollar futures price (i.e., 100 minus the annualized yield). Like the underlying futures, the size of the contract is \$1 million and each 0.01 change in price carries a value of \$25. Likewise, the option premium is quoted in terms of basis points. Thus, for example, an option premium quoted as 20 (or 0.20) implies an option price of \$500; a premium of 125 (or 1.25) implies an option price of \$3125.

Like other debt options, buyers of puts on Eurodollar futures profit as rates move up and buyers of calls profit as rates move down. Consequently, institutions with liabilities or assets that float off short-term rates can use Eurodollar futures options to hedge their exposure to fluctuations in short-term rates. Consider institutions that have liabilities that float off short-term rates. These include banks and thrifts that issue CDs and/or take deposits based on money market rates. Also included are industrial and financial corporations that issue commercial paper, floating-rate notes, or preferred stock that floats off money market rates. Likewise, those who make payments on adjustable-rate mortgages face similar risks.[2] In each instance, as short-term rates increase, the liability becomes more onerous for the borrower. Consequently, the issuers of these liabilities may need a means of capping their interest-rate expense. Although options on Eurodollar futures do not extend as far into the future as many issuers would like, they are effective tools for hedging many short-term rates over the near term. Consequently, an institution with floating-rate liabilities can buy an interest-rate *cap* by buying puts on Eurodollar futures. As rates move up, profits on the put position will tend to offset some or all of the incremental interest expense.

On the other side of the coin, and facing opposite risks, are the purchasers of floating-rate instruments—that is, investors who buy money market deposits, floating-rate notes, floating-rate preferred stock, and adjustable-rate mortgages. Investors who roll over CDs or commercial paper face the same problem. As rates fall, these investors receive less interest income. Consequently, they may feel a need to buy interest-rate *floors,* which are basically call options. As rates fall, calls on debt securities increase in value and will offset the lower interest income received by the investor.

In conclusion, options on Eurodollar futures can be used to limit the risk associated with fluctuations in short-term rates. This is accomplished by buying puts if the exposure is to rising rates, or by buying calls if the exposure is to falling rates.

Mechanics of Trading Futures Options

To take a position in futures options, one works with a futures broker. The types of orders that are used to buy or sell futures options are generally the same as the orders discussed for futures contracts. The clearinghouse associated with the exchange where the futures option is traded once again stands between the buyer and the seller. Furthermore, the commission costs and related issues that we discussed for futures also generally apply to futures options.

There are no margin requirements for the buyer of futures options, but the option price must be paid in full when the option is purchased. Because the option price is the maximum amount that the buyer can lose regardless of how adverse the price movement of the underlying futures contract, there is no need for margin.

Because the seller has agreed to accept all of the risk (and no reward other than the option premium) of the position in the underlying instrument, the seller generally is required to deposit not only the margin required for the underlying futures contract but also with certain exceptions, the option price as well. Furthermore, subsequent price changes adversely affecting the seller's position will lead to additional margin requirements.

2. To the extent that the interest-rate payment on an adjustable-rate mortgage has an upper and lower bound, the risk to issuers and investors is limited by the nature of the instrument.

OTC CONTRACTS

There is a substantial OTC market for fixed income options and forwards. (Forward contracts are the OTC equivalent of futures contracts.) For example, in the OTC market, one can easily buy or sell options on LIBOR, commercial paper, Treasury bills, and prime rates. One can buy and sell options on virtually any Treasury issue. One can buy and sell options on any number of mortgage securities. One can buy and sell options with expirations ranging from as short as one day to as long as 10 years. In the OTC market, one can easily take forward positions in three- and six-month LIBOR going out to about two years.

In the options market in particular, a natural division has evolved between the OTC market and the listed market. Given the relatively small number of futures contracts, the exchanges' need for standardization, and the synergy created by the futures options contract trading side by side with the underlying futures contract, the exchanges have been most successful with options on futures contracts. Because off-exchange options on futures are prohibited, futures options cannot be traded over the counter. On the other hand, because the OTC market is very good at creating flexible structures and handling a diversity of terms, the OTC market has been more successful than the exchanges in trading options on cash securities and on cash market interest rates.

In the following sections, we discuss the structure of the OTC fixed income derivative markets and their advantages and disadvantages relative to the exchange-traded markets. We also discuss the most important contracts traded in the OTC market. These are options on mortgage securities, options on cash Treasuries, caps and floors on LIBOR, and forward rate agreements on LIBOR.

The Structure of the OTC Market

As in other OTC markets, there is no central marketplace for OTC fixed income options and forward contracts. A transaction takes place whenever a buyer and seller agree to a price. Unlike an exchange transaction, the terms, size, and price of the contract generally remain undisclosed to other market participants. Accordingly, the OTC market is much less visible than the exchange markets and it is more difficult to ascertain the current market price for a given option or forward contract. Two groups, however, help to alleviate this problem. First, there are the OTC market-makers. Market-makers in OTC fixed income options and forwards are typically large investment banks and commercial banks. A market-maker, by definition, stands ready to buy or sell a given option or forward contract to accommodate a client's needs. To be effective, the market-maker must be willing and able to handle large orders and must keep the bid/ask spreads reasonably narrow.

The other group that helps bring order to the OTC market is the brokers. The sole job of the brokers is to bring together buyers and sellers; it is not the brokers' job to take positions in option and forward contracts. The buyers and sellers that the brokers bring together can be market-makers or the end users of the contracts. To do their job, the brokers must distribute information about the prices where they see trades taking place and the prices at which they believe further trades can be completed. This information is distributed to potential buyers and sellers over the phone and over publicly available media such as Telerate pages.

Because there is no central market for OTC fixed income options and forwards, there can be no clearinghouse. Consequently, those who position OTC contracts may have to give considerable weight to the creditworthiness of their counterparty. For example, entities that sell options or position forward rate agreements (FRAs) can have potential liabilities equal to several times their net worth. Furthermore, there is no guarantee that these counterparties have effective hedges against their positions or, in fact, that they are hedging at all. Furthermore, financial problems on the part of the counterparty can jeopardize the ability or willingness of the counterparty to make good on the terms of a contract even if it is hedged. Consequently, unlike the exchange-traded markets, where one neither knows nor cares who is on the other side of a trade, in the OTC market it is usually very important to know who is on the other side. Creditworthiness can be one of the most important considerations in the trade.

The potential credit problems associated with OTC trades are mitigated in a number of ways. First, some institutions will not buy options from or take either side of an FRA contract with any party other than a major entity with a sound credit rating. Second, some institutions require their counterparty to post collateral immediately after the transaction is completed. This collateral serves much the same purpose as initial margin in the futures and futures options market. Finally, some institutions reserve the right to call for additional collateral from their counterparties if the market moves against the counterparty. This is analogous to variation margin in the exchange-traded markets. Although these provisions may not be as good as a central clearinghouse, they are apparently good enough for a very large number of institutions and good enough for a very large market to develop.

Liquidity, in terms of being able to easily close out an existing position, can be a constraint in the OTC market. OTC options and forwards generally are not assignable transactions. Thus, for example, if one sells an option, the contingent liability associated with that option cannot be transferred to a third party without the express permission of the option buyer. If an option seller wants to cover a short option position, often the best strategy is to buy a similar option from a third party to offset the risks of the original option. However, if the credit of the offsetting party is in question, or the offsetting option is not identical, risks will remain for the option seller. The option buyer can face similar problems if closing out the option before expiration. Credit considerations and the fact that the option buyer may not be able to sell an identical option to offset the first option make it more difficult to effectively close out the long option position. Because FRAs involve contingent liabilities for both sides of the transaction, similar problems exist for both buyers and sellers of FRAs.

Some of the problems associated with the OTC market arise from the fact that the contracts are not standardized. However, nonstandardization leads to many benefits as well. As indicated earlier, OTC contracts can be specified in virtually any terms that are acceptable to both buyer and seller. A potential buyer or seller thus can approach a market-maker with whatever structure is needed and in many (but certainly not all) cases obtain the desired structure at a reasonable price. Compared to the very rigid structure of the exchange-traded markets, this is a remarkable advantage.

Caps and Floors on LIBOR

The primary OTC options covering the short end of the yield curve are the caps and floors on three- and six-month LIBOR. A cap on LIBOR is, in essence, a series of puts on LIBOR-based debt, whereas a floor on LIBOR is, in essence, a series of calls on LIBOR-based debt.

The buyer of a cap or floor holds most of the rights in the contract, as with other options. The seller of a cap or floor will of course receive an options premium from the buyer but is then obligated to perform on the contract.

To see how these contracts work, consider a five-year, $100 million cap on three-month LIBOR struck at 2%. Such a contract will specify reset dates occurring every three months for a total of 20 resets. The first reset will usually occur immediately or within a couple of weeks of the trade date, and the last reset will usually be about three months before the stated maturity of the contract. To determine what the payoff to the cap buyer will be, on every reset date one compares the three-month LIBOR (taken from a predetermined source) with the 2% strike rate. If the three-month LIBOR is at or below 2%, nothing is owed to the cap buyer. However, if the three-month LIBOR is above 2%, the cap seller must pay the cap buyer the monetary value of the amount by which three-month LIBOR exceeds 2%. In this case, for a 90-day interest accrual period, the value of each basis point is $2500 (from 0.0001 × $100,000,000 × 90/360). Thus, for example, if three-month LIBOR on a particular reset date is 2.50%, the cap seller owes the cap buyer $125,000 for that reset. If, on the next reset date, three-month LIBOR is 4%, the cap seller owes the cap buyer $500,000 for that reset. If, on the next reset date, three-month LIBOR is 1.50%, the cap seller owes nothing to the cap buyer for that reset. In most cases, the cap seller pays the cap buyer the amount of money owed for a particular reset at the end of the interest accrual period-in this case, three months after the reset date.

The mechanics of floors are similar, except that the payoff comes when rates fall below a given level, instead of when they rise above a given level. For example, if one buys a $25 million seven-year 3% floor on six-month LIBOR, there are a total of 14 reset dates. On each of these reset dates, one compares six-month

LIBOR to 3%. If six-month LIBOR is above 3%, nothing is owed to the buyer of the floor for that reset. However, if six-month LIBOR is below 3%, for a 180-day interest accrual period the floor seller owes the floor buyer $1250 for every basis point by which six-month LIBOR is below 3% (from 0.0001 × $25,000,000 × $^{180}/_{360}$).

Like other OTC options markets, the cap and floor market is composed of market-makers, end users, and brokers. The market-makers are once again the large investment banks and commercial banks. However, there are fewer market-makers and generally wider spreads in the cap and floor market than there are in the options market for mortgages or Treasury securities. Nonetheless, there is an active market out to 10 years, particularly for out-of-the-money caps and, to a lesser degree, out-of-the-money floors.

The end-user buyers of caps and floors are primarily institutions with risks that they need to cover. For example, institutions that fund short and lend long will tend to have losses as short-term rates rise. Similarly, businesses that fund by rolling over short-term obligations such as commercial paper or by bank borrowings tied to LIBOR or the prime rate will tend to have losses as short-term rates rise. These institutions, which include many thrifts, banks, and finance companies, as well as industrial and construction companies, can protect themselves against rising short-term rates by buying caps. End-user buyers of floors tend to be firms that face losses if rates fall. Such a case might occur, for example, if an institution borrows at a floating rate with a built-in floor. Such an institution may be structured so that floating rates, per se, pose no problem; the problem arises when the floating rate at which they borrow is no longer really floating because the floor has been hit. This institution may buy a floor so that it will receive monetary compensation from the floor seller whenever the floating rate falls below the floor rate, thus covering the risks of lower rates.

The sellers of caps and floors, other than the market-makers, are quite varied. In some cases, sellers sell caps or floors outright to bring in premium income. Others sell caps and/or floors to smooth out the cash flows on other fixed income instruments, such as certain derivative mortgage products. In other cases, sellers only implicitly sell the caps or floors. The following example illustrates both kinds of sellers.

When the cap market was developing, it quickly became obvious that there were many natural buyers of caps, but few natural sellers of caps. One successful effort to create sellers of caps occurred when investment bankers, who had many potential buyers of caps, realized that caps could be created as a derivative of the floating-rate note (FRN) market. Issuers of FRNs routinely issue notes reset off LIBOR. Furthermore, there were known buyers of *capped* FRNs, but of course, capped FRNs must have a higher coupon than uncapped FRNs to compensate the FRN buyer for the cap risk. If an issuer sells capped floating-rate notes, the issuer, in effect, buys a cap on LIBOR from the buyer of the FRN. This cap can then be sold to the investment banker, who in turn sells it to cap-buying clients. The deals that took place took exactly this form. The investment bankers underwrote capped FRNs for certain FRN issuers who agreed to make cap-like payments to their investment banker. The banker then sold caps to another client but did not incur any market risks because the two sets of potential payments offset one another. Using part of the proceeds of the sale of the cap, the investment bank agreed to make payments to the issuer to bring the cost of the floating-rate debt down to a level below that of uncapped floating-rate notes. Thus, the investment bankers, the issuers of the FRNs, the buyers of the FRNs, and the ultimate cap-buying clients all walked away with a satisfactory transaction.

Such a transaction illustrates how creative financing can be used to create a seller of an instrument when no obvious seller exists. In this example, the issuers of the FRNs are willing to sell caps, given the fact that they, in turn, find someone willing to sell the caps to them. The ultimate seller of caps is the buyer of the capped FRNs. The buyers of the FRNs are, however, only implicit sellers of caps in the sense that they never explicitly have a position in caps on their books.

This example, which is just one of dozens, shows how market-makers explicitly and implicitly induce end users of financial products to buy or sell the instruments that allow the market-makers to cover their positions in the OTC market. This is not to say that the market-makers are taking advantage of the other parties to their trades. As is often the case, all parties to a transaction can come out ahead.

Forward Rate Agreements

The forward rate agreement (FRA) market represents the OTC equivalent of the exchange-traded futures contracts on short-term rates. FRAs are a natural outgrowth of the interbank market for short-term funds. However, unlike the interbank market, virtually any creditworthy entity can buy or sell FRAs.

The liquid and easily accessible sector of the FRA market is for three- and six-month LIBOR. Rates are quoted widely for settlement starting one-month forward and settling once every month thereafter out to about six months forward. Thus, for example, on any given day forward rates are available for both three- and six-month LIBOR one month forward, covering, respectively, the interest period starting in one month and ending in four months, and the interest period starting in one month and ending in seven months. These contracts are referred to as 1×4 and 1×7 contracts. On the same day, there will be FRAs on three- and six-month LIBOR for settlement two months forward. These are the 2×5 and 2×8 contracts. Similarly, settlements occur three months, four months, five months, and six months forward for both three- and six-month LIBOR. These contracts are also denoted by the beginning and end of the interest period they cover.

On each subsequent day, contracts with the same type of structures, that is, contracts with one month, two months, and so on, to settlement date, are offered again. Thus, although on any given day a relatively limited number of structures are widely quoted, new contracts with new settlement dates are offered at the beginning of each day. This is quite different from the futures market, where the same contracts with the same delivery dates trade day after day.

As for other OTC debt instruments, there are market-makers and brokers who make the market work. However, unlike the other OTC derivative instruments, in the FRA market the commercial banks are clearly the dominant force among the market-makers. This dominance is due to the ability of the banks to blend their FRA transactions into their interbank transactions and overall funding operations. Consequently, many banks are willing to quote on a much wider variety of structures than the standard structures explained above. One can choose maturities other than three- and six-month LIBOR, and one can choose many settlement dates other than at an even number of months in the future.

In most cases, FRAs are written so that no money changes hands until the settlement date. To determine the cash flows on the settlement date, LIBOR taken from some predetermined source is compared to the LIBOR rate specified in the FRA contract. The actual dollar amount that changes hands is the dollar value of the difference between the two rates, *present valued* for a period equal to the maturity of the underlying LIBOR, either three or six months. The rationale behind present valuing is that if an FRA is used to hedge the rate on a deposit (or other short-term instrument), the loss (gain) due to a change in interest rates will be paid (saved) at the maturity of the deposit, not at the issue date. Thus, because cash payments on the FRA are made on the settlement date (which presumably is the same as the issue date of the deposit) the present value of the interest expense (or saving) on the deposit will equal the amount of money actually received or paid on the FRA.

Finally, one peculiarity of the FRA market deserves note. Unlike the case of the Eurodollar futures, if one *buys* an FRA, one profits from an *increase* in rates, and if one *sells* an FRA, one profits from a *decline* in rates. Furthermore, while the daily profit or loss on the Eurodollar futures trades is a *linear* function of the changes in the underlying LIBOR rate, the profit and loss on an FRA transaction would be a *convex* function of the underlying rate due to the present valuing of the difference of the contract and reference rates. In practice, though, this convexity bias has a lower impact in the current low interest rate environment than under high yield levels.

KEY POINTS

- A forward contract is an agreement for the future delivery of something at a specified price at the end of a designated period of time but differs from a futures contract in that it is nonstandardized and does not trade on an organized exchange.
- Parties to a forward contract are exposed to counterparty risk, which is the risk that the counterparty will not satisfy its contractual obligations.
- A futures contract is an agreement between a buyer (seller) and an established exchange or its clearinghouse in which the buyer (seller) agrees to take (make) delivery of something at a specified price during a designated period of time.
- The parties to a futures contract are required to satisfy margin requirements.

- An investor who takes a long futures position realizes a gain when the futures price increases; an investor who takes a short futures position realizes a loss when the futures price decreases.
- For the Treasury bond futures contract, the underlying instrument is \$100,000 par value of a hypothetical 20-year, 6% coupon Treasury bond.
- Conversion factors are used to adjust the invoice price of a Treasury bond futures contract to make delivery equitable to both parties.
- The short in a Treasury bond futures contract has several delivery options.
- The 2-year, 5-year, and 10-year Treasury note futures contracts are modeled after the Treasury bond futures contract.
- Three-month LIBOR is the underlying instrument for the Eurodollar futures contract. This futures contract is a cash settlement contract and is one of the most heavily traded futures contracts in the world.
- The federal funds futures contract is a cash settlement contract whose underlying is the average overnight federal funds for the delivery month.
- The underlying instrument for a swap futures contract is the notional price of the fixed-rate side of a 10-year interest-rate swap that has a notional principal equal to \$100,000 and that exchanges semiannual interest payments at a fixed annual rate of 6% for floating interest-rate payments based on three-month LIBOR.
- Interest rate options include options on fixed income securities and options on interest rate futures called futures options.
- Caps and floors are agreements between two parties whereby one party for an upfront fee agrees to compensate the other if a designated interest rate is different from a predetermined level.
- A forward rate agreement is an over-the-counter derivative instrument that is essentially a forward-starting loan, but with no exchange of principal, so the cash exchanged between the counterparties depend only on the difference in interest rates.
- The elements of an FRA are the FRA rate, reference rate, notional amount, contract period, and settlement date.
- The buyer of an FRA is agreeing to pay the FRA rate and the seller of the FRA is agreeing to receive the FRA rate. The amount that must be exchanged at the settlement date is the present value of the interest differential.
- In contrast to an interest-rate futures contract, the buyer of an FRA benefits if the reference rate increases and the seller benefits if the reference rate decreases.

CHAPTER
SIXTY-TWO

PRICING FUTURES AND PORTFOLIO APPLICATIONS

Frank J. Fabozzi, Ph.D., CFA, CPA
Professor of Finance
EDHEC Business School

One of the primary concerns most traders and investors have when taking a position in futures contracts is whether the futures price at which they transact will be a fair price. Buyers are concerned that the price may be too high and that they will be picked off by more experienced futures traders waiting to profit from the mistakes of the uninitiated. Sellers worry that the price is artificially low and that savvy traders may have manipulated the markets so that they can buy at bargain-basement prices. Furthermore, prospective participants frequently find no rational explanation for the sometimes violent ups and downs that occur in the futures markets. Theories about efficient markets give little comfort to anyone who knows of or has experienced the sudden losses that can occur in the highly leveraged futures markets.

Fortunately, the futures markets are not as irrational as they may at first seem; if they were, they would not be so successful. The interest-rate futures markets are not perfectly efficient markets, but they probably come about as close as any market. Furthermore, there are very clear reasons why futures prices are what they are, and there are methods by which traders, investors, and borrowers will quickly eliminate any discrepancy between futures prices and their fair levels.

In this chapter we will explain how the fair or theoretical value of a futures contract is determined. We then explain several portfolio applications of interest-rate futures.

PRICING OF FUTURES CONTRACTS

There are several different ways to price futures contracts. Fortunately, all lead to the same fair price for a given contract. Each approach relies on the *law of one price.* This law states that a given financial asset (or liability) must have the same price regardless of the means by which one goes about creating that asset (or liability). In this section we will demonstrate one way in which futures contracts can be

Previous versions of this chapter were coauthored with Dr. Mark Pitts and Dr. Bruce Collins.

combined with cash market instruments to create cash flows that are identical to other cash securities. The law of one price implies that the synthetically created cash securities must have the same price as the actual cash securities. Similarly, cash instruments can be combined to create cash flows that are identical to futures contracts. By the law of one price, the futures contract must have the same price as the synthetic futures created from cash instruments.

Illustration of the Basic Principles

To understand how futures contracts should be priced, consider the following example. Suppose that a 20-year $100 par value bond with a coupon rate of 12% is selling at par. Also suppose that this bond is the deliverable for a futures contract that settles in three months. If the current three-month interest rate at which funds can be loaned or borrowed is 8% per year, what should be the price of this futures contract?

Suppose the price of the futures contract is 107. Consider the following strategy:

Sell the futures contract at 107.

Purchase the bond for 100.

Borrow 100 for three months at 8% per year.

The borrowed funds are used to purchase the bond, resulting in no initial cash outlay for this strategy. Three months from now, the bond must be delivered to settle the futures contract and the loan must be repaid. These trades will produce the following cash flows:

From settlement of the futures contract	
Flat price of bond	107
Accrued interest (12% for three months)	+3
Total proceeds	110
From the loan	
Repayment of principal of loan	100
Interest on loan (8% for three months)	+2
Total outlay	102
Profit	8

This strategy will guarantee a profit of 8. Moreover, the profit is generated with no initial outlay because the funds used to purchase the bond are borrowed. The profit will be realized *regardless of the futures price at the settlement date.* Obviously, in a well-functioning market, arbitrageurs would buy the bond and sell the futures, forcing the futures price down and bidding up the bond price so as to eliminate this profit. This strategy of purchasing a bond with borrowed funds and simultaneously selling a futures contract to generate an arbitrage profit is called a *cash and carry trade.*

In contrast, suppose that the futures price is 92 instead of 107. Consider the following strategy:

Buy the futures contract at 92.

Sell (short) the bond for 100.

Invest (lend) 100 for three months at 8% per year.

Once again, there is no initial cash outlay. Three months from now a bond will be purchased to settle the long position in the futures contract. That bond will then be used to cover the short position (i.e., to cover the short sale in the cash market). The outcome in three months would be as follows:

From settlement of the futures contract	
Flat price of bond	92
Accrued interest (12% for three months)	+3
Total outlay	95
From the loan	
Principal received from maturing investment	100
Interest earned from the three-month investment (8% for three months)	+2
Total proceeds	102
Profit	7

The 7 profit is a pure arbitrage profit. It requires no initial cash outlay and will be realized regardless of the futures price at the settlement date. Because this strategy involves initially selling the underlying bond, it is called a *reverse cash and carry trade*.

There is a futures price, however, that will eliminate the arbitrage profit. There will be no arbitrage if the futures price is 99. Let's look at what would happen if the two previous strategies were followed and the futures price were 99. First, consider the following cash and carry trade:

Sell the futures contract at 99.

Purchase the bond for 100.

Borrow 100 for three months at 8% per year.

In three months, the outcome would be as follows:

From settlement of the futures contract	
Flat price of bond	99
Accrued interest (12% for three months)	+3
Total proceeds	102
From the loan	
Repayment of principal of the loan	100
Interest on the loan (8% for three months)	+2
Total outlay	102
Profit	0

There is no arbitrage profit.

Next, consider the following reverse cash and carry trade:

Buy the futures contract at 99.

Sell (short) the bond for 100.

Invest (lend) 100 for three months at 8% per year.

The outcome in three months would be as follows:

From settlement of the futures contract	
Flat price of bond	99
Accrued interest (12% for three months)	+3
Total outlay	102
From the loan	
Principal received from maturing investment	100
Interest earned from the three-month investment (8% for three months)	+2
Total proceeds	102
Profit	0

Thus neither strategy results in a profit. The futures price of 99 is the equilibrium price because any higher or lower futures price will permit arbitrage profits.

Theoretical Futures Price Based on Arbitrage Model

Considering the arbitrage arguments just presented, the equilibrium futures price can be determined on the basis of the following information:

- The price of the bond in the cash market.
- The coupon rate on the bond. In our example, the coupon rate was 12% per annum.

- The interest rate for borrowing and lending until the settlement date. The borrowing and lending rate is referred to as the *financing rate*. In our example, the financing rate was 8% per annum.

We will let

r = financing rate

c = current yield, or coupon rate divided by the cash market price

P = cash market price

F = futures price

t = time, in years, to the futures delivery date

and then consider the following cash and carry trade that is initiated on a coupon date:

Sell the futures contract at F.

Purchase the bond for P.

Borrow P until the settlement date at r.

The outcome at the settlement date is as follows:

From settlement of the futures contract	
Flat price of bond	F
Accrued interest	$+ctP$
Total proceeds	$F + ctP$
From the loan	
Repayment of principal of the loan	P
Interest on loan	$+ rtP$
Total outlay	$P + rtP$

The profit will equal

$$\text{Profit} = \text{total proceeds} - \text{total outlay}$$

$$\text{Profit} = F + ctP - (P + rtP)$$

In equilibrium, the theoretical futures price occurs where the profit from this strategy is zero. Thus, to have equilibrium, the following must hold:

$$0 = F + ctP - (P + rtP)$$

Solving for the theoretical futures price, we have

$$F = P + Pt(r - c) = P[1 + t(r - c)] \tag{62-1}$$

Alternatively, consider the following reverse cash and carry trade:

Buy the futures contract at F.

Sell (short) the bond for P.

Invest (lend) P at r until the settlement date.

The outcome at the settlement date would be as follows:

From settlement of the futures contract	
Flat price of bond	F
Accrued interest	$+ ctP$
Total outlay	$F + ctP$
From the loan	
Proceeds received from maturing of investment	P
Interest earned	$+ rtP$
Total proceeds	$P + rtP$

The profit will equal

$$\text{Profit} = \text{total proceeds} - \text{total outlay}$$
$$\text{Profit} = P + rtP - (F + ctP)$$

Setting the profit equal to zero so that there will be no arbitrage profit and solving for the futures price, we obtain the same equation for the futures price as Eq. (62-1).

Let's apply Eq. (62-1) to our previous example in which

$$r = 0.08$$
$$c = 0.12$$
$$P = 100$$
$$t = 0.25$$

Then the theoretical futures price is

$$\begin{aligned} F &= 100 + 100 \times 0.25(0.08 - 0.12) \\ &= 100 - 1 = 99 \end{aligned}$$

This agrees with the equilibrium futures price we derived earlier.

The theoretical futures price may be at a premium to the cash market price (higher than the cash market price) or at a discount from the cash market price (lower than the cash market price), depending on the value of $(r - c)$. The term $r - c$ is called the *net financing cost* because it adjusts the financing rate for the coupon interest earned. The net financing cost is more commonly called the *cost of carry,* or simply *carry. Positive carry* means that the current yield earned is greater than the financing cost; *negative carry* means that the financing cost exceeds the current yield. The relationships can be expressed as follows:

Carry	Futures Price
Positive ($c > r$)	Will sell at a discount to the cash price ($F < P$)
Negative ($c < r$)	Will sell at a premium to the cash price ($F > P$)
Zero ($r = c$)	Will be equal to the cash price ($F = P$)

In the case of interest-rate futures, carry (the relationship between the short-term financing rate and the current yield on the bond) depends on the shape of the yield-curve. When the yield-curve is upward-sloping, the short-term financing rate will generally be less than the current yield on the bond, resulting in positive carry. The futures price will then sell at a discount to the cash price for the bond. The opposite will hold true when the yield-curve is inverted.

A Closer Look at the Theoretical Futures Price

To derive the theoretical futures price using the arbitrage argument, we made several assumptions. We will now discuss the implications of these assumptions.

Interim Cash Flows. No interim cash flows owing to variation margin or coupon interest payments were assumed in the model. However, we know that interim cash flows can occur for both of these reasons. Because we assumed no variation margin, the price derived is technically the theoretical price for a forward contract (which is not marked to market at the end of each trading day). If interest rates rise, the short position in futures will receive margin as the futures price decreases; the margin can then be reinvested at a higher interest rate. In contrast, if interest rates fall, there will be variation margin that must be financed by the short position; however, because interest rates have declined, the financing can be done at a lower cost. Thus, whichever way rates move, those who are short futures gain relative to those who are short forward contracts that are not marked to market. Conversely, those who are long futures lose relative to those who are long forward contracts that are not marked to market. These facts account for the difference between futures and forward prices.

Incorporating interim coupon payments into the pricing model is not difficult. However, the value of the coupon payments at the settlement date will depend on the interest rate at which they can be reinvested. The shorter the maturity of the futures contract and the lower the coupon rate, the less important the reinvestment income is in determining the theoretical futures price.

The Short-Term Interest Rate (Financing Rate). In deriving the theoretical futures price, it is assumed that the borrowing and lending rates are equal. Typically, however, the borrowing rate is greater than the lending rate.

We will let

$$r_B = \text{borrowing rate}$$
$$r_L = \text{lending rate}$$

Consider the following strategy:

Sell the futures contract at F.

Purchase the bond for P.

Borrow P until the settlement date at r_B.

The futures price that would produce no arbitrage profit is

$$F = P + P\,(r_B - c) \tag{62-2}$$

Now consider the following strategy:

Buy the futures contract at F.

Sell (short) the bond for P.

Invest (lend) P at r_L until the settlement date.

The futures price that would produce no profit is

$$F = P + P(r_L - c) \tag{62-3}$$

Equations (62-2) and (62-3) together provide boundaries for the theoretical futures price. Equation (62-2) provides the upper boundary, and Eq. (62-3) the lower boundary. For example, assume that the borrowing rate is 8% per year, or 2% for three months, and the lending rate is 6% per year, or 1.5% for three months. Then, using Eq. (62-2) and the previous example, the upper boundary is

$$F\text{(upper boundary)} = \$100 + \$100(0.02 - 0.03) = \$99$$

The lower boundary using Eq. (62-3) is

$$F\text{(lower boundary)} = 100 + \$100(0.015 - 0.03) = \$98.50$$

In calculating these boundaries, we assumed no transaction costs were involved in taking the position. In actuality, the transaction costs of entering into and closing the cash position as well as the round-trip transaction costs for the futures contract, must be considered and do affect the boundaries for the futures contract.

Deliverable Bond and Settlement Date Unknown. In our example, we assumed that only one bond is deliverable and that the settlement date occurs three months from now. As explained in Chapter 61, futures contracts on Treasury bonds and Treasury notes are designed to allow the short position the choice of delivering one of a number of deliverable issues. Also, the delivery date is not known.

Because there may be more than one deliverable, market participants track the price of each deliverable bond and determine which is the cheapest to deliver. The futures price will then trade in relation to the bond that is cheapest to deliver.

The cheapest to deliver is the bond or note that will result in the smallest loss or the greatest gain if delivered by the short futures position.[1]

In addition to the reasons we have already discussed, there are several reasons why the actual futures price will diverge from the theoretical futures price based on the arbitrage model. First, there is the risk that although an issue may be the cheapest to deliver at the time a position in the futures contract is taken, it may not be the cheapest to deliver after that time. Thus, there will be a divergence between the theoretical futures price and the actual futures price. A second reason for this divergence is the other delivery options granted the short position. Finally, there are biases in the CME conversion factors.

Deliverable Is a Basket of Securities. The municipal index futures contract is a cash settlement contract based on a basket of securities. The difficulty in arbitraging this futures contract is that it is too expensive to buy or sell every bond included in the index. Instead, a portfolio containing a smaller number of bonds may be constructed to track the index. The arbitrage, however, is no longer risk-free because there is the risk that the portfolio will not track the index exactly. This is referred to as *tracking-error risk.* Another problem in constructing the portfolio so that the arbitrage can be performed is that the composition of the index is revised periodically. Therefore, anyone using this arbitrage trade must constantly monitor the index and periodically rebalance the constructed portfolio.

APPLICATIONS TO PORTFOLIO MANAGEMENT

This section describes various ways in which a money manager can use interest-rate futures contracts.

Interest-Rate Risk Control

Interest-rate risk control is probably the most common use of interest-rate futures. This is accomplished by altering the portfolio's duration. Money managers who have strong expectations about the direction of interest rates will adjust the duration of their portfolio to capitalize on their expectations. Specifically, if they expect interest rates to increase, they will shorten the duration of the portfolio; if they expect interest rates to decrease, they will lengthen the duration of the portfolio. Also, anyone using structured portfolio strategies must periodically adjust the portfolio duration to match the duration of some benchmark.

Although money managers can alter the duration of their portfolios with cash market instruments, a quick and less expensive means for doing so (especially on a

1. An alternative procedure is to compute the implied (break-even) repo rate. This rate is the yield that would produce no profit or loss if the bond were purchased and a futures contract were sold against the bond. The cheapest-to-deliver bond is the one with the highest implied repo rate.

temporary basis) is to use futures contracts. By buying futures contracts on Treasury bonds or notes, they can increase the duration of the portfolio. Conversely, they can shorten the duration of the portfolio by selling futures contracts on Treasury bonds or notes.

Hedging

Hedging is a special case of interest-rate risk control whereby the manager seeks to obtain a duration of zero.[2] Hedging with futures involves taking a futures position as a temporary substitute for transactions to be made in the cash market at a later date. If cash and futures prices move together, any loss realized by the hedger from one position (whether cash or futures) will be offset by a profit on the other position such that the the return earned is the risk-free rate. When the net profit or loss from the positions are exactly as anticipated, the hedge is referred to as a *perfect hedge.*

In practice, hedging is not that simple. The amount of net profit will not necessarily be as anticipated. The outcome of a hedge will depend on the relationship between the cash price and the futures price when a hedge is placed and when it is lifted. The difference between the cash price and the futures price is called the basis. The risk that the basis will change in an unpredictable way is called *basis risk.*

In most hedging applications, the bond to be hedged is not identical to the bond underlying the futures contract. This kind of hedging is referred to as *cross-hedging.* There may be substantial basis risk in cross-hedging. An unhedged position is exposed to price risk, the risk that the cash market price will move adversely. A hedged position substitutes basis risk for price risk.

A short (or sell) hedge is used to protect against a decline in the cash price of a fixed income security. To execute a short hedge, futures contracts are sold. By establishing a short hedge, the hedger has fixed the future cash price and transferred the price risk of ownership to the buyer of the futures contract. As an example of why a short hedge would be executed, suppose that a pension fund manager knows that bonds must be liquidated in 40 days to make a $5 million payment to the beneficiaries of the pension fund. If interest rates rise during the 40-day period, more bonds will have to be liquidated to realize $5 million. To guard against this possibility, the manager would sell bonds in the futures market to lock in a selling price.

A long (or buy) hedge is undertaken to protect against an increase in the cash price of a fixed income security. In a long hedge, the hedger buys a futures contract to lock in a purchase price. A pension fund manager may use a long hedge when substantial cash contributions are expected and the manager is concerned that interest rates will fall. Also, a money manager who knows that bonds are maturing in the near future and expects that interest rates will fall can employ a long hedge to lock in a rate.

2. Hedging is discussed in more detail in Chapter 63.

Asset Allocation

A pension sponsor may wish to alter the composition of the pension fund's assets between stocks and bonds. An efficient means of changing asset allocation is to use financial futures contracts: interest-rate futures and stock index futures.

Creating Synthetic Securities for Yield Enhancement

A cash market security can be synthetically created by using a position in the futures contract together with the deliverable instrument. The yield on the synthetic security should be the same as the yield on the cash market security. If there is a difference between the two yields, it can be exploited so as to enhance the yield on the portfolio.

To see how, consider an investor who owns a 20-year Treasury bond and sells Treasury futures that call for the delivery of that particular bond three months from now. The maturity of the Treasury bond is 20 years, but the investor has effectively shortened the maturity of the bond to three months.

Consequently, the long position in the 20-year bond and the short futures position are equivalent to a long position in a three-month riskless security. The position is riskless because the investor is locking in the price that will be received three months from now—the futures price. By being long the bond and short the futures, the investor has synthetically created a three-month Treasury bill. The return the investor should expect to earn from this synthetic position should be the yield on a three-month Treasury bill. If the yield on the synthetic three-month Treasury bill is greater than the yield on the cash market Treasury bill, the investor can realize an enhanced yield by creating the synthetic short-term security. The fundamental relationship for creating synthetic securities is as follows:

$$\text{RSP} = \text{CBP} - \text{BFP} \tag{62-4}$$

where

CBP = cash bond position
BFP = bond futures position
RSP = riskless short-term security position

A negative sign before a position means a short position. In terms of our previous example, CBP is the long cash bond position, the negative sign before BFP refers to the short futures position, and RSP is the riskless synthetic three-month security or Treasury bill.

Equation (62-4) states that an investor who is long the cash market security and short the futures contract should expect to earn the rate of return on a risk-free security with the same maturity as the futures delivery date. Solving Eq. (62-4) for the long bond position, we have

$$\text{CBP} = \text{RSP} + \text{BFP} \tag{62-5}$$

Equation (62-5) states that a cash bond position equals a short-term riskless security position plus a long bond futures position. Thus a cash market bond can be synthetically created by buying a futures contract and investing in a Treasury bill.

Solving Eq. (62-5) for the bond futures position, we have

$$\text{BFP} = \text{CBP} - \text{RSP} \tag{62-6}$$

Equation (62-6) tells us that a long position in the futures contract can be synthetically created by taking a long position in the cash market bond and shorting the short-term riskless security. Shorting the short-term riskless security is equivalent to borrowing money. Notice that it was Eq. (62-6) that we used in deriving the theoretical futures price when the futures was overpriced. Recall that when the futures price was 107, the strategy to obtain an arbitrage profit was to sell the futures contract and create a synthetic long futures position by buying the bond with borrowed funds. This is precisely what Eq. (62-6) states. In this case, instead of creating a synthetic cash market instrument as we did with Eqs. (62-4) and (62-5), we have created a synthetic futures contract. The fact that the synthetic long futures position was cheaper than the actual long futures position provided an arbitrage opportunity.

If we reverse the sign of both sides of Eq. (62-6), we can see how a short futures position can be synthetically created.

In an efficient market, the opportunities for yield enhancement should not exist very long. Even in the absence of yield enhancement, however, synthetic securities can be used by money managers to hedge a portfolio position that they find difficult to hedge in the cash market either because of lack of liquidity or because of other constraints.

PORTABLE ALPHA

There are two basic approaches to investment management: passive and active. The objective of passive management is to match the performance of a benchmark that represents a defined asset class while the objective of active management is to select individual assets that are likely to perform better than the average. The returns to an active strategy will consist of returns based on market exposure and returns based on selection skill. The returns resulting from superior selection skills are referred to as *alpha*. Pure alpha strategies are those with no market risk and thus returns do not depend on market direction. An example is a long/short strategy that is market neutral.

In a period when equity markets have increased volatility and lower prospects for increasing returns, institutional investors look to reallocate funds to asset classes with lower volatility such as fixed income securities. Moreover, institutional investors confront an environment of funding shortfalls and moderate returns, which necessitates the development of alternative and more efficient sources of returns. *Portable alpha strategies* can be employed to maintain exposure to a lower volatility asset class while producing returns that approach equities.

The portable alpha strategy can either be used as a core investment in an asset class or as an overlay strategy.

Portable alpha strategies refer to an investment methodology or process that blends traditional asset class exposure with alternative investment strategies in order to add returns without assuming additional risk. The concept is "portable" in the sense that the integration of alternative with traditional does not impact management style or acceptable risk parameters adversely, which means it is easily transferred into an existing asset class or benchmark through the application of an overlay program to achieve the targeted asset exposure. Thus, the alpha is created independently of the core portfolio and transferred with the use of derivatives in order to maintain the characteristics of the core portfolio.

The significance of portable alpha strategies is that the asset allocation decision can be separated from the search for alpha within the asset class. Thus, portable alpha is a return enhancement strategy and not an asset substitution strategy. The advantage of the portable alpha approach is its flexibility in terms of adding returns without additional risk.[3] Many portable alpha strategies involve long and short positions. Exchange-traded futures contracts can be integral to a portable alpha strategy either as a means to overlay an existing core portfolio or as a means to synthetically maintain the core exposure to the fixed income asset class.

The basis of "portable" alpha is that it explicitly changes the investment management process by separating the management of market returns and pure alpha returns. Pure alpha strategies are factor or market neutral and have no correlation with market direction. The objective of portable alpha strategies is to improve the efficiency of finding positive incremental returns. For equity strategies it involves stock selection and for fixed income it might involve bond selection or the exploitation of yield-curve inefficiencies. In any case, derivatives including futures and swaps are vital to achieve the strategic asset allocation exposures. This paradigm shift that explicitly separates market returns and alpha has implications for manager selection and risk management.

Since alpha is the total return less market returns, the production of alpha does not depend on market direction and therefore positive alpha is possible in all market environments. The portable alpha strategy can be implemented as an overlay on an existing asset class or as a separate investment that uses swaps and futures to maintain the overall strategic asset allocation mix. Theoretically, portable alpha strategies can be produced from any strategy assuming it contains alpha and there is sufficient liquidity to implement the strategy. Thus, there are three basic ways to develop a portable alpha generating strategy.

1. Identify an alpha generating long portfolios, use futures to eliminate market risk, and overlay the strategy on the existing asset class.

3. Furthermore, the implementation of portable alpha strategies significantly expands the universe of managers beyond the limitations imposed by style or orientation.

2. Identify pure alpha generating investments from the hedge fund or fund of fund communities, sell off a portion of the asset class, and replace with futures and alpha generating investments.
3. Replace entire asset class with pure alpha generating strategies and use derivatives to maintain targeted market exposure.

Portable alpha represents a change in the investment process and a different way to think about risk and return. Futures contracts are an integral part of the implementation of many portable alpha investment programs.

KEY POINTS

- The theoretical futures price is determined by the net financing cost, or carry.
- Carry is the difference between the financing cost and the cash yield on the underlying cash instrument.
- The basic futures pricing model must be modified to account for nuances of specific futures contracts.
- Uses of futures contracts by portfolio managers are altering a portfolio's duration (risk control), asset allocation, creation of synthetic securities to enhance returns, and portable alpha.
- Hedging is a special case of controlling interest-rate risk in which the portfolio wants to alter the portfolio's duration to zero.
- Portable alpha strategies can be employed to maintain exposure to a lower volatility asset class while producing returns that approach equities.

CHAPTER

SIXTY-THREE

CONTROLLING INTEREST-RATE RISK WITH FUTURES AND OPTIONS

Frank J. Fabozzi, Ph.D., CFA
Professor of Finance
EDHEC Business School

Shrikant Ramamurthy
Consultant

In Chapter 61 the features and characteristics of interest-rate futures and options were explained. In this chapter, our focus is on how these derivative instruments can be used to control the interest-rate risk of a portfolio.

CONTROLLING INTEREST-RATE RISK WITH FUTURES

The price of an interest-rate futures contract moves in the opposite direction from the change in interest rates: when rates rise, the futures price will fall; when rates fall, the futures price will rise. By buying a futures contract, a portfolio's exposure to a rate increase is increased. That is, the portfolio's duration increases. By selling a futures contract, a portfolio's exposure to a rate increase is decreased. Equivalently, this means that the portfolio's duration is reduced. Consequently, buying and selling futures can be used to alter the duration of a portfolio.

While managers can alter the duration of their portfolios with cash-market instruments (buying or selling Treasury securities), using interest-rate futures

Earlier versions of this chapter were coauthored with Dr. Mark Pitts.

instead of trading long-term Treasuries themselves has the following three advantages:

Advantage 1: Transaction costs for trading futures are lower than trading in the cash market.

Advantage 2: Margin requirements are lower for futures than for Treasury securities; using futures thus permits greater leverage.

Advantage 3: It is easier to sell short in the futures market than in the Treasury market.

Futures also can be used in constructing a portfolio with a longer duration than is available with cash-market securities. For example, suppose that in a certain interest-rate environment a pension fund manager must structure a portfolio to have a duration of 15 to accomplish a particular investment objective. Bonds with such a long duration may not be available. By buying the appropriate number and kind of interest-rate futures contracts, a pension fund manager can increase the portfolio's duration to the target level of 15.

General Principles of Interest-Rate Risk Control

The general principle in controlling interest-rate risk with futures is to combine the dollar exposure of the current portfolio and the dollar exposure of a futures position so that the total dollar exposure is equal to the target dollar exposure. This means that the manager must be able to accurately measure the dollar exposure of both the current portfolio and the futures contract employed to alter the exposure.

There are two commonly used measures for approximating the change in the dollar value of a bond or bond portfolio to changes in interest rates: price value of a basis point (PVBP) and duration. PVBP is the dollar price change resulting from a 1 basis point change in yield. Duration is the approximate percentage change in price for a 100 basis point change in rates. (Given the percentage price change, the dollar price change for a given change in interest rates can be computed.) There are two measures of duration: *modified* and *effective*. Effective duration is the appropriate measure that should be used for bonds with embedded options. In this chapter when we refer to duration, we mean effective duration. Moreover, since the manager is interested in dollar price exposure, it is the effective *dollar* duration that should be used. For a 1 basis point change in rates, PVBP is equal to the effective dollar duration for a 1 basis point change in rates.

To estimate the effective dollar duration, it is necessary to have a good valuation model. It is the valuation model that is used to determine what the new values for the bonds in the portfolio will be if rates change. The difference between the current values of the bonds in the portfolio and the new values estimated by the valuation model when rates are changed is the dollar price exposure. Consequently, the starting point in controlling interest-rate risk is the development of a reliable valuation model. A reliable valuation model also is needed to value the derivative contracts that the manager wants to use to control interest-rate exposure.

Suppose that a manager seeks a *target duration* for the portfolio based on either expectations of interest rates or client-specified exposure. Given the target duration, a target dollar duration for a small basis point change in interest rates can be obtained. For a 50 basis point change in interest rates, for example, the target dollar duration can be found by multiplying the dollar value of the portfolio by the target duration and then dividing by 200. For example, suppose that the manager of a $500 million portfolio wants a target duration of 6. This means that the manager seeks a 3% change in the value of the portfolio for a 50 basis point change in rates (assuming a parallel shift in rates of all maturities). Multiplying the target duration of 6 by $500 million and dividing by 200 gives a target dollar duration of $15 million.

The manager then must determine the dollar duration of the current portfolio. The current dollar duration for a 50 basis point change in interest rates is found by multiplying the current duration by the dollar value of the portfolio and dividing by 200. Thus, for our $500 million portfolio, suppose that the current duration is 4. The current dollar duration is then $10 million (4 times $500 million divided by 200).

The target dollar duration is then compared with the current dollar duration. The difference between the two dollar durations is the dollar exposure that must be provided by a position in the futures contract. If the target dollar duration exceeds the current dollar duration, a futures position must increase the dollar exposure by the difference. To increase the dollar exposure, an appropriate number of futures contracts must be purchased. If the target dollar duration is less than the current dollar duration, an appropriate number of futures contracts must be sold. That is,

$$\text{If target dollar duration} - \text{current dollar duration} > 0, \text{ buy futures}$$

$$\text{If target dollar duration} - \text{current dollar duration} < 0, \text{ sell futures}$$

Once a futures position is taken, the *portfolio's dollar duration* is equal to the *current dollar duration without futures* plus the *dollar duration of the futures position*. That is,

$$\begin{aligned}\text{Portfolio's dollar return} &= \text{current dollar duration without futures}\\ &\quad + \text{dollar duration of futures position}\end{aligned}$$

The objective is to control the portfolio's interest-rate risk by establishing a futures position such that the portfolio's dollar duration is equal to the target dollar duration. Thus

$$\text{Portfolio's dollar duration} = \text{target dollar duration}$$

Or equivalently,

$$\begin{aligned}\text{Target dollar duration} &= \text{current dollar duration without futures}\\ &\quad + \text{dollar duration of futures position} \qquad (63\text{-}1)\end{aligned}$$

Over time, the portfolio's dollar duration will move away from the target dollar duration. The manager can alter the futures position to adjust the portfolio's dollar duration to the target dollar duration.

Determining the Number of Contracts

Each futures contract calls for delivery of a specified amount of the underlying instrument. When interest rates change, the value of the underlying instrument changes, and therefore, the value of the futures contract changes. How much the futures dollar value will change when interest rates change must be estimated. This amount is called the *dollar duration per futures contract*. For example, suppose that the futures price of an interest-rate futures contract is 70 and that the underlying interest-rate instrument has a par value of $100,000. Thus the futures delivery price is $70,000 (0.70 times $100,000). Suppose that a change in interest rates of 50 basis points results in the futures price changing by about $0.03 per contract. Then the dollar duration per futures contract is $2,100 (0.03 times $70,000).

The dollar duration of a futures position is then the number of futures contracts multiplied by the dollar duration per futures contract. That is,

$$\begin{aligned}&\text{Dollar duration of futures position}\\&\quad = \text{number of futures contracts} \times \text{dollar duration per futures contract} \qquad (63\text{-}2)\end{aligned}$$

How many futures contracts are needed to obtain the target dollar duration? Substituting Eq. (63-2) into Eq. (63-1), we get

$$\begin{aligned}&\text{Number of futures contracts} \times \text{dollar duration per futures contract}\\&\quad = \text{target dollar duration} - \text{current dollar duration without futures} \qquad (63\text{-}3)\end{aligned}$$

Solving for the number of futures contracts, we have

$$\begin{aligned}&\text{Number of futures contracts}\\&\quad = \frac{\text{target dollar duration} - \text{current dollar duration without futures}}{\text{dollar duration per futures contract}} \qquad (63\text{-}4)\end{aligned}$$

Equation (63-4) gives the approximate number of futures contracts that are necessary to adjust the portfolio's dollar duration to the target dollar duration. A positive number means that the futures contract must be purchased; a negative number means that the futures contract must be sold. Notice that if the target dollar duration is greater than the current dollar duration without futures, the numerator is positive, and therefore, futures contracts are purchased. If the target dollar duration is less than the current dollar duration without futures, the numerator is negative, and therefore, futures contracts are sold.

Dollar Duration for a Futures Position

Now we turn to how to measure the dollar duration of a bond futures position. Keep in mind what the goal is: it is to measure the sensitivity of a bond futures position to changes in rates.

The general methodology for computing the dollar duration of a futures position for a given change in interest rates is straightforward given a valuation model. The procedure is the same as for computing the dollar duration of any cash-market instrument—shock (change) interest rates up and down by the same number of basis points and determine the average dollar price change.

An adjustment is needed for the Treasury bond and note futures contracts. The pricing of the futures contract depends on the cheapest-to-deliver (CTD) issue.[1] Calculation of the dollar duration of a Treasury bond or note futures contract requires determining the impact of a change in interest rates will have on the price of a futures contract, which, in turn, affects how the futures price will change. The dollar duration of a Treasury bond and note futures contract is determined as follows:

$$\text{Dollar duration of futures contract} = \text{dollar duration of the CTD issue} \times \frac{\text{dollar duration of futures contract}}{\text{dollar duration of the CTD issue}}$$

There is a conversion factor for each issue that is acceptable for delivery for the futures contract. The conversion factor makes deliverable equitable to both the buyer and seller of the futures contract. For each deliverable issue, the product of the futures price and the conversion factor is the adjusted futures price for the issue. This adjusted price is called the *converted price*. Relating this to the preceding equation, the second ratio is approximately equal to the conversion factor of the cheapest-to-deliver issue. Thus we can write

$$\text{Dollar duration of futures contract} = \text{dollar duration of the CTD issue} \times \text{conversion factor for the CTD issue}$$

Why did we focus on dollar duration rather than duration? Recall that duration is the approximate percentage change in price. But what is the price of this leveraged instrument? The investor does not put up the full price of the position in order to acquire the position. Only the initial margin need be made in cash or a cash equivalent. Consequently, what is the base investment made by the investor? Rather than debate what should be used as the base investment in order to compute duration, let's simply ask why we are interested in calculating the exposure to changes in rates. As we have emphasized, it is to determine how a futures position will alter the exposure of a portfolio to changes in rates. Once we know how a futures position changes the dollar duration of a portfolio, we can determine for a portfolio its dollar duration. Given the funds invested by the investor in the portfolio, the portfolio's duration can be computed.

1. The cheapest-to-deliver issue is the one issue from among all those that are deliverable to satisfy a contract that has the highest return in a cash and carry trade. This return is called the *implied repo rate*.

Hedging with Interest-Rate Futures

Hedging with futures calls for taking a futures position as a temporary substitute for transactions to be made in the cash market at a later date. If cash and futures prices move together, any loss realized by the hedger from one position (whether cash or futures) will be offset by a profit on the other position. *Hedging is a special case of controlling interest-rate risk. In a hedge, the manager seeks a target duration or target dollar duration of zero*.

A *short hedge* (or *sell hedge*) is used to protect against a decline in the cash price of a bond. To execute a short hedge, futures contracts are sold. By establishing a short hedge, the manager has fixed the future cash price and transferred the price risk of ownership to the buyer of the futures contract. To understand why a short hedge might be executed, suppose that a pension fund manager knows that bonds must be liquidated in 40 days to make a $5 million payment to beneficiaries. If interest rates rise during the 40-day period, more bonds will have to be liquidated at a lower price than today to realize $5 million. To guard against this possibility, the manager can sell bonds in the futures market to lock in a selling price.

A *long hedge* (or *buy hedge*) is undertaken to protect against an increase in the cash price of a bond. In a long hedge, the manager buys a futures contract to lock in a purchase price. A pension fund manager might use a long hedge when substantial cash contributions are expected, and the manager is concerned that interest rates will fall. Also, a money manager who knows that bonds are maturing in the near future and expects that interest rates will fall can employ a long hedge to lock in a rate for the proceeds to be reinvested.

In bond portfolio management, typically the bond or portfolio to be hedged is not identical to the bond underlying the futures contract. This type of hedging is referred to as *cross-hedging*.

The hedging process can be broken down into four steps:

Step 1. Determining the appropriate hedging instrument

Step 2. Determining the target for the hedge

Step 3. Determining the position to be taken in the hedging instrument

Step 4. Monitoring and evaluating the hedge

We discuss each step below.

Determining the Appropriate Hedging Instrument

A primary factor in determining which futures contract will provide the best hedge is the degree of correlation between the rate on the futures contract and the interest rate that creates the underlying risk that the manager seeks to eliminate. For example, a long-term corporate bond portfolio can be better hedged with Treasury bond futures than with Treasury bill futures because long-term corporate bond rates are more highly correlated with Treasury bond futures than Treasury bill futures. Using the right delivery month is also important. A manager trying to lock in a rate or price for September will use September futures contracts because September futures contracts will give the highest degree of correlation.

Correlation is not, however, the only consideration if the hedging program is of significant size. If, for example, a manager wants to hedge \$600 million of a cash position in a distant delivery month, liquidity becomes an important consideration. In such a case, it might be necessary for the manager to spread the hedge across two or more different contracts.

Determining the Target for the Hedge

Having determined the right contract and the right delivery months, the manager then should determine what is expected from the hedge—that is, what rate will, on average, be locked in by the hedge. This is the *target rate* or *target price.* If this target rate is too high (if hedging a future sale) or too low (if hedging a future purchase), hedging may not be the right strategy for dealing with the unwanted risk. Determining what is expected (calculating the target rate or price for a hedge) is not always simple. We'll see how a manager should approach this problem for both simple and complex hedges.

Risk and Expected Return in a Hedge. When a manager enters into a hedge, the objective is to "lock in" a rate for the sale or purchase of a security. However, there is much disagreement about what rate or price a manager should expect to lock in when futures are used to hedge. Here are the two views:

View 1. The manager can, on average, lock in the current spot rate for the security (i.e., current rate in the cash market).

View 2. The manager can, on average, lock in the rate at which the futures contracts are bought or sold.

The truth usually lies somewhere in between these two views. However, as the following cases illustrate, each view is entirely correct in certain situations.

The Target for Hedges Held to Delivery. Hedges that are held until the futures delivery date provide an example of a hedge that locks in the futures rate (i.e., the second view). The complication in the case of using Treasury bond futures and Treasury note futures to hedge the value of intermediate- and long-term bonds is that because of the delivery options the manager does not know for sure when delivery will take place or which bond will be delivered. This is because of the delivery options granted to the short.[2]

To illustrate how a Treasury bond futures held to the delivery date locks in the futures rate, assume for the sake of simplicity that the manager knows which Treasury bond will be delivered and that delivery will take place on the last day of the delivery month. Suppose that for delivery on the September 1999 futures

2. These delivery options are explained in Chapter 61.

contract, the conversion factor for a deliverable Treasury issue is 1.283, implying that the investor who delivers this issue would receive from the buyer 1.283 times the futures settlement price plus accrued interest. An important principle to remember is that at delivery, the spot price and the futures price times the conversion factor must converge. *Convergence* refers to the fact that at delivery there can be no discrepancy between the spot price and futures price for a given security. If convergence does not take place, arbitrageurs would buy at the lower price and sell at the higher price and earn risk-free profits. Accordingly, a manager could lock in a September 1999 sale price for this issue by selling Treasury bond futures contracts equal to 1.283 times the par value of the bonds. For example, $100 million face value of this issue would be hedged by selling $128.3 million face value of bond futures (1,283 contracts).

The sale price that the manager locks in would be 1.283 times the futures price. This is the converted price. Thus, if the futures price is 113 when the hedge is set, the manager locks in a sale price of 144.979 (113 times 1.283) for September 1999 delivery, regardless of where rates are in September 1999. Exhibit 63-1 shows the cash flows for a number of final prices for this issue and illustrates how cash flows on the futures contracts offset gains or losses relative to the target price of 144.979.

Let's look at all the columns in Exhibit 63-1 and explain the computations for one of the scenarios—that is, for one actual sale price for the $11^{1}/_{4}$% Treasury bond. Consider the first actual sale price of 140. By convergence, at the delivery date the final futures price shown in column (2) must equal the Treasury bond's actual sale price adjusted by the conversion factor. Specifically, the adjustment is as follows. We know that

$$\text{Converted price} = \text{Treasury bond's price} \times \text{conversion factor}$$

and by convergence

$$\text{Final futures price} = \text{converted price}$$

so that

$$\text{Final futures price} = \text{Treasury bond's actual sale price} \times \text{conversion factor}$$

Thus, to compute the final futures price in column (2) of Exhibit 63-1 given the Treasury bond's actual sale price in column (1), the following is computed:

$$\text{Final futures price} = \frac{\text{Treasury bonds actual sale price}}{\text{conversion factor}}$$

Since the conversion factor is 1.283 for the $11^{1}/_{4}$% Treasury issue, for the first actual sale price of 140, the final futures price is

$$\text{Final futures price} = \frac{140}{1.283} = 109.1193$$

Column (3) shows the market value of the Treasury bonds. This is found by multiplying the actual sale price in column (1) by 100 to obtain the actual sale

EXHIBIT 63-1

Treasury Issue Hedge Held to Delivery

Instrument to be hedged: $100 million $11^{1}/_{4}$% Treasury Bonds of 2/15/15
Conversion factor for September 1999 = 1.283
Price of futures contract when sold = 113
Target price = (1.283 × 113) = 144.979
Par value hedged = $100,000,000
Number of futures contracts = 1,283
Futures position = Target = $144,979,000

†Bond futures trade in even increments of 1/32. Accordingly, the futures prices and margin flows are only approximate.
‡Transaction costs and the financing of margin flows are ignored.

price per $1 of par value and then multiplying by the $100 million par value. That is,

$$\text{Market value of Treasury bonds} = (\text{actual sale price}/100) \times \$100{,}000{,}000$$

For the actual sale price of 140, the value in column (3) is

$$\begin{aligned}\text{Market value of Treasury bonds} &= (140/100) \times \$100{,}000{,}000\\ &= \$140{,}000{,}000\end{aligned}$$

Column (4) shows the value of the futures position at the delivery date. This value is computed by first dividing the futures price shown in column (2) by

100 to obtain the futures price per \$1 of par value. Then this value is multiplied by the par value per contract of \$100,000 and further multiplied by the number of futures contracts. That is,

$$\text{Value of futures position}$$
$$= (\text{final futures price}/100) \times \$100{,}0000 \times \text{number of futures contracts}$$

In our illustration, the number of futures contracts is 1,283. For the actual sale price of the bond of 140, the final futures price is 109.1193. Thus, the value shown in column (4) is

$$\text{Value of futures position} = (109.1193/100) \times \$100{,}000 \times 1{,}283$$
$$= \$140{,}000{,}062$$

The value shown in column (4) is \$140,000,000 because the final futures price of 109.1193 was rounded. Using more decimal places, the value would be \$140,000,000.

Now let's look at the gain or loss from the futures position. This value is shown in column (5). Recall that the futures contract was shorted. The futures price at which the contracts were sold was 113. Thus, if the final futures price exceeds 113, this means that there is a loss on the futures position—that is, the futures contract is purchased at a price greater than for which it was sold. In contrast, if the futures price is less than 113, this means that there is a gain on the futures position—that is, the futures contract is purchased at a price less than for which it was sold. The gain or loss is determined by the following formula:

$$(113/100 - \text{final futures price}/100) \times \$100{,}000 \times \text{number of futures contracts}$$

In our illustration, for a final futures price of 109.1193 and 1,283 futures contracts, we have

$$(113/100 - 109.1193/100) \times \$100{,}000 \times 1{,}283 = \$4{,}978{,}938.1$$

The value shown in column (5) is \$4,979,000 because that is the more precise value using more decimal places for the final futures price than shown in Exhibit 63-1. The value is positive, which means that there is a gain in the futures position. Note that for all the final futures prices above 113 in Exhibit 63-1, there is a negative value, which means that there is a loss on the futures position.

Finally, column (6) shows the effective sale price for the Treasury bond. This value is found as follows:

$$\text{Effective sale price for Treasury bond}$$
$$= \text{actual sale price of Treasury bond} + \text{gain or loss on futures position}$$

For the actual sale price of \$140 million, the gain is \$4,979,000. Therefore, the effective sale price for the Treasury bond is

$$\$140{,}000{,}000 + \$4{,}979{,}000 = \$144{,}979{,}000$$

Note that this is the target price for the Treasury bond. In fact, it can be seen from column (6) of Exhibit 63-1 that the effective sale price for all the actual sale prices for the Treasury bond is the target price. However, the target price is determined by the futures price, so the target price may be higher or lower than the cash (spot) market price when the hedge is set.

When we admit the possibility that bonds other than the deliverable issue used in our illustration can be delivered and that it might be advantageous to deliver other issues, the situation becomes somewhat more involved. In this more realistic case, the manager may decide not to deliver this issue, but if she does decide to deliver it, the manager is still assured of receiving an effective sale price of approximately 144.979. If the manager does not deliver this issue, it would be because another issue can be delivered more cheaply, and thus the manager does better than the targeted price.

In summary, if a manager establishes a futures hedge that is held until delivery, the manager can be assured of receiving an effective price dictated by the futures rate (not the spot rate) on the day the hedge is set.

The Target for Hedges with Short Holding Periods. When a manager must lift (remove) a hedge prior to the delivery date, the effective rate that is obtained is much more likely to approximate the current spot rate than the futures rate the shorter the term of the hedge. The critical difference between this hedge and the hedge held to the delivery date is that convergence generally will not take place by the termination date of the hedge.

To illustrate why a manager should expect the hedge to lock in the spot rate rather than the futures rate for very short-lived hedges, let's return to the simplified example used earlier to illustrate a hedge to the delivery date. It is assumed that this issue is the only deliverable Treasury bond for the Treasury bond futures contract. Suppose that the hedge is set three months before the delivery date, and the manager plans to lift the hedge after one day. It is much more likely that the spot price of the bond will move parallel to the converted futures price (i.e., the futures price times the conversion factor) than that the spot price and the converted futures price will converge by the time the hedge is lifted.

A one-day hedge is, admittedly, an extreme example. Other than underwriters, dealers, and traders who reallocate assets very frequently, few money managers are interested in such a short horizon. The very short-term hedge does, however, illustrate a very important point: *when hedging, a manager should not expect to lock in the futures rate (or price) just because he is hedging with futures contracts*. The futures rate is locked in only if the hedge is held until delivery, at which point convergence must take place. If the hedge is held for only one day, the manager should expect to lock in the one-day forward rate,[3] which will very nearly equal the spot rate. Generally, hedges are held for more than one day but not necessarily to delivery.

3. Forward rates are covered in Chapter 31.

How the Basis Affects the Target Rate for a Hedge. The proper target for a hedge that is to be lifted prior to the delivery date depends on the basis. The *basis* is simply the difference between the spot (cash) price of a security and its futures price; that is:

$$\text{Basis} = \text{spot price} - \text{futures price}$$

In the bond market, a problem arises when trying to make practical use of the concept of the basis. The quoted futures price does not equal the price that one receives at delivery. For the Treasury bond and note futures contracts, the actual futures price equals the quoted futures price times the appropriate conversion factor. Consequently, to be useful, the basis in the bond market should be defined using actual futures delivery prices rather than quoted futures prices. Thus the price basis for bonds should be redefined as

$$\text{Price basis} = \text{spot price} - \text{futures delivery price}$$

For hedging purposes, it is also useful frequently to define the basis in terms of interest rates rather than prices. The *rate basis* is defined as

$$\text{Rate basis} = \text{spot rate} - \text{futures rate}$$

where spot rate refers to the current rate on the instrument to be hedged and the futures rate is the interest rate corresponding to the futures delivery price of the deliverable instrument.

The rate basis is helpful in explaining why the two views of hedges explained earlier are expected to lock in such different rates. To see this, we first define the *target rate basis*. This is defined as the expected rate basis on the day the hedge is lifted. A hedge lifted on the delivery date is expected to have, and by convergence will have, a zero rate basis when the hedge is lifted. Thus the target rate for the hedge should be the rate on the futures contract plus the expected rate basis of zero or, in other words, just the futures rate. When a hedge is lifted prior to the delivery date, one would not expect the basis to change very much in one day, so the target rate basis equals the futures rate plus the current difference between the spot rate and futures rate, that is, the current spot rate.

The manager can set the target rate for any hedge equal to the futures rate plus the target rate basis. That is,

$$\text{Target rate for hedge} = \text{futures rate} + \text{target rate basis}$$

If projecting the basis in terms of price rather than rate is more manageable (as is often the case for intermediate- and long-term futures), it is easier to work with the target price basis instead of the target rate basis. The *target price basis* is just the projected price basis for the day the hedge is to be lifted. For a deliverable security, the target for the hedge then becomes

$$\text{Target price for hedge} = \text{futures delivery price} + \text{target price basis}$$

The idea of a target price or rate basis explains why a hedge held until the delivery date locks in a price with certainty, and other hedges do not. The examples have shown that this is true. For the hedge held to delivery, there is no uncertainty surrounding the target basis; by convergence, the basis on the day the hedge is lifted is certain to be zero. For the short-lived hedge, the basis probably will approximate the current basis when the hedge is lifted, but its actual value is not known. For hedges longer than one day but ending prior to the futures delivery date, there can be considerable basis risk because the basis on the day the hedge is lifted can end up being anywhere within a wide range. Thus the uncertainty surrounding the outcome of a hedge is directly related to the uncertainty surrounding the basis on the day the hedge is lifted (i.e., the uncertainty surrounding the target basis).

The uncertainty about the value of the basis at the time the hedge is removed is called *basis risk*. For a given investment horizon, hedging substitutes basis risk for price risk. Thus one trades the uncertainty of the price of the hedged security for the uncertainty of the basis. Consequently, when hedges do not produce the desired results, it is customary to place the blame on basis risk. However, basis risk is the real culprit only if the target for the hedge is defined properly. Basis risk should refer only to the unexpected or unpredictable part of the relationship between cash and futures prices. The fact that this relationship changes over time does not in itself imply that there is basis risk.

Basis risk, properly defined, refers only to the uncertainty associated with the target rate basis or target price basis. Accordingly, it is imperative that the target basis be defined properly if one is to assess the risk and expected return in a hedge correctly.

Determining the Number of Futures Contracts

The final step that must be determined before the hedge is set is the number of futures contracts needed for the hedge. This is called the *hedge ratio*. Usually the hedge ratio is expressed in terms of relative par amounts. Accordingly, a hedge ratio of 1.20 means that for every $1 million par value of securities to be hedged, one needs $1.2 million par value of futures contracts to offset the risk. *In our discussion, the values are defined so that the hedge ratio is the number of futures contracts.*

Earlier we defined a cross-hedge in the futures market as a hedge in which the security to be hedged is not deliverable on the futures contract used in the hedge. For example, a manager who wants to hedge the sale price of long-term corporate bonds might hedge with the Treasury bond futures contract, but since non-Treasury bonds cannot be delivered in satisfaction of the contract, the hedge would be considered a cross-hedge. A manager also might want to hedge a rate that is of the same quality as the rate specified in one of the contracts but that has a different maturity. For example, it is necessary to cross-hedge a Treasury bond, note, or bill with a maturity that does not qualify for delivery on any futures contract. Thus, when the security to be hedged differs from the futures contract specification in terms of either quality or maturity, one is led to the cross-hedge.

Conceptually, cross-hedging is somewhat more complicated than hedging deliverable securities because it involves two relationships. First, there is the relationship between the cheapest-to-deliver (CTD) issue and the futures contract.

Second, there is the relationship between the security to be hedged and the CTD. Practical considerations at times may lead a manager to shortcut this two-step relationship and focus directly on the relationship between the security to be hedged and the futures contract, thus ignoring the CTD altogether. However, in so doing, a manager runs the risk of miscalculating the target rate and the risk in the hedge. Furthermore, if the hedge does not perform as expected, the shortcut makes it difficult to tell why the hedge did not work out as expected.

The key to minimizing risk in a cross-hedge is to choose the right number of futures contracts. This depends on the relative dollar duration of the bond to be hedged and the futures position. Equation (63-4) indicated the number of futures contracts to achieve a particular target dollar duration. The objective in hedging is to make the target dollar duration equal to zero. Substituting zero for target dollar duration in Eq. (63-4) we obtain

$$\text{Number of futures contracts} = -\frac{\text{current dollar duration without futures}}{\text{dollar duration per futures contract}} \tag{63-5}$$

To calculate the dollar duration of a bond, the manager must know the precise point in time that the dollar duration is to be calculated (because volatility generally declines as a bond matures), as well as the price or yield at which to calculate dollar duration (because higher yields generally reduce dollar duration for a given yield change). The relevant point in the life of the bond for calculating volatility is the point at which the hedge will be lifted. Dollar duration at any other point is essentially irrelevant because the goal is to lock in a price or rate only on that particular day. Similarly, the relevant yield at which to calculate dollar duration initially is the target yield. Consequently, the numerator of Eq. (63-5) is the dollar duration on the date the hedge is expected to be delivered. The yield that is to be used on this date in order to determine the dollar duration is the forward rate.

Let's look at how we apply Eq. (63-5) when using the Treasury bond futures contract to hedge. The number of futures contracts will be affected by the dollar duration of the CTD issue. We can modify Eq. (63-5) as follows:

$$\begin{aligned}\text{Number of futures contracts} &= -\frac{\text{current dollar duration without futures}}{\text{dollar duration of the CTD issue}}\\ &\quad\times\frac{\text{dollar duration of the CTD issue}}{\text{dollar duration per futures contract}}\end{aligned} \tag{63-6}$$

As noted earlier, the conversion ratio for the CTD issue is a good approximation of the second ratio. Thus Eq. (63-6) can be rewritten as

$$\begin{aligned}\text{Number of futures contracts} &= -\frac{\text{current dollar duration without futures}}{\text{dollar duration of the CTD issues}}\\ &\quad\times\text{conversion factor for the CTD issue}\end{aligned} \tag{63-7}$$

An Illustration. An example for a single bond shows why dollar duration weighting leads to the correct number of contracts to use to hedge. The hedge illustrated is a cross-hedge. Suppose that on 6/24/99 a manager owned $10 million par value of a 6.25% Fannie Mae (FNMA) option-free bond maturing on 5/15/29 selling at 88.39 to yield 7.20%. The manager wants to sell September 1999 Treasury bond futures to hedge a future sale of the FNMA bond. At the time, the price of the September Treasury bond futures contract was at 113. The CTD issue was the 11.25% of 2/15/15 issue that was trading at the time at 146.19 to yield 6.50%. The conversion factor for the CTD issue was 1.283. To simplify, assume that the yield spread between the FNMA bond and the CTD issue remains at 0.70% (i.e., 70 basis points) and that the anticipated sale date is the last business day in September 1999.

The target price for hedging the CTD issue would be 144.979 (from 113 × 1.283), and the target yield would be 6.56% (the yield at a price of 144.979). Since the yield on the FNMA bond is assumed to stay at 0.70% above the yield on the CTD issue, the target yield for the FNMA bond would be 7.26%. The corresponding price for the FNMA bond for this target yield is 87.76. At these target levels, the dollar duration for a 50 basis point change in rates for the CTD issue and FNMA bond per $100 of par value is $6.255 and $5.453, respectively. As indicated earlier, all these calculations are made using a settlement date equal to the anticipated sale date, in this case the end of September 1999. The dollar duration for $10 million par value of the FNMA bond is then $545,300 ($10 million/100 times $5.453). Per $100,000 par value for the CTD issue, the dollar duration per futures contract is $6,255 ($100,000/100 times $6.255).

Thus we know

$$\begin{aligned}&\text{Current dollar duration without futures}\\&\qquad = \text{dollar duration of the FNMA bond}\\&\qquad = \$545{,}300\end{aligned}$$

$$\text{Dollar duration of the CTD issue} = \$6{,}255$$

$$\text{Conversion factor for CTD issue} = 1.283$$

Substituting these values into Eq. (63-7), we obtain

$$\text{Number of futures contracts} = \frac{\$545{,}300}{\$6{,}255} \times 1.283 = -112 \text{ contracts}$$

Consequently, to hedge the FNMA bond position, 112 Treasury bond futures contracts must be shorted.

Exhibit 63-2 uses scenario analysis to show the outcome of the hedge based on different prices for the FNMA bond at the delivery date of the futures contract. Let's go through each of the columns. Column (1) shows the assumed sale price for the FNMA bond, and column (2) shows the corresponding yield based on the actual sale price in column (1). This yield is found from the

EXHIBIT 63-2

Hedging a Nondeliverable Bond to a Delivery Date with Futures

Instrument to be hedged: $10 million FNMA 6.25% of 05/15/29
Price of FNMA as of hedge date (6/24/99) = 88.39
Conversion factor for September 1999 = 1.283
Price of futures contract when sold = 113
Target price for FNMA bonds = 87.76
Par value hedged = $10,000,000
Number of futures contracts = 112
Futures position = $12,656,000
Target market value for FNMA bonds = $8,776,000

(1) Actual Sale Price of FNMA Bonds	(2) Yield at Sale	(3) Yield of 11.25% Treasury Bond*	(4) Price of 11.25% Treasury Bond	(5) Futures Price†	(6) Value of Futures Position	(7) Gain or Loss on Futures Position	(8) Effective Sale Price‡
8,000,000	8.027	7.327	135.813	105.85581	11,855,850	800,150	8,800,150

*By assumption, the yield on the cheapest-to-deliver issue is 70 basis points lower than the yield on the FNMA bond.
†By convergence, the futures price equals the price of the cheapest-to-deliver issue divided by 1.283 (the conversion factor).
‡Transaction costs and the financing of margin flows are ignored.

price/yield relationship. Given the assumed sale price for the FNMA bond, the corresponding yield can be determined. Column (3) shows the yield for the CTD issue. This yield is computed based on the assumption regarding the yield spread of 70 basis points between the FNMA bond and the CTD issue. Thus, by subtracting 70 basis points from the yield for the FNMA bond in column (2), the yield on the CTD issue (the 11.25% of 2/15/15) is obtained. Given the yield for the CTD issue in column (3), the price per $100 of par value of the CTD issue can be computed. This CTD price is shown in column (4).

Now we must move from the price of the CTD issue to the futures price. As explained in the description of the columns in Exhibit 63-1, by dividing the price for the CTD issue shown in column (4) by the conversion factor of the CTD issue (1.283), the futures price is obtained. This price is shown in column (5).

The value of the futures position is found in the same way as in Exhibit 63-1. First, the futures price per $1 of par value is computed by dividing the futures price by 100. Then this value is multiplied by $100,000 (the par value for the contract) and the number of futures contracts. That is,

$$\text{Value of futures position} \\ = (\text{futures price}/100) \times \$100{,}0000 \times \text{number of futures contracts}$$

Since the number of futures contracts sold is 112,

$$\text{Value of futures position} = (\text{final futures price}/100) \times \$100{,}0000 \times 112$$

The values shown in column (6) use the preceding formula. Using the first assumed actual sale price for the FNMA of $8 million as an example, the corresponding futures price in column (5) is 105.85581. Therefore, the value of the futures position is

$$\begin{aligned}\text{Value of futures position} &= (105.85581/100) \times \$100{,}000 \times 112 \\ &= \$11{,}855{,}850\end{aligned}$$

Now let's calculate the gain or loss on the futures position shown in column (7). This is done in the same manner as explained for Exhibit 63-1. Since the futures price at which the contracts are sold at the inception of the hedge is 113, the gain or loss on the futures position is found as follows:

$$(113/100 - \text{final futures price}/100) \times \$100{,}000 \times \text{number of futures contracts}$$

For example, for the first scenario in Exhibit 63-2, the futures price is 105.85581, and 112 futures contract were sold. Therefore,

$$(113/100 - 105.85581/100) \times \$100{,}000 \times 112 = \$800{,}150$$

There is a gain from the futures position because the futures price is less than 113. Note that for all the final futures prices above 113 in Exhibit 63-2, there is a negative value, which means that there is a loss on the futures position. For all futures prices below 113, there is a profit.

Finally, column (8) shows the effective sale price for the FNMA bond. This value is found as follows:

$$\text{Effective sale price for FNMA bond} \\ = \text{actual sale price of FNMA bond} + \text{gain or loss on futures position}$$

For the actual sale price of \$8 million, the gain is \$800,150. Therefore, the effective sale price for the FNMA bond is

$$\$8{,}000{,}000 + \$800{,}150 = \$8{,}800{,}150$$

Looking at column (8) of Exhibit 63-2, we see that if the simplifying assumptions hold, a futures hedge using the recommended number of futures contracts (112) very nearly locks in the target price for \$10 million par value of the FNMA bonds.

Refining for Changing Yield Spread. Another refinement in the hedging strategy is usually necessary for hedging nondeliverable securities. This refinement concerns the assumption about the relative yield spread between the CTD issue and the bond to be hedged. In the prior discussion, we assumed that the yield spread was constant over time. Yield spreads, however, are not constant over time. They vary with the maturity of the instruments in question and the level of rates, as well as with many unpredictable and nonsystematic factors.

Regression analysis allows the manager to capture the relationship between yield levels and yield spreads and use it to advantage. For hedging purposes, the variables are the yield on the bond to be hedged and the yield on the CTD issue. The regression equation takes the form

$$\text{Yield on bond to be hedged} = a + b \times \text{yield on CTD issue} + \text{error} \qquad (63\text{-}8)$$

The regression procedure provides an estimate of b, which is the expected relative yield change in the two bonds. This parameter b is called the *yield beta*. Our example that used constant spreads implicitly assumes that the yield beta b equals 1.0 and a equals 0.70 (because 0.70 is the assumed spread).

For the two issues in question, that is, the FNMA bond and the CTD issue, suppose that the estimated yield beta was 1.05. Thus yields on the FNMA issue are expected to move 5% more than yields on the Treasury issue. To calculate the number of futures contracts correctly, this fact must be taken into account; thus the number of futures contracts derived in our earlier example is multiplied by the factor 1.05. Consequently, instead of shorting 112 Treasury bond futures contracts to hedge \$10 million of the FNMA bond, the investor would short 118 (rounded up) contracts.

The formula for the number of futures contracts is revised as follows to incorporate the impact of the yield beta:

$$\begin{aligned}\text{Number of futures contracts} = &-\frac{\text{current dollar duration without futures}}{\text{dollar duration of the CTD issue}} \\ &\times \text{ conversion factor for the CTD issue} \\ &\times \text{ yield beta} \qquad (63\text{-}9)\end{aligned}$$

where the yield beta is derived from the yield of the bond to be hedged regressed on the yield of the CTD issue (Eq. 63-8).

The effect of a change in the CTD issue and the yield spread can be assessed before the hedge is implemented. An exhibit similar to that of Exhibit 63-2 can be constructed under a wide range of assumptions. For example, at different yield levels at the date the hedge is to be lifted (the second column in Exhibit 63-2), a different yield spread may be appropriate and a different acceptable issue will be the CTD issue. The manager can determine what this will do to the outcome of the hedge.

Monitoring and Evaluating the Hedge

After a target is determined and a hedge is set, there are two remaining tasks. The hedge must be monitored during its life and evaluated after it is over. Most futures hedges require very little active monitoring during their life. In fact, overactive management poses more of a threat to most hedges than does inactive management. The reason for this is that the manager usually will not receive enough new information during the life of the hedge to justify a change in the hedging strategy. For example, it is not advisable to readjust the hedge ratio every day in response to a new data point and a possible corresponding change in the estimated value of the yield beta.

There are, however, exceptions to this general rule. As rates change, dollar duration changes. Consequently, the hedge ratio may change slightly. In other cases, there may be sound economic reasons to believe that the yield beta has changed. While there are exceptions, the best approach is usually to let a hedge run its course using the original hedge ratio with only slight adjustments.

A hedge normally can be evaluated only after it has been lifted. Evaluation involves, first, an assessment of how closely the hedge locked in the target rate—that is, how much error there was in the hedge. To provide a meaningful interpretation of the error, the manager should calculate how far from the target the sale (or purchase) would have been had there been no hedge at all. One good reason for evaluating a completed hedge is to ascertain the sources of error in the hedge in the hope that the manager will gain insights that can be used to advantage in subsequent hedges. A manager will find that there are three major sources of hedging errors:

1. The dollar duration for the hedged instrument was incorrect.
2. The projected value of the basis at the date the hedge is removed can be in error.
3. The parameters estimated from the regression (a and b) can be inaccurate.

Recall from the calculation of duration in Chapter 5 that interest rates are changed up and down by a small number of basis points and the security is revalued. The two recalculated values are used in the numerator of the duration formula. The first problem just listed recognizes that the instrument to be hedged may be a complex instrument (i.e., one with embedded options) and that the valuation model does not do a good job of valuing the security when interest rates change.

The second major source of errors in a hedge—an inaccurate projected value of the basis—is the more difficult problem. Unfortunately, there are no satisfactory simple models like regression that can be applied to the basis. Simple models of the basis violate certain equilibrium relationships for bonds that should not be violated. On the other hand, theoretically rigorous models are very unintuitive and usually soluble only by complex numerical methods. Modeling the basis is undoubtedly one of the most important and difficult problems that managers seeking to hedge face.

HEDGING WITH OPTIONS

Hedging strategies using options involve taking a position in an option and a position in the underlying bond in such a way that changes in the value of one position will offset any unfavorable price (interest rate) movement in the other position. We begin with the basic hedging strategies using options. Then we illustrate these basic strategies using futures options to hedge the FNMA bond for which a futures hedge was used earlier in this chapter. Using futures options in our illustration of hedging the bond is a worthwhile exercise because it shows how complicated hedging with futures options is and the key parameters involved in the process. We also compare the outcome of hedging with futures and hedging with futures options.

Basic Hedging Strategies

There are three popular hedging strategies: (1) a protective put-buying strategy, (2) a covered call-writing strategy, and (3) a collar strategy. We discuss each strategy below.

Protective Put-Buying Strategy

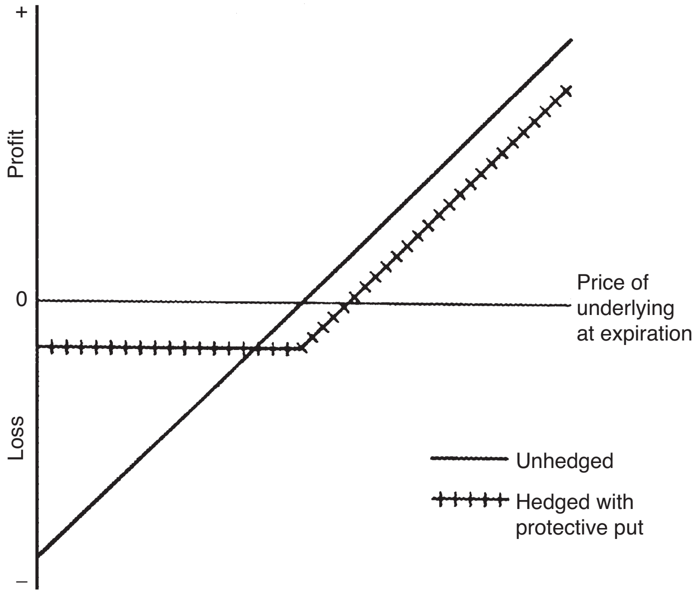
Consider a manager who has a bond and wants to hedge against rising interest rates. The most obvious options hedging strategy is to buy put options on bonds. This hedging strategy is referred to as a *protective put-buying strategy*. The puts are usually out-of-the-money puts and may be either puts on cash bonds or puts on interest-rate futures. If interest rates rise, the puts will increase in value (holding other factors constant), offsetting some or all of the loss on the bonds in the portfolio.

This strategy is a simple combination of a long put option with a long position in a cash bond. Such a position has limited downside risk, but large upside potential. However, if rates fall, the price appreciation on the bonds in the portfolio will be diminished by the amount paid to purchase the puts. Exhibit 63-3 compares the protective put-buying strategy to an unhedged position.

The protective put-buying strategy is very often compared with purchasing insurance. Like insurance, the premium paid for the protection is nonrefundable

EXHIBIT 63-3

Protective Put-Buying Strategy



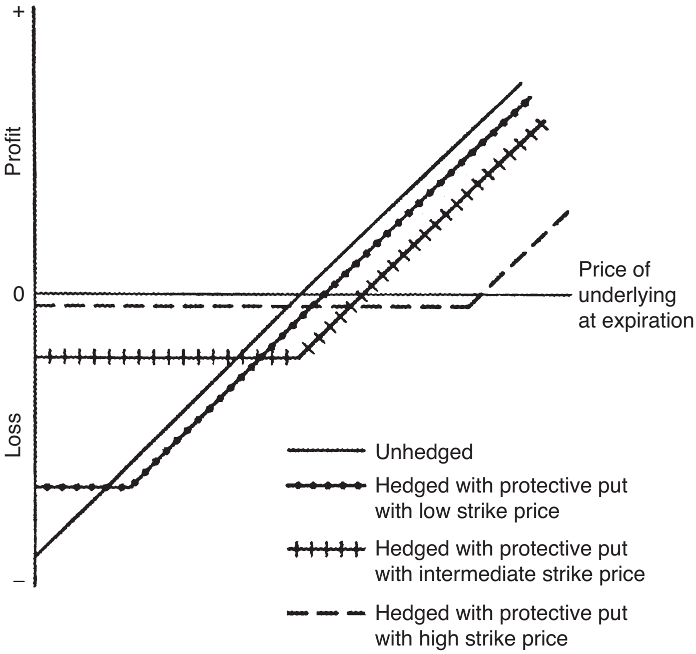
and is paid before the coverage begins. The degree to which a portfolio is protected depends on the strike price of the options; thus the strike price is often compared with the deductible on an insurance policy. The lower the deductible (i.e., the higher the strike price for the put), the greater is the level of protection, and the more the protection costs. Conversely, the higher the deductible (the lower the strike price on the put), the more the portfolio can lose in value, but the cost of the insurance is lower. Exhibit 63-4 compares an unhedged position with several protective put positions, each with a different strike price, or level of protection. As the exhibit shows, no one strategy dominates any other strategy, in the sense of performing better at all possible rate levels. Consequently, it is impossible to say that one strike price is necessarily the "best" strike price or even that buying protective puts is necessarily better than doing nothing at all.

Covered Call-Writing Strategy

Another options hedging strategy used by many portfolio managers is to sell calls against the bond portfolio. This hedging strategy is called a *covered call-writing strategy.* The calls that are sold are usually out-of-the-money calls and can be either calls on cash bonds or calls on interest-rate futures. Covered call writing is just an outright long position combined with a short call position. Obviously, this strategy entails much more downside risk than buying a put to protect the value

EXHIBIT 63-4

Protective Put-Buying Strategy with Different Strike Prices

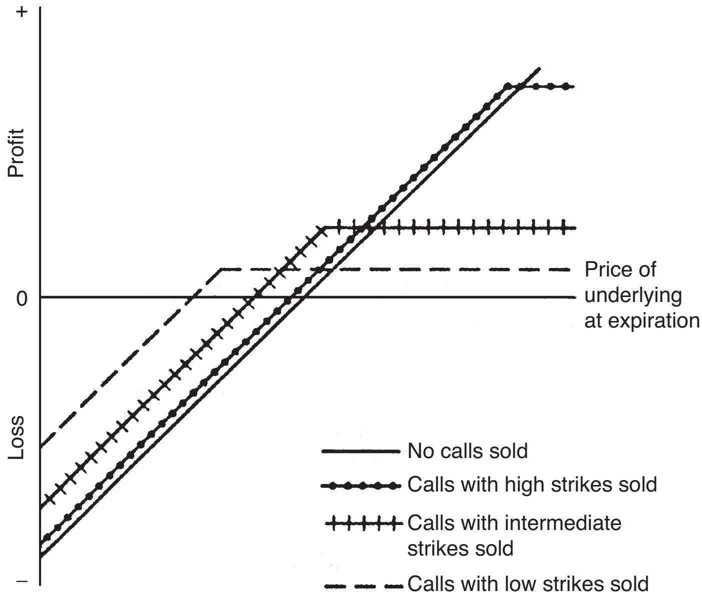


of the portfolio. In fact, many portfolio managers do not consider covered call writing a hedge.

Regardless of how it is classified, it is important to recognize that while covered call writing has substantial downside risk, it has less downside risk than an unhedged long position alone. On the downside, the difference between the long position alone and the covered call-writing strategy is the premium received for the calls that are sold. This premium acts as a cushion for downward movements in prices, reducing losses when rates rise. The cost of obtaining this cushion is that the manager gives up some of the potential on the upside. When rates decline, the call options become greater liabilities for the covered call writer. These incremental liabilities decrease the gains the manager would otherwise have realized on the portfolio in a declining rate environment. Thus the covered call writer gives up some (or all) of the upside potential of the portfolio in return for a cushion on the downside. The more upside potential that is forfeited (i.e., the lower the strike price on the calls), the more cushion there is on the downside. Exhibit 63-5 illustrates this point by comparing an unhedged position to several covered call-writing strategies, each with a different strike price. Like the protective put-buying strategy, there is no "right" strike price for the covered call writer.

EXHIBIT 63-5

Covered Call-Writing Strategy with Different Strike Prices



Collar Strategy

There are other hedging strategies employing options that are used frequently by managers. For example, many managers combine the protective put-buying strategy and the covered call-writing strategy. By combining a long position in an out-of-the-money put and a short position in an out-of-the-money call, the manager creates a long position in a *collar.* Consequently, this hedging strategy is called a *collar strategy*. The manager who uses the collar eliminates part of the portfolio's downside risk by giving up part of its upside potential. A long position hedged with a collar is shown in Exhibit 63-6.

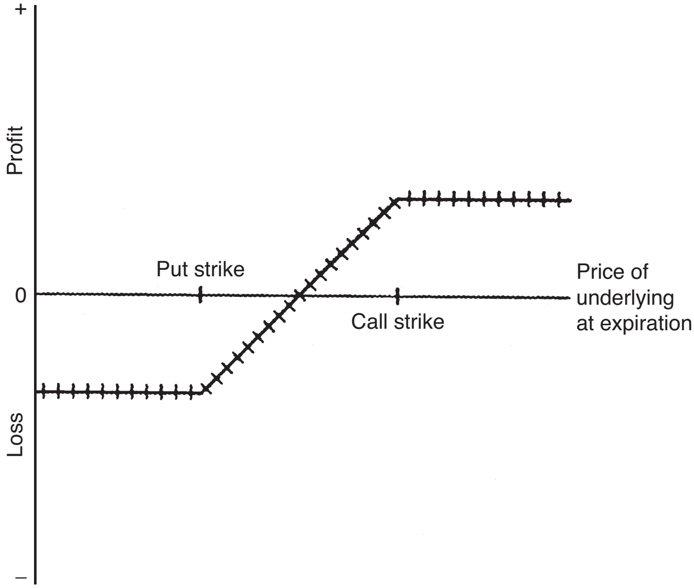
The collar in some ways resembles the protective put, in some ways resembles covered call writing, and in some ways resembles an unhedged position. The collar is like the protective put-buying strategy in that it limits the possible losses on the portfolio if interest rates go up. Like the covered call-writing strategy, the portfolio's upside potential is limited. Like an unhedged position, within the range defined by the strike prices, the value of the portfolio varies with interest rates.

Selecting the "Best" Strategy

Comparing the two basic strategies for hedging with options, one cannot say that the protective put-buying strategy or the covered call-writing strategy is necessarily

EXHIBIT 63-6

Long Position Hedged with a Collar



the better or more correct options hedge. The best strategy (and the best strike price) depends on the manager's view of the market. Purchasing a put and paying the required premium are appropriate if the manager is fundamentally bearish. If, instead, the manager is neutral to mildly bearish, it is better to receive the premium on the covered call-writing strategy. If the manager prefers to take no view on the market at all, and as little risk as possible, then the futures hedge is the most appropriate. If the manager is fundamentally bullish, then no hedge at all is probably the best strategy.

Steps in Options Hedging

Like hedging with futures, there are steps that managers should consider before setting their hedges. These steps include

Step 1. Determine the option contract that is the best hedging vehicle. The best option contract to use depends on several factors. These include option price, liquidity, and correlation with the bond(s) to be hedged. In price-inefficient markets, the option price is important because not all options will be priced in the same manner or with the same volatility assumption. Consequently, some options may be overpriced and some underpriced. Obviously, with other factors equal, it is better to use the underpriced options when buying and the overpriced options when selling.

Whenever there is a possibility that the option position may be closed out prior to expiration, liquidity is also an important consideration. If the particular option is illiquid, closing out a position may be prohibitively expensive, and the manager loses the flexibility of closing out positions early or rolling into other positions that may become more attractive. Correlation with the underlying bond(s) to be hedged is another factor in selecting the right contract. The higher the correlation, the more precisely the final profit and loss can be defined as a function of the final level of rates. Poor correlation leads to more uncertainty.

While most of the uncertainty in an options hedge usually comes from the uncertainty of interest rates themselves, the degree of correlation between the bonds to be hedged and the instruments underlying the options contracts add to that risk. The lower the correlation, the greater the risk.

Step 2. Find the appropriate strike price. For a cross-hedge, the manager will want to convert the strike price on the options that are actually bought or sold into an equivalent strike price for the actual bonds being hedged.

Step 3. Determine the number of contracts. The hedge ratio is the number of options to buy or sell.

Steps 2 and 3, determining the strike price and the number of contracts, can best be explained with examples using futures options.

Protective Put-Buying Strategy Using Futures Options

As explained earlier, managers who want to hedge their bond positions against a possible increase in interest rates will find that buying puts on futures is one of the easiest ways to purchase protection against rising rates. To illustrate a protective put-buying strategy, we can use the same FNMA bond that we used to demonstrate how to hedge with Treasury bond futures.[4] In that example, a manager held $10 million par value of a 6.25% FNMA bond maturing 5/15/29 and used September 1999 Treasury bond futures to lock in a sale price for those bonds on the futures delivery date. Now we want to show how the manager could use futures options instead of futures to protect against rising rates.

4. As explained in Chapter 61, futures options on Treasury bonds are used more commonly by institutional investors. The mechanics of futures options are as follows: If a put option is exercised, the option buyer receives a short position in the underlying futures contract and the option writer receives the corresponding long position. The futures price for both positions is the strike price for the put option. The exchange then marks the positions to market and the futures price for both positions is then the current futures price. If a call option is exercised, the option buyer receives a long position in the underlying futures contract and the option writer receives the corresponding short position. The futures price for both positions is the strike price for the call option. The exchange then marks the positions to market and the futures price for both positions is then the current futures price.

On 6/24/99, the FNMA bond was selling for 88.39 to yield 7.20%, and the CTD issue's yield was 6.50%. For simplicity, it is assumed that the yield spread between the FNMA bond and the CTD issue remains at 70 basis points.

Selecting the Strike Price

The manager must determine the minimum price that he wants to establish for the FNMA bonds. In our illustration, we will assume that the minimum price before the cost of the put options purchased is 84.453. This is equivalent to saying that the manager wants to establish a strike price for a put option on the hedged bonds of 84.453. But the manager is not buying a put option on the FNMA bond. He is buying a put option on a Treasury bond futures contract. Therefore, the manager must determine the strike price for a put option on a Treasury bond futures contract that is equivalent to a strike price of 84.453 for the FNMA bond.

This can be done with the help of Exhibit 63-7. We begin at the top left-hand box of the exhibit. Since the minimum price is 84.453 for the FNMA bond, this means that the manager is attempting to establish a maximum yield of 7.573%. This is found from the relationship between price and yield: given a price of 84.453 for the FNMA bond, this equates to a yield of 7.573%. (This gets us to the lower left-hand box in Exhibit 63-7.) From the assumption that the spread between the FNMA bond and the cheapest-to-deliver issue is a constant 70 basis points, setting a maximum yield of 7.573% for the FNMA bond is equivalent to setting a maximum yield of 6.873% for the cheapest-to-deliver issue. (Now we are at the lower box in the middle column of Exhibit 63-7.) Given the yield of 6.873% for the CTD issue, the minimum price before the cost of the puts purchased can be determined (the top box in the middle column of the

EXHIBIT 63-7

Calculating Equivalent Strike Prices and Yields for Hedging with Futures Options

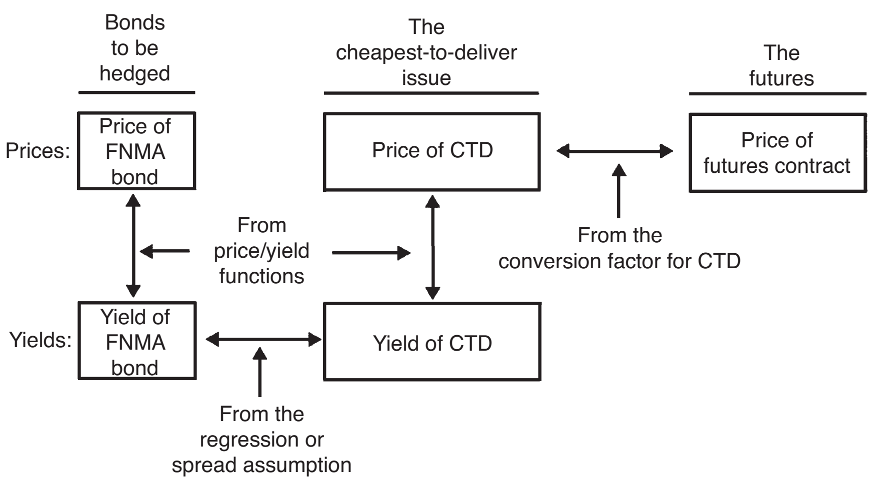


exhibit). A 6.873% yield for the CTD issue gives us a price of 141.136. (This is determined from the characteristics of the CTD issue.) The corresponding futures price is found by dividing the price of the CTD issue by the conversion factor. This gets us to the box in the right-hand column of Exhibit 63-7. Since the conversion factor is 1.283, the futures price is about 110 (141.136 divided by 1.283). This means that a strike price of 110 for a put option on a Treasury bond futures contract is roughly equivalent to a put option on our FNMA bond with a strike price of 84.453.

The foregoing steps are always necessary to obtain the appropriate strike price on a put futures option. The process is not complicated. It simply involves (1) the relationship between price and yield, (2) the assumed relationship between the yield spread between the bonds to be hedged and the cheapest-to-deliver issue, and (3) the conversion factor for the cheapest-to-deliver issue. As with hedging employing futures illustrated earlier in this chapter, the success of the hedging strategy will depend on (1) whether the cheapest-to-deliver issue changes and (2) the yield spread between the bonds to be hedged and the cheapest-to-deliver issue.

Calculating the Number of Options Contracts

The hedge ratio is determined using the following equation similar to Eq. (63-7) because we will assume a constant yield spread between the bond to be hedged and the cheapest-to-deliver issue:

$$\text{Number of options contracts} = \frac{\text{current dollar duration without options}}{\text{dollar duration of the CTD issue}} \times \text{conversion factor for CTD issue}$$

The dollar durations are as follows per 50 basis point change in rates:

Current dollar duration without options = \$512,320

Dollar duration of the CTD issue = \$6,021

Notice that the dollar durations are different from those used in calculating the number of futures contracts for the futures hedge. This is so because the dollar durations are calculated at prices corresponding to the strike price of the futures option (110) rather than the futures price (113). The number of futures options contracts is then

$$\text{Number of options contracts} = \frac{\$512{,}320}{\$6{,}021} \times 1.283 = 109 \text{ put options}$$

Thus, to hedge the FNMA bond position with put options on Treasury bond futures, 109 put options must be purchased.

Outcome of the Hedge

To create a table for the protective put hedge, we can use some of the numbers from Exhibit 63-2. Exhibit 63-8 shows the scenario analysis for the protective

EXHIBIT 63-8

Hedging a Nondeliverable Bond to a Delivery Date with Puts on Futures

Instrument to be hedged: $10 million FNMA 6.25% of 05/15/29
Price of FNMA as of hedge date (6/24/99) = 88.39
Conversion factor for September 1999 = 1.283
Price of futures contract when sold = 113
Target price per bond for FNMA bonds = 84.453
Effective minimum sale price = 83.908
Par value hedged = $10,000,000
Strike price for put = 110
Number of puts on futures = 109
Price per contract = $500.00
Cost of put position = $54,500

‡Does not include transaction costs or the financing of the options position.

put-buying strategy. The first five columns are the same as in Exhibit 63-2. For the put option hedge, column (6) shows the value of the put option position at the expiration date. The value of the put option position at the expiration date will be equal to zero if the futures price is greater than or equal to the strike price of 110.

If the futures price is below 110, then the options expire in the money, and the value of the put option position is

$$\text{Value of put option position} = (110/100 - \text{futures price}/100) \times \$100{,}000 \times \text{number of put options}$$

For example, for the first scenario in Exhibit 63-8 of \$8 million for the actual sale price of the FNMA bond, the corresponding futures price is 105.85581. The number of put options purchased is 109. Therefore

$$(110/100 - 105.85581/100) \times \$100{,}000 \times 109 = \$45{,}717$$

The effective sale price for the FNMA bonds is then equal to

$$\text{Effective sale price} = \text{actual sale price} + \text{value of put option position} - \text{option cost}$$

Let's look at the option cost. Suppose that the price of the put option with a strike price of 110 is \$500 per contract. With a total of 109 options, the cost of the protection is \$54,500 (109 × \$500, not including financing costs and commissions). This cost is shown in column (7) and is equivalent to 0.545 per \$100 par value hedged.

The effective sale price for the FNMA bonds for each scenario is shown in the last column of Exhibit 63-8. This effective sale price is never less than 83.908. This equals the price of the FNMA bonds equivalent to the futures strike price of 110 (i.e., 84.453) minus the cost of the puts (i.e., 0.545 per \$100 par value hedged). This minimum effective price is something that can be calculated before the hedge is ever initiated. (As prices decline, the effective sale price actually exceeds the target minimum sale price of 83.908 by a small amount. This is due only to rounding and the fact that the hedge ratio is left unaltered, although the relative dollar durations that go into the hedge ratio calculation change as yields change.) As prices increase, however, the effective sale price of the hedged bonds increases as well; unlike the futures hedge shown in Exhibit 63-2, the options hedge protects the investor if rates rise but allows the investor to profit if rates fall.

Covered Call-Writing Strategy with Futures Options

Unlike the protective put-buying strategy, covered call writing is not entered into with the sole purpose of protecting a portfolio against rising rates. The covered call writer, believing that the market will not trade much higher or much lower than its present level, sells out-of-the-money calls against an existing bond portfolio. The sale of the calls brings in premium income that provides partial protection in case rates increase. The premium received does not, of course, provide the kind of protection that a long put position provides, but it does provide some additional income that can be used to offset declining prices. If, instead, rates fall, portfolio appreciation is limited because the short call position constitutes a liability for the seller, and this liability increases as rates decline. Consequently, there is limited upside price potential for the covered call writer. Of course, this is not so bad if prices are essentially going nowhere; the added income from the sale of call options is obtained without sacrificing any gains.

To see how covered call writing with futures options works for the bond used in the protective put example, we construct a table much as we did before. With futures selling around 113 on the hedge initiation date, a sale of a 117 call option on futures might be appropriate. As before, it is assumed that the hedged bond will remain at a 70 basis point spread over the CTD issue. We also assume for simplicity that the price of the 117 calls is \$500 per contract. The number of options contracts sold will be the same, namely, 109 contracts for \$10 million face value of underlying bonds. Thus, the proceeds received from the sale of the 109 call options is \$54,500 (109 contracts × \$500) or 0.545 per \$100 par value hedged.

Exhibit 63-9 shows the outcomes of the covered call-writing strategy given these assumptions. The first five columns of the exhibit are the same as for Exhibit 63-8. In column (6), the liability resulting from the call option position is shown. The liability is zero if the futures price for the scenario is less than the strike price of 117. If the futures price for the scenario is greater than 117, the liability is calculated as follows:

$$(\text{Futures price}/100 - 117/100) \times \$100{,}000 \times \text{number of put options}$$

For example, consider the scenario in Exhibit 63-9, where the actual sale price of the FNMA bond is \$9.5 million. The corresponding futures price is 119.31255. The number of call options sold is 109. Therefore

$$(119.31255/100 - 117/100) \times \$100{,}000 \times 109 = \$252{,}068$$

That is,

$$\begin{aligned}\text{Effective sale price} = {} & \text{actual sale price} \\ & + \text{proceeds from sale of the call options} \\ & - \text{liability of call position}\end{aligned}$$

Since the proceeds from sale of the call options is \$54,500, then

$$\text{Effective sale price} = \text{actual sale price} + \$54{,}000 - \text{liability of call position}$$

The last column of Exhibit 63-9 shows the effective sale price for each scenario.

Just as the minimum effective sale price could be calculated beforehand for the protective put-buying strategy, the maximum effective sale price can be calculated beforehand for the covered call-writing strategy. The maximum effective sale price will be the price of the hedged bond corresponding to the strike price of the option sold plus the premium received. In this case, the strike price on the futures call option is 117. A futures price of 117 corresponds to a price of 150.111 (from 117 times the conversion factor of 1.283) and a corresponding

EXHIBIT 63-9

Writing Calls on Futures Against a Nondeliverable Bond

Instrument to be hedged: $10 million FNMA 6.25% of 05/15/29
Price of FNMA as of hedge date (6/24/99) = 88.39
Conversion factor for September 1999 = 1.283

8,400,000	8,781,481	8,389,763	8,454,500
8,500,000	8,779,171	8,445,500	8,554,500
8,600,000	8,778,170	8,545,500	8,654,500
8,700,000	8,777,256	8,645,500	8,754,500
8,800,000	8,776,343	8,745,500	8,854,500
8,900,000	8.776,739	8,845,500	9,954,500
9,000,000	8,777,222	8,945,500	9,054,500
9,100,000	8,779,015	9,045,500	9,154,500
9,200,000	8,782,117	9,145,500	9,254,500
9,300,000	8,785,306	9,245,500	9,289,593
9,400,000	8,788,496	9,345,500	9,295,375
9,500,000	8,792,995	9,445,500	9,302,432

assumed, the maximum effective sale price for the hedged bond is, in fact, slightly over 92.858. The discrepancies shown in the exhibit are due to rounding and the fact that the position is not adjusted even though the relative dollar durations change as yields change.

Comparing Alternative Strategies

In this chapter we reviewed three basic strategies for hedging a bond position: (1) hedging with futures, (2) hedging with out-of-the-money puts, and (3) covered call writing with out-of-the-money calls. Similar but opposite strategies exist for managers who are concerned that rates will decrease. As might be expected, there is no "best" strategy. Each strategy has its advantages and its disadvantages, and we never get something for nothing. To get anything of value, something else of value must be forfeited.

To make a choice among strategies, it helps to lay the alternatives side by side. Using the futures example and the futures options examples, Exhibit 63-10 shows the final values of the portfolio for the various hedging alternatives. It is easy to see from Exhibit 63-10 that if one alternative is superior to another alternative at one level of rates, it will be inferior at some other level of rates.

Consequently, we cannot conclude that one strategy is the best strategy. The manager who makes the strategy decision makes a choice among probability distributions, not usually among specific outcomes. Except for the perfect hedge, there is always some range of possible final values of the portfolio. Of course, exactly what that range is, and the probabilities associated with each possible outcome, is a matter of opinion.

Hedging with Options on Cash Instruments

Hedging a position with options on cash bonds is relatively straightforward. Most strategies, including the purchase of protective puts, covered call writing, and buying collars, are essentially the same whether futures options or options on physicals are used. There are some mechanical differences in the way the two types of option contracts are traded, and there may be substantial differences in their liquidity. Nonetheless, the basic economics of the strategies are virtually identical.

Using options on physicals frequently relieves the manager of much of the basis risk associated with a futures options hedge. For example, a manager of Treasury bonds or notes usually can buy or sell options on the exact security held in the portfolio. Using options on futures, rather than options on Treasury bonds, is sure to introduce additional elements of uncertainty.

Given the illustration presented earlier, and given that the economics of options on physicals and options on futures are essentially identical, additional illustrations for options on physicals are unnecessary. The only important difference is the hedge ratio calculation and the calculation of the equivalent strike price. To derive the hedge ratio, we always resort to an expression of relative dollar durations. Thus, for options on physicals assuming a constant spread, the hedge ratio is

$$\frac{\text{Current dollar duration without options}}{\text{Dollar duration of underlying for option}}$$

If a relationship is estimated between the yield on the bonds to be hedged and the instrument underlying the option, the appropriate hedge ratio is

$$\frac{\text{Current dollar duration without options}}{\text{Dollar duration of underlying for option}} \times \text{yield beta}$$

Unlike futures options, there is only one deliverable, so there is no conversion factor. When cross-hedging with options on physicals, the procedure for finding the equivalent strike price on the bonds to be hedged is very similar. Given the strike price of the option, the strike yield is easily determined using the price/yield relationship for the instrument underlying the option. Then, given the projected relationship between the yield on the instrument underlying the option and the yield on the bonds to be hedged, an equivalent strike yield is derived for the bonds to be hedged. Finally, using the yield-to-price formula for the bonds to be hedged, the equivalent strike price for the bonds to be hedged can be found.

KEY POINTS

- Buying an interest-rate futures contract increases a portfolio's duration; selling an interest-rate futures contract decreases a portfolio's duration.
- The advantages of adjusting a portfolio's duration using futures rather than cash-market instruments are that transaction costs are lower, margin requirements are lower, and short selling in the futures market is easier.
- The general principle in controlling interest-rate risk with futures is to combine the dollar exposure of the current portfolio and that of a futures position so that it is equal to the target dollar exposure. The number of futures contracts needed to achieve the target dollar duration depends on the current dollar duration of the portfolio without futures and the dollar duration per futures contract.
- Hedging with futures calls for taking a futures position as a temporary substitute for transactions to be made in the cash market at a later date, with the expectation that any loss realized by the manager from one position (whether cash or futures) will be offset by a profit on the other position.
- Hedging is a special case of controlling interest-rate risk in which the target duration or target dollar duration is zero.
- Cross-hedging occurs when the bond to be hedged is not identical to the bond underlying the futures contract. A short or sell hedge is used to protect against a decline in the cash price of a bond; a long or buy hedge is employed to protect against an increase in the cash price of a bond.
- The steps in hedging include (1) determining the appropriate hedging instrument, (2) determining the target for the hedge, (3) determining the position to be taken in the hedging instrument, and (4) monitoring and evaluating the hedge.
- The key factor to determine which futures contract will provide the best hedge is the degree of correlation between the rate on the futures contract and the interest rate that creates the underlying risk that the manager seeks to eliminate.
- The manager should determine the target rate or target price, which is what is expected from the hedge. The hedge ratio is the number of futures contracts needed for the hedge.

- The basis is the difference between the spot price (or rate) and the futures price (or rate).
- In general, when hedging to the delivery date of the futures contract, a manager locks in the futures rate or price. Hedging with Treasury bond futures and Treasury note futures is complicated by the delivery options embedded in these contracts. When a hedge is lifted prior to the delivery date, the effective rate (or price) that is obtained is much more likely to approximate the current spot rate than the futures rate the shorter the term of the hedge.
- The proper target for a hedge that is to be lifted prior to the delivery date depends on the basis. Basis risk refers only to the uncertainty associated with the target rate basis or target price basis.
- Hedging substitutes basis risk for price risk.
- Hedging non-Treasury securities with Treasury bond futures requires that the hedge ratio consider two relationships: (1) the cash price of the non-Treasury security and the cheapest-to-deliver issue, and (2) the price of the cheapest-to-deliver issue and the futures price.
- In computing the hedge ratio for nondeliverable securities, the yield beta should be considered; regression analysis is used to estimate the yield beta and captures the relationship between yield levels and yield spreads.
- After a target is determined and a hedge is set, the hedge must be monitored during its life and evaluated after it is over. It is important to ascertain the sources of error in a hedge in order to gain insights that can be used to advantage in subsequent hedges.
- Three popular hedge strategies using options are the protective put-buying strategy, the covered call-writing strategy, and the collar strategy.
- A manager can use a protective put-buying strategy to hedge against rising interest rates. A protective put-buying strategy is a simple combination of a long put option with a long position in a cash bond.
- A covered call-writing strategy involves selling call options against the bond portfolio. A covered call-writing strategy entails much more downside risk than buying a put to protect the value of the portfolio, and many managers do not consider covered call writing a hedge.
- It is not possible to say that the protective put-buying strategy or the covered call-writing strategy is necessarily the better or more correct options hedge. The best strategy (and the best strike prices) depends on the manager's view of the market.
- A collar strategy is a combination of a protective put-buying strategy and a covered call-writing strategy. A manager who implements a collar

strategy eliminates part of the portfolio's downside risk by giving up part of its upside potential.

- The steps in options hedging include determining the option contract that is the best hedging vehicle, finding the appropriate strike price, and determining the number of options contracts. At the outset of options hedging, a minimum effective sale price can be calculated for a protective put-buying strategy and a maximum effective sale price can be computed for a covered call-writing strategy.
- The best options contract to use depends on the option price, liquidity, and correlation with the bond(s) to be hedged.
- For a cross-hedge, the manager will want to convert the strike price for the options that are actually bought or sold into an equivalent strike price for the actual bonds being hedged. When using Treasury bond futures options, the hedge ratio is based on the relative dollar duration of the current portfolio, the cheapest-to-deliver issue, and the futures contract at the option expiration date, as well as the conversion factor for the cheapest-to-deliver issue.
- While there are some mechanical differences in the way options on physicals and options on futures are traded and there may be substantial differences in their liquidity, the basic economics of the hedging strategies are virtually identical for both contracts. Using options on physicals frequently relieves the manager of much of the basis risk associated with an options hedge.

CHAPTER

Financial institutions are routinely exposed to interest rate risks that arise from the fundamental nature of their business, as well as any interest rate uncertainty and volatility. This risk is especially severe for financial institutions that show a mismatch between the average duration of their assets and liabilities. In such cases, because the interest-rate sensitivity of assets and liabilities is not synchronized, any changes in market interest rates will have a disproportionate effect on the net worth of the institution. Given that direct restructuring of the asset and liability mix, which essentially involves changes in the contractual characteristics of such instruments, may not always be possible, institutions increasingly have to rely on synthetically managing the interest-rate exposure of the firm. This chapter and Chapter 67 examine the role of capital market innovations such as interest-rate swaps and interest-rate caps and floors (and derivatives such as interest rate collars and corridors) in asset/liability management. The focus in this chapter is on interest-rate swaps.

INTEREST-RATE SWAPS

An interest-rate swap is an agreement whereby two parties (called *counterparties*) agree to exchange periodic interest payments. The dollar amount of the interest payments exchanged is based on some predetermined dollar principal, which is called the *notional principal amount.* The dollar amount each counterparty

The authors thank Dr. John Breit for his contribution to earlier versions of this chapter.

pays to the other is the agreed-upon periodic interest rate multiplied by the notional principal amount. The only dollars that are exchanged between the parties are the interest payments, based on the notional principal amount (or simply *notional amount*). The notional amount also provides important documentation for corporate financial statements and helps determine the contingent liability of swap market-makers in the event that the market-maker is a regulated financial institution, such as a bank. The notional amount of swaps is also relevant for determining capital requirements.

FEATURES OF A GENERIC SWAP

In the most common type of swap, one party agrees to pay the other party fixed interest payments at designated dates for the life of the contract. This party is referred to as the *fixed-rate payer.* The other party agrees to make interest-rate payments that float with some index and is referred to as *the floating-rate payer.* The fixed-rate payment is determined as a spread over the relevant Treasury rate. Additionally, depending upon the credit risk of the counterparty, the spread may increase.

For example, suppose that for the next five years party X agrees to pay party Y 5% per year, while party Y agrees to pay party X six-month LIBOR. Party X is a fixed-rate payer/floating-rate receiver, while party Y is a floating-rate payer/fixed-rate receiver. Assume that the notional amount is $50 million, and that payments are exchanged every six months for the next five years. This means that every six months, party X (the fixed-rate payer/floating-rate receiver) will pay party Y $1.25 million (5% times $50 million divided by 2). The amount that party Y (the floating-rate payer/fixed-rate receiver) will pay party X will be six-month LIBOR times $50 million divided by 2. For example, if six-month LIBOR is 3%, party Y will pay party X $750,000 (3% times $50 million divided by 2). Note that we divide by two because a half-year's interest is being paid.

The interest-rate benchmarks that are commonly used for the floating rate in an interest-rate swap are those on various money market rates such as LIBOR,[1] Treasury bills, commercial paper composite, prime rate, certificate of deposit composite, and federal funds rate. Although the fixed rate at which the cash flows are determined is fixed over the life of the swap, the floating-rate cash flows vary based on the periodic valuation of the index at the swap reset date. Swaps may be structured so that the floating rate resets on a daily, weekly, monthly, quarterly, or semiannual basis for either monthly, quarterly, semiannual, or annual settlement.

Swap contracts are typically written between a market-maker or *swap dealer* and a nondealer financial institution. Since there is no exchange involved, the transaction is considered an over-the-counter (*OTC*) contract. However, the sheer

1. While many of the examples cited in this chapter reference LIBOR as the floating rate, we note that LIBOR is scheduled to be replaced by some form of the Secured Overnight Funding Rate (SOFR) and may not be published after 2020.

size and complex nature of the swap market, along with issues involved with sorting out the swap businesses of financial institutions that failed during the financial crisis that started in 2007, created concerns that the product was creating systemic risks to the financial system. As a result, the Dodd-Frank Act of 2010 reorganized much of swap trading around Swap Execution Facilities (*SEFs*) that "clear" contracts by acting as a centralized counterparty for transactions. While generic swaps are cleared, contracts with unusual terms and/or that are difficult to value are still executed *bilaterally* between counterparties and are not cleared through SEFs.

INTERPRETING A SWAP POSITION

There are two ways that a swap position can be interpreted: (1) as a package of forward/futures contracts and (2) as a package of cash flows from buying and selling cash market instruments.

Package of Forward Contracts

Interest-rate swaps can be viewed as a package of more basic interest-rate control tools, such as forward rate contracts. The pricing of an interest-rate swap will then depend on the price of a package of forward contracts with the same settlement dates and similar indices. Although an interest-rate swap may be nothing more than a package of forward contracts, it is not a redundant contract for several reasons. First, for forward or futures contracts, the longest maturity does not extend out as far as that of an interest-rate swap; an interest-rate swap with a term of 15 years or longer can be obtained. In view of this observation, the analogy with respect to forward/futures contracts applies mainly for short dated swaps since liquidity for futures/forwards is the highest for shorter maturities. Second, an interest-rate swap is a more transactionally efficient instrument; in one transaction an entity can effectively establish a payoff equivalent to a package of forward contracts. The forward contracts would each have to be negotiated separately. In recent years, due to the increased usage of swaps as hedging alternatives to Treasuries, the liquidity of the generic swap market has increased exponentially.

Package of Cash Market Instruments

In order to understand the equivalence of a swap as a package of cash market instruments, consider the following. Suppose that an investor enters into the following transaction:

- Buys \$50 million par of a five-year floating-rate bond that pays six-month LIBOR every six months.
- Finances the purchase of the five-year floating-rate bond by borrowing \$50 million for five years with the following terms: 5% annual interest rate paid every six months.

The cash flow of the above transaction is presented in Exhibit 64-1. The second column of the exhibit sets out the cash flow from purchasing the five-year floating-rate bond. There is a $50 million cash outlay and then cash inflows. The amount of the cash inflows is uncertain because they depend on future LIBOR. The third column shows the cash flow from borrowing $50 million on a fixed-rate basis. The last column shows the net cash flow from the entire transaction. As can be seen in the last column, there is no initial cash flow (no cash inflow or cash outlay). In all 10 six-month periods the net position results in a cash inflow of LIBOR and a cash outlay of $1.25 million. This net position, however, is identical to the position of a fixed-rate payer/floating-rate receiver.

EXHIBIT 64-1

Cash Flow for the Purchase of a Five-Year Floating-Rate Bond Financed by Borrowing on a Fixed-Rate Basis

	Cash Flow (in Millions of Dollars) from:		
Six-Month Period	Floating-Rate Bond	Borrowing Cost	Net(*)
0	–$50	+$50.0	$0
1	$+(\text{LIBOR}_1/2) \times 50$	–1.25	$+(\text{LIBOR}_1/2) \times 50 - 1.25$
2	$+(\text{LIBOR}_2/2) \times 50$	–1.25	$+(\text{LIBOR}_2/2) \times 50 - 1.25$
3	$+(\text{LIBOR}_3/2) \times 50$	–1.25	$+(\text{LIBOR}_3/2) \times 50 - 1.25$
4	$+(\text{LIBOR}_4/2) \times 50$	–1.25	$+(\text{LIBOR}_4/2) \times 50 - 1.25$
5	$+(\text{LIBOR}_5/2) \times 50$	–1.25	$+(\text{LIBOR}_5/2) \times 50 - 1.25$
6	$+(\text{LIBOR}_6/2) \times 50$	–1.25	$+(\text{LIBOR}_6/2) \times 50 - 1.25$
7	$+(\text{LIBOR}_7/2) \times 50$	–1.25	$+(\text{LIBOR}_7/2) \times 50 - 1.25$
8	$+(\text{LIBOR}_8/2) \times 50$	–1.25	$+(\text{LIBOR}_8/2) \times 50 - 1.25$
9	$+(\text{LIBOR}_9/2) \times 50$	–1.25	$+(\text{LIBOR}_9/2) \times 50 - 1.25$
10	$+(\text{LIBOR}_{10}/2) \times 50 + 50$	–51.25	$+(\text{LIBOR}_{10}/2) \times 50 - 1.25$

Transaction: Purchase for $50 million a five-year floating-rate bond: floating rate = LIBOR, semiannual payments

Borrow $50 million for five years: fixed rate = 5% semiannual payments

* The subscript for LIBOR indicates six-month LIBOR as per the terms of the floating-rate bond at time *t*.

It can be seen from the net cash flow in Exhibit 64-1 that a fixed-rate payer has a cash market position that is equivalent to a long position in a floating-rate bond and borrowing the funds to purchase the floating-rate bond on a fixed-rate basis. But the borrowing can be viewed as issuing a fixed-rate bond, or equivalently, being short a fixed-rate bond. Consequently, the position of a fixed-rate payer can be viewed as being long a floating-rate bond and short a fixed-rate bond.

What about the position of a floating-rate payer? It can be easily demonstrated that the position of a floating-rate payer is equivalent to purchasing a fixed-rate bond and financing that purchase at a floating rate, with the floating rate being the reference interest rate for the swap. That is, the position of a floating-rate payer is equivalent to a long position in a fixed-rate bond and a short position in a floating-rate bond.

TERMINOLOGY, CONVENTIONS, AND MARKET QUOTES

Here we review some of the terminology used in this market and explain how swaps are quoted.

The date that the counterparties commit to the swap is called the *trade date.* The date that the swap begins accruing interest is called the *effective date,* and the date that the swap stops accruing interest is called the *maturity date.* The *settlement date* refers to the actual date on which cash flows are exchanged.

Although our illustrations assume that the timing of the cash flows for both the fixed-rate payer and floating-rate payer will be the same, this is rarely the case in a swap. In fact, an agreement may call for the fixed-rate payer to make payments annually but the floating-rate payer to make payments more frequently (semiannually or quarterly). Also, the way interest accrues on each leg of the transaction differs, because there are several day-count conventions in the fixed income markets.

The terminology used to describe the position of a party in the swap markets is a blend of cash market jargon and futures jargon. The obvious reason as we just explained is that a swap position can be interpreted as a position in a package of cash market instruments or a package of futures/forward positions. The counterparty to an interest-rate swap is either a fixed-rate payer or floating-rate payer. There are a number of ways to describe these positions:

Fixed-Rate Payer

- Is short the bond market
- Has bought a swap
- Is long a swap
- Has established the price sensitivities of a longer-term liability and a floating-rate asset

Floating-Rate Payer

- Is long the bond market
- Has sold a swap
- Is short a swap
- Has established the price sensitivities of a longer-term asset and a floating-rate liability

To understand why the fixed-rate payer is viewed as short the bond market and the floating-rate payer is viewed as long the bond market, consider what happens when interest rates change. Those who borrow on a fixed-rate basis will benefit if interest rates rise because they have locked in a lower interest rate. But those who have a short bond position will also benefit if interest rates rise. Thus, a fixed-rate payer can be said to be short the bond market. A floating-rate payer benefits if interest rates fall. Because a long position in a bond benefits if interest rates fall, terminology describing a floating-rate payer as long the bond market has been adopted. From the discussion of both the interpretation of a swap as a package of cash market instruments above and the duration of a swap discussed later in this chapter, the description of a swap in terms of the sensitivities of long and short cash positions follows accordingly.

The convention that has evolved for quoting swaps levels is for a swap dealer to set the floating rate equal to the index and then quote the fixed rate that will apply. To illustrate this convention, consider the following 10-year swap offered by a dealer to market participants.

Floating-Rate Payer:
Pay floating rate of 6-month LIBOR
Received fixed rate of 3.75%

Fixed-Rate Payer:
Pay fixed rate of 3.85%
Receive floating rate of 6-month LIBOR

The offer price that the dealer would quote the fixed-rate payer would be to pay 3.85% and receive LIBOR flat. (The term *flat* means with no spread.) The bid price that the dealer would quote the floating-rate payer would be to pay LIBOR flat and receive 3.75%. The bid/offer spread is 10 basis points.

The fixed rate is some spread above the Treasury yield curve with the same term-to-maturity as the swap. In our illustration, suppose that the 10-year Treasury yield is 3.35%. Then the offer price that the dealer would quote to the fixed-rate payer is the 10-year Treasury rate plus 50 basis points versus receiving LIBOR flat. For the floating-rate payer, the bid price quoted would be LIBOR flat versus the 10-year Treasury rate plus 40 basis points. The dealer would quote the swap above as 40–50, meaning that it is willing to enter into a swap to receive LIBOR and pay a fixed rate equal to the 10-year Treasury rate plus 40 basis points; it would be willing to enter into a swap to pay LIBOR and receive a fixed rate equal to the 10-year Treasury rate plus 50 basis points. The difference between the Treasury rate paid and received is the bid/offer spread.

Swap spreads are driven by market supply and demand forces as well as credit risk considerations, and have varied over time. Prior to 2008, most swap spreads were generally positive, reflecting the perception that receiving fixed-rate cash flows as part of a contractual agreement was riskier than owning a

Treasury security. Since the financial crisis, however, most swap spreads have narrowed, and many have been negative for considerable periods of time. The factors driving swap spreads into negative territory continue to be debated, but can generally be narrowed down to several factors, including (1) the relative increases in Treasury supply due to consistent budget deficits, (2) the perception that the clearing of many transactions through Swap Execution Facilities (SEFs) has reduced counterparty exposure and improved the credit profile of swaps, and (3) changes in capital treatment that reduce dealers' incentives to pay fixed rates unless their rates (and spreads) are very low or negative.

APPLICATIONS

Here we describe how interest-rate swaps can be used in asset/liability management.

Converting Floating-Rate Debt to Fixed-Rate Debt Using Swaps

Fixed-rate payer/floating-rate receiver swaps can be used to convert floating-rate liabilities synthetically to fixed-rate liabilities because the floating cost of liabilities is "counterbalanced" by floating-rate receipts associated with the swap. Any increase or decrease in liability costs is matched by a similar change in the floating-rate inflows, as long as the notional amount of the swap is equal to the principal amount of the liability. The net effect of this strategy is to lock in the liability cost at a fixed rate as long as the swap is not terminated prior to maturity.

As an example, consider the case of a financial institution issuing floating-rate liabilities that are priced at a spread of 10 basis points over three-month LIBOR at a rate of 3.10%. The preponderance of the institution's assets, however, are fixed-rate instruments. As long as interest rates either remain stable or fall, the institution will be able to earn a spread over its floating-rate funding costs. However, if interest rates increase, the institution's spread will decrease. In order to synthetically convert the floating liability cost to fixed debt expense, the institution enters into an interest-rate swap for five years with another entity paying fixed and receiving floating cash flows. Suppose that the fixed-rate side of the swap is priced at a spread of 80 basis points over the five-year Treasury rate at a rate of 3.40% and that the floating side of the swap is three-month LIBOR at 3.00%. The funding cost to the institution in various interest-rate scenarios is illustrated in Exhibit 64-2.

In this example, if the institution had not swapped the floating-rate debt cost for fixed-rate cash flows, the liability rate would have repriced in every interest-rate scenario at a spread of 10 basis points over three-month LIBOR, assuming parallel shifts in the yield curve. By entering into the interest-rate swap, the floating outflow of the liability is partially canceled by the floating inflow from the swap in all interest-rate scenarios. The net funding cost is determined as follows:

Floating-rate liability cost + Fixed rate of swap – Floating rate of swap

The effectiveness of this strategy will depend on the extent of basis risk between the liability rate and the swap floating-rate index. In the previous example, because the liability rate and the floating side of the swap are both based on three-month LIBOR, there is no basis risk. However, in other instances, where the liability rate is keyed off another benchmark, such as the Treasury bill index or the prime rate, the existence of basis risk may mitigate the swap's effectiveness. For instance, if the liability rate increases by 1% and LIBOR increases by only 0.85%, the synthetic fixed rate will be 0.15% higher than it would have been in the absence of such imperfect correlation. Conversely, if the liability rate increases by 0.85% and LIBOR by 1%, the synthetic liability rate will be 0.15% lower than the swap fixed rate. The synthetic funding rate will also be affected by any discrepancies in the repricing frequency of the liability and the reset period of the swap. Ideally, close synchronization between these dates will minimize the deviation of the synthetic liability cost from the swap fixed rate that occurs because of reset date mismatch.

EXHIBIT 64-2

Converting Floating-Rate Debt to Fixed-Rate Debt Using Interest-Rate Swaps

		Swap Cash Flows		
Interest-Rate Scenario	**Liability Cost**	**Fixed Outflow**	**Floating Inflow (LIBOR)**	**New Funding Cost**
300 bps	6.10%	6.40%	6.00%	3.50%
200	5.10	5.40	5.00	3.5
100	4.10	4.40	4.00	3.5
Stable	3.10	3.40	3.00	3.5
–100	2.10	2.40	2.00	3.5
–200	1.10	1.40	1.00	3.5
–300	0.10	0.40	0.00	3.5

Converting Fixed-Rate Debt to Floating-Rate Debt Using Reverse Swaps

A similar strategy using reverse swaps, where the financial institution receives fixed-rate cash flows and pays floating-rate cash flows, is used to convert the fixed cost of liabilities to a synthetic floating rate. In this case, the fixed-rate interest cost of the liability is offset by the fixed-rate inflow of the swap. If the liability rate is higher (lower) than the swap fixed rate, then the synthetic floating rate will be higher (lower) than the swap floating rate. A financial institution that has fixed-rate debt and a preponderance of floating-rate assets, such as adjustable-rate mortgages, collateralized mortgage obligation (CMO) floater bonds, or floating-rate notes, may adopt this strategy to better match the average duration of their assets and liabilities.

As an example, consider the case of an institution that has three-year fixed-rate debt at a coupon rate of 3.85%. In order to convert this fixed-rate debt into floating-rate liabilities, the institution enters into a reverse swap (floating-rate payer/fixed-rate receiver) for three years. The terms of the swap involve paying three-month LIBOR and receiving fixed-rate cash flows at a spread of 65 basis points over the three-year Treasury yield at a rate of 3.70%. An illustration of this example is presented in Exhibit 64-3. An analysis of this illustration reveals that the effective funding cost is determined as follows:

Fixed-rate liability cost – Fixed rate of swap + Floating rate of swap

The institution has converted fixed-rate debt to LIBOR-based debt at a spread of 15 basis points over LIBOR. A schematic of the cash flows involved in synthetically converting floating-rate liability costs to fixed-rate funding, and vice versa, is presented in Exhibit 64-4. Although the dynamics of the cash flow are essentially reversed, most dealers will charge a higher spread (offer side) for fixed-rate-paying swaps than fixed-rate-receiving swaps (bid side). This bid/ask differential, which is a function of variables such as hedging costs, dealer inventory, relative supply of fixed- and floating-rate payers in the market, conditions in the Treasury market, and quality spreads in the domestic and international bond markets, is used to compensate the dealers for the market-making function.

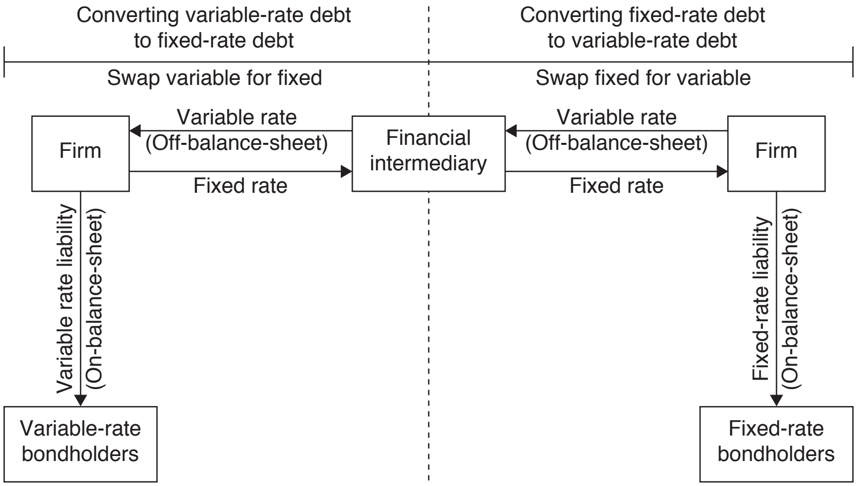
EXHIBIT 64-3

Converting Floating-Rate Debt to Fixed-Rate Debt Using Interest-Rate Swaps

		Swap Cash Flows		
Interest-Rate Scenario	**Liability Cost**	**Fixed Outflow**	**Floating Inflow (LIBOR)**	**New Funding Cost**
300 bps	3.85%	3.70%	6.00%	6.15%
200	3.85	3.70	5.00	5.15
100	3.85	3.70	4.00	4.15
Stable	3.85	3.70	3.00	3.15
–100	3.85	3.70	2.00	2.15
–200	3.85	3.70	1.00	1.15
–300	3.85	3.70	0.00	0.15

EXHIBIT 64-4

Synthetic Conversion of Interest-Rate Liability



In the foregoing discussion, it has been tacitly assumed that the payment frequencies and the payment basis of the fixed and floating legs of the swap and the liability being swapped are identical. Any differences in the frequencies or basis will change the net spread calculations. This observation also applies to asset swaps (discussed later). For example, in swapping a fixed liability to a floating-rate obligation, the net spread over LIBOR usually will be slightly different from the spread between the liability coupon and the coupon of the swap. This difference arises because swaps usually pay fixed on an actual/365 or 30 /360 basis and floating on an actual/360 basis. Hence, the net spread over LIBOR will be 360/365 of the nominal spread between coupons.

DOLLAR DURATION OF A SWAP

As with any fixed income contract, the value of a swap will change as interest rates change. As explained in Chapter 5, dollar duration is a measure of the change in the dollar value of an asset due to a change in interest rates. From our earlier discussion of how to interpret an interest-rate swap, it was explained that from the perspective of the party who pays floating and receives fixed, the position can be viewed as follows:

Long a fixed-rate bond – Short a floating-rate bond

This means that the dollar duration of an interest-rate swap from the perspective of a floating-rate payer is just the difference between the dollar duration of the two bond positions that constitute the swap. That is,

Dollar duration of a swap = Dollar duration of a fixed-rate bond –
Dollar duration of a floating-rate bond

Most of the interest-rate sensitivity of a swap will result from the dollar duration of the fixed-rate bond because the dollar duration of the floating-rate bond will be small. It will always be less than the length of time to the next reset date. Therefore, the dollar duration of a floating-rate bond for which the coupon rate resets every six months will be less than six months. The dollar duration of a floating-rate bond becomes smaller as the swap gets closer to its reset date.

INNOVATIONS IN SWAP MARKETS

In addition to allowing a firm to issue debt for which it has a comparative relative advantage and then swapping the cash flows to fine-tune the asset/liability gap, interest-rate swaps also serve other useful purposes, especially because of the off-balance-sheet treatment accorded them. It often has been argued that swaps are preferable to refunding because the latter often is constrained by restrictive covenants. Periodically, firms may want to make adjustments in the capital structure with respect to the composition of debt by refinancing longer-term debt with short-term debt at lower interest costs. In certain instances, this may not be easy to accomplish, especially if the debt is noncallable. Swaps provide an effective means to alter the covenants of a debt issue to accomplish asset/liability objectives without incurring the administrative, legal, and underwriting costs of issuing additional debt. In this case, the firm may swap the higher-coupon debt to a cheaper floating-rate liability based on a variety of indexes, such as the Treasury bill index, prime rate, and LIBOR. In recent years, swaptions have been increasingly used to contractually create callable liabilities at issuing entities.

In order to address such specific investor needs, several innovations, such as basis swaps, yield-curve swaps, amortizing swaps, asset swaps, forward swaps, equity swaps, and swaptions have been developed to further expand the degree of flexibility provided by generic swaps. A discussion of the salient features of these capital market innovations is presented in this section.

Basis Swaps

Basis swaps are designed to manage the basis risk inherent in a balance sheet where the asset returns and liability costs are based on different indexes. For instance, a financial institution that invests in a CMO floater with a return of 60 basis points over one-month LIBOR funded by six-month certificates of deposit at an interest cost of prime less 200 basis points is subject to basis risk, despite the minimal duration mismatch. This risk arises because the asset resets monthly off LIBOR, whereas the liability resets every six months based on movements in the prime rate. To alleviate this risk, the institution could enter into a floating-to-floating basis swap, where the institution receives cash flows that are reset every six months at a rate of prime less 150 basis points and pays swap cash flows on a monthly basis indexed off one-month LIBOR. The basis risk will be controlled for the *tenor,* or time period, of the swap.

As an illustration, assume one-month LIBOR is 3% and the prime rate is 4%. Without the basis swap, the spread earned by the institution is defined as the difference between the asset return and the liability cost, 1.60% (3.60% – 2.00%) in our illustration. (For the sake of simplicity, it is assumed that the asset returns are not constrained by caps inherent in CMO floaters.) Assuming that the correlation between the prime rate and one-month LIBOR is imperfect, in that a 1% change in the prime results in less or more than a 1% change in one-month LIBOR, the spread will not be maintained in all interest-rate scenarios. As previously indicated, the institution enters into a basis swap to lock in the spread over funding costs without incurring the basis risk between the prime rate and LIBOR. Although basis swaps are used most often to refine the interest-rate sensitivity of assets and liabilities, these swaps can also be used to arbitrage spreads between various funding sources. The dynamics of the basis swap are illustrated in Exhibit 64-5.

EXHIBIT 64-5

Locking in a Floating Spread over Funding Costs Using Basis Swaps

				Swap Cash Flows		
LIBOR	Asset Return[a]	Prime Rate	Liability Costs[b]	Floating Inflows[c]	Floating Outflows[d]	Net Spread[e]
1.00	1.60	3.00	1.00	1.50	1.00	1.10
3.00	3.60	4.00	2.00	2.50	3.00	1.10
5.00	5.60	6.00	4.00	4.50	5.00	1.10

[a] Asset return = LIBOR + 60 basis pionts.

[b] Liability costs = Prime – 200 basis points.

[c] Swap floating inflows = Prime – 150 basis points.

[d] Swap floating outflows = LIBOR.

[e] New spread = Asset return + Swap inflows – Liability costs – Swap outflows.

Yield-Curve Swaps

In a yield-curve swap, the counterparties agree to exchange payments based on the difference between interest rates at two points on a given yield curve. These swaps are therefore an example of a floating rate for floating-rate swap, or basis swap.

To illustrate a yield-curve swap, suppose party A agrees to receive six-month Treasury bill rate and to pay party B the yield on a 10-year Treasury minus 200 basis points, with the rate on both reset every six months. If at a reset date the six-month T-bill rate is 2.5% and 10-year Treasury yield is 4%, party A receives 2.5% and pays party B 2%. If the yield curve flattens such that the six-month Treasury bill rate is 3% and the 10-year Treasury is 3.5%, then party A receives 3% and pays 1.5%.

Amortizing and Accreting Swaps

In the preceding discussion, it was implicitly assumed that the notional amount does not change over the life of the swap. However, with respect to amortizing assets such as mortgage loans and other mortgage-backed instruments such as CMO bonds and automobile receivables, the spread over funding costs will not be maintained because of the asset principal balance declining over time. This declining spread is especially critical for assets whose average life and duration may exhibit dramatic changes due to the possibility of prepayments. In such instances, if bullet swaps with the same notional amount are used, there is the risk of being either underhedged or overhedged with respect to liability costs. If interest rates decrease and prepayments increase substantially, the average life of the asset will shorten. In such instances, the asset may not generate funds sufficient to earn a positive spread. On the other hand, if interest rates rise and prepayments slow down, resulting in an extension of the average life of the asset, the swap may have to be extended or additional swap coverage obtained (at higher cost, owing to bearish interest-rate conditions[2]) to maintain a positive spread.

In such instances, the institution may enter into an amortizing swap, which permits the notional amount of the swap, and hence the exchange of the cash flows, to change in accordance with the amortization rate of the asset. Note that the amortization rate of the notional amount cannot usually be changed over the life of the swap. Because the amortizing swap can be replicated by using a strip of swaps, the swap rate is determined as a blended rate of individual bullet swap rates. This feature of amortizing swaps also provides a market participant with the choice of entering into a series of swaps to match the amortization rate of assets or entering into an amortizing swap at an annual blended rate.

Although amortizing swaps improve the match between the asset and hedged liability cash flows, such swaps do not completely alleviate the risk of being overhedged with respect to liability costs. A major portion of this risk is mitigated for assets such as Planned Amortization Class (PAC) CMO bonds, which provide for a specified amortization rate within a wide band of prepayment scenarios. For assets that exhibit a higher degree of prepayment volatility, if falling interest rates lead to an increase in prepayments and an attendant shortening of average life, the firm may have to continue exchanging swap cash flows for a period longer than the average life of the asset, unless the swap can be terminated. An alternative version of amortizing swaps, labeled "balance guaranteed

2. A bearish interest-rate scenario refers to one in which rates are rising and market prices are falling (a bearish market). In a bullish interest-rate scenario, rates are falling, and market prices are rising.

swaps," has been used to guarantee floating-rate returns to investors. Rather than the swap's amortization being defined at a given rate, the swap's balance at any point in time is based on the actual outstanding balance of a reference pool of assets. The reference pool can be an MBS or ABS pool, a designated cohort, a CMO tranche, or some other asset that has variable balances.

In instances where the liability schedule is expected to increase, an interest-rate swap with an accreting balance may be used to fix the interest cost of the liabilities. Perhaps the most common example of this type of swap application is found in the construction industry, where accreting swaps may be used to fix the rate on a project funded with a floating-rate drawdown facility.

Forward Swaps

A forward swap allows a market participant to initiate a swap with a specified delayed start. Such swaps can be used to hedge debt refinancings or anticipated debt issuance in conjunction with expenditures expected in the future. For instance, suppose a firm has $200 million of noncallable fixed-rate debt maturing in three years. In order to lock in anticipated funding requirements three years hence for a period of five years at current rates, the firm could enter into a forward swap to pay fixed and receive floating cash flows starting three years from now. If rates have increased at the time of issuance, the firm would issue floating-rate debt and effectively convert the floating-rate funding to a fixed-rate liability, because the firm would be a floating-rate receiver.

Equity Swaps

In recent years, the concept of swapping cash flows has been applied to the equity area. In an *equity swap,* the cash flows that are swapped are based on the total return on some stock market index and an interest rate (either a fixed rate or a floating rate). Moreover, the stock market index can be a non-U.S. stock market index and the payments could be non-dollar denominated. For example, a money manager can enter into a two-year quarterly reset equity swap based on the German DAX market index versus LIBOR in which the money manager receives the market index in euros and pays the floating rate in euros.

Swaptions

Swaptions are representative of the class of second-generation derivative products that have developed around the swaps, caps, and floor markets. Swaptions can take many forms, but typically they are options to pay or receive a predetermined fixed rate in exchange for LIBOR at some time in the future. As the market develops, it is likely that additional variable-rate indexes will be used to determine floating-rate cash flows, especially if LIBOR is de-emphasized or phased out. Alternatively, swaptions can contain an option to cancel an existing swap. The second structure is essentially the same as the first, because a swap can be canceled by entering into a new swap in the opposite direction.

In view of this overlap between options to enter swaps and options to cancel swaps, the usual shorthand terminology of puts and calls is rarely used for swaptions. Rather, the option characteristic is spelled out in more detail—for instance, an option to receive fixed at 5% for three years, starting two years hence. Swaption exercise can be European (exercisable on only one date in the future) or American (exercisable on any date up to and including the expiration date), with the bulk of the interbank market structured as European exercise. A typical American swaption structure would be to enter into, say, a seven-year swap paying fixed at 4% at any time before maturity. As an example, if the option is exercised after one year, the option holder will pay 4% and receive LIBOR for seven years.

In terms of flexibility and costs, swaptions lie between swaps and customized interest-rate protection instruments, such as caps and floors. If LIBOR increases, the fixed payer of a swap, the holder of an option to pay fixed, and the cap buyer all benefit equally. If LIBOR decreases, the fixed payer of a swap incurs an opportunity loss and the holder of the swaption or cap loses only the up-front premium. The premium for a cap is usually greater than that for a swaption because the buyer of the cap essentially has purchased a strip of options, whereas the holder of a swaption owns only one option. If rates increase and the swaption is exercised, the owner of the swaption is exposed to the risk of a fall in interest rates. However, the holder of the cap can still take advantage of the beneficial movement in rates. In view of this observation, swaptions can be viewed as instruments that provide some of the protection and flexibility afforded by caps and floors.

The pricing of swaptions is still somewhat of an art. The development of models for pricing and hedging swaptions is on the cutting edge of options theory. Dealers differ greatly in the models they use to price such options, and the analytical tools range from modified Black-Scholes models to binomial lattice versions to systems based upon Monte Carlo simulations. As a result, bid/ask spreads are wide, and it pays to shop around, particularly for more complicated structures that cannot be reversed in the interbank markets.

Swaptions provide the sophisticated firm with an additional, flexible tool for asset/liability management. On the liability side, the primary uses of swaptions have been in hedging uncertain funding requirements and issuing synthetically callable debt. With respect to fixing liability costs, a corporation can lock in coupon rates for future funding by paying fixed in a forward swap. However, the firm may desire to preserve the opportunity to save on these funding costs in the event that rates decline in the future by purchasing a swaption, despite the attractiveness of the current interest-rate structure. In the event that funding requirements are uncertain, the flexibility of these instruments really comes into play as swaptions can lock in current rates without committing the firm to future borrowing.

Much of the current activity in swaptions has been fueled by an arbitrage between the swaption and callable bond markets. Historically, investors have not demanded full compensation for call options embedded in corporate bonds.

Hence, corporations can issue callable debt and then effectively strip off the embedded call option by writing a swaption, thereby lowering the all-in cost of the debt. On the asset side, the primary use of swaptions has been in hedging prepayable swapped assets, such as mortgage-backed instruments. An investor may purchase fixed-rate mortgage-backed securities, swap the fixed rate to floating, and earn an attractive spread over LIBOR. However, this spread is subject to erosion if the asset balance declines because of high prepayments. By giving up some of this spread and purchasing swaptions, the investor can reduce prepayment risk exposure. In addition to these types of specific uses, swaption volatility has also become a widely used indicator of future volatility embedded in current expectations.

ASSET SWAP

Our earlier applications focused exclusively on the use of interest-rate swaps and associated issues in swap-based liability hedging. Such swaps are referred to as *liability-based swaps. Asset-based swaps,* which use principles involved in liability hedging, are becoming increasingly popular to customize asset coupons and maturities, thereby expanding the asset universe available to portfolio managers. Asset swaps serve several useful functions, such as facilitating yield enhancement, creating assets that are not available in the marketplace, and changing the interest-rate sensitivity of the portfolio without actually trading the securities.

Similar to the use of swaps in converting fixed-rate debt to floating-rate debt and vice versa, interest-rate swaps also can be used to accomplish the same objective with fixed- and floating-rate assets. For instance, floating-rate notes (FRNs) can be converted synthetically to fixed-rate assets using a receive fixed-rate and pay floating-rate swap. Similarly, fixed-rate assets such as mortgage-backed securities (especially certain types of CMO bonds such as PAC classes) and receivable-backed securities (such as manufactured housing, credit card, and automobile loan collateralized bonds) can be converted to floating-rate instruments by using a receive floating-rate and pay fixed-rate swap. Asset-based swaps can also be used to alter the duration characteristics and, hence, the interest-rate sensitivity of an asset portfolio. For instance, a financial institution that has a predominance of long-term fixed-rate assets can reduce the duration of its portfolio, thereby increasing the interest-rate sensitivity of the assets by creating synthetic floating-rate assets. Characteristics of interest-rate swaps, such as amortizing features and option covenants, can be used to customize and reasonably ensure a particular yield level.

The flexibility afforded by swaps in the design of such synthetic assets becomes apparent when it is realized that investors seeking a particular type of asset, say, a floating-rate asset, can evaluate traditional floating-rate instruments, such as FRNs and CMO floaters as well as fixed-rate assets, by using interest-rate swaps to synthetically convert them to floating-rate assets. Asset-based swaps can also tailor the maturity (tenor) of the swap without having to depend on conditions in the debt markets. The latter feature is especially important for institutions that have "underwater" assets. Under current conditions, firms can always use a collateralized financing structure to raise funds and then reinvest the proceeds in assets of desired maturity and coupon. However, this option, besides being time-consuming, involves administrative, legal, and investment banking costs. Also, assets of particular maturity and coupon may not always be traded in the markets. Asset-based swaps fulfill this particular need in the market mainly because of ease of execution, customization features, and flexibility of swap termination.

TERMINATION OF INTEREST-RATE SWAPS

There are two ways to terminate a swap: (1) a reverse swap and (2) a swap sale.

Reverse Swap

The simplest way to terminate an interest-rate swap is to enter into an offsetting position. For illustrative purposes, assume that a firm entered into a five-year swap, paying fixed at a rate of 5.40% and receiving three-month LIBOR. After two years, the firm decides to terminate the swap by entering into a reverse swap, paying floating rate and receiving fixed rate. By matching the reset and settlement periods of the *reverse swap* to those of the original swap, the floating-rate payment of the reverse swap is counterbalanced by the floating-rate inflow from the original swap.

Two cases are illustrated in Exhibit 64-6—a bearish scenario and a bullish scenario. In a bearish interest-rate scenario, the new fixed rate on the reverse swap is likely to be higher than the fixed rate on the original swap. The new fixed rate in Exhibit 64-6 is assumed to be 6.40%. In this bearish scenario, there will be a profit associated with the reverse swap. The firm has effectively created an annuity of 1% of the notional amount for the remaining period of the swap.

In a bullish interest-rate scenario, rates are falling and market prices are rising. In the illustration in Exhibit 64-6, the new fixed rate is assumed to be 4.40%, resulting in a loss on the reverse swap. In this illustration, the firm has created a reverse annuity of 1% per annum for three years.

In either case, because the closing transaction involves receiving the fixed side of a swap, the spread over Treasury is based on the bid side of the market, whereas the original swap involves payment of the swap at the offer spread.

Swap Sale

Instead of managing the cash flows of two swaps and the credit risk of two counterparties, the firm may sell the swap for either a profit or loss in the secondary market. In the event that current market swaps with a maturity equal to the remaining maturity of the swap to be terminated are being offered at a higher

EXHIBIT 64-6

Termination of Interest-Rate Swaps

	Bearish	Bullish
Swap		
Pay fixed (5-year original maturity/3-year remaining maturity)	5.40%	5.40%
Receive 3-month LIBOR	LIBOR	LIBOR
Reverse Swap		
Receive fixed (3-year remaining maturity)	6.40%	4.40%
Pay 3-month LIBOR	LIBOR	LIBOR
Profit/(Loss)	1.00%	–(1.00%)

fixed rate, the swap could be sold for a fee. On the other hand, if current market swaps with a maturity similar to the swap to be liquidated are being originated at lower rates, then an exit fee may have to be paid for terminating the swap. Formally, the termination value of a swap is determined as the present value of an annuity discounted for the remaining term-to-maturity at the current swap rate. The periodic value of the annuity payments is approximated as the difference between the old fixed swap rate and the new fixed swap rate multiplied by the remaining notional amount of the original swap.[3] Formally, this is stated as

$$\text{Termination value of swap} = \text{PV of annuity at } r_s t$$

where

$$\text{Annuity payments } (r_s - r_m) \times \text{Notional amount}$$

$r_{s\,=}$ Original swap fixed rate
r_m = Current swap fixed rate
t = Time remaining to maturity of swap

KEY POINTS

- In the management of interest-rate volatility and associated asset/liability structural decisions, customized risk-management instruments such as interest-rate swaps provide a high degree of coverage flexibility and customization.

3. For a more detailed discussion of the calculation of the termination of the value of a swap that takes into days in payment periods, see chapter 14 in Frank J. Fabozzi, *Valuation of Fixed Income Securities and Derivatives* (New Hope, PA: Frank J. Fabozzi Associates, 1998).

- Interest-rate swaps can be used either to synthetically extend or to shorten the duration characteristics of any asset or liability.
- The benefit of interest-rate swaps is that direct changes in the contractual characteristics of either assets or liabilities are associated with administrative, legal, and investment banking costs.
- Additional swaps covenants, such as amortizing and accreting features and option riders, can be included in the contractual agreement either to better match the funding of an asset or to lock in the return of a synthetic asset.

CHAPTER
SIXTY-FIVE

THE VALUATION OF INTEREST-RATE SWAPS AND SWAPTIONS

Gerald W. Buetow, Jr., Ph.D., CFA, CIPM
President and Founder
BFRC Services, LLC

Brian J. Henderson, Ph.D., CFA
Associate Professor
The George Washington University

An interest-rate swap is an agreement involving two parties who agree to exchange payments at future dates. The cash-flow amounts exchanged in the future are determined by an agreed-upon interest rate and the size, or notional principal, of the agreement. In the most basic interest-rate swap, commonly referred to as a "plain vanilla interest-rate swap," one party agrees to make variable payments that "float" with a short-term rate while the other party makes fixed-rate payments at an agreed-upon fixed-rate.

Swaps are important tools for risk managers, offering a cost-effective means to altering interest-rate exposure. This useful tool for controlling interest rates may be customized in a variety of ways. For example, in an amortizing swap the notional principal declines over time. In an accreting swap, the notional principal increases over time. Other swaps, named forward-start swaps, are swap agreements that commence at a specified date in the future. Another variation of the swap agreement is the basis swap that involves the exchange of payments referencing two different interest rates, such as three-month LIBOR and the three-month Treasury bill.

In this chapter, our focus is on more complex swap structures. We assume the reader is familiar with plain vanilla swaps and the traditional valuation method involving the use of implied forward rates from LIBOR futures contracts to value a swap agreement to compute the swap fixed-rate (SFR). In addition to swaps, we cover the valuation of swaptions. A swaption gives its owner the right to enter into a swap agreement at a future time.

Unlike plain vanilla interest-rate swaps, swaptions have cash flows that depend on an interest rate at a future point in time. This feature requires a versatile approach to valuation. The lattice approach to valuation proves useful due to two important features. First, the interest-rate model driving the lattice approach is fit to no-arbitrage conditions, meaning that the pricing fits the arbitrage values for cash flows using forward rates. Second, the interest-rate models behind the interest-rate lattice incorporate an assumed interest-rate volatility, enabling this approach to handle option-like features.

The balance of the chapter proceeds as follows. We begin by illustrating the lattice approach to valuation with a plain vanilla interest-rate swap. Next, we demonstrate the versatility of the lattice approach through the valuation of forward-start swaps. The chapter proceeds by presenting and pricing swaptions with a focus on the pricing impact of the important parameters (time-to-expiration, strike rate, and volatility). Next, the chapter presents basis swaps and concludes.

SWAP VALUATION USING THE LATTICE APPROACH

The traditional approach to valuing swaps involves obtaining a no-arbitrage value for the swap cash flows by discounting at the implied forward rates. The implied forward rates come from market prices of Eurodollar futures contracts. Unfortunately the traditional approach is not equipped for valuing cash flows that vary depending on interest rates in the future. For this purpose, the lattice model is a useful tool for valuing interest-rate derivative instruments such as swaps and swaptions. In contrast to the traditional approach to valuing swaps, the lattice model incorporates the volatility of interest rates to consider how interest rates may change in the future, providing a flexible valuation framework easily adapted to exotic (non–plain vanilla) instruments.

In general, the lattice approach to valuation begins with the construction of the interest-rate lattice.[1] The values on the interest-rate lattice represent possible interest rates in future periods, describing potential evolutions of interest rates through time. After constructing the interest-rate lattice, the swap cash flows are computed at each "node" on the lattice, resulting in the swap cash-flow lattice. The interest rates from the lattice are then used to compute the present value of the possible future cash flows. This process is referred to as *backwardation:* working backward through the tree to discount the expected future cash flows to a present value.

Constructing the interest-rate lattice begins with an interest-rate model to describe the dynamics of interest rates through time. Although many interest-rate models are used by practitioners, the most common models are one-factor models that describe the evolution of the short rate (one period interest rate) through time. The term *one factor* simply means that the short rate is the only interest rate being modeled and it solely determines the *term structure*. An interest-rate model makes important assumptions about the relationship between short-term interest rates and interest-rate volatility, typically measured as the standard deviation.[2] The examples in this chapter employ a version of the Kalotay, Williams, and Fabozzi interest-rate model.[3]

1. The approach employed here applies regardless of whether a lattice (binomial, trinomial), grid (finite differences), or paths (Monte Carlo) are used to generate the evolution of interest rates.

2. The details of term structure modeling are beyond the scope of this chapter.

3. Andrew J. Kalotay, George O. Williams, and Frank J. Fabozzi, "A Model for the Valuation of Bonds with Embedded Options," *Financial Analysts Journal* (May-June 1993), pp. 35–46. See also Chapter 34 in this handbook.

After selecting an interest-rate model to describe the possible evolution of the interest rate through time, it is useful to express that model in a lattice comprising discrete time periods. Each node on the binomial tree represents a possible short rate over that discrete time step. The interest rate may evolve to the next time step by taking two possible values. There are other models allowing for more than two possible rates in each subsequent period; for example, the trinomial model allows for three rates. To avoid complication, we illustrate the lattice valuation procedure using the binomial model. The important feature of the interest-rate models is that they satisfy the "no-arbitrage" condition, meaning the interest rates they produce match the implied spot rates from bond prices. Additionally, interest-rate models incorporate an assumption regarding interest-rate volatility. The volatility of interest rates is a critical component when valuing interest-rate contingent claims since the cash flows to the claim are determined by interest rates in the future. We will see later that the volatility assumption has direct effects on the value of swaptions.

To illustrate the lattice model approach to valuation, we begin by pricing a five-year plain vanilla interest-rate swap with a swap fixed-rate (SFR) of 3%. To simplify the presentation, and without loss of generality, we consider the swap to have semiannual payments instead of quarterly payments.

Exhibit 65-1 presents the interest-rate lattice that will be used in the valuation process. The model is a one-factor model and describes the possible paths of the short rate (one-period interest rate) through time. The current short rate is 0.3850%, and according to the model, the short rate for the next time period will be either 0.7950% or 0.6902%, where each of these values is equally likely. The interest-rate tree has 10 semiannual time periods, covering the five-year tenor of the swap agreement.

The next step in the valuation process is to compute the cash flow at each node. The swap payments occur in arrears, but are determined at the start of the period. For instance, the first swap payment is determined today, at $t = 0$, and is based on the current short rate of interest. Referring to Exhibit 65-1, the current rate is 0.3850%. At the end of the first period, the swap counterparty making the fixed-rate payment will make a payment of:

$$\text{Fixed-Rate Payment} = \text{SFR} \times \text{NP} \times (\text{Days in Period}/360)$$

where NP is the notional principal and Days in Period is the number of days in the payment period.

To simplify the presentation, we assume semiannual cash flows and that the fraction of the year is 0.5. The other swap counterparty, the floating-rate payer, makes a payment that is equal to:

$$\text{Floating-Rate Payment} = \text{Floating-Rate} \times \text{NP} \times (\text{Days in Period}/360)$$

Since the swap cash flows are typically netted, the swap cash flow at the end of the period will be:

$$\text{Net Cash Flow} = (\text{Floating-Rate} - \text{SFR}) \times \text{NP} \times (\text{Days in Period}/360)$$

Note that when the periodic floating-rate is greater than the SFR, the floating-rate payer makes the net cash-flow payment to the fixed-rate payer. Conversely, when the periodic floating-rate is less than the SFR, the fixed-rate payer makes payment of the net cash-flow amount to the floating-rate payer. Exhibit 65-2 presents the net cash flows at each node on the lattice in Exhibit 65-1 for the five-year semiannual swap agreement with a SFR of 3% and notional principal of $100. To illustrate the computation, refer to the node on the upper-right-hand side of the interest-rate lattice in Exhibit 65-1 where the short rate is 9.1446% at time 4.5 years. At that node, the short rate is 9.1446%. Recall the cash flow is determined at the start of the period but paid in arrears. Thus, the short rate at time 4.5 years determines the cash flow at t = 5 years. The net cash flow from the swap is:

$$\begin{aligned}\text{Net Cash Flow} &= (\text{Floating-Rate} - \text{SFR}) \times \text{NP} \times (\text{Days in Period}/360)\\ &= (9.1446\% - 3.0\%) \times 100 \times 0.5 = 3.0723.\end{aligned}$$

The procedure repeats for each node on the tree. Recall that the cash flows to the swap occur in arrears (at the end of the period) but are determined at the beginning of the period based on the interest rate at that time.

At this point in the valuation process, we have used the interest-rate lattice to compute the swap cash flows at each node on the lattice. To arrive at a value for the interest-rate swap, the next step is to construct another lattice referred to as the *cumulative swap valuation lattice*. Each node of the cumulative swap valuation lattice is the present value of the swap cash flows from all nodes on the cash-flow lattice occurring after that time (see Exhibit 65-2) discounted using the rates on the binomial lattice (see Exhibit 65-1). To illustrate the process, refer to the shaded region in the top right portion of Exhibit 65-3. The cumulative swap valuation at the nodes where t = 4.5 are the present values of the cash flows at t = 5. Note the time reference here—cash flows (t = 5) verse present value of cash flows (t = 4.5). Since the swap agreement matures at t = 5 years, there are no subsequent cash flows to consider. Thus, the values in the shaded region at t = 4.5 years are computed as the present values of the t = 5 cash flows (see Exhibit 65-3) discounted at the rates in Exhibit 65-1:

$$\begin{aligned}3.0723/(1 + 9.1446\%/2) &= 2.9380\\ 2.4693/(1 + 7.9386\%/2) &= 2.3750\\ 1.9458/(1 + 6.8917\%/2) &= 1.8810.\end{aligned}$$

Working backward to the next time step (t = 4) requires discounting the values at t = 4.5 plus the arrears cash flow that take place at t = 4.5. At each node, there are two possible values at the next time step and they are equally likely to occur. To illustrate, the values at the shaded t = 4 nodes in Exhibit 65-3 are determined as:

$$\begin{aligned}(0.5 \times 2.9380 + 0.5 \times 2.3750 + 2.3104)/(1 + 7.6208\%/2) &= 4.7846\\ (0.5 \times 2.3750 + 0.5 \times 1.8810 + 1.8079)/(1 + 6.6158\%/2) &= 3.8099.\end{aligned}$$

After computing the cumulative swap values at t = 4, backwardation continues by computing the values at t = 3.5 years. To illustrate, the shaded value in

Exhibit 65-3 at $t = 3.5$ is computed as the present value of the nodes at $t = 4$ plus the arrears cash flow received at $t = 4$:

$$(0.5 \times 4.7846 + 0.5 \times 3.8099 + 1.7608)/(1 + 6.5216\%/2) = 5.8667.$$

The process continues through each node, arriving finally at the present value of the swap. Referring to Exhibit 65-3, the present value of the swap with \$100 notional principal, 3% swap fixed-rate, and five-year tenor is –1.5892. Recall that we computed the cash flows from the perspective of the fixed-rate payer, meaning that the cash flow is negative (an outflow) when the floating-rate is less than the swap fixed-rate. Thus, the negative value indicates that the present value of the fixed-rate payments (3% SFR) is greater than the present value of receiving the floating-rate payments. At the time the counterparties enter into a plain vanilla swap, the present value is zero, meaning the SFR can be determined in the lattice model by iterating on the SFR until the present value at $t = 0$ of the cumulative swap valuation line equals zero. In this example, a SFR of 2.6650% results in the initial value of the swap equaling zero, illustrating why the swap value is negative to the fixed-rate payer in the example where the SFR is 3%. Interest rates must have declined since the inception of the SFR 3% plain vanilla swap.

It is important to note that the value of the plain vanilla swap obtained through the lattice model is identical to the value obtained through the traditional valuation method. This equivalence is due to the fact that the interest-rate model is derived through no-arbitrage conditions based on forward rates determined by market data. The key advantage to the lattice approach will be clear in later sections when we value interest-rate swaptions and need to account for volatility in the possible paths of future interest rates.

Now that we have introduced the binomial lattice, we proceed by introducing more complicated swap structures and swaptions.

FORWARD START SWAPS

A forward start swap is a swap agreement commencing at some specified date in the future. An example is a two-year swap that begins three years from today. We refer to a forward start swap by the date at which the swap begins and the maturity date of the swap using the notation (y_{start}, y_{end}). Thus, the two-year swap beginning three years from today is denoted (3,5). In addition to the start date and maturity date, the forward start swap agreement also specifies the swap fixed-rate and the notional principal. The swap fixed-rate for a forward start swap is referred to as the forward swap fixed-rate.

To illustrate the valuation of a forward start swap, we will use the interest-rate lattice presented in Exhibit 65-1 to value the two-year swap that begins three years from today with a fixed-rate of 3.250% and notional principal of 100. The process begins by calculating the swap cash flows at each node on the interest-rate lattice and then constructing the cumulative valuation lattice through the process outlined in the previous section. Exhibit 65-4 presents the cumulative valuation

lattice for this swap. Note that the swap begins three years from today and the possible values at time $t = 3$ years are highlighted in the lattice.

The cumulative value lattice produces seven possible values for the forward start swap at $t = 3$ years, and these values can be used to determine the value of the swap agreement. At this point, the missing link is the probability of each of the possible lattice values. The probability of reaching any node in the tree is determined by the number of paths through the lattice that arrive at that node. In the binomial lattice, where there are two possible movements for the rate in the next period, the following formula can be used to calculate the number of paths arriving at any given node:

$$\text{Number of Paths} = \frac{n!}{j!(n-j)!'}$$

where n is the number of periods and j is the number of down-states. Exhibit 65-5 presents the number of paths arriving at each node. By referring to the paths at time 3 in the tree, we illustrate the computation using the above formula. Since time on the tree at $t = 3$ corresponds to the sixth semiannual time step, $n = 6$. At the very top node, there are no down nodes so $j = 0$. Evaluating the formula, we

find that the number of paths arriving at the top node is 6!/(0!(6!)) = 1 path, which makes sense since the one and only path arriving at the top node consists solely of up-movements. At the node that is second from the top at $t = 3$, the time periods are still 6 but at this node there is one down-step so $j = 1$. Evaluating the formula, there are 6!/(1!(5!)) = 6 possible paths arriving at this node.

To finish the demonstration, we compute the number of nodes at the third node from the top at $t = 3$. At this node, $n = 6$ and there are two down nodes so $j = 2$. Applying the formula, the number of paths arriving at the third node are 6!/(2!(4!)) = 15 paths.

Across the six nodes at $t = 3$, there are a total of 64 possible paths. The probability of arriving at each node is simply the number of paths to that node divided by the number of possible paths arriving at all nodes at this time. The value of the forward start swap is determined by weighting each of the cumulative swap valuation nodes corresponding to the forward start swap start date by the probability of arriving at that node. This calculation is illustrated in Exhibit 65-6, which presents the seven nodes at $t = 3$ and the corresponding cumulative swap valuation from the $t = 3$ node in Exhibit 65-5. The probability of arriving at each node is computed as the number of paths arriving at that node divided by the total number of paths arriving at any node at this time. The product of the cumulative swap valuation and the probability result in the probability weighted value. Summing the probability weighted values results in the forward start swap value. In this case, the value for 100 notional principal of the (3,5) forward start swap with a 3.250% forward start fixed-rate is 1.87089. Note that this is the value to the fixed-rate payer. Recall that we computed the cash flows at each node as the rate on the interest-rate lattice minus the swap fixed-rate. Thus, the positive value indicates that the value of the floating-rate payments exceeds the value of the fixed-rate

EXHIBIT 65-6

payments, implying a positive value to the fixed-rate payer. The value to this swap for the floating-rate swap payer is the negative of this amount, –1.87089. The SFR that would produce an FSS value of zero is 4.233% and is computed in the same manner as the iterative routine used to compute the SFR of a zero value plain vanilla swap.

Once we understand the process, we can value forward-start swaps with the same SFR that begin at each node on the lattice and end at five years. That is to say we may compute the values of the otherwise identical (0,5), (0.5,5), (1,5), (1.5,5), (2,5), (2.5,5), (3.5,5), (4,5), and (4.5,5) swaps. Exhibit 65-7 illustrates the computation of forward start swap values at each time period on the lattice.

VALUING SWAPTIONS

A swaption is an option contract on an interest-rate swap. The owner of a swaption has the right to initiate a swap agreement on or by a specified future date. The swaption specifies several important features of the swap, including the tenor of the swap and the swap fixed-rate. The swap fixed-rate is the strike rate for the option. Unlike a forward start swap, where both counterparties have the obligation to participate in the swap, the swaption owner has the right, but not the obligation, to enter into the swap. We will demonstrate the valuation procedure for swaptions using the interest-rate lattice and discuss how the important parameters affect the swaption valuation.

A payer's swaption (a pay fixed swaption) gives the owner the right to enter into an interest-rate swap as the fixed-rate payer and receive floating-rate payments. Swaptions may be either European or American style. The difference is that the owner of a European style swaption may exercise their right to enter into the swap at the expiration of the swaption, while the owner of an American style swaption may exercise that right any time up to the expiration date. For our purposes, we will consider European style swaptions.

A receiver's swaption (receive fixed swaption) gives the owner the right to enter into an interest-rate swap as the floating-rate payer and fixed-rate receiver. As an example, consider a swaption with a fixed-rate of 3.650%, option expiration date of two years, and the swap tenor is three years. The buyer of this swaption has the right at the end of two years to enter into a swap in which they make floating-rate payments and receive fixed-rate payments of 3.650%. We introduce the notation ($y_{expiration}$, y_{tenor}) for swaptions to refer to the expiration date of the swaption and the tenor of the swap. Thus, the receiver's swap is a (2,3) swaption.

To illustrate swaption pricing, we will price several payers' swaps with a strike rate of 3.650%. The lattice approach is helpful to value swaptions, and the valuation example uses the interest-rate lattice from Exhibit 65-1. After constructing the interest-rate lattice, the next step in the valuation process is to construct the pay fixed cash-flow lattice for a plain vanilla swap with a notional principal of $100, based on a swap fixed-rate of 3.650%. Recall that at each node on the

lattice, the cash flow is determined by the swap fixed-rate, the notional principal, the corresponding node on the interest-rate lattice:

$$\text{Cash Flow}_{i,j} = (F_{i,j\text{-}1} - SFR) \times NP_j \times 0.5$$

where $F_{i,j\text{-}1}$ is the floating-rate at node (i,j-1), indicating the arrears cash flow at time j. Exhibit 65-8 presents the cash-flow lattice for the plain vanilla swap with a strike rate of 3.650%. To illustrate the computation of the cash flows, refer to the top-right node on the tree. Note that this cash flow occurs at time $t = 5$, but is determined by the rate at $t = 4.5$. The corresponding rate from the interest-rate lattice is 9.1446%, so the cash flow at this node is:

$$\text{Cash Flow}_{1,5} = (9.1446\% - 3.650\%) \times 100 \times 0.5 = 2.7473$$

After constructing the cash-flow lattice in Exhibit 65-8, the next step in the swaption valuation process is to construct the cumulative swap valuation lattice for the plain vanilla pay-fixed swaption. Exhibit 65-9 presents the cumulative valuation lattice. The cumulative swap valuation lattice can then be used to value pay fixed swaptions.

To illustrate the swaption valuation, we price the (3,2) pay fixed swaption, as illustrated in Exhibit 65-10. The option expires in year 3 and the values corresponding to expiration are referred to as the expiration values. The expiration value at each node (here $t = 3$) come from the values in the cumulative valuation lattice (see Exhibit 65-9). Recall that the swaption gives the owner the right, but not the obligation to enter into the pay fixed swap. The owner will only exercise this right when the value of the two-year swap commencing at $t = 3$ is positive. Thus, the expiration values for the swaption are the maximum of zero or the value at the corresponding node on the cumulative valuation lattice. To illustrate, at the bottom node on the tree at $t = 3$, the cumulative valuation for the pay-fixed swap is –0.7711. Intuitively, this makes sense since the bottom nodes correspond to low interest rates that adversely affect the fixed-rate payer.

After determining the expiration values for the swaption, the remaining portion of the lattice is populated using backward induction. The corresponding rates from the interest-rate lattice determine the discount factors. To illustrate the process, the top value at year 2.5 in Exhibit 65-10 is computed as:

$$0.5\,(5.058457 + 3.537322)/(1 + 4.4031\%/2) = 4.205307$$

Repeating this process throughout the lattice in Exhibit 65-10 results in a value of \$1.170195 for the (3,2) pay fixed swaption per \$100 of notional principal. It is worth noting that the lattice valuation process requires as inputs the interest-rate lattice and the swaps valuation lattice. Once these have been determined, it is straightforward to price any variation of the swaption having the same fixed-rate. The lattice valuation framework is very flexible and handles easily any adjustments such as varying the notional principal (amortizing or accreting). This flexibility makes the lattice approach to valuation attractive.

VALUING BASIS SWAPS AND NON-LIBOR-BASED SWAPS

To this point, we have focused on the valuation of swap structures involving the exchange of floating and fixed-rate payments in which the floating leg of the swap is based off LIBOR. Next, we generalize our discussion to include swaps in which both legs of the swap float and to swap structures based on interest rates other than LIBOR.

A basis swap is a swap agreement in which both legs of the swap are based on different rates. For example, the spread between the 90-day Treasury bill rate and the three-month LIBOR is referred to as the *TED spread*. In a LIBOR TED swap, one counterparty makes payments based on LIBOR and receives payments based on the 90-day Treasury bill rate plus a spread. This is referred to as a *pay LIBOR TED swap*.

We illustrate the lattice approach to valuation for a one-year pay LIBOR TED swap with a *Spread* of 0.376%. Since each leg of the swap references a floating-rate, the lattice approach requires a lattice for each rate. Exhibit 65-11 presents the one-year interest-rate lattices for LIBOR and the 90-day Treasury bill rate. Note that we assume a 10% volatility for LIBOR and 7.5% for the Treasury bill rate. In previous examples, we assumed semiannual periodicity for payments. In this example we assume quarterly.

After the two interest-rate lattices are in place, the next step in the valuation process is to compute the cash flows for the pay LIBOR TED swap. Each cash flow at node i in period j is computed as follows. Note that in the example

EXHIBIT 65-11

we ignore the exact day count and assume each period is exactly one quarter of the year.

$$CF_{i,j} = (\text{T-Bill}_{i,j-1} + \text{Spread} - \text{LIBOR}_{i,j-1}) \times 0.25 \times NP_j$$

It is important to point out that the *Spread* is the adjustment to the Treasury bill rate such that the present values of the two payment streams are equal. To obtain the spread that equates the two cash-flow streams, we can iterate on the *Spread* value.

Following the two interest-rate lattices in Exhibit 65-11, the next step is the computation of the pay LIBOR TED swap cash flow at each node on the tree. To illustrate, consider the highest node on the tree at maturity of the swap. Referring to Exhibit 65-11, the LIBOR and Treasury bill rate at this node are 1.01% and 0.29%, respectively. Using the *Spread* of 0.376%, the payment on \$100 notional principal is:

$$\begin{aligned} CF_{i,j} &= (\text{T-Bill}_{i,j-1} + \text{Spread} - \text{LIBOR}_{i,j-1}) \times 0.25 \times NP_j \\ &= (0.29\% + 0.376\% - 1.01\%) \times 0.25 \times NP_j \\ &= -0.085 \end{aligned}$$

Time in Years	**0.25**	**0.5**	**0.75**	**1**

The cash flows for the swap at all times are presented in Exhibit 65-12. After constructing the cash flows, the final step for valuing the pay LIBOR TED swap is to compute the cumulative value lattice. This procedure is exactly the same as demonstrated in previous sections. The values are presented in Exhibit 65-13. Note that the present value of the expected payments is zero, indicating that the spread of 0.376% produces zero value for the swap. This means the present value of the LIBOR and the Treasury bill plus *spread* legs are identical. For spreads greater (smaller) than 0.376%, in this example the pay LIBOR TED swap would have positive (negative) present value. To note the flexibility of the lattice approach to valuation, note that it is straightforward to extend the valuation for a swaption on a basis swap following the procedure outlined in the previous section.

FACTORS AFFECTING SWAP VALUATION

The flexibility of the lattice approach to valuation facilitates the analysis of a swaption's sensitivity to changes in the swaption terms and changes in market inputs such as volatility. In this section, we illustrate the sensitivity of swaption valuations to interest-rate volatility and the strike rate.

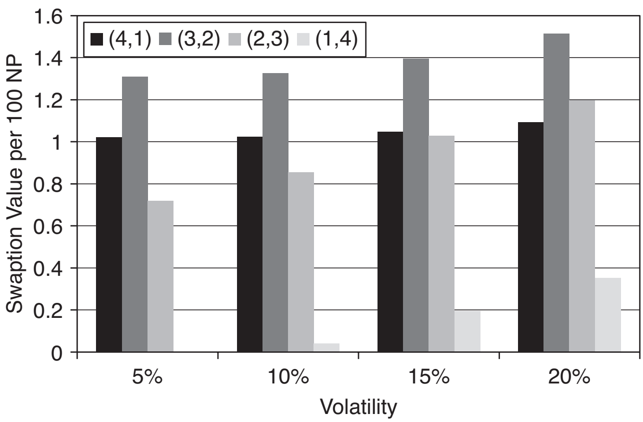
There are two main determinants of the values in the interest-rate lattice: the current term structure and interest-rate volatility. Recall that the interest-rate lattice is the basic building block in the lattice approach to valuing swaptions. Changing the expiration date of a swap changes the value of the swaption, but the directional change in value depends on the current term structure, volatility, and strike price. Interest-rate volatility, however, increases the value of swaptions, holding all else constant.

The chart in Exhibit 65-14 illustrates the effect of interest-rate volatility and the expiration of the swap on the valuation of four different pay fixed swaptions. To construct the example, we use the LIBOR interest-rate lattice from Exhibit 65-1 and consider pay fixed swaptions each having a strike rate equal to 3.5%. In the figure, there is not a monotonic relation between the swaption expiration and value. Each swaption's value, however, does increase as volatility increases.

We next consider the joint effect of the strike rate and interest-rate volatility on interest-rate swaptions. Exhibit 65-14 illustrates that swaption values increase as interest-rate volatility increases, holding all else constant. The strike rate has an important impact on the value of the swaption. For a pay

EXHIBIT 65-14

Pay Fixed Swaption Values and Volatility, Strike Rate = 3.5%



fixed swaption, in which the option owner has the right to enter into a swap agreement where they pay the fixed-rate and receive floating payments, as the strike rate increases, the value of the pay fixed swaption declines since the value of the fixed-rate payments rises relative to the floating-rate payments that party will receive. Conversely, in a receive fixed swaption, in which the option owner has the right to enter into a swap agreement where they receive fixed-rate payments and make floating-rate payments, the value of that right increases as the strike rate increases.

Exhibit 65-15 illustrates the joint effect of the strike rate and interest-rate volatility on the value of a (2,3) pay fixed swaption. The surface plot of the swaption value is increasing in the volatility (at higher levels of volatility, the swaption's value is greater), and decreasing in the strike rate (at lower strike rates, the pay-fixed swaption's value is greater). Exhibit 65-16 illustrates the receive fixed swaption value across strike rates and levels of volatility. It is important to note that, across the strike rate dimension, the graph in Exhibit 65-16 is the mirror image of Exhibit 65-15, demonstrating that strike rate has the opposite impact on the values of receive fixed swaptions as it has on pay fixed options. The value of the receiver's swaption, is positively related to the level of volatility, in which the receiver's swaption increases in value as the assumed lever of interest-rate volatility increases.

EXHIBIT 65-15

The Effect of Strike Rate and Interest-Rate Volatility on the (2,3) Pay Fixed Value

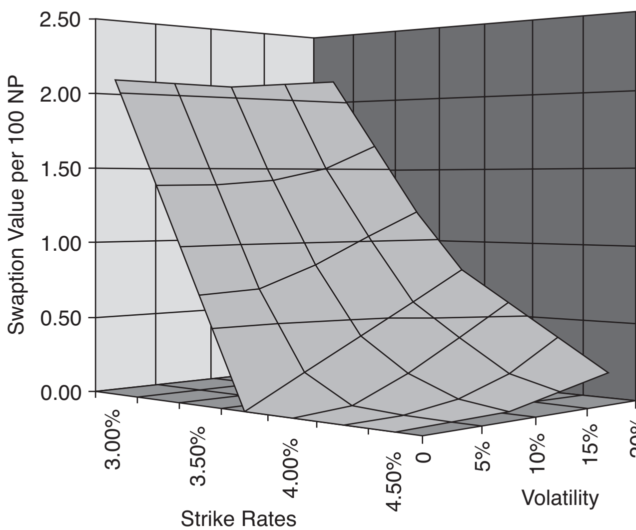


EXHIBIT 65-16

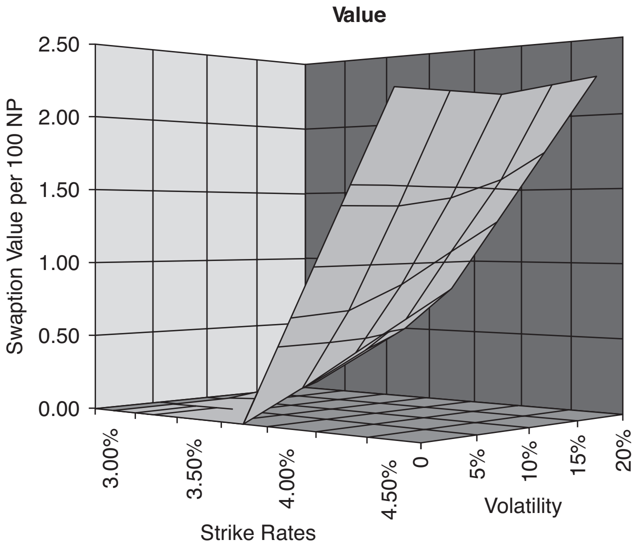
The Effect of Strike Rate and Interest-Rate Volatility on the (2,3) Receive Fixed Swaption Value



KEY POINTS

- Interest-rate swap agreements involve two parties agreeing to exchange payments in the future at agreed-upon terms.
- Exotic swap agreements are customized contracts. Common variations include forward-start swaps, amortizing notional principal swaps, accreting notional principal swaps, basis swaps, and non-LIBOR swaps.
- Swaptions are option contracts in which the owner has the right, but not the obligation, to enter into a swap agreement in the future.
- The lattice approach to swap and swaption valuation is a powerful, flexible valuation framework easily adapted to handle variations of exotic swaps.
- Swaption values are determined by market inputs such as the term structure of interest rates and interest-rate volatility in addition to contract specifications such as tenor and strike rate. Holding all else constant, volatility increases swaption values. Holding all else constant, increasing the strike rate decreases the value of a pay-fixed swaption but increases the value of a receive-fixed contract.

CHAPTER

SIXTY-SIX

THE BASICS OF INTEREST-RATE OPTIONS

William J. Gartland, CFA
Vice President, Fixed-Income Data and Analytics
Broadridge

Nicholas C. Letica
Managing Director
TD Securities

As the sophistication and diversity of investors and financial products have grown, the need for derivative instruments such as options has increased accordingly. Knowledge of option strategies is necessary for everyone who wishes to maintain a competitive edge in an increasingly technical market. The analysis of many complex products, such as swaptions or bonds with embedded calls (like callable bonds or mortgage-backed securities) relies on having the ability to understand and price options.

In Chapter 61, option contracts were described: exchange-traded options on physical securities, exchange-traded options on futures, and over-the-counter (OTC) options. In this chapter we will review how options work, their risk/return profiles, the basic principles of option pricing, and some common trading and portfolio management strategies. A more detailed discussion of hedging strategies is provided in Chapter 63.

Throughout most of the discussion, our focus will be on options on physicals. The principles, however, are equally applicable to options on futures or options on off-balance sheet contracts like interest-rate swaps.

HOW OPTIONS WORK

An *option* is the right but not the obligation to buy or to sell a security at a fixed price. The right to buy is called a *call,* and the right to sell is called a *put;* a call makes money if prices rise and a put makes money if prices fall.

If the owner of an option uses the option to buy or to sell the underlying security, we say that the option has been *exercised.* Because the holder is never required to exercise an option, the holder can never lose more than the purchase price of the option—an option is a limited-liability instrument.

An option on a given security can be specified by giving its strike price and its expiration date. The *strike price* is the price on the optional purchase. For example, a call with a strike price of par is the right to buy that security at par. The *expiration date* is the last date on which the option can be exercised: after that, it is worthless, even if it had value on the expiration date. If an option is allowed to expire, it is said to be *terminated.* On or before the expiration date, the option holder may decide to sell the option for its market value. This is called a *pair-off.*

Some options can be exercised at any time until expiration: they are called *American* options. On the other hand, some options can only be exercised at expiration and are called *European* options. Because it is always possible to delay the exercise of an American option until expiration, an American option is always worth at least as much as its European counterpart. In practice, there are only a limited number of circumstances under which early exercise is advantageous, so the American option rarely costs significantly more than the European.

The easiest way to analyze a position in a security and options on that security is with a *profit/loss graph.* A profit/loss graph shows the change in a position's value between the *analysis date* ("now") and a *horizon date* for a range of security prices at the horizon.

Suppose that a call option struck at par is bought today for 1 point. At expiration, if the security is priced below par, the option will be allowed to expire worthless; the position has lost 1 point. If the security is above par at expiration, the option will be exercised; the position has made 1 point for every point the security is above par, less the initial one-point cost of the option. Exhibit 66-1 shows the resulting profit/loss graph.

EXHIBIT 66-1

Long Call versus Underlying Security Price
Call Struck at Par, at Expiration, with 1-Point Premium

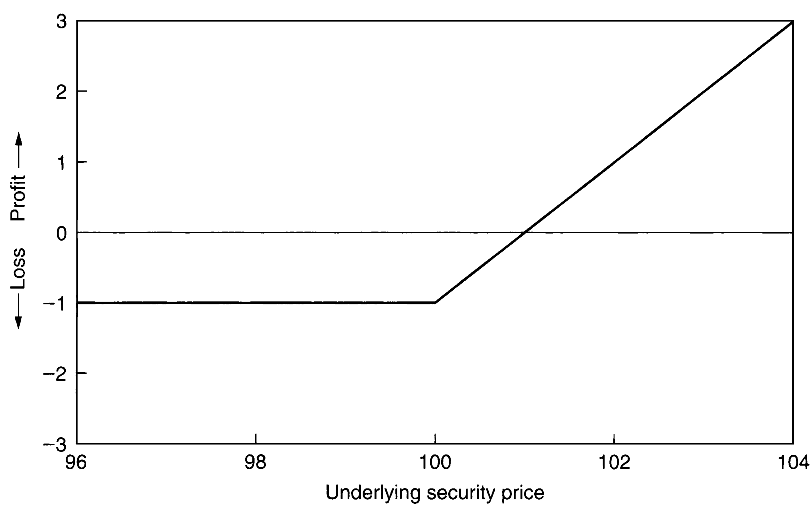


EXHIBIT 66-2

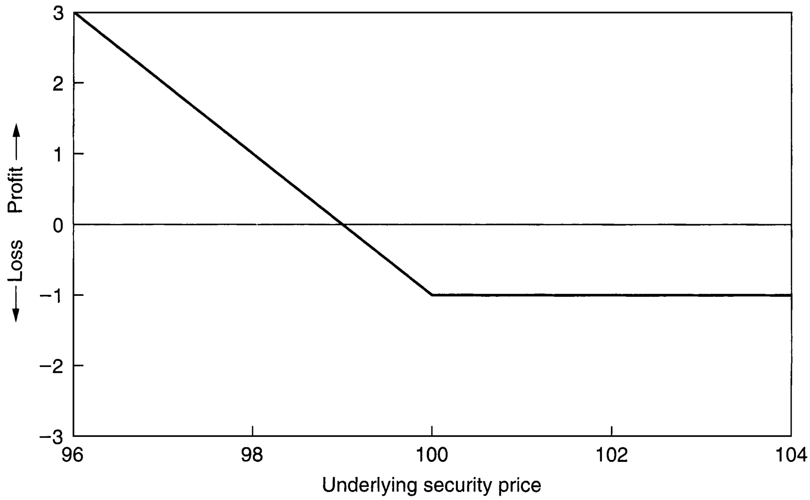
Long Put versus Underlying Security Price
Put Struck at Par, at Expiration, with 1-Point Premium



Note that if the price of the underlying increases by 1 point, the option purchase breaks even. This happens because the value of the option at expiration is equal to the initial purchase price. A price of 101 is the break-even price for the call: the call purchase will make money if the price of the underlying exceeds 101 at expiration.

A put is the reverse of a call. Look at Exhibit 66-2, which is the profit/loss graph of a put option struck at par bought for 1 point. At expiration, the put is worth nothing if the security's price is more than the strike price and is worth 1 point for every point that the security is priced below the strike price. The break-even price for this trade is 99, so the put purchase makes money if the underlying is priced below 99 at expiration.

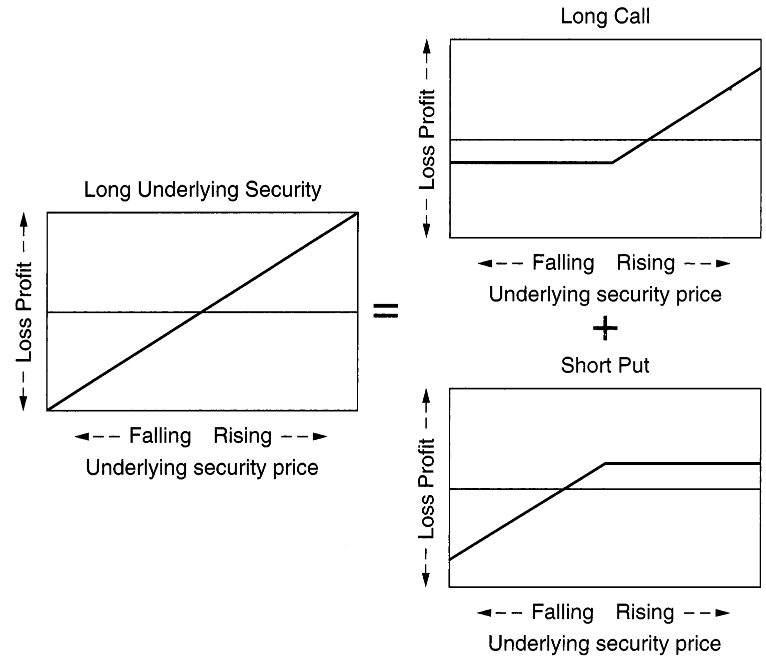
Put-Call Parity

A put and a call struck at-the-money split up the profit/loss diagram of the underlying security into two parts. Consider the position created by buying a call and selling a put such that the strike price of the two options is equal to the price of the underlying. If the price of the security goes up, the call will be exercised; if the price of the security goes down, the put will be exercised. In either case, at expiration the underlying is delivered at the strike price. Thus, in terms of profit and loss, owning the call and selling the put are the same as owning the underlying.

Exhibit 66-3 divides the profit/loss graph of the underlying security into graphs for a long call and a short put, respectively. The following three facts

EXHIBIT 66-3

Long Security = Long Call + Short Put



can be deduced:

Long security = long call + short put	(Exhibit 66-3)
Long call = long security + long put	(Exhibit 66-4)
Long put = short security + long call	(Exhibit 66-5)

This relationship is called *put-call parity;* it is one of the foundations of the options markets. Using these facts, a call can be created from a put by buying the underlying, or a put made from a call by selling the underlying. This ability to convert between puts and calls at will is essential to the management of an options position.

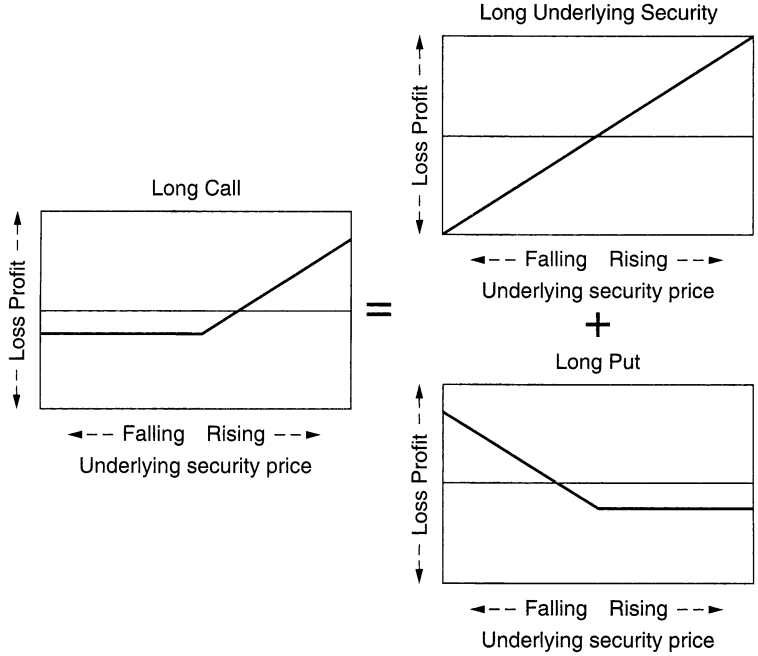
Valuing an Option

The first fact to determine about an option is its worth. There are many option valuation models for each class of options, each of which uses different parameters and returns slightly different values. However, the five main determinants of option value are the price of the underlying, the strike price of the option, the expiration of the option, the volatility of the underlying, and the cost of financing the underlying.

The most apparent component of option value is intrinsic value. The *intrinsic value* of an option is its value if it were exercised immediately. An option with

EXHIBIT 66-4

Long Call = Long Security + Long Put



intrinsic value is an *in-the-money* option. When the underlying security trades right at the strike price, the option is called *at-the-money.* Otherwise, an option with no intrinsic value is called *out-of-the-money.*

An option may have value over and above its intrinsic value, called *time value.* The intrinsic value is the value of the option if exercised immediately, whereas the time value is the remaining value in the option due to time expiration. Clearly, the more time there is to expiration, the greater is the time value.

Exhibit 66-6 graphs the value of an option as time to expiration increases. Exhibit 66-7 compares the value of an option at expiration with the values of options with one and three months to expiration. There is a sharp corner in the graph at the strike price that becomes more pronounced as the time to expiration decreases. This sharp corner makes an at-the-money option increasingly difficult to hedge as expiration approaches.

If the option is out-of-the-money, it has some time value because there is a chance that the option will expire in-the-money; as it gets further out-of-the-money, this is less likely and the time value decreases.

If the option is in-the-money, its time value is due to the fact that it is better to hold the option than the corresponding position in the underlying security because if the security trades out-of-the-money the potential loss on the option is

EXHIBIT 66-5

Long Put = Short Security + Long Call

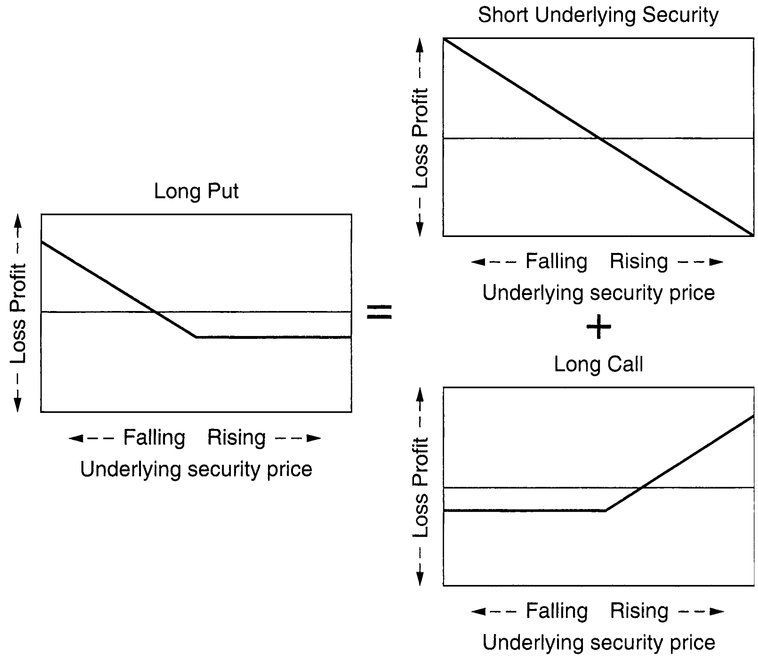


EXHIBIT 66-6

Call Option Value versus Time Until Expiration
Three Calls: At-the-Money, 1 Point In-the-Money, 1 Point Out-of-the-Money

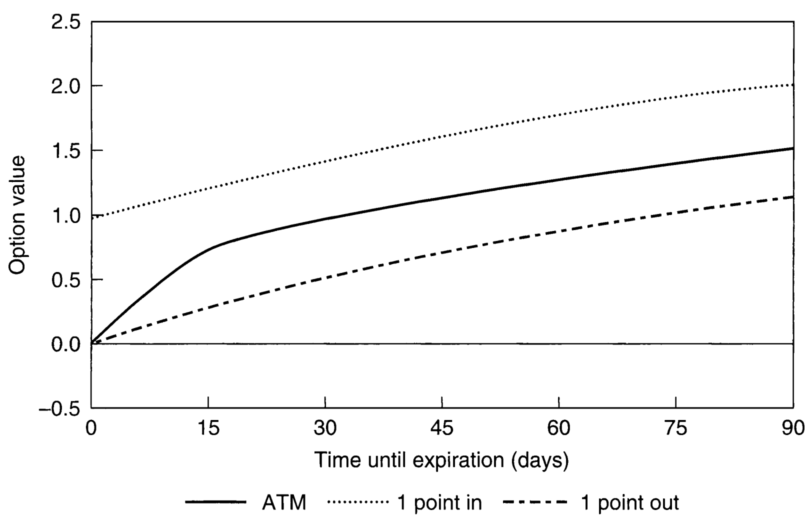

EXHIBIT 66-7

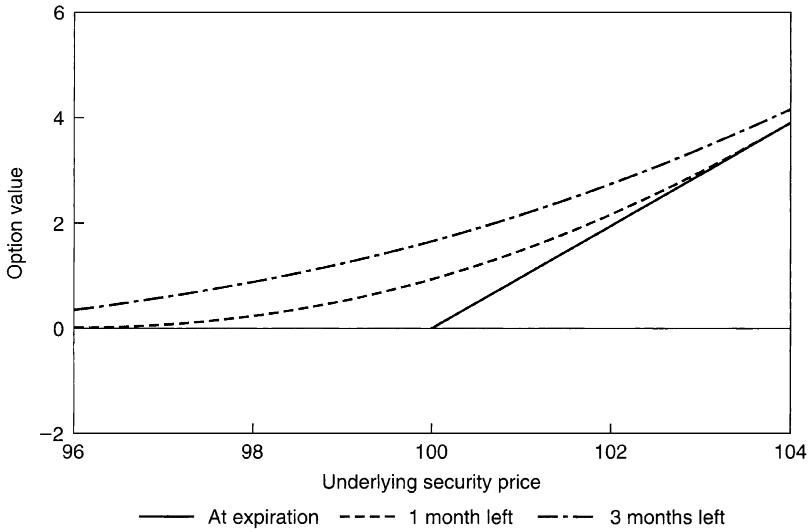
Call Option Value versus Underlying Security Price
Call Struck at Par with One and Three Months to Expiration



limited to the value of the option; as the option gets further in-the-money, this possibility becomes more farfetched and the time value decreases.

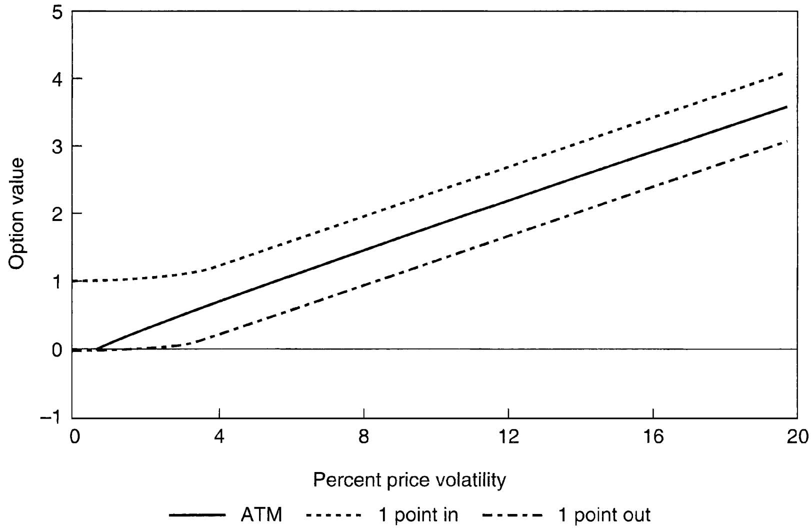
Either way, the time value depends on the probability that the security will trade through the strike price. In turn, this probability depends on how far from the strike price the security is trading and how much the security price is expected to vary until expiration.

Volatility measures the variability of the price or the yield of a security. It measures only the magnitude of the moves, not the direction. Standard option pricing models make no assumptions about the future direction of prices but only about the distribution of these prices. Volatility is the ideal parameter for option pricing because it measures how wide this distribution will be. We discuss volatility in more detail at the end of this chapter.

The higher the volatility of a security, the higher is the price of options on that security. If a security had no volatility, for example, that security would always have the same price at time of purchase of an option as at its expiration, so all options would be priced at their intrinsic value. Increasing the volatility of a security increases the time value of options on that security as the chance of the security price moving through the strike price increases. Increases in the value of an at-the-money option are approximately proportional to increases in the volatility of the underlying. Exhibit 66-8 shows how the price of an option behaves as the volatility of the underlying security increases.

EXHIBIT 66-8

Call Option Value versus Percent Price Volatility
Three Calls: At-the-Money, 1 Point In-the-Money, 1 Point Out-of-the-Money; Three Months from Expiration



The final factor that influences options prices is the *carry* on the underlying security. Carry is the difference between the value of the coupon payments on a security and the cost of financing that security's purchase price. With the usual upward-sloping yield-curve, most securities have a positive carry.

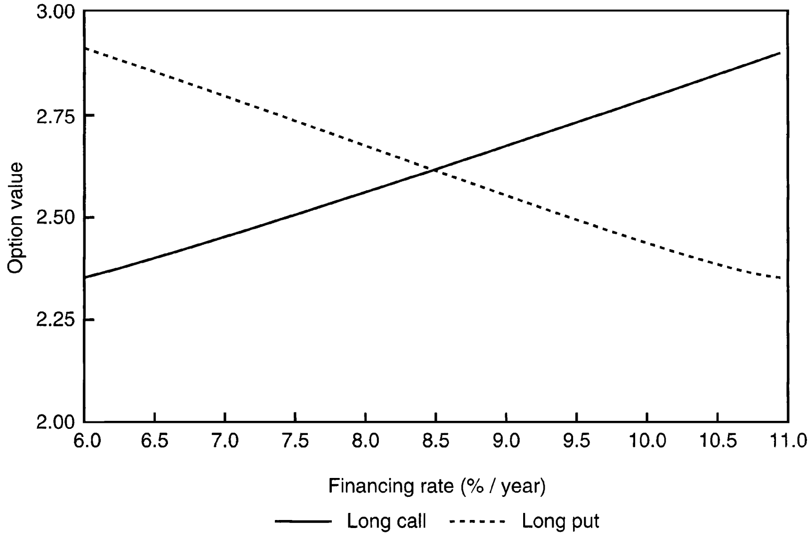
The effect of the carry can be seen by comparing the price of an at-the-money call with an at-the-money put where the underlying security has a positive carry. The writer of the call anticipates the chance of being required to deliver the securities and thus buys the underlying as a hedge; the put writer hedges by selling the underlying. The call writer earns the carry while the put writer loses the carry, so the call should cost less than the put. When the yield-curve inverts and short-term rates are higher than long-term rates, carry becomes negative and calls cost more than puts.

By put-call parity, selling an at-the-money call and buying an at-the-money put are equivalent to shorting the underlying security. The cash taken out of the option trade, accounting for transaction costs, compensates the option holder for the carry on the position in the underlying until expiration. This trade is called a *conversion,* and it is used frequently to obtain the effect of a purchase or sale of securities when buying or selling the underlying is impossible for accounting reasons.

Exhibit 66-9 compares the cost of an at-the-money call and put for a range of financing rates. The two graphs intersect where the call and the put have the same value: this happens when the cost of financing the underlying is equal to the coupon

EXHIBIT 66-9

Treasury Option Value versus Financing Rate
Long Call, Long Put Struck at Par, Three Months to Expiration



yield on the security, so the carry is zero and there is no advantage to holding the underlying over shorting it.

Exhibit 66-10 summarizes the parameters that affect the value of an option and how much raising each parameter affects that value.

Delta, Gamma, and Theta: Hedging an Option Position

More precise quantitative ways to describe the behavior of an option are needed to manage an option position. Options traders have created the concepts of delta,

EXHIBIT 66-10

The Effect of an Increase of a Factor on Option Values

	Call	Put
Underlying price	Increase	Decrease
Strike price	Decrease	Increase
Carry	Decrease	Increase
Time to expiration	Increase	Increase
Volatility	Increase	Increase

gamma, and theta for this purpose. Delta measures the price sensitivity of an option, gamma the convexity of the option, and theta the change in the value of the option over time.

For a given option, the *delta* is the ratio of changes in the value of the option to changes in the value of the underlying for small changes in the underlying. A typical at-the-money call option would have a delta of 0.5; that means for a 1-cent increase in the price of the underlying the value of the call would increase by 0.5 cent. On the other hand, an at-the-money put would have a delta of –0.5; puts have negative deltas because they decrease in value as the price of the underlying increases (see Exhibit 66-10).

The standard method of hedging an options position is called *delta hedging,* which unsurprisingly makes heavy use of the delta. The idea behind delta hedging is that for small price moves, the price of an option changes in proportion with the change in price of the underlying, so the underlying can be used to hedge the option. For example, 1,000,000 calls with a delta of 0.25 would for small price movements track a position of 250,000 of the underlying bonds, so a position consisting of 1,000,000 of these long calls and 250,000 of the security sold short would be delta-hedged. The total delta of a position shows how much that position is long or short. In the preceding example, the total delta is

$$0.25 \times 1{,}000{,}000 - 1 \times 250{,}000 = 0$$

so the position is neither long nor short.

Intuitively, the delta of an option is the number of bonds that are expected to be delivered into this option. For example, an at-the-money call has a delta of 0.5, which means that one bond is expected to be delivered for every two calls that are held. In other words, an at-the-money call is equally as likely to be exercised as not. An option that is deeply out-of-the-money will have a delta that is close to 0 because there is almost no chance that the option will ever be exercised. An option that is deeply in-the-money almost certainly will be exercised. This means that a deeply in-the-money put has a delta of –1 because it is almost certain that the holder of the option will exercise the put and deliver one bond to the put writer.

Put-call parity tells us that a position in the underlying security may be duplicated by buying a call and selling a put with the same strike price and expiration date. Thus the delta of the call less the delta of the put should be the delta of the underlying. The delta for the underlying is 1, so we get the following equation:

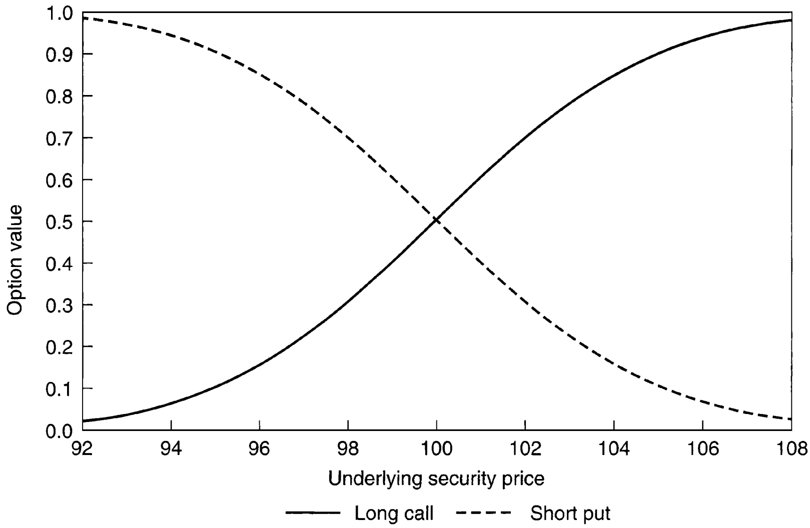
$$\text{Delta}(call) - \text{delta}(put) = 1$$

where call and put are options on the same security with the same strike price and expiration date. This says that once the call is bought and the put sold, the bond is certain to be delivered; if the call is out-of-the-money, the put is in-the-money. Moreover, as the chance of having the underlying delivered into the call becomes smaller, the chance of having to accept delivery as the put is exercised becomes larger. Exhibit 66-11 compares the deltas for a long and a short put.

Making the position delta-neutral does not solve all hedging problems, however. This is demonstrated in Exhibit 66-12. Each of the three positions

EXHIBIT 66-11

Option Delta versus Underlying Security Price
Long Call, Short Put Struck at Par, Three Months to Expiration



shown is delta-neutral, but position 1 is clearly preferable to position 2, which is, in turn, better than position 3. The difference between these three positions is *convexity*. A position such as position 1 with a profit/loss graph that curves upward has a positive convexity, whereas position 3 has a graph that curves downward and thus has negative convexity.

Gamma measures convexity for options; it is the change in the delta for small changes in the price of the underlying. If a position has a positive gamma, then as the market goes up the delta of the position increases and as it declines the delta decreases. Such a position becomes longer as the market trades up and shorter as the market trades down. A position like this is called *long convexity* or *long volatility.* These names come from the fact that if the market moves in either direction this position will outperform a position with the same delta and a lower gamma. Exhibit 66-13 shows this phenomenon.

A long option always has a positive gamma. The delta of a call increases from 0 to 1 as the security trades up, and the delta of a put increases also, moving from −1 to 0. Exhibits 66-1 and 66-2 show that the profit/loss graph of options curves upward. Because of this, options traders often speak of buying or selling volatility as a synonym for buying or selling options.

A position with a zero gamma is called *flat convexity* or *flat gamma.* Here, a change in the underlying security price does not change the delta of the position. Such a position trades like a position in the underlying with no options bought or sold. If the position has in addition a delta of zero, then its value is not affected by

EXHIBIT 66-12

Delta-Neutral Positions with Different Gamma

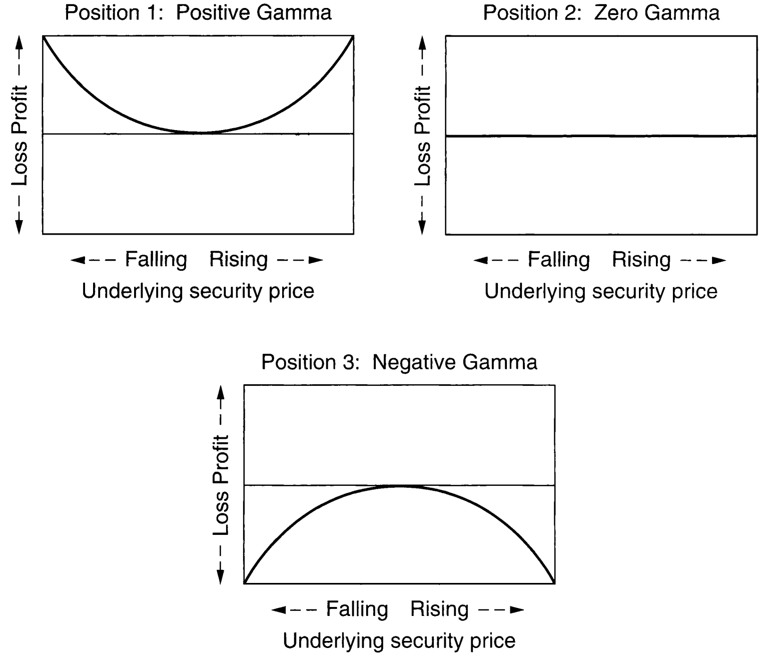


EXHIBIT 66-13

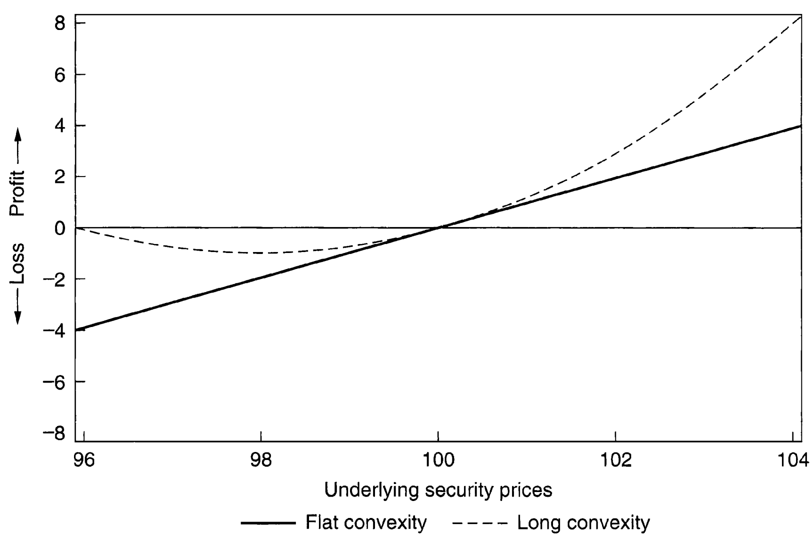
Profit/Loss Diagram with Convexity
Long Security with Flat and Long Convexity



small changes in the price of the underlying security in either direction. Position 2 in Exhibit 66-12 is a profit/loss graph for a position with no delta or gamma.

A position with negative gamma is called *short volatility* or *short convexity.* The profit/loss curve slopes downward in either direction from the current price on the underlying; thus the position gets longer as the market trades down and shorter as the market trades up. Either way, this position loses money if there are significant price movements. Position 3 demonstrates this behavior.

A position that is long volatility is clearly preferable to an otherwise identical position that is short volatility. The holder of the short-volatility position must be compensated for this. In order to create a position that is long volatility it is necessary to purchase options and spend money; moreover, if the market does not move, the values of the options will decrease as their time to expiration decreases, so the position loses money in a flat market.

Conversely, creating a position that is short volatility involves selling options and taking in cash. As time passes, the value of these options sold decreases because their time value falls, so the position makes money in a flat market. Large losses could be sustained in a volatile market, however.

To describe the time behavior of options, there is one last measure called *theta.* The theta of an option is the overnight change in value of the option if all other parameters (prices, volatilities) stay constant. This means that a long option has a negative theta because as expiration approaches, the time value of the option will erode to zero. For example, a 90-day at-the-money call that costs 2 points might have a theta of –0.45 ticks per day.

Exhibit 66-14 shows the effects of different volatility exposures.

EXHIBIT 66-14

Comparison of Different Volatility Positions (All Positions Are Delta-Neutral)

	Short Volatility	Flat Volatility	Long Volatility
Convexity	Position has negative convexity: gamma < 0	Position has no convexity: gamma = 0	Position has positive convexity: gamma > 0
Options purchased	More sold than bought	Sold as many as bought	More bought than sold
Time value	Position earns value as time passes: theta > 0	Position stays flat as time passes: theta = 0	Position loses value as time passes: theta < 0
Market moves	Position loses money if the market moves in either direction	Position is invariant with respect to market moves	Position makes money if the market moves in either direction

OPTIONS STRATEGIES—REORGANIZING THE PROFIT/LOSS GRAPH

Investors have many different goals: reducing risk, increasing rates of return, or capturing gains under expected market moves. Often these objectives are simply to rearrange the profit/loss graph of a position in accordance with the investor's expectations or desires. By increasing the minimum value of this graph, for example, the investor reduces risk.

Options provide a precise tool to accomplish this rearrangement. Because it is impossible to replicate the performance of an option position using just the underlying, options allow a much broader range of strategies to be used. The following characteristics of options provide an explanation.

Directionality

Both a put and a call are directional instruments. A put, for example, performs only in a decreasing market. This property makes options ideal for reducing directional risk on a position. Take, for example, a position that suffers large losses in a downward market and makes a consistent profit if prices rise. By purchasing a put option, some of these profits are given up in exchange for dramatically increased performance if the market declines.

Convexity

Buying and selling options makes it possible to adjust the convexity of a position in almost any fashion. Because OTC options can be purchased for any strike price and expiration, convexity can be bought or sold at any place in the profit/loss graph. For example, an investor holding mortgage-backed securities priced just over par might anticipate that prepayments on this security would start to increase dramatically if the market traded up, attenuating possible price gains. In other words, the investor feels that the position is short convexity above the market. To adjust the profit/loss graph, calls could be purchased with strike prices at or above the market. This trade sells some of the spread over Treasuries in exchange for increased performance in a rising market.

Fee Income

An investor who wishes to increase the performance of a position in a stable market can sell convexity by writing options and taking in fees. This increases the current yield of the position, at the cost of increasing volatility risk in some area of the profit/loss graph. A typical example of this is the venerable covered call strategy, where the manager of a portfolio sells calls on a portion of the portfolio, forgoing some profits in a rising market in exchange for a greater return in a stable or decreasing market.

Leveraged Speculation

Investors with a higher risk/reward profile wish to increase their upside potential and are willing to accept a greater downside risk. In this case, options can be used as a highly leveraged position to capture windfall profits under a very specific market move. A strongly bullish investor might purchase 1-point out-of-the-money calls with 30 days to expiration for 1/2 point. If the market traded up 2 points by expiration, the option then would be worth 1 point, and the investor would have doubled the initial investment; a corresponding position in the underlying would have appreciated in value by only about 2%. Of course, if the market did not trade up by at least 1 point, the calls would expire worthless.

CLASSIC OPTION STRATEGIES

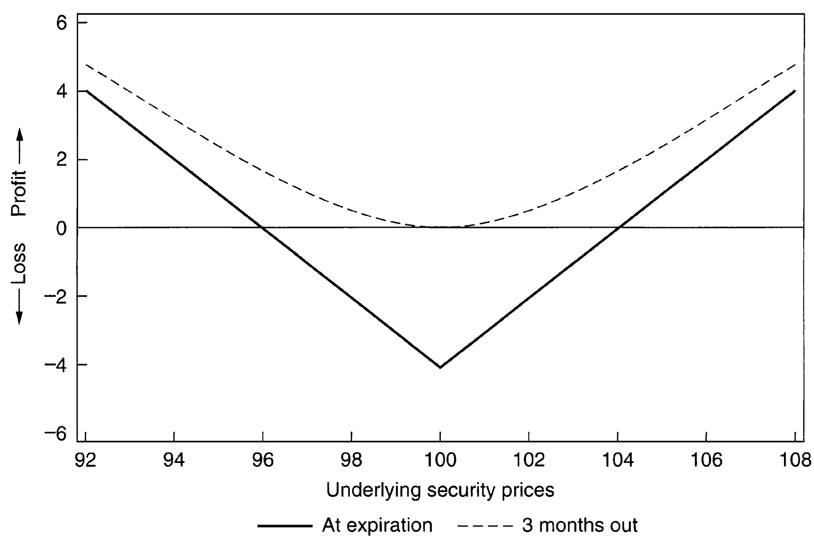
This section gives a brief explanation of some of the simplest pure options strategies.

Straddle

The most pure convexity trade is called a *straddle,* composed of one call and one put with the same strike price. Exhibit 66-15 shows the profit/loss graph of a straddle struck at-the-money at expiration and with three months to expiration.

EXHIBIT 66-15

Profit/Loss Diagram for a Long Straddle
Struck at Par, at Expiration, and Three Months Out



This position is delta-neutral because it implies no market bias. If the market stays flat, the position loses money as the options' time value disappears by expiration. If the market moves in either direction, however, either the put or the call will end up in-the-money, and the position will make money. This strategy is most useful for buying convexity at a specific strike price. Investors who are bearish on volatility and anticipate a flat market could sell straddles and make money from time value.

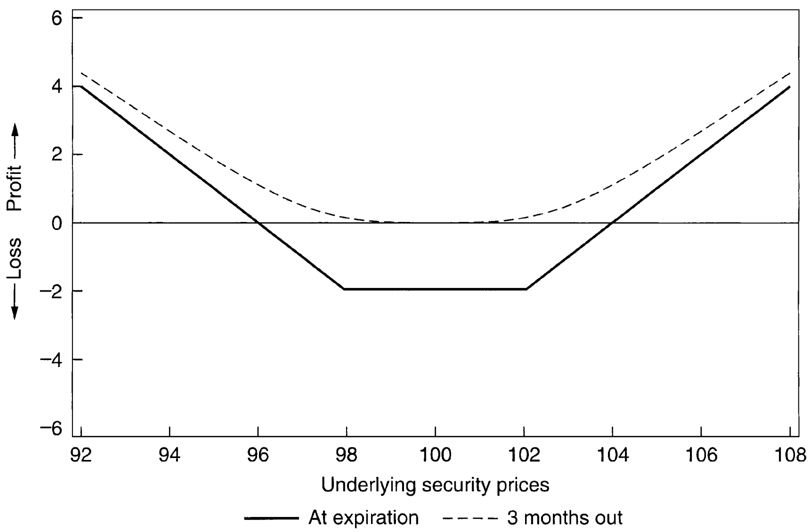
Strangle

A *strangle* is the more heavily leveraged cousin of a straddle. An at-the-money strangle is composed of an out-of-the-money call and an out-of-the-money put. The options are struck so that they are both equally out-of-the-money, and the current price of the security is halfway between the two strikes. The profit/loss graph is found in Exhibit 66-16.

Just like a straddle, a strangle is a pure volatility trade. If the market stays flat, the position loses time value, whereas if the market moves dramatically in either direction the position makes money from either the call or the put. Because the options in this position are both out-of-the-money, the market has to move significantly before either option moves into the money. The options are much cheaper, however, so it is possible to buy many more options for the same money.

EXHIBIT 66-16

Profit/Loss Diagram for a Long Strangle
Struck at Par, at Expiration, and Three Months Out



This is the ideal position for the investor who is heavily bullish on volatility and wants windfall profits in a rapidly moving market.

Writing strangles is a very risky business. Most of the time the market will not move enough to put either option much into the money, and the writer of the strangle will make the fee income. Occasionally, however, the market will plummet or spike, and the writer of the strangle will suffer catastrophic losses. This accounts for the picturesque name of this trade.

Spread Trades

Spread trades involve buying one option and funding all or part of this purchase by selling another. A *bull spread* can be created by owning the underlying security, buying a put struck below the current price, and selling a call above the current price. Because both options are out-of-the-money, it is possible to arrange the strikes so that the cost of the put is equal to the fee for the call. If the security price falls below the put strike or rises above the call strike, the appropriate option will be exercised and the security will be sold. Otherwise, any profit or loss will just be that of the underlying security. In other words, this position is analogous to owning the underlying security except that the final value of the position at expiration is forced to be between the two strikes. Exhibit 66-17 shows the profit/loss graph of this position at expiration and with three months left of time value.

EXHIBIT 66-17

Profit/Loss Diagram for a Bull Spread
Struck at Par, at Expiration, and Three Months Out

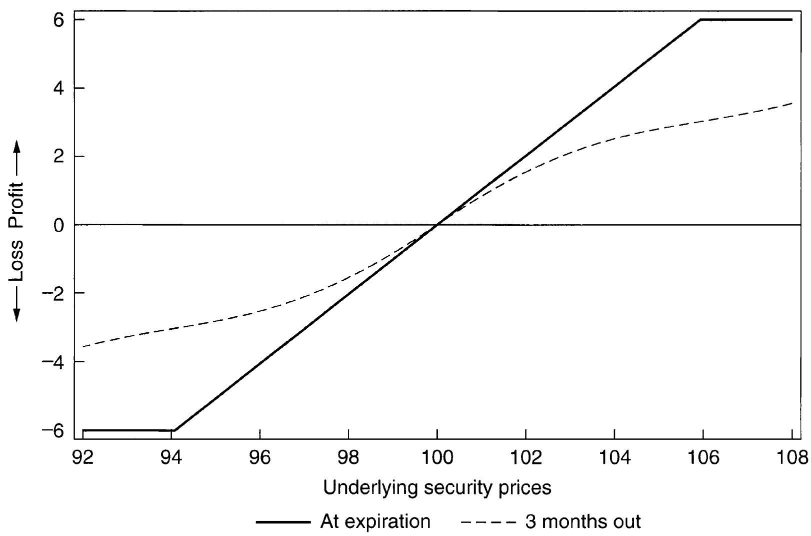


EXHIBIT 66-18

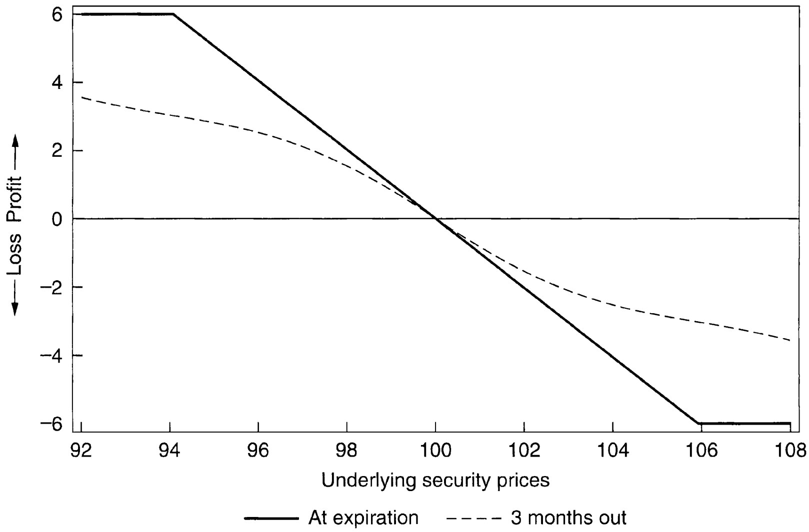
Profit/Loss Diagram for a Bear Spread Struck at Par, at Expiration, and Three Months Out



The other spread trade is a *bear spread:* It is the reverse of a bull spread. It can be created by selling a bull spread. Using put-call parity, it also can be set up by holding the underlying security, buying an in-the-money put, and selling an in-the-money call. A bear spread is equivalent to a short position in the underlying, where the position must be closed out at a price between the two strike prices. Exhibit 66-18 shows the profit/loss graph of a bear spread.

PRACTICAL PORTFOLIO STRATEGIES

The strategies discussed in the preceding section are the basic techniques used by speculators to trade options. The usual fixed income investor has a lower risk/reward profile than the speculator and specific objectives that must be accomplished; a floor on rate of return or an increase in current yield, for example. Such investors need a class of strategies different from that needed by speculators; even though the same strategies are often used, the risk is carefully controlled.

Portfolio Insurance

This is the most obvious and one of the most commonly used options strategies. An investor with a portfolio of securities who fears a decreasing market buys puts on some or all of the portfolio; if the market falls, the puts are exercised, and the securities are sold at the strike price. Alternatively, the investor may keep the underlying security and pair off the in-the-money puts, receiving cash in compensation for the decreased value of the security. Either way, the investor has limited losses on the portfolio in exchange for selling off return in a stable or rising market.

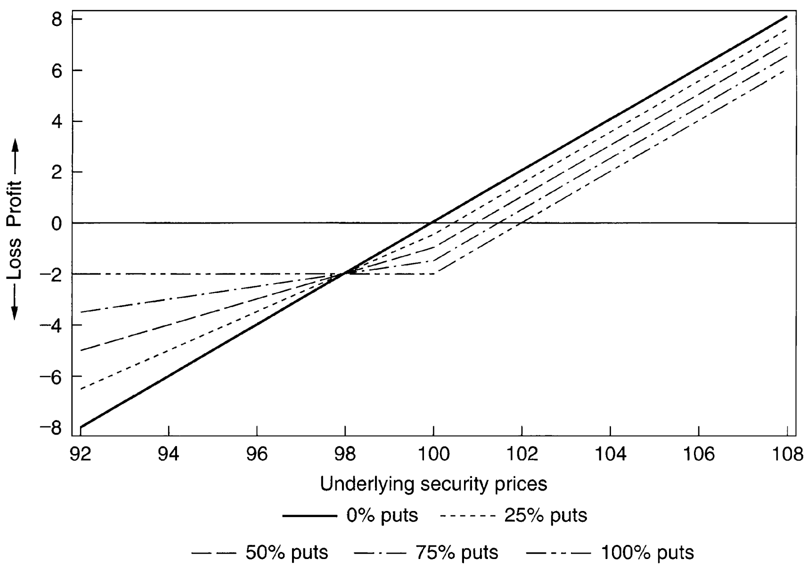
As the strike price of the put increases, so does its cost and the resulting impact on the stable market rate of return. Often, out-of-the-money options are used; the floor on returns is lower because the strike price is lower, but the lower cost of the options means that less return is given up if the market is flat or rises. By put-call parity, such a position is equivalent to holding a call option struck at or in-the-money.

Another popular strategy is to buy at-the-money options on a portion of the portfolio. This reduces but does not eliminate downside risk: Exhibit 66-19 shows the profit/loss graphs at expiration for positions with different percentages of the portfolio hedged with an at-the-money put. Note that all the graphs intersect at a single point. This is the point where the initial cost of the option is equal to the value of the option at expiration, which is the break-even price for this trade.

It is not possible to buy options on many classes of securities that may well be held in a portfolio. Perfect insurance for such securities is unattainable, but cross-market hedging often will permit a reduction in downside risk to acceptable levels.

EXHIBIT 66-19

Hedged Underlying Security with Puts
Long Puts Struck at Par, at Expiration



Covered Calls

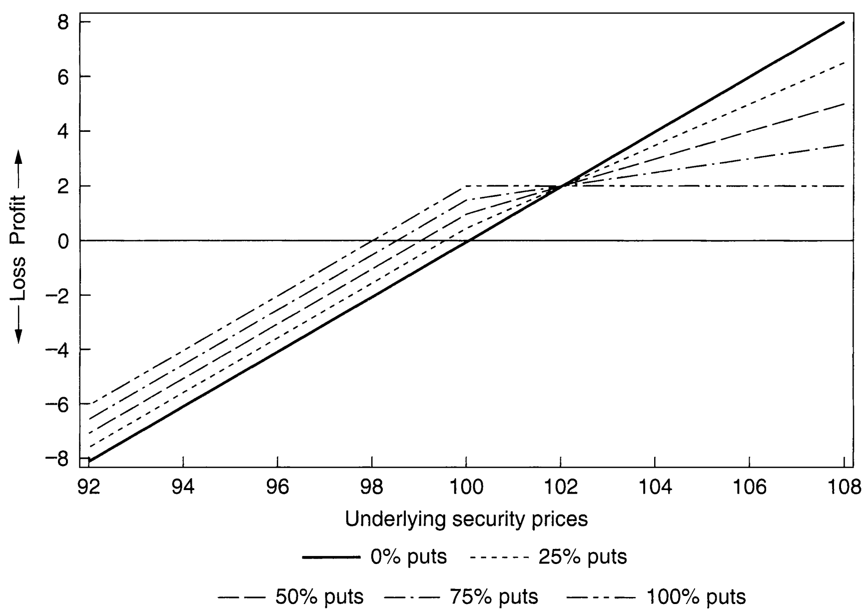
Writing covered calls is a strategy that sells volatility in return for fees. An investor who holds a portfolio sells calls on some or all of the portfolio in return for fees. If the market stays the same or falls, the investor pockets the option fees. If the market increases until the calls are in-the-money, the investor is called out by the option holder. In other words, possible gains on the portfolio are sold for fee income.

Often the investor wishes to preserve some upside potential. Just as in the portfolio insurance example, there are two different ways to do this. The calls can be struck out-of-the-money, that is, above the current market price. This strategy allows all gains up to the strike price to be captured. If the bonds in the portfolio are currently trading below the original purchase price, a popular strategy is to sell calls struck at this purchase price. This provides fee income and increased current yield but prevents the possibility that the bonds will be called at a price below the original purchase price and the portfolio will book a capital loss.

Otherwise, calls can be sold on a portion of the portfolio. This allows unlimited price gains to be captured on the remainder. Exhibit 66-20 shows the profit/loss graph of a covered call program where different portions of the portfolio have calls sold against them.

EXHIBIT 66-20

Covered Call Writing Program
Short Calls Struck at Par, at Expiration



Buy-Writes and Writing Puts

Buy-writes and writing puts are two very closely related strategies for selling volatility that most investors think of as entirely different. To execute a buy-write, a bond is purchased, and simultaneously, a call is written on this bond for the fee income. If the security is trading above the strike price at expiration, the security is called, and the investor is left with just the option fee. If the price of the security has fallen, the investor is left holding the security, but the total cost of the security is reduced by the fee from the call. By put-call parity, this trade is identical to writing a put struck at-the-money. In both cases, the investor is delivered the security only if the price of the security is lower than the price of the original sale.

In the MBS market, a buy-write is composed of forward purchases and short calls on forward delivery contracts (standard TBA transactions). If the call is exercised, it offsets the forward sale, and the buyer never takes delivery of the security, keeping the fee income. Otherwise, the buyer will receive the security on the forward settlement date for the original forward sale price, although the total price is decreased by the value of the option fee.

Put writing is a more general strategy that applies to all fixed income options markets. The investor writes a put for the fee income and receives the underlying instrument at expiration if the security trades below the strike price. This can be a very effective strategy if carefully structured. An investor may feel that a security offers real value if bought at a certain price below the market. The investor could then write puts struck at that price. If the security falls below the strike, it is delivered at a price that is more agreeable than the current price. Otherwise, the investor simply pockets the fee income.

VOLATILITY

Volatility plays a key role in the valuation of options and in option strategies. In this section we focus on methods for estimating volatility.

Statistically, volatility is a measure of the dispersion or spread of observations around the mean of the set of observations. If volatility seems strangely like a standard deviation, then you remember your statistics. When people speak of volatility, all they really are talking about is a standard deviation.

For fixed income securities, volatility is expressed in yield or price units, either on a percentage or on an absolute basis. Price volatilities can be computed for any security. Yield volatilities should be computed only for those securities with a consistent method for computing yield. Given the complexity of calculating a yield on a MBS and the variation of results, the predominant volatility measure in the MBS market is price volatility. The government bond market, where yields are easily calculated, favors yield volatility.

There are two types of volatility: empirical volatility and implied volatility. Each is described below.

Empirical Volatility

Empirical volatility is the actual, historical market volatility of a specific security. These numbers typically are calculated for various time periods (10 days, 30 days, 360 days) and usually are annualized.[1] Calculating an empirical volatility is nothing more than calculating the standard deviation of a time series. Thus an absolute volatility is the annualized standard deviation of daily price or yield changes, assuming a normal distribution.

Percentage volatility is the annualized standard deviation of the daily change in the log of prices or yields, assuming a lognormal distribution of prices or yields. Similar to the daily absolute yield changes, the logs of the daily yield changes have a slight bias toward lower yields. The intuitive approach to calculating a percentage volatility is to find the standard deviation of daily *returns,* assuming a normal distribution. This approach is equivalent to the lognormal assumption as long as the distribution can be characterized as being equally normal and log normal and, the changes in prices are taken on a small interval, such as daily.

As mentioned previously, empirical volatility can be measured over various time periods. The most common interval on which the standard deviation is taken is 30 days; other common intervals are 10 days and 360 days. The choice of interval determines how quickly and to what degree an empirical volatility responds to deviations. As the time period shortens, volatility increasingly reflects current conditions but is more unstable as each sample asserts greater influence in the deviation. Conversely, as the interval increases, more of a lag and a smoothing are introduced into the calculation.

The interval used to calculate an empirical volatility should be chosen to match the length of the option contract. This provides the investor with an indication of how volatile the underlying security has been recently and how this relates to the volatility employed to price the option.

With no industry standard for volatility units, converting between the price and yield expression of absolute or percentage volatility is a useful skill. The path to follow to convert from one unit to the next is shown in Exhibit 66-21. The modified duration of a security provides the link between price and yield volatilities. Modified duration is defined as the percentage change in price divided by the absolute change in yield.

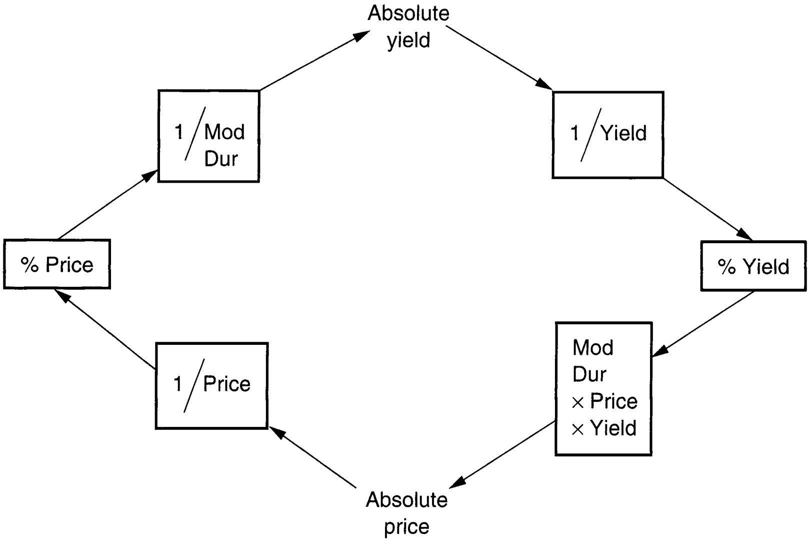
Implied Volatility

Implied volatility is merely the market's expectation of future volatility over a specified time period. An option's price is a function of the volatility employed, so where an option's price is known, the implied volatility can be derived. Although it sounds straightforward, calculating an implied volatility is far more

1. When annualizing a volatility, certain assumptions are inherent to the calculation. To convert from daily to yearly volatility, for example, the daily volatility is multiplied by the square root of the number of business days in the year, approximately 250.

EXHIBIT 66-21

Converting Volatility Measures



complicated than calculating an empirical volatility because expectations cannot be observed directly. An option pricing model along with a mathematical method to infer the volatility must be employed. The result of this calculation is a percentage price volatility that can be converted to the various types of volatility measures discussed previously (see Exhibit 66-21).

Owing to the existence and liquidity of fixed income options, proxies for implied volatilities can be derived from Treasuries. Options on Treasury futures listed on the Chicago Board of Trade (CBOT) are often the best vehicles for implied volatility calculations. The resulting implied volatility provides a good indication of the market's expected volatility for the Treasuries with maturities similar to that of the particular bond futures contract in question. The implied volatility on the 10-year bond futures contract, for example, is a useful proxy for the market's expected volatility on intermediate-term Treasury securities.

KEY POINTS

- An option is the right but not the obligation to buy (a call option) or to sell (a put option) a security at a fixed price (strike price or exercise). The expiration date is the last date on which the option can be exercised. Some options can be exercised at any time until expiration (American options); some options can only be exercised at expiration (European options).

- The relationship among the price of a security, the price of a put, and the price of a call is called the put-call parity and is one of the foundations of the options markets.
- The price of an option is the sum of its intrinsic value and time value.
- Volatility measures the variability of the price or the yield of a security. It measures only the magnitude of the moves, not the direction. Standard option pricing models make no assumptions about the future direction of prices but only about the distribution of these prices. Volatility is the parameter used for option pricing because it measures how wide this distribution will be. The higher the volatility of a security, the higher is the price of options on that security.
- To manage an option position, quantitative ways to describe the behavior of an option are needed. These include an options delta, gamma, and theta.
- Any investor with specific goals can use option strategies to tailor the performance of a portfolio.
- Because it is impossible to obtain the effects of options by using only the underlying securities, a whole new universe of strategic possibilities is opened up. In particular, investors with contingent liabilities cannot create an adequate hedge without the use of options.
- Increased liquidity in the options markets and a better understanding of the properties of options make option strategies more accessible to the average investor and allow these strategies to be used for a wider range of securities. In particular, the over-the-counter options markets allow the purchase and sale of options with any desired strike price and expiration date.
- Refinements to option valuation technology continue to improve cross-market arbitrage trades where securities and options in one market can duplicate securities in another. As options trading removes the arbitrages, the relationships among the various markets are reinforced.

CHAPTER
SIXTY-SEVEN

INTEREST-RATE CAPS AND FLOORS

Anand K. Bhattacharya, Ph.D.

Bill Berliner
Managing Director
Research and Fixed Income Investor Relations
PennyMac

Interest-rate caps and floors provide asymmetric interest-rate risk management capabilities similar to those provided by options, except that protection can be customized to a much greater degree. As indicated by the nomenclature, *interest-rate caps,* also referred to as *interest-rate ceilings,* allow the purchaser to ''cap'' the contractual rate associated with a liability. Alternatively, *interest-rate floors* allow the purchaser to protect the total rate of return of an asset. The seller of the cap pays the purchaser any amount that the contractual rate closes above the periodic capped rate on the last day of each contractual period. Conversely, the purchaser of the floor receives from the seller any amount that the contractual rate closes below the periodic protected rate on the relevant date. The protection provided by caps and floors is asymmetric, in that the purchaser is protected from adverse moves in the market but maintains the advantage of beneficial moves in market rates. In this respect, caps and floors differ from interest-rate swaps and are more akin to put and call options based on the level of an interest rate. Recall that interest-rate swaps seek to insulate the user from the economic effects of interest-rate volatility, regardless of the direction of interest rates.

Interest-rate protection obtained by purchasing caps and floors can be customized by selecting various contractual features. The following decision variables are commonly used in determining the parameters of either interest-rate caps or floors.

The version of this chapter that appeared in the third edition was coauthored with Dr. John Breit.

FEATURES OF INTEREST-RATE CAPS AND FLOORS

The *underlying index* from which the contractual payments will be determined can be chosen from a set of indexes based on LIBOR,[1] commercial paper, prime rate, Treasury bills, or certificates of deposit. Because these instruments are originated along several maturities, an additional variable associated with the index concerns the maturity of the index.

The *strike rate* is the rate at which the cash flows will be exchanged between the purchaser and seller of the customized interest-rate protection instrument. Caps with a higher strike rate have lower up-front premiums, although the trade-off between the premium and the strike rate is not directly proportional. Similarly, floors with a lower strike rate have a lower up-front premium. Increasing (decreasing) the strike rate does not necessarily result in a proportionate decrease in the up-front fee for interest-rate caps (floors).

The term of the protection may range from several months to about 30 years, although the liquidity of longer-dated caps is not very good.

The *settlement frequency* refers to the frequency with which the strike rate will be compared to the underlying index to determine the periodic contractual rate for the interest-rate protection agreement. The most common frequencies are monthly, quarterly, and semiannually. At settlement, the cash flows exchanged could be determined on either the average daily rate prevalent during the repricing interval or the spot rate on the settlement date.

The *notional amount* of the agreement on which the cash flows are exchanged is usually fixed, unless the terms of the agreement call for the amortization of the notional amount. For instance, in ‘‘spread enhancement’’ strategies, which involve the purchase of an amortizing asset such as a fixed-rate mortgage-backed security funded by floating-rate capped liabilities, amortization of the cap notional amount may be necessary in order to maintain the spread. Unless the amortization feature is included in the design of the cap, the spread between the asset cash flows and the liability costs will be eroded.

PRICING OF CAPS AND FLOORS

The *upfront premium* is the fee paid by the purchaser to the seller of the interest-rate agreement at the inception of the contract. This fee is similar to the premium paid to purchase options and is determined by factors such as the strike rate, the current level of the contractual rate, the volatility of the underlying index, the length of the agreement, the notional amount, and any special features, such as amortization of the notional principal.

1. While many of the examples cited in this chapter reference LIBOR as the underlying index, we note that LIBOR is scheduled to be replaced by some form of the Secured Overnight Funding Rate (SOFR) and may not be published after 2020.

The pricing of both caps and floors draws heavily on option pricing theory; for instance, an increase in market volatility results in a higher premium for both the cap and the floor. The strike rate for a cap is inversely related to the premium paid for the cap because rates have to advance before the cap is in the money or the payoff is positive. On the other hand, the strike rate for interest-rate floors is positively correlated with the up-front premium. A higher strike indicates that the likelihood of the index falling below this rate is greater, which indicates a higher likelihood of positive payoff from the floor. The longer the term-to-maturity the greater the premium, because optional protection is available for a longer period of time. Hence, there is a higher probability that the payoff associated with these instruments will be positive. With respect to the payment frequency, the agreement with a shorter payment frequency will command a higher premium because there is a greater likelihood of payoff and the payments are determined only on the settlement date. This may be an important determinant of cash flows, especially in highly volatile markets. Any advantageous changes in market volatility for interest-rate agreements with longer settlement frequencies may not result in a payoff for the purchaser of the agreement because the option-like characteristics of caps and floors are European rather than American in design.

There also may be additional contractual features associated with caps and floors, such as variable premiums, cost of termination options prior to stated maturity, conversion privileges from one program to another, and purchase of a combination of programs, such as *interest-rate collars* and *corridors*.

INTEREST-RATE CAPS

As noted above, an interest-rate cap can be used to create an upper limit on the cost of floating-rate liabilities. The purchaser of the cap pays an up-front fee to establish a ceiling on a particular funding rate. If the market rate exceeds the strike rate of the cap on the settlement date, the seller of the cap pays the difference. As an illustration, consider the following example, where an institution purchases an interest-rate cap to hedge the coupon rate of LIBOR-indexed liabilities, which reprice every three months.

Notional amount:	$10,000,000
Underlying index:	3-month LIBOR
Maturity:	3 years
Cap strike level:	6%
Premium:	145 basis points or 1.45% of $10,000,000 = $145,000
Settlement frequency:	Quarterly
Day count:	Actual/360

The up-front premium can be converted to an annual basis-point equivalent by treating \$145,000 as the present value of a stream of equal quarterly payments with a future value of zero at the maturity of the cap. Ideally, this should be computed at the rate at which the up-front premium can be funded for three years. Assuming that this premium can be funded at a rate of 5% and the cap has 12 reset periods, the annual basis-point equivalent of the up-front premium is 52 basis points.[2]

In this example, the payments to the purchaser of the cap by the seller can be determined as the quarterly difference between the three-month LIBOR index and the cap strike rate of 6% times the notional amount of the agreement. Specifically, the cap payments are computed as follows:

$$(\text{Index rate} - \text{Strike rate}) \times (\text{Days in settlement period}/360) \times \text{Notional amount}$$

For instance, where three-month LIBOR is 7%, the payments made by the cap seller, assuming 90 days in the settlement period, would be determined as follows:

$$(7\% - 6\%) \times (90/360) \times 10{,}000{,}000 = \$25{,}000$$

The purchaser does not receive any payments when the reference rate, as indicated by the value of three-month LIBOR, is below the strike rate of 6%. The payoff profile of this capped liability is illustrated in Exhibit 67-1. Because the annual amortized premium of the cap is 52 basis points, the maximum rate associated with the capped liability at a strike of 6% is 6.52%. In interest-rate scenarios where the value of three-month LIBOR is below 6%, the interest expense of the capped liability is higher than the unhedged interest expense by the amount of the amortization of the up-front premium. Given that the maximum risk exposure associated with the purchase of the cap is limited to the up-front premium, the dynamics of caps are similar to those of debt options. On a more specific basis, because the purchaser of the cap benefits in rising rate scenarios, the conceptual options analog is a strip of put options. However, caps can be purchased for maturities longer than those associated with a strip of puts. By increasing the strike rate of the cap, say, from 6% to 6.5%, the up-front premium (and hence the annual amortized premium) can be reduced. However, as illustrated in Exhibit 67-2, the maximum interest expense of the capped liability increases with a higher cap strike rate.

There are several advantages associated with the use of the cap in protecting the interest expense of a floating-rate liability. The purchaser of the cap can obtain protection against higher rates and also fund the liabilities at a floating rate to take advantage of lower interest rates. In this respect, the capped liability strategy can result in a lower cost of funds than certain fixed-rate alternatives.

---

2. This represents the annuity over three years (12 periods), which when discounted quarterly (1.25%) at an annual rate of 5% equals the up-front premium of 145 basis points.

EXHIBIT 67-1

Effective Interest Expense of a Capped Liability

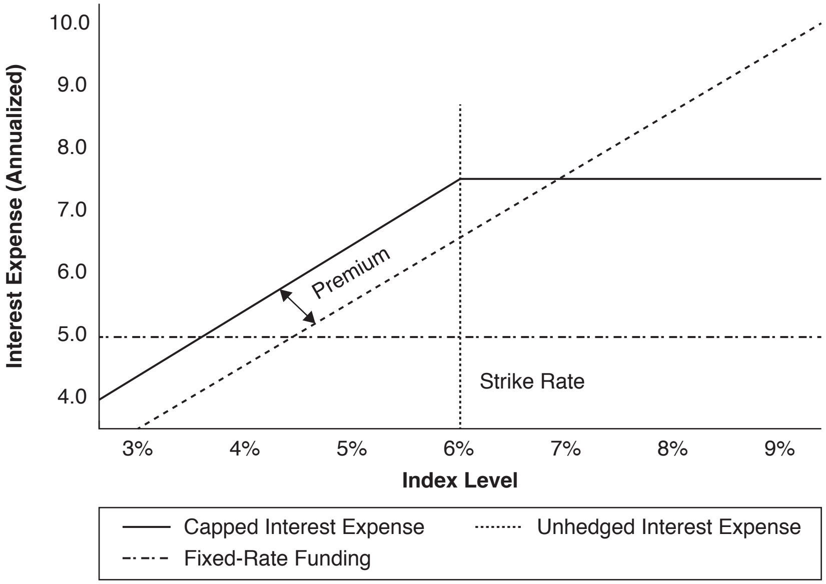

EXHIBIT 67-2

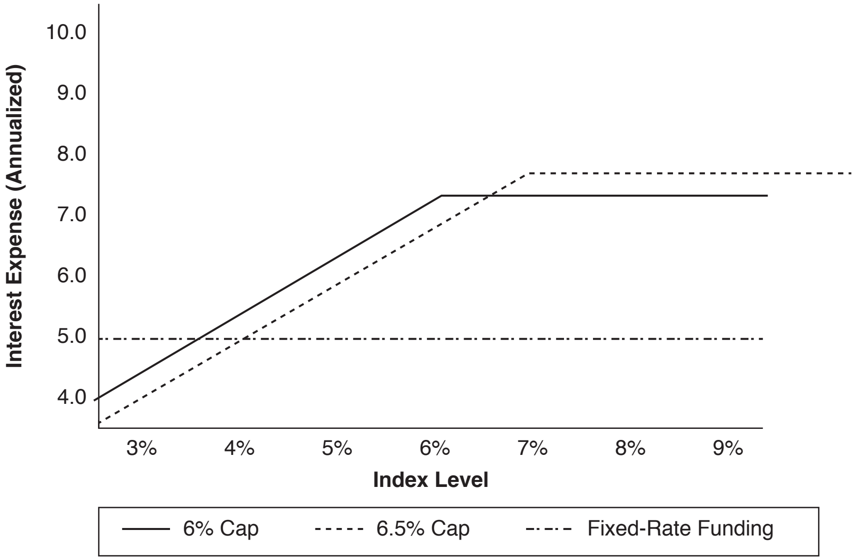
Effective Interest Cost Under Two Cap Levels



In addition to capping the cost of liabilities, interest-rate caps can also be used to synthetically offset embedded caps in floating-rate instruments such as CMO floaters and adjustable-rate mortgages. For instance, consider the case of an institution owning a CMO floater bond that reprices monthly at a spread of 60 basis points over LIBOR with an 8% cap (i.e., a maximum coupon rate) when LIBOR is at 3.0%. Because the only sources of cash flow available to CMO bonds are the principal, interest, and prepayment streams of the underlying mortgages, CMO floaters must be structured with a cap that is set at the time of issuance. The institution could strip off the embedded cap in the CMO floater by buying a cap at a strike rate of 7.4% (i.e., the LIBOR rate at which the coupon cap will be reached). With a strike rate that is 440 basis points out of the money, the cap could be purchased fairly inexpensively. If LIBOR exceeds 7.4%, the loss in coupon by the embedded cap feature of the CMO bonds would be compensated by the cash inflows from the cap. The same strategy could be applied to strip caps inherent in adjustable-rate mortgages. However, the exercise of stripping caps associated with adjustable-rate mortgages is somewhat more difficult because the product is typically associated with both periodic and lifetime caps. While there is theoretical appeal in this strategy, the efficacy of the process may be hampered by the presence of multiple caps as well as the unexpected prepayments associated with the assets.

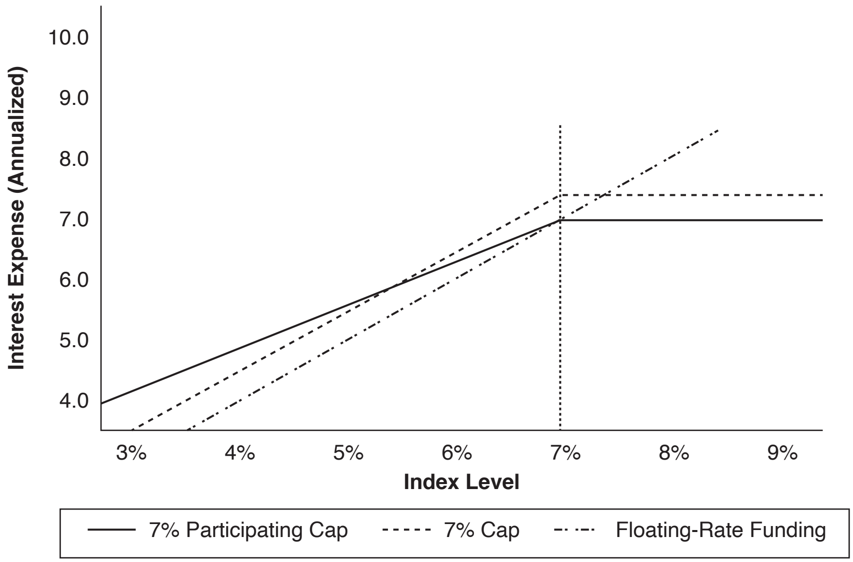
PARTICIPATING CAPS

It is difficult to pinpoint the exact nature of financial instruments labeled as participating caps. A common theme in the definition of such instruments is the absence of an up-front fee used to purchase the cap. The confusion in definition arises from the variations of the term *participating*. One type of participating cap involves the purchase of cap protection where the buyer obtains full protection in the event that interest rates rise. However, in order to compensate the seller of the cap for this bearish protection, the buyer shares a percentage (the participation) of the difference between the capped rate and the level of the floating-rate index in the event that interest rates fall.

For illustrative purposes, assume that a firm purchases a LIBOR participating cap at a strike rate of 7% with a participation rate of 60%. If LIBOR increases to levels greater than 7%, the firm will receive cash flows analogous to a nonparticipating cap. However, if LIBOR is below the capped rate, say, 5%, then the firm gives up 60% of the difference between LIBOR and the capped rate, that is, (7% – 5%) × 0.6 = 1.2%. In this case, the effective interest expense would be 6.20% (5.00% + 1.20%) instead of LIBOR plus the annual amortized premium, as in a nonparticipating cap. In bullish interest-rate scenarios, the effective interest expense using a participating cap would be higher than a nonparticipating cap owing to the participation feature. However, in bearish interest-rate scenarios, the effective interest cost of the floating-rate liability would be higher for a nonparticipating cap owing to the annualized cost of the up-front premium. An illustration of the effective interest costs using both hedging alternatives is presented in Exhibit 67-3.

EXHIBIT 67-3

Effective Interest Expense for Participating Cap



Other participating instruments, also known as *participating swaps,* combine the analytical elements of interest-rate swaps and caps to create a hedge for floating-rate liability costs. In a participating swap structure, the firm uses interest-rate swaps to convert the floating liability rate to a fixed rate and uses caps to create a maximum upper limit on the remainder of the interest expense of the floating-rate liability. However, what distinguishes this structure is that the caps are purchased without paying an up-front fee. The purchase is funded by executing the swap (fixed-rate payer/floating-rate receiver) at an off-market rate involving a higher spread than the current market rate for equivalent maturity swaps. Such participations can be structured in one of the following ways.

The buyer decides the maximum rate on the floating-rate liability, which leads to the problem of determining the mixture of notional amounts of caps and swaps.

The buyer decides on the relative mix of swaps and caps, which leads to the problem of determining the maximum rate level that can be attained with this combination.

Regardless of the choice by the buyer, the following relationship should hold in this type of participating structure:

$$\text{(Present value of annuity at } r_o - r_m, t) \times (\text{\% of swap}) = \text{Cap premium} \times (\text{\% of cap})$$

or

$$\text{Present value of annuity at } r_o - r_m, t \times (\% \text{ of swap}) = \text{Cap premium} \times (1 - \% \text{ of swap})$$

or

$$\% \text{ of cap } \frac{\text{Present value of annuity at } r_{o\,-}\, r_m, t}{\text{Cap premium} + \text{Present value of annuity at } r_{o\,-}\, r_m, t}$$

where

r_m = Current market swap fixed rate for t periods
r_o = Off-market swap fixed rate for t periods

As an example, consider the case of an institution desiring to cap a floating-rate liability expense that floats at a spread of 10 basis points over three-month LIBOR at a maximum rate of around 7% for a period of five years using this type of participating cap structure. The current market rate on a five-year pay-fixed and receive-floating (three-month LIBOR) swap is 80 basis points over the five-year Treasury yield at a rate of 4.40%. The current level of LIBOR is 4% and off-market five-year swaps are priced at a fixed rate of 5%. The cap premium for a five-year cap indexed off three-month LIBOR at a strike rate of 7% is 200 basis points, or 2% of notional amount.

The value of the annuity for five years is the difference between the off-market and the current market swap rate (that is, 5% – 4.40% = 0.60%). The present value of this annuity for five years at a discount rate of 4.40% (current swap rate) is 2.76%. Therefore, using the above equation for participating structures, the amount of the caps is defined as [2.76/(2.76 + 2.0000)] = 58%. Hence, the amount of swaps is (1 – 0.58) = 0.42, or 42%. Using this structure, the effective liability expense in various interest-rate scenarios is presented in Exhibit 67-4. In this example, the synthetic fixed rate using swaps is based on the higher off-market rate, whereas the blended rate is determined as a weighted average of the cap and the swap fixed rate.

EXHIBIT 67-4

Effective Interest Expenses Using Participating Cap Structure

LIBOR	Unhedged	Capped Rate 58% Caps	Synthetic Fixed Rate 42% Swaps	Blended Rate
6.0%	6.1%	7.1%	6.0%	6.64%
4.0	4.1	7.1	4.0	5.80
2.0	2.1	7.1	2.0	4.96

In bullish interest-rate scenarios, the blended rate is higher than the unhedged expense owing to the existence of the swap. The full benefit of the fall in rates is attained only partially by the portion of the liability mix that is capped. As interest rates increase, the blended rate is also higher than current market swaps owing to the existence of the higher-priced off-market swap that is used to fund the cap premium.

INTEREST-RATE FLOORS

Interest-rate floors are used to protect the overall rate of return associated with a floating-rate asset. As an example, consider the case of a financial institution that owns adjustable-rate mortgages in its portfolio. In the event that interest rates decrease, the coupon payments on floating-rate assets will be lower because the repricing of variable-coupon assets is based on a floating-rate index. In order to protect the asset rate of return in bullish interest-rate scenarios, the firm could purchase an interest-rate floor. Analogous to caps, the protective features of a floor can be customized by choosing various attributes of interest-rate protection. As an illustration, consider the following interest-rate floor purchased by an institution to protect the return on Treasury bill–indexed floating-rate assets:

Notional amount:	$10,000,000
Underlying index:	3-month Treasury bill
Maturity:	3 years
Floor strike level:	2%
Premium:	85 basis points or 0.85% of $10,000,000 = $85,000
Settlement frequency:	Quarterly
Day count:	Actual/360

The cash-flow dynamics of interest-rate floors are opposite to those of interest-rate caps, as illustrated in Exhibit 67-5. As can be seen in this illustration, a floor is beneficial in bullish interest-rate scenarios. Hence, purchasing a floor is analogous to buying a strip of call options. In bearish interest-rate scenarios, the floating-rate asset earns returns constrained only by the contractual features of such instruments (if any), such as embedded caps. However, the asset return is reduced marginally by the amortization of the floor premium. In bullish interest-rate scenarios, where the asset returns are subject to erosion, the seller of the floor pays the buyer the difference between the strike rate of the floor and the value of the underlying index, adjusted for the days in the settlement period to compensate for the loss in asset coupon.

INTEREST-RATE COLLARS

Interest-rate collars involve the purchase of a cap to hedge a floating-rate liability at a higher strike rate and the sale of a floor at a lower strike rate to offset the cost of purchasing the cap. If the underlying index rate exceeds the capped rate on the reference date, the seller of the cap pays the firm the amount above the capped rate; if the market rate is less than the floor strike rate, the firm pays the buyer the difference between the floor rate and the index level. If the market rate is between the strike rate of the cap and the strike rate of the floor, the effective interest costs of the firm are normal floating-rate funding costs plus the amortized cap premium (outflow) less the amortized floor premium (inflow). The net effect of this strategy is to limit the coupon rate of the floating-rate liability between the floor strike rate and the cap strike rate. The coupon liability rate is adjusted by the net amount of the amortized cap premium paid and the amortized floor premium received to determine the effective interest cost.

For example, assume that a firm has floating-rate liabilities that are indexed at three-month LIBOR. In order to cap this floating-rate liability for one year, the firm purchases an interest-rate cap at a strike rate of 8% for a premium of 85 basis points. In order to offset this cost, the firm sells a floor at a strike rate of 5% for a premium of 60 basis points. The profit and loss profile of this strategy is presented in Exhibit 67-6. As interest rates rise above the cap strike rate, the firm receives cash flows from the seller of the cap offsetting the higher outflow on the floating-rate liability. As interest rates fall below the floor strike rate, the falling interest expenses associated with the floating-rate liability are offset by the cash outflows to the buyer of the floor. In interest-rate scenarios between the floor and cap strike rate, there are no cash outflows or inflows associated with the hedges. This results in interest expenses associated with the floating-rate liability equal to normal borrowing costs. However, effective interest costs will be slightly higher to account for the net cap less floor premium, unless the collar is structured with a zero premium. In zero-premium collars, the idea is to equate the premium paid with the premium received. However, this strategy could be potentially risky as a higher notional amount may have to be sold to equate the premia. In view of this consideration, the short side of the zero-premium strategy involves notional amounts greater than the notional amount of the long side of the strategy.

The main benefit from an interest-rate collar is that the firm obtains protection from interest-rate increases at a considerably lower cost than with the purchase of a cap. However, in return for the benefit of lower-cost interest-rate protection, the firm gives up the benefit from market rallies below the floor strike rate. Because the interest-rate protection is obtained without fixing rates, interest-rate collars are sometimes also described as *swapping into a bond.* However, this is an inefficient form of creating a collar because of the bid–ask volatility spread[3] associated with the structure. Given that the strategy involves buying a cap and

3. See the discussion on termination of caps and floors later in this chapter.

EXHIBIT 67-5

Effective Return of a Floored Asset

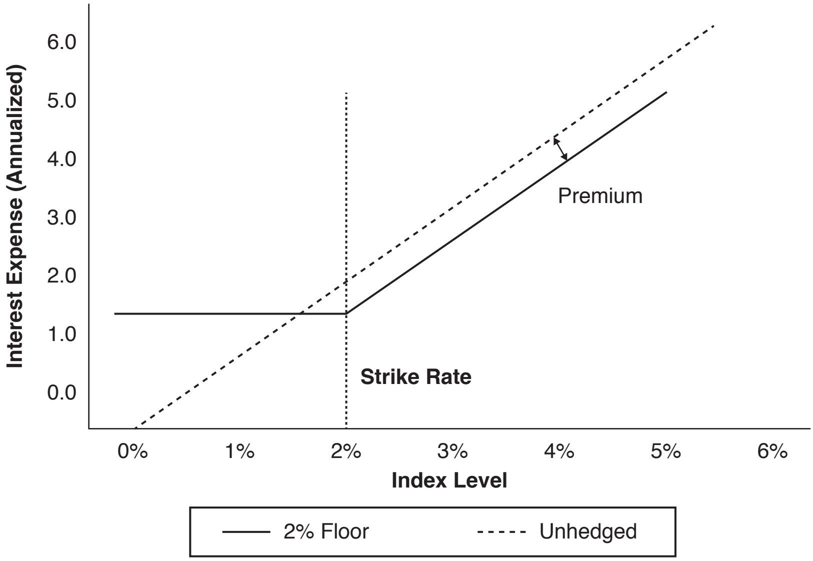


EXHIBIT 67-6

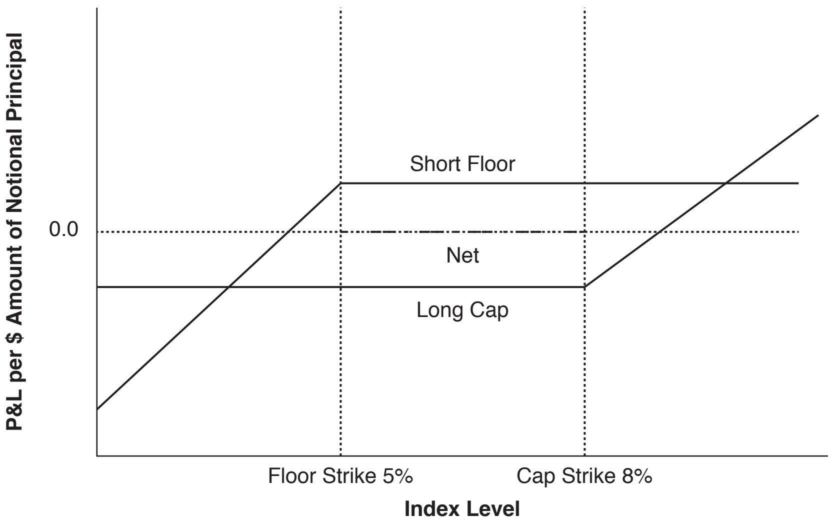
Interest-Rate Collar



selling a floor, the premium paid for the cap is based on a higher offer volatility, whereas the premium received for the floor is based on a lower bid volatility.

INTEREST-RATE CORRIDORS

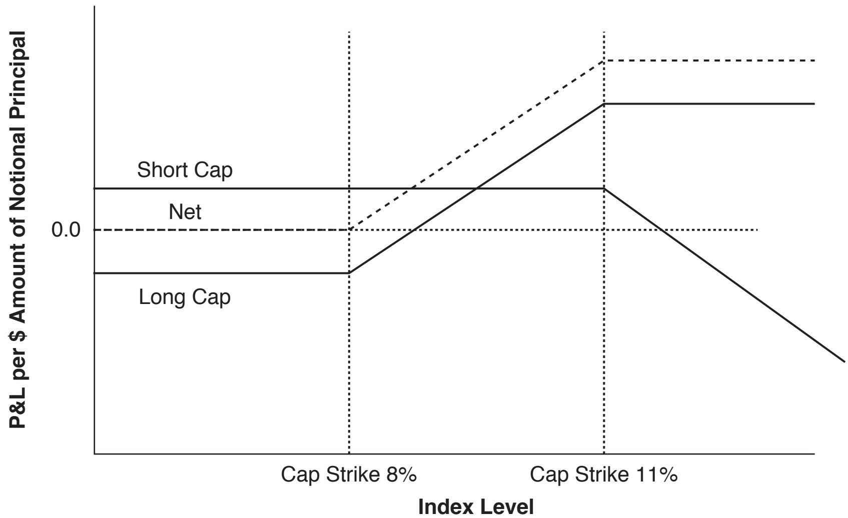
An alternative strategy to reduce the cost of the cap premium is to buy a cap at a particular strike rate and sell a cap at a higher strike rate, reducing the cost of the lower strike cap and hedging the interest expense of a floating-rate liability. In contrast to an interest-rate collar, the firm maintains all the benefit of falling interest rates, because there is no sale of a floor. As long as rates are below the strike rate of the lower strike cap, the effective interest expense of the firm is limited to normal borrowing cost plus the amortized net cap premium. As interest rates increase above the lower strike rate, the interest cost to the firm is capped until market rates are above the higher strike cap. As interest rates rise above the strike rate of the second cap, interest costs increase by the amount of the outflow of the cap.

As an illustration, consider the case of a firm that purchases a cap at a strike rate of 8% and sells a cap at a strike rate of 11% to offset the cost of the first cap. The profit and loss profile of this strategy is presented in Exhibit 67-7. At market rates below 8%, the caps are out of the money, and the firm's effective interest cost floats at normal borrowing costs plus the net amortized cap premium. As interest rates increase above 8%, the first cap is in the money and starts paying cash flows to the firm to offset the higher coupon associated with the floating-rate liability. This allows the firm to cap the effective interest expense at a rate of 8% plus the net amortized cap premium. However, at rates higher than 11%, the second cap becomes in the money, and the firm has to start paying cash flows to the cap buyer. The net effect of this development is to increase the liability costs by the amount of cash outflows associated with the second cap.

Although interest-rate corridors allow the firm to offset the cost of capping floating-rate liabilities, a word of caution is in order, especially if the caps are struck under the auspices of a zero-premium strategy. Cap premiums are determined by principles of option pricing theory; consequently, the premium received for an 11% cap will be less than the premium paid for the 8% cap because of the higher strike rate and bid–offer volatility spreads. Therefore, in a zero-premium strategy, to equate the premium received for the higher strike cap to that paid for the lower strike cap, the notional amount of caps sold must be larger than the notional amount of caps purchased. Although this allows the firm to cap the liability rate at zero cost up to the strike rate of 11%, the firm is exposed to tremendous risk in a high-interest-rate, or "doomsday," scenario. As market interest rates increase to over 11%, the cash outflows paid to the buyer of the higher-strike cap may negate any cash flows received from the lower-strike cap and result in much higher interest costs than the lower-strike cap rate. The extent of this offsetting effect will be an inverse function of the ratio of the notional amount of higher-strike to lower-strike caps—the greater this ratio, the smaller will be the effect of the cash inflows of the lower-strike cap and the higher will be the effective interest cost.

EXHIBIT 67-7

Interest-Rate Corridor



CAP/FLOOR PARITY

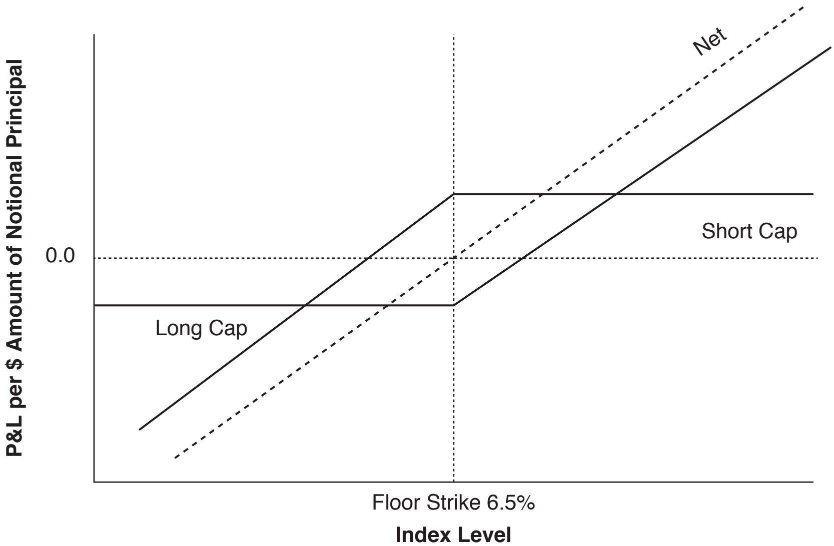
Similar to put/call parity for options, which essentially specifies the relationship between these types of options and the price of the underlying security, caps and floors are related to interest-rate swaps. As an example, consider a strategy that involves buying a cap at 6.50% and selling a floor at 6.50%, both based off the same index, for example, LIBOR. This is equivalent to entering into an interest-rate swap, paying fixed at 6.5%, and receiving floating payments based on LIBOR. If interest rates increase to above the cap level, say, 8%, the cap will pay 1.5%. At the same level, the holder of the swap will receive LIBOR at 8%. This translates into a positive cash flow of the difference between LIBOR and the fixed rate of the swap, that is, 8% – 6.5% = 1.5%. If interest rates decrease to below the floor level, say, 4.5%, the holder of the floor pays the difference between the index and the floor strike rate, that is, 6.5% – 4.5% = 2%. At the same level, the swap holder loses the difference between the swap fixed rate and LIBOR, that is, 2%. Therefore, the cap/floor swap parity may be stated as

Long cap + Short floor = Fixed swap

However, for cap/floor swap parity to hold, the fixed rate of the swap should be paid on the same basis (actual/360 days, 30/360 days, or actual/365 days) as the floating rate, not on a varying basis for the two rates. A graphical illustration of cap/floor swap parity is presented in Exhibit 67-8.

EXHIBIT 67-8

Synthetic Swap Cap/Floor Swap Parity



The cost of a market swap is zero because no premium cash flows are exchanged at inception. Therefore, using cap/floor swap parity, the cost of a cap should be the same as the cost of a floor struck at the same rate on an identical index. This relationship should hold irrespective of the pricing model used to value the caps and floors. Unless this relationship is true at every point, an arbitrage exists in these markets that could be used to emulate the characteristics of the overpriced instrument. For instance, if caps are overpriced, a synthetic cap could be created by buying a floor and entering into an interest-rate swap, paying fixed at the floor strike rate, and receiving floating using the same underlying index as the floor. Such arbitrage possibilities due to deviation from cap/floor swap parity also ensure efficient pricing in these markets.

TERMINATION OF CAPS AND FLOORS

As is apparent from the discussion on the characteristics of caps (floors), these instruments are essentially a strip of put (call) options on forward interest rates. Hence, caps and floors are priced using the same theoretical and analytical concepts involved in pricing options. The termination value of caps and floors can be determined using concepts similar to those involved in determining the market value of options (i.e., the premium) prior to expiration; by contrast to interest-rate swaps, where the termination of swaps is based on the bid–ask spread to the Treasury yield, the bid–ask spread for caps and floors is stated in terms of volatility. On a practical basis, this is a much "cleaner" method of determining bid–ask spreads in the cap and floor market than deriving forward curves using bid and ask yield spreads. In order to compensate the financial intermediary for the market-making function, the offer volatility is higher than the bid volatility. Because option premia are directly related to volatility, the difference between the offer premium and bid premium for either a cap or floor prior to maturity will be directly related to the magnitude of the spread between bid and offer volatility.

KEY POINTS

- Swaps, floors, and caps are customized risk-management instruments.
- Whereas interest-rate swaps are intended to insulate the user from changes in interest rates, caps and floors are designed to provide asymmetric coverage in capping liability costs and protecting the rate of return on assets.
- In either case, the user retains the right to participate in upside movements of the market. In order to reduce the up-front cost of purchasing caps and floors, the user can either enter into participating agreements that involve giving up a proportional share of beneficial market moves or enter into agreements, such as collars and corridors, that are analogous to option spread strategies.
- Because the termination of such agreements involves exit costs, these instruments may prove beneficial for passive hedging where interest-rate protection is desired for longer periods of time.

CHAPTER

SIXTY-EIGHT

CREDIT DERIVATIVES

Dominic O'Kane, D.Phil. (Oxon)
Affiliated Professor of Finance
EDHEC Business School

Since the turn of the century, the credit derivatives market has become the main destination for those wishing to hedge credit risk and those looking for credit-based investments not available in the traditional cash credit markets. Two products dominate. The first is the single-name credit default swap (CDS), which transfers the default risk of a specific corporate or sovereign. The second is the CDS index, essentially a portfolio of CDS packaged into a single transaction. Together they constitute over 90% of all credit derivative transactions.

The purpose of this chapter is to set out a comprehensive description of the CDS contract, and specifically the detailed mechanics of how it works. We follow this with a detailed description of the mechanics of the CDS indices. We defer a detailed discussion of the pricing and risk management of CDS and CDS indices to Chapter 68. However, we begin with a history of the evolution of the credit derivatives market.

EVOLUTION OF THE CREDIT DERIVATIVES MARKET

The credit derivatives market began in the early 1990s as a branch of structured finance that involved creating highly bespoke transactions customized to a particular requirement. These included hedging a credit risk, creating a structured investment product, or managing the regulatory capital of both sovereign and corporate credit risk.

By the mid 1990s the concept of a CDS contract had been established. However, the market lacked standardized legal definitions for the credit events that trigger the contract, and for the protected debt obligations. This meant that pretrade negotiations between parties often required legal assistance in order to ensure that the triggering events and the hedged debt obligations were clearly defined and understood. In addition to increasing transaction costs, this meant that trades could take several days to approve and settle.

The significant growth phase of the CDS market therefore only started following the publication of the first *Credit Derivative Definitions* by the International

The author acknowledges the helpful comments of Samuel Morgan and Mark Ames.

Swaps and Dealers Association (ISDA) in 1999. This document, which became known as ISDA '99, was a response to the legal disputes that arose following the Asian crisis of 1997 and the Russian default of 1998. In addition to the new definitions, ISDA '99 also created a short-form confirmation document that required parties to simply tick a box in order to specify the characteristics of their trade. This made it possible for the market to develop a standard contract, i.e., a contract that has a certain number of characteristics that a majority of buyers and sellers can agree on and which therefore attracts the greatest liquidity. Following its adoption of ISDA '99, the CDS market began a period of very rapid expansion, growing from a total outstanding notional of $632 billion in 2001 to $62 trillion by the end of 2007.[1]

A number of important changes were made to the credit derivatives market between 2000 and 2003. Many of these changes were in response to some of the credit events that had occurred[2] after the end of the dot.com boom and the events of September 11, 2001, and addressed such issues as reference entity specification, guarantees, debt restructuring, deliverability, and successors. Of these, perhaps the most problematic, since it led to a regional split in the market standard, was in relation to the treatment of restructuring as a credit event. This is discussed in detail later.

The period from 2004 to 2007 saw the arrival of the CDS indices. These were adopted very rapidly by the market and became highly traded and highly liquid. They were particularly favored by credit investors who viewed them as a simple and cheap way to take a macro-level exposure to the credit markets, in much the same way as equity index futures permit investors to take a macro-level exposure to the equity markets.

In late 2003, the credit derivatives market established an automatic trade confirmation system at the Depository Trust and Clearing Corporation (DTCC) in New York, the aim being to speed up the confirmation of trades and to remove the backlog of unsigned confirmations that had built up. Then in late 2007, the DTCC also established itself as the keeper of the comprehensive trade database—the official legal record for all confirmed trades. It also set an infrastructure to automate and standardize post-trade processing.

The period 2008–2010 saw a considerable upheaval in the CDS market as regulators responded to the aftermath of the Lehman bankruptcy and the financial crisis. Despite the fact that there were $72 billion of CDS linked to Lehman Brothers registered at the DTCC at the time of its bankruptcy, settlement of the credit event went smoothly as it used a market-wide auction procedure.[3] Nevertheless, this event caused regulators to become very concerned about

1. These numbers come from the ISDA which conducts a semiannual survey of its members who are distributed around the world.

2. These included Argentina, Armstrong, Conseco, Enron, Marconi, National Power, Railtrack, Worldcom, and Xerox.

3. The Trade Information Warehouse at the DTCC, which handled the bulk of the triggered Lehman referenced CDS contracts, reported no failures to perform.

systemic risk in the financial sector caused by the large number of outstanding contracts and a lack of transparency with respect to where the actual credit risk was sitting.[4]

In an attempt to reduce counterparty risk, regulators decided to require standard credit derivatives trades to be assigned to a centralized counterparty (CCP). To prepare the ground for these changes, the market introduced some new legal protocols. The first protocol, known as “Big Bang,” was introduced in April 2009 and made the following changes:

1. Creation of a market-wide determinations committee (DC) charged with determining whether or not a credit event has occurred.
2. An automatic market-wide auction mechanism for the settlement of triggered CDS contracts following all credit events with the exception of restructuring.
3. Moving the date on which the CDS credit event protection[5] begins to the date 60 days before the date on which the request to consider whether a credit event has occurred is made to the determinations committee. This change was made in order to ensure that all existing contracts are triggered by a credit event even if the contract was initiated after the credit event occurred, but before the credit event had been determined.

At the same time, there was also a recouponing process in which the market switched to trading all CDS contracts on each credit with the same coupon irrespective of when the trade was done. This differed from the previous convention in which the coupon on a CDS was set at trade initiation in order to ensure that the contract had zero initial value. The market has also changed so that standard contracts now trade with a full first coupon, i.e., the first coupon starts accruing on the previous coupon payment date even if it is traded mid-period. Both changes have been made in order to increase the fungibility of contracts and to facilitate contract netting as a precursor to the centralized clearing of CDS contracts.

In late 2009, a second protocol known as “Small Bang” was adopted. This extended the “Big Bang” protocol to deal with the restructuring event as a trigger for the CDS. This protocol was intended for the European CDS market since restructuring is not a standard credit event in the North American CDS market

At the start of 2010, the DTCC formally linked itself to the Federal Reserve System where it is expected to fall under a global oversight framework involving U.S. and international regulators. The initiative to move credit derivative trades

4. It is worth noting that of the more than 900,000 OTC derivative contracts on Lehman’s trading books, only one has been challenged due to an open confirmation. See *Report of the Financial Crisis Inquiry Commission* at http://www.fcic.gov/report.

5. For a succession event, the legal protection begins 90 days before the request.

onto CCPs was well underway, especially for CDS indices, with over $15 trillion of index trades already cleared by ICE in North America and Europe by early 2011. The first CDS to be cleared via a CCP and in compliance with the new Dodd-Frank regulations was traded in February 2011. Although most CCPs are based at exchanges, trading in the CDS market trades continue to be executed in the OTC market. The CCP then steps into the trade, placing itself between the two initial parties.

As of 2011, the size of the CDS market and CDS index markets is roughly half what it was at the market peak in 2007. A significant part of this decline can be attributed to the numerous compression cycles (discussed below) that have been carried out in the last two years. Some of it may also be due to the decrease in CDS-based and CDS index–based hedging activities of more exotic credit derivatives, in particular synthetic CDOs. Indeed a snapshot of the credit derivatives market in early 2011 shows that CDS made up 57% of the gross notional of credit derivatives, whereas CDS indices made up 34%, leaving just 9% to other transaction types.[6]

Market Participants

Since its inception, the credit derivatives market has been dominated by commercial and investment banks. Commercial banks have used CDS to hedge the credit risk of their loan book. The advantage of CDS is that they permit the bank to hedge the risk of a specific loan privately and bilaterally. This is often preferred to selling the loan because the sale of a loan by a bank usually requires the bank to notify the borrower and such a sale may be considered to be a negative signal by the borrower and as such may be damaging to the bank–borrower relationship. Surveys of the credit derivatives market have generally found that commercial banks buy more protection than they sell as their loan book hedging requires them to be net protection buyers. Their reason for selling protection is to earn income and diversify their portfolio credit exposure.

Investment banks and the dealer arms of commercial banks play an important role in the credit derivatives markets where they act as dealers. Overall they tend to run balanced books with equal amounts of protection bought and sold.

Insurance companies are also an important user of credit derivatives, primarily as a form of investment on the asset side of their business where they tend to be net sellers of protection. Hedge funds are an important market participant as they are able to play the credit markets from a long or short position and they also tend to buy roughly as much protection as they sell. They are particularly attracted by the ability to go short and the ability to leverage as the upfront payment needed to enter a CDS contract is typically much smaller than the contract notional.

Other users of the market with a lower market share include pension funds, mutual funds, and companies. Funds may be more interested in CDS indices in

6. These numbers are based on a snapshot of market positions on February 11, 2011, taken from the DTCC Trade Information Warehouse Reports.

particular, as they provide a quick way to establish a diversified macro credit exposure onto which they can then add specific credit exposures.

The use of credit derivatives by companies is generally quite bespoke as it may be connected with a need to hedge or assume a very specific credit exposure that they may not wish to sell or cannot find in the bond market. For example, a company may use a CDS to hedge the credit risk of future receivables from a specific company.

Uses of Credit Derivatives

The considerable growth in the size of the CDS and CDS index market has been driven by its various uses. These are as follows:

- *Transferring credit risk:* CDS are first and foremost a tool used to transfer credit risk from one party to another. For example, banks can use CDS to transfer loan credit risk off their balance sheets into the capital markets where this risk may be assumed by an investor. This creates new loan capacity on their balance sheet.
- *Hedge credit risk:* Before the advent of CDS, it was difficult to hedge an existing credit risk by shorting corporate bonds. Buying protection using a CDS is a much easier way to achieve the same objective. CDS indices can also be used as a hedge against changes in the market-wide pricing of credit risk and also the default of individual reference entities.
- *Customization:* As the CDS market is a bilateral OTC market, parties can structure the features of a CDS in almost any way they wish. Features that can be varied include the currency, maturity, and seniority. The more the customization deviates from the market standard, the greater the associated cost and the lower the subsequent liquidity.
- *Ease*: A CDS index makes it simpler for an investment manager to assume an exposure to a diversified portfolio of credits in one transaction. The tight bid/offer spread also makes the cost of unwinding the position cheaper than the cash equivalent.
- *Leverage and yield enhancement:* A CDS and a CDS index typically require only a small upfront payment. This makes it easier to leverage the underlying risk and return compared to a fully funded cash bond.
- *Pure credit play:* The CDS and CDS index are almost a pure credit play since unlike fixed-rate corporate bonds, they have very little interest-rate sensitivity. This isolation of the credit risk is attractive for credit fund managers.
- *Risk decomposition:* CDS can be used to hedge out specific risks in securities with multiple risks. For example, they can be used to hedge

out the credit risk of convertible bonds in an attempt to isolate the economics of the embedded equity option.

- *Speculation:* CDS enable market participants to express a positive or negative view on an underlying credit while a CDS index makes it possible to go long or short macro-level credit.
- *Structured credit investments:* CDS can be used as the building blocks for more exotic structured credit investments that are created to provide a more tailored risk-return profile to specific types of investor.
- *Manage regulatory capital:* Banks can use CDS to hedge credits that have a high regulatory capital charge, provided such a hedge is recognized as being economically effective by regulators.

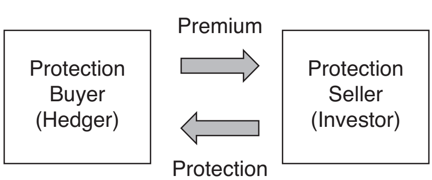
THE CREDIT DEFAULT SWAP

The simplest way to think of the CDS is as an insurance contract in which one party, the "protection buyer," pays a premium to be protected against a credit loss on a specific face amount of bonds or loans issued by a specified corporate or sovereign reference entity. The other party, known as the "seller of protection," receives the premium and takes on the credit risk. Since there is a buyer and a seller of the credit risk, a CDS contract does not create credit risk, it simple transfers it from the protection buyer to the protection seller as shown in Exhibit 68-1. However, unlike an insurance contract, a CDS is a traded contract that can be valued at any time. The protection seller is any investor who takes a view that the premium is attractive given his or her view of the risk of default of the reference entity.

Care needs to be taken when trading CDS to be clear about to which side of the contract we are referring. In the market, "buying" a CDS contract is usually associated with buying protection. However, buying protection is economically equivalent to shorting credit risk or selling a corporate bond issued by the reference entity. Equally, "selling" a CDS contract is economically equivalent to assuming credit risk and so is akin to buying a corporate bond issued by the

EXHIBIT 68-1

A CDS Is a Bilateral Contract Between a Protection Buyer and a Protection Seller



reference entity. Indeed we will demonstrate this equivalence in Chapter 69. To avoid misunderstandings, the term *buying a CDS* should always be qualified with the word *protection;* that is, *buying CDS protection*. Equally *selling a CDS* should be qualified as *selling CDS protection*. Note that this differs from the CDS index market, in which the "buyer" is usually an investor who is selling protection on the underlying portfolio of CDS. This is another reason why clarity is essential in order to prevent confusion.

CDS MECHANICS

As just stated, the purpose of the contract is to transfer the *credit event* risk of a specified face value amount of debt obligations issued by a stated *reference entity* (a corporate or sovereign) from the protection buyer to the protection seller.

The debt obligations covered by the contract are known as the *deliverable obligations* and these are usually bonds and loans of a specified seniority. This seniority is defined by specifying a *reference obligation* of the issuer with respect to which the deliverable obligations should be senior or *pari passu*. If a credit event occurs, then the protection buyer will receive a payment, which is economically equal to the difference between the price of the impaired deliverable obligations and par.

The reason for protecting a basket of deliverable obligations rather than a specific obligation is that it enhances the liquidity of the market because the same contract can be used by hedgers to protect themselves against any one of many obligations of the issuer. If the market were to trade CDS on each specific debt obligation of the issuer, then liquidity and fungibility would be reduced and the cost of protection would almost certainly increase. However, there is a negative side effect because the protection buyer has the right to choose which bond is protected by the contract. He is therefore long a *delivery option*. The effect of this and how it is treated is discussed below in the section on restructuring-type credit events.

To enter into a CDS, a party trades via a dealer. This is done via the telephone or an electronic trading system. At initiation, the party usually makes an upfront payment that (depending on various factors discussed below) can be positive or negative, i.e., the payment could be from the protection seller to the protection buyer or vice versa. The model used to determine the upfront value is set out in detail in Chapter 69.

Credit protection starts on the *effective date*. Prior to the 2009 "Big Bang" protocols, this was the calendar date immediately following the trade date. However, under the new protocols, protection now begins 60 days before any request to consider whether a credit event occurred is made to the determinations committee. This change was made to ensure that all existing contracts would cancel out irrespective of whether they were traded yesterday or last year. This can create a rather strange scenario in which a protection buyer can buy protection *after the credit event* and be paid out. However, this is not as anachronistic as it may seem since the protection would have to be purchased before the credit event was determined. Also, if the information that a likely credit event had occurred was already public at the time of the purchase then the cost of the protection would have been high and close to its post-credit event determination value.

Credit protection lasts until the scheduled termination date, more commonly known as the CDS maturity date. This will fall on one of the following dates: March 20, June 20, September 20, or December 20 of a specified year. These dates are not adjusted for holidays if they fall on a weekend. They are known as the *CDS Dates*. What this means is that at any moment in time, the scheduled termination date of the most liquid T-year CDS contract will be on the first CDS Date that falls after the date exactly T years in the future. So, for example, on April 3, 2011, the standard five-year CDS contract has a scheduled termination date of June 20, 2016. The most liquid contracts have terms of 1, 3, 5 7, and 10 years, with greatest liquidity focused on the 5-year contract.

The Premium Leg

To pay for the credit protection, the protection buyer pays the protection seller a combination of an upfront payment (which may be negative) plus a regular fixed coupon. These payments are known as the *premium leg* of the CDS. Here we will discuss the fixed coupon, deferring the discussion of the upfront payment to the end of this section.

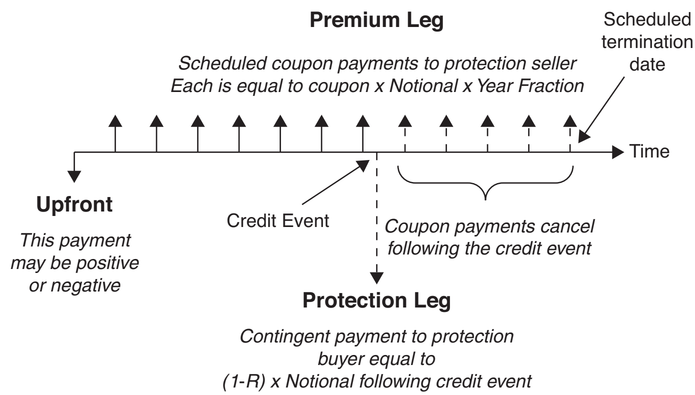
The fixed coupon is specified at contract initiation and determines the size of the quarterly regular payments from the protection buyer to the protection seller. The size of each actual cash payment is calculated by multiplying the fixed coupon by the contract notional. This is then multiplied by the year fraction between the current and previous coupon date calculated according to an actual 360-day count convention.

Before 2009, the size of this coupon depended not just on the reference entity but also on when the CDS trade was initiated. This was because the coupon was set such that the value of the CDS contract at inception was zero, thereby requiring no upfront payment. However since 2009, contracts linked to each issuer now have a fixed coupon irrespective of when they were traded. As a result, the price of the credit risk is not reflected in the size of the coupon, but in the size of the upfront payment.

The exact details of how the premium schedule is calculated are beyond the scope of this section, although more information can be found in Chapter 69. However, it is worth noting that since 2008, the market standard is for contracts to trade with a full first coupon even if they are traded between two coupon payment dates. This enables a new contract to always have exactly the same cash flows as another existing contract with the same maturity date. This is discussed with specific examples in Chapter 69.

EXHIBIT 68-2

The Premium and Protection Legs of a CDS



Note: In this example we have a three-year CDS contract with quarterly coupon payments on the premium leg.

A key feature of the premium leg is that the payments terminate following a credit event. This is shown in Exhibit 68-2. All that is paid by the protection buyer on the premium leg is the amount of coupon that has accrued between the previous coupon payment date and the credit event. This feature of a CDS means that once a credit event has occurred, the premium leg terminates and the contract can be closed out.

The Protection Leg

The other leg of the CDS is the *protection leg,* also known as the contingent leg. This is the payment from the protection seller to cover the loss on the face value of debt, which is only triggered if there has been a credit event. Economically, the value of the payment equals par minus the recovery price of the deliverable obligations. Determination of the size of the recovery price or value is now done using a market-wide auction process that is discussed in detail below.

The market provides two mechanisms for the protection seller to effect the payment of protection. Either the protection seller can choose to pay a cash amount equal to par minus the recovery price determined by an auction, or the protection seller can request physical settlement, which means that they will pay the contract notional in cash and receive the corresponding face value of deliverable obligations at the price determined by the auction.

There are also two mechanisms for the protection buyer to receive the payment of protection. Either the protection buyer can choose to receive a cash amount equal to par minus the recovery price determined by the auction, or the protection buyer can request physical settlement, which means they will receive the notional amount in cash and deliver the corresponding face value of deliverable obligations at the price determined by the auction.

The protection buyer who elects for physical settlement can choose which deliverable obligations to deliver. They are long a "delivery option" whose value depends on the range of prices of the deliverable obligations. The protection seller who has chosen physical settlement has to accept what is delivered. This is discussed in more detail below.

The Upfront Payment

The cost of protection is paid for through both the payment of the fixed coupon on the premium leg of the CDS and through upfront payment. This is the cost that has to be paid in order to enter into the CDS contract and may be positive or negative. Whether it is positive or negative depends primarily on whether the party is buying or selling protection and how the market perceived credit quality of the reference credit compares with the fixed coupon on the CDS. The market perceived credit quality of the reference credit is captured by the CDS "quoted" spread, which is defined in detail in Chapter 69.

For example, consider a short protection CDS position on a credit that trades with a fixed coupon of 100 bp, but whose credit quality has recently deteriorated so that its CDS market quoted spread is currently 160 bp. This will require an upfront payment as the protection buyer will pay cash to the protection seller in order to offset the fact that the coupon is not high enough to compensate the protection seller for the market perceived credit risk of the reference credit. Before 2009, this contract would have had no upfront cost, as it would have paid a coupon of 160 bp.

Once a CDS has been traded, its mark-to-market value begins to change due to changes in the market view of the credit risk of the reference entity as expressed by the quoted spread and changes in interest rates.

For those familiar with the valuation of CDS contracts before the introduction of fixed coupons, the valuation and risk management has not changed in any significant way. Once the contract has traded and the upfront payment made, the value of the contract looking forward is identical to before. For example, consider a long protection CDS contract with a coupon of 100 bp in which the current quoted spread is 160 bp. This will have a positive value for the protection buyer as he is paying only 100 bp for protection, which the market now considers to be worth 160 bp. However we do not have enough information to determine whether the position has a positive P&L (ignoring for a moment the impact of coupons paid) since this depends on the upfront value when the contract was entered into. Before the arrival of fixed coupons, the coupon on the CDS would have told us the spread when the contract was initiated and as the initial cost would have been zero, the mark to market of the CDS would, excluding coupons, be the P&L of the position.

The valuation and risk management of a CDS are covered in Chapter 69.

CREDIT EVENTS

The *credit event* is the term used by the credit derivative market to define each of the events that can trigger the payment of the CDS protection. Companies can default or enter into a restructuring. The situation is even more complicated for sovereign debt since countries do not formally file for bankruptcy. Instead they can default in a number of different ways, for example, by repudiating their debt or by re-denominating their foreign currency debt. The standard credit events used in CDS need to be broad enough to encompass this range of scenarios. A list of the main such credit events is provided in Exhibit 68-3.

In Exhibit 68-3 we have stipulated which credit events are "hard" and which are "soft." This designation refers to what happens to the debt obligations of the reference entity following the credit event. For most credit events, the debt becomes immediately due and payable. This means that all debt obligations, irrespective of maturity and coupon, which are *pari passu* with each other have an equal claim on the remaining value of the company and so should trade at the same price. These are what we call *hard credit events*.

EXHIBIT 68-3

The Main Credit Events Used in the CDS Market

Credit Event	Hard or Soft	Description
Bankruptcy	Hard	Corporate becomes insolvent or is unable to pay its debts.
Failure to pay	Hard	Failure of the reference entity to make due payments, taking into account some grace period.
Obligation acceleration	Hard	Obligations have become due and payable earlier than they would have due to default and have been accelerated. This event is used mainly in the case of emerging market sovereigns.
Obligation default	Hard	Obligations have become due and payable prior to maturity. This event is used rarely.
Repudiation/ Moratorium	Hard	A reference entity or government authority rejects the validity of the obligations. This is used for sovereign credits.
Restructuring	Soft	Changes in the debt obligations of the reference entity which result in a credit deterioration for the debt holders.

The Restructuring Credit Event

There is only one soft credit event. This is the event of restructuring in which a company does not file for bankruptcy but agrees with its creditors a consensual restructuring of its debt obligations, but in a way that has a negative impact for the creditors.

The restructuring credit event refers to out-of-court pre-insolvency restructuring that usually requires the unanimous approval of all impaired creditors. Since the company continues to trade as a going concern, debt does not become immediately due and payable. Therefore, a restructuring credit event does not cause all *pari passu* debt to trade at the same price and so the debt obligations continue to trade with prices that take into account a term structure, and coupon effects (i.e., higher coupon bonds trade at a higher price than lower coupon bonds of the same maturity).

The reason why we single out soft credit events is that they present a delivery option for the protection buyer. Recall that the protection buyer can choose which obligations they wish to deliver from a basket of possible deliverables. As the deliverable obligations continue to trade at different prices caused by different coupons and maturities, there may be some value in the delivery option, and the protection buyer will always be motivated to deliver the cheapest bond or loan he can find.

As a result, if the debt obligations held by the protection buyer are not the cheapest to deliver, it will be economically preferable to sell these in order to buy the cheapest to deliver, gaining the price difference as a windfall gain. The act of always delivering the cheapest deliverable causes the protection seller to take a larger loss than if another deliverable had been chosen.

Such a situation occurred following the restructuring of the debt of the U.S. insurer Conseco Inc. in 2000. In this case, banks that held short-maturity loans that were not particularly impaired by the restructuring, and which had bought CDS protection on these loans, were able to sell these loans for close to par and use the proceeds to purchase deep discount bonds trading in the $65 to $80 range, which they could then deliver in return for par. They were therefore able to make a windfall gain at the expense of the protection sellers.

Following this, complaints were made by Conseco protection sellers. This resulted in the introduction of a new clause that formed part of the revised CDS documentation released in 2001. Called the *modified-restructuring (Mod-Re) clause,* it was intended to reduce the value of the delivery option following a restructuring by reducing the range of deliverable obligations in the basket. This was done by restricting the maturity of the deliverable obligations. This clause only applied to the North American CDS market.

In 2003, Europe followed by introducing its own restructuring clause. As it was a variation of the North American clause, it was known as *modified-modified restructuring (Mod-Mod Re).* These regional differences were due to the differing requirements of the local financial regulators and the differing importance of banks versus investors in the different regions.

We now have three different restructuring clauses, each with its own restrictions on the maturity of the deliverables. These are as follows:

- *Old-Restructuring (Old-Re):* This is the pre-2003 standard which only imposes a 30-year maturity limit on deliverables.
- *Modified-Restructuring (Mod-Re):* The exact maturity limits of the Mod-Re deliverable obligations are quite complicated. A rough and ready approximation is that the deliverable obligations cannot have a maturity longer than the greater of the scheduled termination date of the CDS and the restructuring date plus 30 months. If we use RMLD to denote the restructuring maturity limitation date then

$$\text{RMLD} = \text{Max}\ [\text{TD}, \text{RD} + 30 \text{ months}]$$

  where TD is the scheduled termination date of the CDS contract and RD is the date of the restructuring event.
- *Modified-Modified Restructuring (Mod-Mod Re):* This is similar to modified restructuring. The difference is that the formula for the restructuring maturity limitation date is given by

$$\text{RMLD} = \text{Max}\ [\text{TD}, \text{RD} + \text{A}]$$

  where A equals 60 months for restructured obligations and 30 months for nonrestructured obligations.

There is a fourth alternative, which is to remove restructuring from the list of credit events. This is simply called No-Restructuring (No-Re). The situation as of early 2011 is summarized in Exhibit 68-4.

EXHIBIT 68-4

The Standard Credit Events by Region for CDS and CDS Indices

Geographic Region	Credit Events in Standard CDS and CDS Index Contracts
North America*	Bankruptcy Failure to pay
Europe	Bankruptcy Failure to Pay Restructuring according to Mod-Mod Re
Asia	Bankruptcy Failure to Pay Restructuring according to Old-Re

*The Standard North American Contract is known as SNAC.

Settlement of a Credit Event

Ultimately, the post-credit event settlement of a CDS contract is all about determining the final recovery price for the deliverable obligations. This is done via an auction. The main objectives of the auction process are as follows:

1. To be able to handle cases in which the notional of protection bought approaches or exceeds the total outstanding notional of deliverable obligations. In this case there can be a short squeeze as protection buyers who do not own deliverables attempt to buy these obligations in order to settle their contracts. In the past this has led to the prices of deliverable obligations to rise after the credit event as protection buyers rush to buy them in order to deliver them.
2. To ensure that the recovery price is the same across the entire CDS market. This is necessary if market participants who are both long and short protection to the same maturity on a reference credit are to be sure that they will be hedged. This requires a common recovery price to be set via a public auction procedure described below.
3. To handle the soft restructuring credit event. Recall that hard credit events cause all of the *pari passu* debt obligations to trade at the same price. However following restructuring credit events, the debt obligations continue to trade with a term structure and the value of this delivery option led to the introduction of the Mod-Re and Mod-Mod Re restructuring clauses as described earlier. The auction needs to be able to handle these restructuring clauses.

As we shall see, these requirements have all been met by the procedure that we now describe in detail.

THE CDS SETTLEMENT TIMELINE

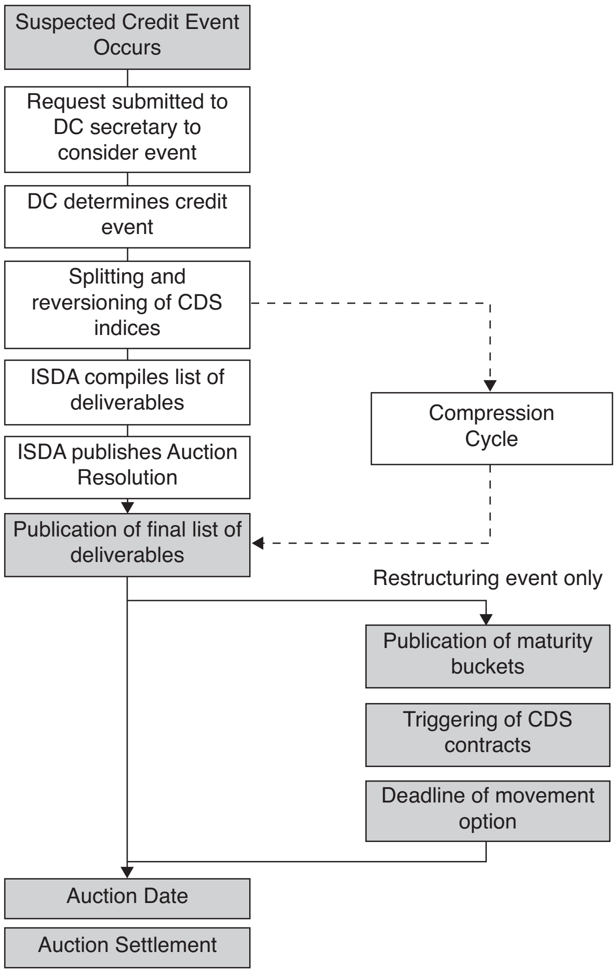
We now set out the mechanics of settlement of a CDS contract once a credit event has occurred. Many important changes have been made to these mechanics over the past few years. To provide an overview, Exhibit 68-5 shows a timeline of the different stages that begin with credit event determination.

Credit Event Determination

Until 2009, the determination of whether a credit event had occurred was a bilateral decision that involved the protection buyer sending the protection seller evidence that a credit event had occurred. This evidence would consist of publicly available information such as newspaper or wire service reports of a bankruptcy,

EXHIBIT 68-5

Timeline for a Credit Event



failure to pay, or restructuring.[7] In most cases in which the source of the information was reputable and the events described clearly satisfied one of the specified credit events, the contract would trigger.

However, in cases in which the information was not public, was unclear, or was contested, there was a risk that different pairs of parties could come to different conclusions. This would be a problem for hedged intermediaries who would find

7. Or any other form of credit event included in the contract.

that one contract might be triggered but the offsetting contract would not, or that the recovery rate on one contract was not the same as the recovery rate on the offsetting contract, generating an unexpected gain or loss.

To address this concern, the market introduced a new credit event determination procedure as part of the legal protocols ushered in by the 2009 Big Bang. This introduced a new body known as the *determinations committee* (DC) that is tasked with the job of determining whether a credit event has occurred. In actual practice there are five such DCs, one for each of the following: the Americas, Asia (excluding Japan), Japan, Australia-New Zealand, and EMEA (Europe, the Middle East, and Africa).

In order to remove any bias and to ensure that decisions are not finely balanced, the membership of each committee consists of both buy-side and sell-side representatives, and the approval of decisions of the committee requires an 80% supermajority.

The credit event determination process begins when any market participant who has signed up to the new credit derivative protocols introduced in 2009 makes a request to the secretary of the DC to investigate whether a specific reference credit has experienced a credit event. This request should be accompanied by a notice of publicly available information reporting that a credit event may have occurred. The DC then has two business days to meet, investigate, and then vote on whether a credit event has occurred. If more time is needed, they can vote to extend this time period.

Once the credit event has been determined and it is a hard credit event, all CDS contracts linked to this reference credit are automatically triggered. This is a change from the pre-Big Bang procedure in which one of the parties to the CDS would choose to trigger the contract.

However if the credit event is determined to be a restructuring, either the protection buyer or the protection seller must choose to trigger the contract. Furthermore, the exact constituents of the basket of deliverable obligations depend on which party triggered first. This is discussed in more detail below.

The rationale for not making the triggering automatic is that restructuring is not a bankruptcy event but could be a precursor to one. As a result, a protection buyer may prefer not to trigger, thereby keeping the CDS protection "alive" for a later and possibly lower recovery hard credit event.

The Compression Cycle

One of the recent innovations of the credit derivatives market has been the use of what has become known as the "compression cycle." This is a procedure designed to enable groups of counterparties to cancel out mutually offsetting positions. This process is run periodically (typically once a quarter) across the entire credit derivatives market.

Although previously a rather ad hoc procedure, it has also become an important stage in the settlement of a credit event, where it is run across the relevant CDS contracts after it has been determined that a credit event has occurred and before the auction begins. However, this is only done for those contracts held by dealers who choose to participate in the compression cycle. The effect of running the compression cycle is to reduce the number of contracts that have to participate in the subsequent auction. This will reduce the amount of physical assets needed to settle the credit event.

The main provider of this compression service is a company called TriOptima. A third party is used to provide this service because compression is all about the cancellation of sets of contracts between three or more dealers. To do this, the parties either need to reveal their full positions list to each other or they need to involve a neutral third party. Dealers prefer the latter, and so introduce a third party to collect the information on the condition that they do not disclose position data to the other parties.

An algorithm is run that calculates the specific set of transactions that if executed would most reduce the outstanding number of contracts. These transactions are then reported back to the dealers who then can choose whether or not to execute them. Between 2008 and 2010, this compression process eliminated around $14.5 trillion of credit derivative contracts from the market.

Deliverables for a Nonrestructuring Credit Event

Within a short period of the credit event being determined by the DC to be a hard credit event, the DC publishes a timetable of when the credit event was determined, when the auction will be held and when the auction will be settled. A list of the deliverable obligations is also published.[8] For hard credit events, there is just one auction as there is just one basket of deliverables for all CDS contracts since the maturity limitation is at 30 years.

Deliverables for a Restructuring Credit Event

When the credit event is a restructuring, the situation depends on the region. In North America, there is no restructuring credit event in standard contracts and so there is only one auction. In Asia, the use of the old-restructuring convention means that there is only one basket for all contracts. In Europe, the situation is more complicated. The market standard is to include a restructuring credit event. However the standard restructuring clause is modified-modified restructuring in which the basket of deliverables depends on the scheduled termination date of the CDS contract.

The purpose of the standard modified-modified restructuring clause found in European CDS contracts is to limit the basket of deliverables in order to reduce the value of the delivery option. In approximate terms, the restructuring maturity limitation date for a deliverable into a CDS contract with a scheduled termination date (TD) is given by

$$\text{RMLD} = \text{Max}\ [\text{TD}, \text{RD} + 60\ \text{Months}]$$

8. All of this information is publicly available on the ISDA website: http://www2.isda.org/.

for restructured obligations, and

$$\text{RMLD} = \text{Max}\,[\text{TD}, \text{RD} + 30 \text{ Months}]$$

for nonrestructured obligations. In both cases the basket of deliverables depends mainly on the TD of each CDS contract.

Reconciling this restructuring clause with an auction mechanism presents an immediate difficulty. If the reference credit has a large number of deliverable obligations distributed across the maturity spectrum, it is possible that there will be a different basket of deliverable obligations for each possible CDS scheduled termination date. Given that the longest maturity CDS contracts have a scheduled termination date in around 10 years, and given that CDS scheduled termination dates are quarterly, this implies that we could have more than 30 distinct baskets of deliverables[9] for a given reference entity. However, holding this many auctions in parallel would be organizationally burdensome. It would also split the universe of relevant contracts across many auctions, resulting in a loss of liquidity and price competition in each auction.

To overcome this problem, the market has decided to run a maximum of eight different auctions by assigning each CDS contract to one of eight maturity buckets. The buckets and what they contain are listed in Exhibit 68-6. In practice, fewer than eight buckets may be used if a lack of deliverables across the maturity spectrum means that two or more buckets are identical. In this case only the earliest of these buckets will have an auction. In addition, a minimum liquidity requirement states that an auction will only be held if 300 or more contracts

EXHIBIT 68-6

The Maximum Set of Auction Buckets Used After a Restructuring Credit Event

Bucket
Nonrestructured debt obligations out to 30 months and restructured debt obligations out to 5 years;
All deliverable obligations to 5 years;
All deliverable obligations to 7.5 years;
All deliverable obligations to 10 years;
All deliverable obligations to 12.5 years;
All deliverable obligations to 15 years;
All deliverable obligations to 20 years; and
All deliverable obligations to 30 years.

9. Out to 30 months there is just one bucket according to Mod-Mod Re. Beyond 30 months, the remaining deliverable buckets depend on the contract scheduled termination date. These are quarterly so for example could be in 33, 36, 39, …, 120 months giving a total of 1 + 30 = 31 buckets.

linked to that bucket are triggered and if there are five or more dealers who are party to these transactions.

If a bucket is not used, then the protection buyer and seller have a *movement option*. This allows the protection buyer to choose to move the contract to use the next earliest maturity bucket. The protection seller also has a movement option and can also choose to move the contract to the longest maturity 30-year bucket. If both parties wish to exercise the movement option, then the protection buyer's decision is the one that takes priority.

Prior to the auction, each CDS contract must be assigned to one of these buckets. To simplify matters, one of the duties performed by the DC is to calculate and publish a table that maps ranges of scheduled termination dates to specific buckets. However, there is one final step before CDS holders know which maturity bucket, and hence which auction, is relevant to their contract. This is the triggering decision.

Restructuring: Triggering a Credit Default Swap

Unlike hard credit events, the triggering of a contract following a restructuring credit event is not automatic. In fact it is actually asymmetric in the sense that the basket of deliverable obligations depends on which party, if any, is the first to trigger the contract. The rules are as follows:

- If the contract is triggered by the protection buyer, then the basket that applies is the one that corresponds to the scheduled termination date of the CDS contract.
- If the contract is triggered by the protection seller, then the basket that applies is the longest maturity (30-year) basket.

The consequence of these rules is that each party wants the other to trigger. To see why, consider the holder of five-year CDS protection. He will prefer the protection seller to trigger because the 30-year bucket contains more deliverable obligations than the 5-year bucket, and so the value of the delivery option is greater. At the same time the protection seller wants the protection buyer to trigger since he does not wish to be delivered a long-dated obligation.

However, the protection buyer also knows that if he fails to trigger within the specified period, the ability to trigger for this credit event is lost. This is known as *use it* or *lose it*. Suffice to say that both protection buyers and sellers will usually wait until the last moment to trigger. However, great care needs to be taken not to miss the triggering deadline altogether.

There is another complicating factor, which is that the decision period for the protection buyer and seller are not always the same. Typically these periods begin together, but the protection buyer has five days, whereas the protection seller has three days to decide.[10]

10. A discussion of all of the issues is beyond the scope of this chapter. For more information, see Dominic O'Kane, "Testing the Protocols," Nomura International Fixed Income Research, March 2010.

If the contract is not triggered by either party, it does not follow that the protection is lost altogether. It just means that it cannot be used for this credit event but can be used for any subsequent credit event.

The Auction Process

Before the auction, holders of CDS contracts need to decide whether they wish to use cash or physical settlement. A protection buyer who elects for physical settlement will end up with par in cash and a short position in the deliverable obligation after the auction. This replicates the economics of delivering a bond to the protection seller in return for par. Equally a protection seller who elects for physical settlement will end up paying par in cash and owning a deliverable obligation. This replicates the economics of paying par and taking delivery of a deliverable obligation from the protection buyer.

The auction breaks the link between the protection buyer and seller since each party to a CDS can choose a settlement mechanism that may be different to that of their counterparty.

Prior to the auction, market participants who wish to have physical settlement are able to submit physical settlement requests via their dealers. These must arrive before 5 p.m. on the day before the auction. Each request must be in line with the market participant's net CDS position (i.e., a net long protection position must correspond with a request to sell bonds, and vice versa).

A protection seller will choose physical rather than cash settlement in order to realize a view that the current recovery price is too low and will rise after the auction. This view requires the protection seller to hold the physical asset.

The auction is a two-stage process that is administered by Creditex and Markit. It is carried out via the Creditex inter-dealer electronic trading platform. This means that non-dealers cannot participate directly but must do so via their chosen dealer. Both stages occur on the same auction date, with stage one usually occurring in the morning and stage two in the afternoon.

Auction: Stage One

Stage one of the auction is used to determine an indicative recovery price for the deliverable obligations and the net open interest to buy or sell physical assets that will be used in stage two of the auction. Stage one is limited to parties who have CDS positions and have submitted physical settlement requests.

The process is short, lasting only 15 minutes. In this time, the participating dealers submit two-way bid/offer prices for the deliverable obligations. At the same time, the dealers submit physical settlement requests on behalf of their customers and on their own behalf. Note that there is a maximum limit on the bid/offer spread submitted by dealers that prevents dealers from making uncompetitive markets. There is also a minimum trade size. Both of these constraints are set in advance by the DC and are a function of the liquidity and market outstanding notional of the reference credit.

At the end of this 15-minute period, the auction administrator has a further 15-minute period during which they calculate and then publish the indicative recovery price. This is more formally known as the internal market midpoint price (IMMP) and is calculated using an algorithm that rejects outlying price combinations (to prevent manipulation) and averages the remaining bid/offer spreads that are then rounded to the nearest 1/8th of a point. The internal market midpoint price will then be used in stage two of the auction procedure to constrain the final auction price.

The final calculation is the net open interest, which is simply the aggregation of the physical settlement requests. This establishes the size and direction of the demand of market participants to use physical settlement, i.e., the total amount of deliverable obligations to be traded in stage two of the auction and whether the net open interest is to buy or sell these deliverable obligations.[11]

Auction: Stage Two

Stage two of the auction occurs when the parties bid to satisfy the net open interest determined in stage one. This process results in a market-wide recovery price that is then used to settle all CDS contracts, including both those that are cash and physically settled.

Stage two begins two or three hours after the end of stage one, thereby giving market participants time to decide how to respond to the results of stage one. Unlike stage one it is an auction that is open to all parties who have signed up to the ISDA protocol, not just those who hold a CDS position in the relevant reference entity. This maximizes the number of participants and should maximize the chances of a competitive auction.

If the net open interest of stage one of the auction is to sell bonds, then the aim of stage two is to match this open interest with those who wish to buy the bonds. If the net open interest of stage two of the auction is to buy bonds, then the aim of stage two of the auction is to find bond sellers.

At the start of stage two, auction participants have a 15-minute window during which they submit limit orders of a size that is only limited by the size of the net open interest. The order prices can be at whatever price they decide. To do so, they have to commit that they will be willing to transact the limit order size of deliverable obligations at the final auction price.

When this period is over, an order matching algorithm is run on all of the submitted orders. If the open interest was to buy bonds, then the auction is one in which participants submit offer prices to sell bonds. The open interest is then filled starting at the lowest price until all of the open interest has been filled. The price at which this happens is the final auction price. If the open interest was to sell bonds, then the auction is one in which participants submit bid prices to buy bonds. The open interest is then filled starting at the highest price

11. The open interest, the various bids and offers, and the calculated internal market midpoint price are all published on the www.creditfixings.com website.

until all of the open interest has been filled. The price at which this happens is the final auction price.

This final auction price may not become the official final auction price, as there is a condition that requires that the final price be within a certain range, known as the *cap amount,* of the IMMP calculated in stage one. If the final auction price is above the IMMP by more than the cap amount, then it is set equal to the IMMP plus the cap amount. If the final auction price is below the IMMP by more than the cap amount, then it is set equal to the IMMP minus the cap price.

After the auction, dealers are paired off with each other so that the demand to buy or sell deliverable obligations that were submitted in the first stage of the auction can be satisfied by the demand to satisfy the open interest that was filled by the orders submitted in the second stage of the auction. The dealers then in turn enter into trades with their customers to satisfy their physical settlement requests, and the settlement procedure is then complete.

CDS INDICES

Following the CDS, the most important product in the credit derivatives market is the CDS index. Unlike CDS, CDS indices are primarily used by investors to easily obtain a diversified credit exposure as they enable an investor to take a broad exposure to the credit market in a single transaction. The upfront cost required to enter into a CDS index is usually a small percentage of the notional and this makes it possible to leverage the risk of a CDS position. CDS indices are also used as a way to hedge the credit risk associated with a broad portfolio of credit names. This can be useful for credit funds, hedge funds, or banks wishing to hedge the so-called systemic market credit risk.

The first CDS indices appeared in 2002 to the extent that there were competing index providers in each regional market. This situation persisted until the middle of 2004. At this time the North American indices fell under the name CDX, while their European and Asian equivalents fell under the name iTraxx. The main CDS indices that now trade are listed in Exhibit 68-7. Of these the most liquid are the North American and European investment-grade indices, known as CDX IG and iTraxx Europe, respectively.

Note that in the CDS index market, "buying the index" means assuming the credit risk by selling protection and receiving the coupon. This differs from the CDS market, in which "buying" generally means buying protection. It is worth noting that the CDS indices are equally weighted when issued. This differs from stock indices, which are either market cap-weighted or price-weighted. It also differs from the traditional fixed income benchmark indices found in the credit markets, which are almost always weighted by the outstanding debt of each issuer. This was done for reasons of simplicity and to maximize diversification. However, this can change during the life of an index if one or more companies in the index splits (de-merges) or two or more of the companies in the index merge.

CDS Index Constituents

A CDS index is essentially a portfolio of CDS in which the credits in the index satisfy a certain set of inclusion criteria. For example, the CDX IG index is the CDS index, which contains the 125 most liquid investment-grade (IG) credits that trade in the CDS market and are domiciled in North America. The main inclusion criteria for the main CDS indices are shown in Exhibit 68-7.

At any moment in time, there is not just one of each of the CDS indices trading in the market but several series. This is because a new series of each CDS index is issued every six months. Although the new version of the index will have the same credit inclusion criteria as the whole series, the actual credit names of each series of the index may differ if certain credits were upgraded or downgraded, defaulted, or became less liquid since the previous issue date. The most recently issued series of any index is known as the "on-the-run" and is usually the most liquid.

There is also a further subdivision of a CDS index series by maturity. On the issue date, new series of a specific index are issued with terms which will typically include 1, 3, 5, 7, and 10 years. The maturity date of the T-year index will be on one of the standard CDS Dates—March 20, June 20, September 20, and December 20.

EXHIBIT 68-7

The Standard CDS Indices Showing the Type and Number of Credits in Each

Name	Domicile and Type of Credits	Number of Credits
CDX.NA.IG	North American investment-grade	125
CDX.NA.HY	North American high-yield	100
CDX.NA.XO	North American crossover[12]	35
CDX.EM	Emerging market sovereign	15
CDX.EM.Diversified	Emerging market sovereign/corporate	40
iTraxx Europe	European investment-grade	125
iTraxx Europe Crossover	European crossover	40
iTraxx Japan	Japanese investment-grade	50
iTraxx Asia ex-Japan	Asian non-Japanese investment-grade	50
iTraxx Australia	Australian investment-grade	25

12. The term *crossover* refers to credits that were initially investment-grade but have since been downgraded to subinvestment-grade.

For a series that rolls on March 20 and September 20 each year, the corresponding maturity dates will be June 20 and December 20 T years later. This means that the time to maturity of the term T index will actually be T years plus three months at issue and this will have fallen to T years minus three months by the time the next series of the index is issued six months later. This allows an investor to continuously roll his index position into the next "on-the-run" index and so be able to maintain his average maturity at close to T years.

CDS Index Mechanics

To enter into a CDS index, the buyer (or protection seller) pays an upfront cost. The value of this may be positive or negative, and so may actually result in a payment to the index buyer. This depends on the size of the fixed coupon paid by the index and the current trading level of the index.

Each series of a CDS index has its coupon set on the issue date, and this coupon is fixed thereafter. It is usually set at a value that makes the initial upfront value of the index close to zero. Once the index series has been issued, changes in the market perceived credit quality of the index causes the upfront value to change. This is exactly analogous to the mechanics of the CDS market, in which contracts linked to each specific reference entity adopted a fixed coupon in 2009.

The economics of a CDS index are identical to those of a portfolio of CDS contracts where the coupons on the CDS contracts equal the index coupon. As with a CDS, there is both a premium leg and a protection leg.

The Premium Leg

The premium leg of a CDS index is the payment of the coupon to the buyer of the index. The actual payment amounts are determined by multiplying the index fixed coupon by the day count fraction[13] that has elapsed since the previous coupon date and then by the *surviving notional* of the index reference portfolio. The surviving notional at initiation is the contract notional. However, over time this may change if there are credit events.

As credits in the reference portfolio experience credit events, the surviving notional of the index is reduced in proportion to the number of credits remaining. So if two credits in a reference portfolio of initially 125 credits experience a credit event, the surviving notional of the index is 123/125 times the initial notional and the size of the coupon is also reduced to 123/125 times the initial coupon. Note that the notional does not depend on the size of the recovery rate of the defaulted credits, just the number of credit events.

The economics of a CDS index premium leg are therefore equivalent to that of a portfolio of CDS premium legs linked to each of the reference credits in the index, which all pay a fixed coupon equal to the index coupon. The premium leg

13. The day count fraction is usually calculated according to an Actual 360 basis convention.

is paid until the end of the contract, the exception being the unlikely case of all of the credits in the reference portfolio experiencing a credit event.

The Protection Leg

The protection leg of the CDS index is identical to that of an equally weighted portfolio of CDS protection legs on the reference portfolio. If a credit event occurs on a reference credit in the index, the index buyer must pay the index seller the loss on that credit. The process is as follows:

1. The credit is immediately removed from that index series across all maturities.
2. The new index without the credit is thereafter assigned a new version number to distinguish it from earlier versions of the index series.
3. The reference credit that was removed then becomes a standalone CDS position with the notional corresponding to its notional size in the index, e.g., if the index position size was $10 million and there were 125 credits in the index, then the notional of the standalone CDS contract will be $80,000.

The standalone CDS position then takes part in the standard auction procedure as described earlier. In economic terms, this will result in the index buyer having to pay the index seller par minus the auction recovery rate on the CDS notional.

There is an added complication if the credit event was a restructuring. In this case, the index buyer and seller have the option to trigger the standalone contract. If they both choose not to trigger, then the standalone CDS position continues to sit on their respective books until maturity or until it is triggered by a subsequent credit event. However, this is usually only a consideration for European and Asian index holders since, as shown in Exhibit 68-4, the standard for North American indices is to exclude restructuring as a credit event.

IMPORTANCE OF THE CDS MARKET

The credit derivatives market has become an important branch of the credit markets. The ease with which a single-name CDS can be traded has made it an invaluable hedging tool for many, most notably bank loan risk managers. The CDS index has also become an important investment tool for credit investors seeking to quickly and easily obtain a macro-level credit exposure.

In the aftermath of the financial crisis of 2008, the market quickly responded with a number of fundamental changes in the format and mechanics of the contract to increase fungibility and so decrease counterparty risk. The triggering and settlement of credit events were revised to ensure that there is a common market-wide process and to minimize the risk of failing to settle.

Many of the changes were intended to facilitate making all market participants face centralized counterparties (CCPs) rather than dealers in an attempt to reduce the systemic risk associated with the default of a major dealer. This process began in 2009 and by February 2011, one of the major clearing houses, the ICE Trust in North America and ICE Clear in Europe, had together cleared more than $15 trillion of credit derivatives, of which over 80% were CDS indices.

One area of valid criticism of the market was its opaqueness pre-2008, which was unsurprising given the OTC nature of credit derivative transactions. The publication of high-level position data by the New York–based DTCC who are responsible for CDS settlements has added a new level of transparency with respect to market size, the reference entities being traded and the different types of counterparties.

A recurring pattern of the credit derivative market has been that each time there is a credit crisis that exposes any flaws in the mechanics of the market, the market moves quickly to attempt to eliminate such flaws so that the same problems will not recur. This reflects the importance that the market attributes to a well-functioning credit derivatives market. As a result, the market is now better settled, more transparent, less exposed to systemic risk, and better regulated than it has ever been.

KEY POINTS

- The credit derivatives market is dominated by the single-name credit default swap (CDS) and the CDS indices.
- The growth of the CDS and CDS index market has been driven by its many uses. These include transferring credit risk, hedging credit risk, isolating credit risk, leveraging and yield enhancement, structured credit investments, and managing regulatory risk.
- The simplest way to think of the CDS is as an insurance contract in which one party, the "protection buyer," pays a premium to be protected against a credit loss on a specific face amount of bonds or loans issued by a specified corporate or sovereign reference entity.
- The other party to the CDS, known as the "seller of protection," receives the premium and takes on the credit risk. The protection seller makes a contractual payment to the protection buyer if a credit event occurs during the tenure of the contract.
- The "credit event" is the term used by the credit derivative market to define each of the events that can trigger the payment of the CDS protection. Credit events may include bankruptcy, failure to pay, obligations acceleration, repudiation/moratorium of debt, and restructuring of debt.

- The event of restructuring is a "soft" credit event since debt can continue to trade with a term structure after a restructuring. Since this can create a potentially valuable "delivery option" for protection buyers, it is excluded from the standard CDS contract on North America–domiciled companies. However, regulatory and other differences mean that it is included in standard contracts on Europe- and Asia-domiciled companies.
- To avoid a "short squeeze" following a credit event and to ensure that the same recovery rate is used across the market, the CDS market has introduced an auction process in which holders of the relevant CDS engage and only the net amount of deliverable obligations need to be physically traded.
- Credit default swap indices are equally weighted portfolios of up to 125 CDS that can be traded in one single highly liquid transaction. The CDS index market provides asset managers with a highly liquid way to assume or hedge an exposure to market-wide or sector-wide credit risk.
- Following the financial crisis of 2008–2009, the credit derivative market made a number of substantial reforms in order to ensure a well-ordered market-wide settlement mechanism following credit events, to improve transparency and reduce systemic risk via the use of centralized counterparties.
- A CDS or CDS index contract can be sold at any time before maturity, allowing the owner to realize any gain or loss resulting from changes in the market perceived credit quality of the reference entity.

CHAPTER
SIXTY-NINE

CREDIT DERIVATIVE VALUATION AND RISK

Dominic O'Kane, D.Phil. (OXON)
Affiliated Professor of Finance
EDHEC Business School

The purpose of this chapter is to set out the valuation methodology for credit swaps (CDS) and CDS indices. As described in Chapter 68, a credit default swap (CDS) is the most commonly traded credit derivative contract. It is also the building block for the CDS indices. An understanding of the valuation and risk management of CDS is therefore essential if we are to understand the valuation and risk management of CDS indices and other credit derivatives.

CDS VALUATION

For valuation purposes the essential features of a CDS contract are as follows:

- A regular fixed coupon is paid on the premium leg from the protection buyer to the protection seller according to a frequency and basis convention as set out in Exhibit 69-1. The coupon is paid until contract maturity date or a credit event, whichever occurs first. If the credit event occurs between two coupon payment dates, the market standard convention is that the portion of the coupon that had accrued from the previous payment date until the Event Determination Date[1] must be paid by the protection buyer.
- A payment of par minus the recovery rate is paid following a credit event. The recovery rate is set at the auction (which was described in Chapter 68) and paid shortly after on the auction settlement date.

We therefore have future cash flows which are contingent on a credit event. The CDS value is given by the expected present value of these flows calculated in the "risk-neutral" measure (i.e., using probabilities of a credit event that exactly reprice the term structure of market prices of quoted CDS).

The author acknowledges the helpful comments from Samuel Morgan and Mark Ames.

1. This is the date the question to determine a credit event was submitted to the determinations committee (DC).

EXHIBIT 69-1

Standard CDS Contract Specifications for North American and European Markets

Specification	North America	Europe
Maturity Date	CDS dates unadjusted	CDS dates unadjusted
Accrual Dates	CDS dates adjusted except for maturity date	CDS dates adjusted except for maturity date
Payment Dates	CDS dates that are holiday adjusted	CDS dates that are holiday adjusted
Coupons	100 bp and 500 bp	25 bp, 100 bp, 500 bp, and 1,000 bp
Frequency	Quarterly	Quarterly
Day Count Basis	Actual/360	Actual/360
Pay Accrued on Default	Yes	Yes

The precise rules that generate the schedule of premium leg payments are listed in Exhibit 69-1. The CDS dates referred to in this exhibit are March 20, June 20, September 20, and December 20.

Need for a Model

The pricing and risk management of a CDS contract requires the use of a pricing model. There are a number of reasons for this:

1. The CDS market is OTC. As such, there is no central location where trades are executed from which prices can be instantly reported. Prices are instead agreed bilaterally and privately. Market pricing providers such as Markit[2] only provide end-of-day pricing based on aggregating pricing submissions from various dealers.
2. Even if CDS contracts were exchange-traded, the quotation of prices would be complicated by the fact that there are so many different variations in the contracts outstanding. Consider just those contracts written against a single reference entity and assume that the longest maturity contract is 10 years and that all contracts trade with the same coupon and credit events. Since maturity dates are on a quarterly schedule, we can have as many as 40 different contracts being traded, albeit with varying degrees of liquidity. Quoting so many numbers per issuer can be cumbersome. A model that allows pricing based on a smaller number of market inputs is certainly preferable.

2. www.markit.com.

3. Although there is the concept of a standard CDS contract, market participants can request customized features which may deviate from this standard. For example, a company may wish to buy a forward CDS contract in which protection starts at some future date. To price this correctly relative to other CDS, a model is required that must also reprice the current market prices.
4. A valuation model is also important for risk management. With bonds, we need, at the very least, to introduce the concept of a yield-to-maturity and yield-curve before we can start to hedge the interest rate risk of a bond portfolio with other bonds. The same is true with a portfolio of credit default swaps. A model is needed in order to be able to quantify spread risk and to hedge the credit risk sensitivity of one CDS against another.

The value of a CDS contract is simply the upfront value at which the CDS contract should trade. For a protection seller, this is equal to the expected present value of the incoming coupons on the premium leg minus the expected present value of the protection leg. For a protection buyer, it is the negative of this since the protection buyer is receiving the protection but paying the coupons.

Even without a model, we can begin to think about the factors that affect the CDS value. We consider the two legs separately:

1. The value of the premium leg is the expected present value of the coupons paid until maturity or a credit event, whichever happens first. If the credit quality of the reference credit falls then this will make an early credit event more likely and so it is more likely that not all of the coupons will be received. The expected present value of the premium leg will then fall. Also, as it is an annuity of fixed coupons, its present value will also fall if interest rates rise. The value of the premium leg also increases with CDS maturity since more coupons are to be paid.
2. The value of the protection leg increases if the credit deteriorates since it becomes more likely that the payment of par minus the recovery rate will be received. It will also increase with increasing contract maturity as protection for a longer period is always more valuable than for a shorter period. However, it falls as interest rates increase since it is the present value of a future contingent payment.

Before we move on to describe a model that can value each of the legs, we first wish to show that it is possible to actually determine the no-arbitrage value of the upfront cost of protection by reference to the cash bond market.

THE CDS–BOND RELATIONSHIP

Subject to a number of important assumptions, there is a fundamental no-arbitrage relationship between the upfront value of a CDS and the price of a specific floating rate bond issued by the same reference entity. Specifically, our aim is to show that there is an exact relationship between the upfront cost of a time T maturity CDS, U, and the price P of a floating rate note with a time T maturity where the floating rate note pays a floating rate coupon equal to LIBOR plus a spread C. This spread must be equal to the fixed spread of the CDS. We need to consider the following trading strategy:

1. At time zero, an investor borrows an amount $P + U$ at a funding rate of LIBOR. This assumes that the investor has a credit quality similar to that of highly rated commercial banks. This funding is locked in until future time T. Interest payments are made quarterly.
2. At time zero, the investor uses P of the borrowed money to buy one unit of face value of a time T maturity floating rate note issued by the reference entity at a specific seniority. The full price of this bond is P. For simplicity we assume that the purchase begins on a coupon payment date so that there is no accrued interest to consider.
3. At the same time, the investor uses U of the borrowed money to buy CDS protection on one unit of face value of the reference entity that matures at future time T. Note that U can be positive or negative. Following this, the now hedged investor will have to make quarterly coupon payments.

To analyze this strategy, we need to determine the payments at four different types of event: (1) initiation, (2) coupon payment dates, (3) following a credit event, and (4) maturity time T (assuming that no credit event has occurred). These are shown in Exhibit 69-2.

For simplicity we assumed that the credit event occurs on a coupon payment date so that the repayment of the funding simply costs par, i.e., the face value of the borrowing, which in this case is (P + U), and so that there is no coupon accrued to be paid on the CDS.

As the initial net cash flow is zero—the strategy costs nothing to enter—the expected value of the future payments should equal zero. For this to be true, we require that $P + U = 100\%$, i.e., there is a fundamental no-arbitrage relationship

EXHIBIT 69-2

No-Arbitrage Strategy of Bond Plus CDS Protection

Time	Funding	Bond	CDS	Net
Initiation	$P + U$	$-P$	$-U$	0
Coupon Dates	$-(P + U)\Delta L$	$(L + C)\,\Delta$	$-C\Delta$	$-(P + U)L\Delta + L\Delta$
Credit Event	$-(P + U)$	R	$(100\% - R)$	$100\% - (P + U)$
Maturity	$-(P + U)$	100%	0	$100\% - (P + U)$

between the upfront cost of the CDS and the price of a floating rate note issued by the same reference entity. For example, if the LIBOR floater is priced at par, then the upfront value is zero. However if the LIBOR floater is worth more than par, then the upfront cost of protection is negative. If the LIBOR floater is worth less than par, then the upfront cost of protection is positive.

In order to establish this relationship, we have had to make a number of simplifying assumptions. The main ones are:

1. We assumed that the bond buyer funded at LIBOR flat and that funding at this level can be locked in until the maturity of the CDS. In practice, the funding of the bond will be done in the repo market where it will generally not be possible to lock-in the funding level for any extended period. The hedged investor therefore has funding risk, which can work for or against them. There may also be a haircut on the amount funded and this depends on the market risk of the bond, which is used as collateral in the repo.
2. We assumed the existence of a T-maturity *pari passu* floater, which pays LIBOR plus C where C is equal to the fixed spread of the CDS contract.
3. We ignored the effect of the delivery option, which could allow the protection buyer to deliver a cheaper bond (if one exists). This is most likely to be of value if the CDS includes restructuring as a credit event. The value of this option should make the cost of protection higher.
4. We assumed that the credit event falls on a coupon payment date. In practice a default between coupon payment dates will mean an additional payment by the protection buyer of the accrued coupon on the CDS. For the bond, it may mean that the unpaid coupons are added to the bondholders' claim in bankruptcy.
5. We ignored the effect of counterparty risk on the CDS. Counterparty risk is typically mitigated by the posting of upfront collateral.
6. We ignored tax effects that may treat the coupon and principal differently.
7. We ignored transaction costs and market technical effects. In the latter case, we note that since the CDS market makes it easier to short credit risk, any negative news on a credit will typically impact the CDS market first, causing the CDS upfront price to increase before bond prices fall.

What we have done here is to establish a link between the upfront costs of CDS and the pricing of a specific bond issued by the same reference entity. However, in practice, this is not a viable way to price CDS contracts since it is almost certain that the required T-maturity *pari passu* floater, which pays a spread equal to the coupon on the CDS, does not exist. Also, the list of assumptions means that although there is a strong relationship between bond prices and CDS upfront costs, the relationship is not exact.

The CDS Basis

The difference between the cash and CDS market is known as the CDS basis. It is defined as

$$\text{CDS Basis} = \text{CDS Par Spread} - \text{Bond LIBOR Spread}$$

This is not an exact definition since there are various ways to quote the bond LIBOR spread.[3] One LIBOR spread widely used by the market is the asset swap spread of a bond of the issuer with a similar maturity to the CDS, which is trading at a price close to par.

Trading the CDS basis has become a relative value strategy of a number of credit investors, in particular credit hedge funds. The aim of basis trading is to determine which of the assumptions listed above is driving the difference between CDS spreads and bond spreads and to take a view on whether these are correctly or incorrectly priced and liable to change.

The standard basis trade is the "negative basis trade" in which the investor buys the bond and buys protection. It is called a negative basis trade because the investor receives the bond spread and pays the CDS spread—the investor receives negative of the basis as defined above.

Valuation of an Existing Contract

Consider an investor who sells protection using a five-year CDS contract at time zero. The upfront cost, which is the amount paid in cash to enter the contract is $U(0)$. In return, the investor receives a regular coupon C and we call the expected present value of this the value of the premium leg. He also has to pay the counterparty $(1 - R)$ on the face value of the protection if there is a credit event between the effective date and the contract maturity time. The expected present value of payment is the value of the protection leg. We can therefore state that $U(0)$ is the cost of this where

$$U(0) = V_{\text{Premium}}(0,5) - V_{\text{Protection}}(0,5)$$

This is at initiation. Subsequently, at time t, the value of the premium leg and protection leg will change as coupons are received, maturity approaches, and the market's view of the default risk of the reference credit changes. At this time the value of the contract is given by

$$U(t) = V_{\text{Premium}}(t,5) - V_{\text{Protection}}(t,5)$$

One year later, the investor wishes to unwind his position. Given that he sold protection, he must now buy protection. The cost of entering into the long protection position is given by $-U(1)$ where

$$U(1) = V_{\text{Premium}}(1,5) - V_{\text{Protection}}(1,5)$$

3. These include the asset swap spread, the par floater spread, the discount margin, and the zero volatility spread.

Since the coupon dates and any contingent protection payments on this new contract match exactly the coupon payment dates and any contingent protection payment on the existing contract, the combined position has future cash flows equal to zero. The mark-to-market value of this short protection CDS position at any time is therefore simply the upfront cost of buying protection to the same maturity as the initial contract. This is different from the P&L which is the money earned or lost by first selling protection and then closing out the trade one year later by buying protection. This is equal to the upfront cost $U(1)$ which was received plus all of the rolled-up coupon payments minus the cost of repaying any initial loan $U(0)$.

Market Pricing

The pricing of CDS is done with reference to the spreads at which the current market standard contracts trade. These are for contracts that terminate at the main maturity points, which include six months and 1, 2, 3, 4, 5, 7, and 10 years. The market has two conventions for quoting spreads. They are:

1. Par Spreads: The T-year par spread is defined as the coupon that would be paid for protection on a T-year contract *which has no initial cost*.
2. Flat Quoted Spread: The T-year flat quoted spread is defined as the level at which a flat CDS par spread curve needs to be marked in order that the model-implied upfront value matches the upfront value quoted in the market. It therefore ignores the shape of the term structure of the CDS market—it is the CDS equivalent of the bond yield-to-maturity.

The par spread was the quotation convention for the CDS market until 2010. The "problem" with the par spread is that calculation of the upfront value requires knowledge of the full term structure of par spreads of quoted CDS contracts with the same or shorter maturities. Therefore, several par spreads may be needed to calculate one CDS upfront value and one CDS upfront value cannot be used to imply a term structure of par spreads. As a result, the quoted flat spread has become the market standard. Its existence is based on a need to have a spread-based quotation for the price of a CDS contract. Use of the quoted flat spread also entails using the market standard recovery rate assumption, which is currently set at 40% for senior unsecured debt.

Because the quoted spread convention assumes that the spread curve is flat, there is a one-to-one mapping (based on the pricing model that we will describe below) between the T-year maturity quoted flat CDS spread and the upfront cost of a T-year CDS contract. Note also that if the par spread curve is actually flat, then the quoted flat spreads will all be the same for all maturity points and par and quoted flat spreads will be equal.[4] In order to assist clarity, we will be using the notation in Exhibit 69-3 to denote these different coupons and spread measures in what follows.

4. This presumes that the same recovery rate assumption is used.

EXHIBIT 69-3

Notation for Spreads and Coupons

Symbol	Description
$C(T)$	The coupon of a T-year maturity CDS contract.
$U(t)$	The upfront value of a T-year maturity CDS contract at time t.
$S(t, T)$	The time t par spread paid on a T-year maturity CDS contract that has no initial cost.
$\bar{S}(t, T)$	The "quoted" spread is the level of a flat par CDS spread curve that sets the model-implied upfront cost of a T-year CDS equal to its market value at time t.

MODEL

To value a CDS, we need a model. This model must satisfy the following requirements:

1. It must capture a credit event as a single event that can occur at any future time.
2. It must capture the timing of the default and the fact that the market may expect the future default rate to be a varying function of time, i.e., it can have a term structure.
3. It must capture the payment of par minus the recovery rate following a credit event.
4. It must be able to reprice the term structure of market prices exactly.
5. It must be fast to calibrate to the market and fast to price.

The standard model in the market is based on the use of the survival probability $Q(T)$. This is the probability that the reference credit survives without experiencing a credit event from today (time zero) to time T in the future. The value of $Q(T)$ must be between 0 and 1, and must be a constant or decreasing function of T.

Valuation of the Premium Leg

The premium leg of a CDS is the payment of the fixed coupon that continues at quarterly intervals until a credit event or maturity, whichever occurs first. Each coupon is therefore a conditional payment—conditional on the reference entity surviving until the coupon payment date. We also need to discount these future conditional coupons at the LIBOR rate. If we assume that the premium leg has N remaining coupons, we can write

$$V_{\text{Premium}} = C(T)\sum_{i=1}^{N} \Delta(t_{i-1}, t_i) Z(t_i) Q(t_i)$$

That is, for each payment date we multiply the fixed coupon $C(T)$ by the year fraction $\Delta(t_{i-1}, t_i)$ since the previous coupon payment date in the corresponding basis.[5] We then weight it by the probability of the reference entity surviving to the coupon payment date by multiplying by $Q(t_i)$. We finally discount it back to today at the LIBOR rate using the discount factor $Z(t_i)$.

By itself, this equation fails to take into account the coupon accrued that has to be paid if there is a credit event between coupon payment dates as it assumes that the CDS only pays a coupon if the reference credit survives up to the coupon payment date. An exact calculation of the value of the contribution of the coupon accrued is beyond the scope of this chapter. However, we can approximate the value of the contribution by simply assuming that if the reference credit experiences a credit event in the period before the coupon is paid, it will on average occur in the middle of the period. In this case, the amount of accrued coupon will be

$$\frac{C(T)\Delta(t_{i-1}, t_i)}{2}$$

i.e., one-half of the full coupon. The probability of defaulting in the period before the coupon is due to be paid is given by $Q(t_{i-1}) - Q(t_i)$. For simplicity and without any significant loss of accuracy we can assume that this is then paid at the end of the period. We therefore have a coupon accrued contribution given by

$$\frac{C(T)}{2}\sum_{i=1}^{N} \Delta(t_{i-1}, t_i) Z(t_i)(Q(t_{i-1}) - Q(t_i))$$

Adding this to the value of the premium leg above gives

$$V_{\text{Premium}} = \frac{C(T)}{2}\sum_{i=1}^{N} \Delta(t_{i-1}, t_i) Z(t_i)(Q(t_i) + Q(t_{i-1}))$$

We can rewrite this as

$$V_{\text{Premium}} = C(T)A(T)$$

where

5. The market standard is Actual/360. Care needs to be taken since in practice there may be a difference between the accrual dates and the actual payment dates. In particular the actual final payment date at maturity is usually holiday/weekend adjusted while the final accrual date is not.

$$A(T) = \frac{1}{2}\sum_{i=1}^{N} \Delta(t_{i-1}, t_i) Z(t_i)(Q(t_i) + Q(t_{i-1}))$$

The quantity is known as the risky annuity. It is the expected present value of the premium leg assuming it pays an annualized coupon of \$1 and any accrued fraction of this coupon if there is a credit event. It is a function of the entire shape of the survival curve since each premium payment is weighted by the survival probability to the premium payment date.

Value of the Protection Leg

The protection leg pays $(1 - R)$ at the time of a credit event.[6] To find the present value of this we have to take into account when the payment occurs. We need to split the time between today and the end of the contract into lots of small intervals and determine the probability of defaulting in each small time period and then discount the payment back to today.

Suppose we split the time between now, time 0, and the maturity date in T years into M such intervals of length T/M. The value of the protection is then given by

$$V_{\text{Protection}} = (1 - R)\sum_{n=1}^{M} Z(t_n)(Q(t_{n-1}) - Q(t_n))$$

where $(1-R)$ is the amount paid following a credit event, which we assume does not depend on the timing of the credit event, and $Q(t_{n-1}) - Q(t_n)$ is the probability of defaulting between time t_{n-1} and t_n.

In practice, the value of M must be a large number in order to best capture the full shape of the survival probability curve and the discount curve. However, it cannot be too large otherwise it would become numerically slow to price a CDS contract.[7]

The Upfront Cost

Here we define the upfront cost as the cost which must be paid by a protection buyer to enter into a CDS contract. It is therefore the expected present value of the protection leg minus the expected present value of the premium leg; that is, it is given by

$$U(0) = V_{\text{Protection}} - V_{\text{Premium}}$$

where

6. Strictly speaking, payment occurs on the settlement date of the post-credit event auction. The two steps in the auction are described in Chapter 68.

7. A discussion of appropriate values for M is provided in Dominic O'Kane, *Modelling Single-Name and Multi-name Credit Derivatives* (John Wiley & Sons, 2008).

$$V_{\text{Premium}} = \frac{C(T)}{2}\sum_{i=1}^{N}\Delta(t_{i-1},t_i)Z(t_i)(Q(t_i)+Q(t_{i-1})) = C(T)A(T)$$

and

$$V_{\text{Protection}} = (1-R)\sum_{n=1}^{M} Z(t_n)(Q(t_{n-1})-Q(t_n))$$

These are all at time 0.

The Upfront and the Par CDS Spread

The T-year par spread $S(T)$ is the value of the coupon on the T-year CDS, which makes the current value of the contract equal to zero. Therefore

$$S(T)A(T) - V_{\text{Protection}} = 0 \Rightarrow V_{\text{Protection}} = S(T)A(T)$$

But the value of the contract at time zero using its actual coupon is

$$U(0) = V_{\text{Protection}} - C(T)A(T)$$

and we can substitute in the protection leg value to write this as

$$U(0) = \left(S(T) - C(T)\right)A(T)$$

The situation changes when we calculate the value of the contract using the flat spread. This is simply defined via the equation

$$U(0) = (\overline{S}(T) - C(T))\overline{A}(T)$$

This equation looks almost identical to the par spread valuation above. However there is one major difference. The value of the risky annuity here is only a function of the quoted flat spread $\overline{S}(T)$, whereas the value of the risky annuity using the par spread is a function of the *term structure of par spreads*. Clearly, the quoted flat spread does not take into account the term structure of spreads.

Interpolation of the Survival Curve

Before we can use this model, we must calibrate it to the term structure of market prices. This can mean a number of things. It could mean calibrating it to a term structure of upfront costs, a term structure of par spreads, or a term structure of flat spreads. Whichever it is, we will usually have market price data at maturity points starting at six months and then up to 10 years in annual steps. To use these 11 market prices to calibrate a term structure of survival probabilities we need to simplify the term structure of survival probabilities so that it is described by exactly 11 variables. Then we will have one unknown variable for each piece of data and we should then be able to fit exactly the market prices using this simplified term structure.

There are many ways to do this simplification. The market standard is to introduce the continuously compounded forward default rate $h(t)$. This is defined in terms of the survival probability as

$$Q(T) = \exp\left(-\int_0^T h(t)dt\right)$$

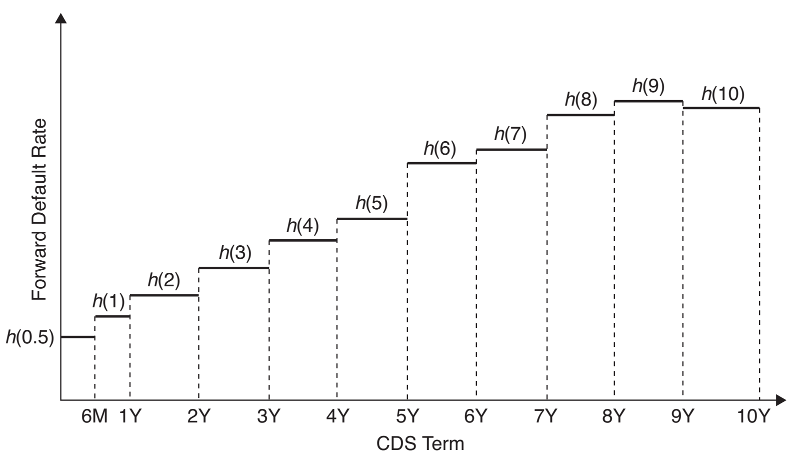
A common simplification is to assume that this continuously compounded forward default rate is piecewise flat as shown in Exhibit 69-4.

Given 11 market prices, the term structure of this continuously compounded forward default rate takes 11 different values: $h(0.5)$, $h(1.0)$, $h(2.0), \ldots, h(10)$, where each $h(t)$ is the value of the continuously compounded forward default rate from the previous time to time t. We then have

$$Q(0.5) = \exp(-0.5 \times h(0.5))$$
$$Q(1) = Q(0.5) \times \exp(-0.50 \times h(1.0))$$
$$\ldots$$
$$Q(10) = Q(9.0) \times \exp(-h(10.0))$$

EXHIBIT 69-4

Piecewise Flat Term Structure of the Forward Default Rate in Which We Calibrate to the 6M, 1Y, 2Y, ..., 10Y CDS Upfront Prices



However, the power of this approach is that it allows us to interpolate the value of the survival curve to other times. So, for example, we have

$$Q(0.3) = \exp(-0.3 \times h(0.5))$$
$$Q(0.7) = Q(0.5) \times \exp(-0.20 \times h(1.0))$$
$$Q(1.9) = Q(1.0) \times \exp(-0.90 \times h(2.0))$$

The whole term structure of survival probabilities is determined by these 11 values of the continuously compounded forward default rate. As long as the value of $h(t)$ is greater than or equal to zero, the term structure of CDS spreads will be arbitrage-free.[8]

Calibration by Bootstrap

Given the model and this interpolation scheme, we need one more input before we can calibrate the values of the continuously compounded forward rates to the market prices of CDS. This is the value of the expected recovery rate R. Note that this does not have to be the same value as the one used by the market to convert the flat quoted spread to an upfront and back which is currently set equal to 40%. It can be a value chosen by the model user.[9] With all of this information, the calibration can then be performed. This is done using a bootstrap.[10] The process is as follows:

1. Search for the value of $h(0.5)$ for which the model-implied upfront value equals the market quoted upfront of the six-month contract given the fixed coupon. As there is one unknown and one price, we should be able to determine $h(0.5)$ so that the market price is fitted exactly.
2. Using $h(0.5)$, now search for the value of $h(1.0)$ for which the model implied upfront equals the market quoted upfront of the one-year contract given its fixed coupon.
3. Repeat step two for each next longer maturity CDS, each time using knowledge of all the previously calibrated values of $h(t)$ to calculate the next one.

8. A term structure of CDS spreads can exhibit an arbitrage if the value of the protection leg to time T_1 is greater than the value of the protection leg to time T_2 where $T_2 > T_1$. In some cases this can allow for a strategy which can guarantee a positive income at no initial cost.

9. The effect of choosing a different recovery rate is that although the model will be calibrated to the market prices of quoted CDS contracts, the value of the protection and premium legs taken separately may differ from the value of the protection and premium legs according to the market standard recovery rate assumption.

10. A bootstrap is the name given to an algorithm that recursively solves a system of coupled equations one at a time, with each solution being found only after a set of the previous parameters have been found.

At the end of this process, we should have a value of h for each market price. From this we are able to compute the market-implied value of $Q(T)$ to any future time T. The value of $Q(T)$ that emerges from our market calibration is the "risk-neutral" survival probability. By risk-neutral, we mean the probability that, according to our model, reprices the market prices of CDS spreads—any other set of probabilities would not reprice the market and hence could create arbitrage possibilities. These spreads are credit-specific, forward-looking measures of the compensation required by a protection seller to sell protection until time T.

It is generally found[11] that credit spreads overcompensate the investor for the expected loss based on the incidence of default of other credits that had the same credit rating. There are a number of reasons why this may be the case. Mainly it is because the market is forward looking and may not consider historical default probabilities, especially when averaged over an economic cycle, to be appropriate given the current state of the economy. Also, because there is typically a large systemic and hence nondiversifiable component to credit spreads, investors demand an additional premium.

NEW AND EXISTING CONTRACTS

The price calculated by a CDS valuation model is the full price, i.e., the cash amount actually paid for the protection. One of the contractual details that determines this value is the date when the contract starts accruing the premium. In order to improve market fungibility of CDS contracts, the standard is for all new contracts to have a full first coupon; i.e., they begin accruing from the previous coupon payment date even if the contract was traded and settled more recently. This makes all contracts with the same maturity date identical in terms of their cash flows. It also means that a hedger who buys protection mid-payment period will have to pay for protection that was not received and should expect to be reimbursed for this through the value of the upfront payment. After all, the upfront cash amount to be paid to enter into this contract for protection is the expected present value of the protection leg minus the expected value of the premium leg. This premium leg will include a full first coupon.

The simplest example we can use to examine the effect of this is to assume that the CDS has a fixed coupon of 100 bp and the par spread to the same maturity is also at 100 bp. However, the par spread is based on a CDS contract that starts accruing at $T + 1$, i.e., one day after the trade date, which must by definition have zero upfront value. Calibration of our CDS model determines the survival probability curve that ensures that this is the case. In more general terms, the value of the same maturity CDS used to calibrate the CDS valuation model is given by:

$$U_{Calibration}(t) = V_{Protection} - C(T)A(t,T) = 0$$

11. For a literature review. see John Hull, Mirela Predescu, and Alan White, "Bond Prices, Default Probabilities and Risk Premiums," *Journal of Credit Risk* 1(2) (2005), pp. 53–60.

If we then use this curve to price our existing contract, we will find that the value of the contract will be

$$U_{Contract}(t) = V_{Protection} - C(T)A(t_0, 0)$$

where t_0 is the time of the previous coupon. But we can then write

$$A(t_0, T) \approx A(t, T) + \Delta(t_0, 0)$$

which should be a very good approximation.[12] This gives

$$U_{Contract}(t) = V_{Protection} - C(T)A(t, T) - C(T)\Delta(t_0, 0)$$

The first two terms on the right-hand side equal the value of the CDS contract we are calibrating to, which is zero, and so we have

$$U_{Contract}(t) = -C(T)\Delta(t_0, 0)$$

This is the negative of the coupon which has accrued since the previous coupon date. The protection buyer therefore finds that the contract pays him for the portion of coupon which accrued since the last coupon date which he has to pay on the next payment date, but whose benefit he did not enjoy since he wishes to enter the contract today. Clearly the payment of the coupon can be up to three months in the future (this is offset by the fact that the further in the future the coupon payment occurs the less that has accrued) while the upfront cost is paid on the settlement date which is the trade date plus three days, holiday adjusted. For this reason, setting the value of the contract equal to the negative of the accrued coupon is a good approximation but one that would only be exact in a world of zero interest rates.

There is one more issue to consider—the CDS contract provides protection against a credit event which occurred between T-60 and today. If such an event has been determined by the Determinations Committee (see Chapter 68) then the CDS contract would be in its post-credit event settlement process and the upfront cost would be close to par minus the expected recovery rate. If the event has not been determined, the implicit assumption is that market expectations that a credit event occurred in the past 60 days are already priced into the CDS spread curve.

RISK MANAGEMENT

We now wish to understand the factors that drive the valuation of a CDS contract. Specifically, we want to be able to calculate the hedge ratios needed to ensure that the value of a portfolio of CDS contracts on the same reference credit is immunized

12. It is based on the observation that any already accrued coupon will either be paid on the next coupon date if there is no default or it will be paid immediately if there is a default. In this sense it is a risk-free payment made at some point in the short period between today and the next coupon date. Since the period is short we can almost always ignore the time-value issue and not discount it.

against parallel moves in the CDS spread curve and the LIBOR interest rate curve. We begin by writing the time t upfront value of a (short protection) CDS contract as

$$U(t,S(t,T)) = \left(C - S(t,T)\right) A(T,S(t,T))$$

where $S(t, T)$ is the time T maturity par CDS spread as seen at time t. Note that we have inserted an explicit par spread dependency into the upfront value and the risky annuity term $A(T, S(t, T))$ to remind ourselves that a change in the par spread followed by a recalibration will cause the term structure of survival probabilities to change and so will change the present value of the risky annuity and the value of the upfront.

Spread DV01 of a CDS

The credit duration of a CDS contract is usually known as the Spread DV01. It is defined as the change in the upfront value of the contract for a 1 bp parallel bump upward in the CDS spread curve. For a short protection position, we can write this as

$$\text{Spread DV01} = U(t,S+1bp) - U(t,S)$$

This gives

$$\text{Spread DV01} = -A(T,S+1bp)\cdot 1bp + \left(S-C\right)\cdot\left(A(T,S) - A(T,S+1bp)\right)$$

There are two contributions to the Spread DV01:

1. The first term describes a fall in the upfront value of the short protection position by $A(T, S + 1\ bp)$ times the change in the spread. The value falls because we have sold protection and the credit quality of the reference credit, as implied by the spread which was bumped, has worsened so the position has lost value.
2. There is a second term due the fact that the change in spread also causes the value of $A(T, S)$ to change. Because this term is multiplied by the spread difference $(S - C)$, it is usually much smaller then the first term. Also, the sign of the change is driven by the sign of $(S - C)$. If this is positive, it means that this term will offset the effect of the first term and reduce the Spread DV01. If negative it can increase the Spread DV01.

The Spread DV01 of a short protection position is therefore typically close in value to the negative of the risky annuity given by $A(T, S)$ multiplied by 1 basis point and approaches[13] it if $S = C$. The spread sensitivity from the perspective of a long protection position is simply the negative of that of a short protection position.

Hedging different CDS positions using the Spread DV01 is only really effective if the quoted spread or par spread of the different contracts move by

13. It does not equal it exactly, since when $S = C$ the Spread DV01 equals –A(S + 1) and not –A(S).

the same amount. For contracts of differing maturity, this requires the CDS curve to move in parallel shifts, which is not always the case. For this reason, use of the Spread DV01 should generally only apply to contracts of a similar maturity. To go beyond Spread DV01, we would need to calculate the sensitivity of a CDS contract to movements of different curve points (e.g., 1-year, 3-year, 5-year, 7-year, and 10-year), and determine the set of positions in each of these contracts needed to immunize the hedged portfolio against spread movements.[14]

Interest Rate Duration of a CDS

The interest rate sensitivity of a CDS contract is known as its IR DV01. It is defined as the change in the upfront value of the contract for a 1 bp parallel bump upward in the LIBOR curve while keeping the par spread curve fixed. As the only interest rate dependency is in the annuity term, we have

$$\text{IR } 01 = (C - S) \cdot (A^*(T) - A(T))$$

where $A^*(T)$ is the value of the risky annuity calculated using the bumped interest rate curve. Since this is the present value of future cash flows, we can conclude that $A^*(T) - A(T) < 0$. We can therefore conclude that: (1) if $C = S$ the interest rate sensitivity of a CDS is zero, (2) if $S < C$ then the IR DV01 is negative, and (3) if $S > C$ then the IR DV01 is positive.

In general the interest rate sensitivity of a CDS is low, especially when compared with a fixed-rate corporate bond with the same maturity date. This is due to the fact that the bond has coupons plus a payment of par at maturity, while the CDS is effectively a credit risky annuity with annualized coupon payments of $(C - S)$ and unlike a bond there is no payment of par at maturity. In fact the interest rate sensitivity of a CDS actually closely resembles the interest rate sensitivity of a same-maturity par floating rate note issued by the reference entity.

Example

Exhibit 69-5 shows an example[15] of the pricing of a real CDS trade to buy protection until March 20, 2016. The CDS coupon (deal spread) has been fixed at 100 bp. The pricing of the CDS is captured by the current flat spread, called the "quoted spread," to the contract maturity date, which is 34.32 bp. This is the only spread quote needed to determine the upfront value. Both the deal and the quoted spread assume the market standard recovery rate of 40%.[16]

14. This procedure is discussed in detail in O'Kane, *Modelling Single-Name and Multi-name Credit Derivatives.*

15. The valuation here reproduces that produced by the standard CDS valuation calculator found on Bloomberg, which is accessed via the code CDSW.

16. These would only differ if the user was attempting to price a fixed recovery default swap.

EXHIBIT 69-5

The Value of the CDS Contract

Trade Description

Notional:	$10m	Trade Date:	3rd February 2011
Maturity:	20 March 2016	Settlement:	8th February 2011
Buy/Sell:	Buy Protection	Quoted Spread:	34.32 bp
Deal Spread	100 bp	Currency:	USD

Valuation Results

Price	103.22035	Accrued	–$12,778 (46 days)
Principal	–$322,035	Spread DV01:	5,036.41
Cash Amount	–$334,813	IR DV01:	84.26

We explain the valuation outputs in Exhibit 69-5:

- **Price:** This is the "clean" price for a protection seller who was to buy the CDS together with a par LIBOR floating rate note. It excludes the payment of accrued interest that would need to be added to the actual price paid.
- **Principal:** This is the clean (excluding accrued interest) value of the contract. It is computed by subtracting the accrued interest from the cash amount defined below.
- **Accrued Interest:** This is the amount of coupon that has accrued since the last coupon payment date or the first accrual date. For a new contract and an existing contract this is always the CDS Date that falls before the trade date. For a protection buyer the accrued interest is always negative while for a protection seller it is always positive. The valuation shows 46 days of a 100 bp coupon that has accrued from the previous payment date December 20, 2010, to T+1 calendar, which falls on February 4, 2011.
- **Cash Amount:** This is the actual upfront amount that has to be paid to enter into this contract. The valuation is –$334,813 meaning that the protection buyer receives $334,813 to enter into this contract. This is because the protection buyer who enters into this contract has to pay an annualized coupon of 100 bp for up to five years for a reference entity with a quoted flat spread of 34.32 bp. Because the coupon being paid is higher than the cost of protection implied by the quoted spread, the protection buyer has to be compensated upfront.
- **Spread DV01:** The spread sensitivity of the long protection position is calculated to be $5,036, meaning that a 1 bp increase in the quoted spread curve would cause the value of the CDS position to increase by this amount.

- **IR DV01:** The interest rate sensitivity of the contract is also positive, but much smaller at $84.24. This makes it very clear that a CDS is almost purely a credit-spread product.

Exhibit 69-6 shows the cash flows on the premium leg of the CDS. We see the payment dates and the corresponding amounts calculated using the Actual 360-day count convention. We also see the discount factors implied by the LIBOR deposit rates and swap rates used. Finally we see the survival probabilities implied by our CDS valuation model. The default probability is simply one minus the survival probability.

EXHIBIT 69-6

Approximation

For those wishing to evaluate trading strategies, the Bloomberg pricer found under CDSW can be limiting and a simple Excel-based pricer would be quite useful, even if it is not exact. It is therefore worth describing a simple approximation that is based on the observation that the value of the risky annuity of a new CDS contract can be linked directly to the quoted flat spread $\overline{S}$ and the recovery rate assumption R using the following approximation

$$A(\overline{S},T) \approx \frac{1-\exp\left(-\left(\mathrm{W}+\frac{\overline{S}}{(1-R)}\right)T\right)}{\mathrm{W}+\frac{\overline{S}}{(1-R)}} \times \frac{365}{360}$$

where W is the swap rate to the contract maturity in T years and the ratio of 365/360 is used to adjust for the Actual 360 convention used to determine the size of premium payments.[17] The value of a long protection CDS position is simply given using the standard valuation equation:

$$U(t) = \left(\overline{S} - C\right) A(\overline{S},T)$$

Taking the example above where the quoted spread is 34.23 bp, the time from today to contract maturity is 5.122 years and the five-year swap rate is 2.4%, we find that

$$A(\overline{S},T) = \frac{1-\exp\left(-\left(0.024+\frac{0.003432}{(1-0.4)}\right)\cdot 5.122\right)}{0.024+\frac{0.003432}{(1-0.4)}} \times \frac{365}{360} = 4.81764$$

We therefore calculate

$$U_{Existing}(t) = \$10{,}000{,}000 \cdot \frac{(34.32-100)}{10000} \cdot 4.81764 - \$12{,}778 = -\$329{,}992$$

This should be compared to the cash amount calculated by the Bloomberg valuation (not shown) which was –\$334,813, a difference of about \$5,000 on a \$10 million face value. Note that we had to subtract the 46 days of accrued coupon which have to be paid by the protection buyer at the end of this coupon period. These are worth \$12,778. The reason for doing this is that this contract requires the protection buyer to pay a full coupon on the next payment date. However the quoted spread of 34.32 bp is for a contract that starts accruing from T + 1. To account for this we need to

17. Using an Actual 360 basis the sum of the actual coupon payments over a year exceeds the amount implied by the annualized coupon by this ratio in non-leap years. Any good approximation of the risky annuity needs to account for this.

compensate the protection buyer for having to make this extra future payment and to a very good first approximation, this can be done by subtracting the accrued coupon. The valuation is within 1.5% of the Bloomberg result—corrections to the interest rate used to discount the CDS cash flows to account for the slope in the swap curve can further improve the accuracy of this approximation.[18]

CDS INDEX VALUATION

The mechanics of the CDS index have been set out in Chapter 68. We showed that a CDS index is equivalent to a portfolio of CDS in which the individual CDS all pay the same index coupon given by $C_I(T)$. In this section, we wish to show that for valuation purposes a CDS index can actually be treated as though it were a CDS contract. We recall from Chapter 68 that the buyer of a time T-maturity CDS index is selling protection on a portfolio of P different time T-maturity CDS contracts, and receiving a coupon $C_I(T)$ in return for assuming this risk. Credit events in the portfolio result in the relevant CDS being removed from the index and settled via the standard auction procedure described in Chapter 68.

On each coupon payment date the size of the coupon payment is proportional to the size of the remaining portfolio of CDS. It therefore falls in absolute terms as credit events occur.

Therefore, unlike a single-name CDS, a CDS index does not have a single credit event which causes it to pay out a single loss and then cancel. Instead, the contract remains active[19] until maturity, with loss payments being made as and when credit events occur.

Index Valuation

From the perspective of an index buyer (protection seller), the CDS index value is equal to the premium legs of the P underlying CDS contracts that each pay the index coupon, minus the expected present value of the P protection legs. Using the notation set out in Exhibit 69-5, we can therefore write the value of the index premium leg as

$$\frac{C_I(T)}{P}\sum_{p=1}^{P} A_p(T)$$

18. The main reason for the difference is the upward sloping swap curve in February 2011, which rises from 0.46% at six months to 2.4% at five years. This is not consistent with our assumption of a flat swap curve. Using a maturity-weighted average swap rate of 1.67%, we obtained a valuation with an error of less than 0.1%.

19. Strictly speaking, the CDS index contract would cancel if all of the credits in the reference portfolio experienced a credit event. However given that the reference portfolio usually consists of 50–125 individual credits, the probability of this happening within the lifetime of a typical CDS index contract is considered to be close to zero.

EXHIBIT 69-7

Notation Used in the Valuation of CDS Indices

Symbol	Description
$C_I(T)$	The coupon of a T-year maturity CDS index.
$U_I(T)$	The upfront value of a T-year maturity CDS index.
$S_I(T)$	The par spread paid on a T-year maturity CDS index which has no initial cost.
$S_P(T)$	The par spread paid on a T-year maturity CDS on reference credit p.
$\bar{S}_I(T)$	The "quoted" spread is the level of a flat par CDS index spread curve which sets the model-implied upfront cost of a T-year CDS index equal to its market value.

We can also write the value of the index protection leg in terms of the individual CDS spreads as

$$\frac{1}{P}\sum_{p=1}^{P} S_p(T)A_p(T)$$

We are assuming here that the reference credits are all equally weighted.[20] The value of the index (short protection) position is then

$$V^{Index} = \frac{1}{P}\sum_{p=1}^{P}(C_I(T) - S_p(T))A_p(T)$$

The most common application for CDS index pricing is Bloomberg's CDSW function. This treats a CDS index as a standard CDS contract. As with CDS, price quotations for the CDS indices are almost exclusively done using the "quoted" flat index spread defined as the level at which we would mark a flat CDS index par spread so that, when using the standard CDS pricing model, it would cause the index model price to refit the market upfront index price. We therefore have

$$V^{Index} = \frac{1}{P}\sum_{p=1}^{P}(C_I(T) - S_p(T))A_p(T) = (C_I(T) - \bar{S}_I(T))\bar{A}_I(T)$$

The point here is that this mapping of a CDS index onto a single CDS contract allows us to use our single-name CDS analytics to value and risk manage the

20. This is always the case on the issue date of an index. However, if one or more company splits or merges then this could cause some reference credits to have a smaller or larger notional than the others. Even if this does occur, it does not affect any of the index pricing analysis presented in this chapter.

CDS index. By doing so, we price the CDS index as though it has its own index survival probability $Q_I(t)$. Note that if we assume that the expected recovery rates of all of the credits in the index are the same, we can write

$$Q_I(t) = \frac{1}{P}\sum_{p=1}^{P} Q_p(t) = N_I(t)$$

where $N_I(t)$ is the expected surviving notional of the index at time t. We do not use this relationship in pricing because it assumes that all recovery rates are the same, which is not always the case. However, in general, it is approximately true and does provide some intuition about the interpretation of the index survival probability.

The CDS Index Basis

If this relationship is not obeyed, there is then a theoretical mispricing. However, this theoretical mispricing may not be arbitrageable for a number of reasons:

1. Model prices are usually mid-market. Therefore, if we take into account the cost of crossing the bid-offer spread that would need to be done to monetize any mispricing, this mispricing may not be a real arbitrage opportunity after all.
2. Obtaining accurate and contemporaneous flat spreads for all of the constituents of a CDS index may not be possible.
3. Where CDS and CDS indices trade with different restructuring clauses, the replication is not exact and this relationship should not be exactly obeyed.

Despite these caveats, CDS indices have traded away from their CDS-implied spread. This will generally be due to market technical factors such as a market demand to buy or sell systemic versus single-name credit protection. If the deviation becomes large enough to be arbitraged, then hedge funds and other market players will step in to monetize the profit until their activities eliminate the arbitrage.

Risk Management

Since the CDS index contract is valued as though it was a single-name CDS contract, its price sensitivities are identical to those of a single-name CDS contract with the same term structure of par spreads or quoted spread, the same recovery rate, the same maturity, and the same interest rate environment. As a result, we refer the reader to the section on CDS risk management.

KEY POINTS

- Since the introduction of fixed coupons for CDS contracts in 2009, entry to a CDS contract almost always involves some initial upfront cash payment, which can be positive or negative.
- From the perspective of a protection seller, the size and sign of the initial cash value of the contract depends on whether the fixed coupon is sufficient to compensate the protection seller for the market perceived risk of a credit event. If the coupon is low, the protection seller may receive cash at trade initiation. If the coupon is high, the protection seller may have to pay cash at trade initiation. The situation is reversed for a protection buyer.
- The purpose of the valuation of CDS and CDS indices is to calculate this upfront cash payment. This requires a model in order to determine the expected present value of the premium and protection leg of the contract.
- This model needs to take into account the probability of and the timing of a credit event. For the premium leg, it needs to take into account the risk that not all coupons will be paid. For the protection leg it needs to value the unknown payment of par minus recovery made at the time of the credit event, if one occurs. It also needs to be flexible enough to exactly reprice the term structure of quoted market spreads.
- One type of market quote is the CDS par spread. This is the value of the coupon that would need to be paid on the premium leg of a CDS in order for the contract to have zero upfront value on trade date. The value of a CDS is a function of the term structure of CDS par spreads.
- Since 2011, the CDS market has also begun to use an alternative measure known as the flat "quoted" spread. This is the level at which a flat term structure of par spreads would need to be set in order that they reprice the market quoted upfront value. As a result, only one quoted spread is needed to value a CDS contract.
- The probability of a CDS experiencing a credit event as implied by CDS market spreads usually exceeds the historical default probability implied by the default rate of credits that were initially assigned the same credit rating. This is because spreads are forward-looking and embed a risk premium.
- The model allows the holder of a CDS position to calculate the sensitivity of the value of the contract to changes in the quoted spread and so enables him to hedge it with other CDS contracts.
- For valuation purposes, a CDS index can be treated as a single-name CDS and valued and risk-managed using the same model as the CDS.

CHAPTER
SEVENTY

PRINCIPLES OF PERFORMANCE ATTRIBUTION

Barclays

Performance measurement and attribution is an important function of portfolio management. It helps bring clarity to the sources of portfolio risk and performance, quantify the contributions of individual decision-makers, and identify structural issues. Performance attribution algorithms typically follow either a sector-based allocation or a factor-based allocation methodology, but neither is sufficient to cope with the complexity of modern portfolio management. In this chapter, we first discuss the principles of performance attribution. We review the sector-based and factor-based attribution frameworks and then describe a hybrid attribution model[1] that blends the two and has the flexibility to adapt to the particular management structure of most portfolios. The chapter finishes with the application of performance attribution, both as a portfolio management tool and a data quality tool. Where possible, we introduce the best practices for performance measurement and discuss practical considerations in real-world applications. Throughout the chapter, we utilize examples produced by the Hybrid Performance Attribution (HPA) model[2] as implemented in POINT, the portfolio analytics and modeling platform then offered by Barclays.

PRINCIPLES OF PERFORMANCE ATTRIBUTION

Managing a global diversified portfolio of financial assets is a complex task that requires adopting views in different markets and implementing them with regular trading activities. Expressing and implementing views in a variety of markets that interact with each other in complex ways, makes it very difficult to quantify the

---

This chapter was coauthored by Anthony Lazanas, António Baldaque da Silva, Chris Sturhahn, Eric P. Wilson, and Pam Zhong when they were employees of Barclays.

1. For another discussion of the hybrid performance attribution model also see Chapter 27 in Lev Dynkin, Anthony Gould, Jay Hyman, Vadim Konstantinovsky, and Bruce Phelps, *Quantitative Management of Bond Portfolios* (Princeton University Press, 2007).
2. For details of the model see Anthony Lazanas, Chris Sturhahn, and Pamela Zhong, *The Barclays Capital Hybrid Performance Attribution (HPA) Model* (Barclays Capital Publications, October 2010).

contribution of each decision-maker to the performance of the portfolio. Performance attribution is a mathematical framework that attempts to split the total outperformance of a portfolio versus a benchmark into the contributions of individual decisions and actions.

Complex portfolios are typically managed by breaking down the investment process into a sequence of decisions made by different managers, each of whom specializes in a specific market or type of security. Traditionally, this process follows product and sector lines. Risk-factor-based portfolio management became popular with the advent of modern portfolio risk management and the realization that certain risks are common for multiple asset classes. Foreign exchange (FX) and interest rates are examples of risks that are now commonly being managed separately for the entire portfolio while product/sector experts focus on managing excess returns.

The total outperformance of a portfolio depends on the combined outcome of the decisions of all portfolio agents, as well as the market performance. Often, the effects of different agents' decisions depend on each other in a way that makes it difficult to disentangle them. A successful performance attribution algorithm will do so in a way that satisfies three important requirements:

- *Additivity*: The contribution of two or more agents combined is equal to the sum of the contributions from those agents.
- *Completeness*: The sum of all outperformance contributions is equal to the total portfolio outperformance.
- *Fairness*: The allocation of outperformance to different interacting agents is performed in a way that is perceived to be fair by all agents.

These requirements are important because performance attribution is often used to measure the skill level and determine the compensation of portfolio managers. The fair decomposition of portfolio outperformance must take into account the management structure of the portfolio. In addition, a good performance attribution model or system needs to successfully address multi-period compounding and have sufficient flexibility in order to meet the demands of modern portfolio management.

Multi-Period Attribution and Compounding

Generally speaking, a performance attribution model measures the exposure of a portfolio to various markets at the beginning of a period and then explains the contribution of each market to the performance of the portfolio over the period as the product of its exposure to the market times the market move. Since actively managed portfolios dynamically adjust exposures to various markets frequently, such performance attribution over a period of time will not capture the effect of active portfolio management.

For example, consider a portfolio that begins the attribution period with no exposure to a particular sector. During the period the sector rallied and in response the manager allocated positive exposure to the sector. Subsequently the sector lost all of its gains and ended the period flat. Since the portfolio had no exposure when the sector rallied but positive exposure when the sector retreated, the portfolio realizes losses over the period. An attribution system that looks at exposure at the beginning of the period (zero) and the return of the sector over the period (also zero) will not be able to explain the realized losses. A system using average exposure over the period will also fail to explain the losses since the return of the sector is zero over the period. On the other hand, a system that splits the attribution exercise in two (or more) subperiods and then combines the results of the subperiods to explain the total portfolio performance over the entire period will be able to identify the intra period exposure adjustment as the reason for the portfolio losses.

The length of the subperiods that an attribution system uses to explain performance over longer periods determines the frequency of the attribution system. Linking the returns of subperiods is called compounding. Timing affects investment performance, especially when intermediate cash flows occur. Since cash flows impact portfolio market value, the fundamental question is whether subperiod returns should be compounded without regard to the portfolio size during each subperiod (time-weighted compounding) or whether subperiod returns should be weighted by the portfolio market value in each period (money-weighted compounding). For example, consider a portfolio with a seed investment of \$1,000,000 that earns a rate of return of 100% doubling its value for the first half of the year. Because of its success, the portfolio attracts additional investments of \$100,000,000 and its market value becomes \$102,000,000. Unfortunately, in the second half of the year it has losses of 10% ending the year with a value of \$91,800,000. What is the annual return of the portfolio? Assuming the inflow occurred in the middle of the year, money-weighted rate of return estimates the annual return by solving for the internal rate of return:

$$1{,}000{,}000 \times (1+r) + 100{,}000{,}000 \times (1+r)^{0.5} = 91{,}800{,}000 \Rightarrow r = -17.24\%$$

Time-weighted rate of return ignores the portfolio size and reports an annual return of:

$$r = (1+100\%) \times (1-10\%) - 1 = 80\%$$

Given the dramatic differences between the two methods when portfolio flows are significant relative to its current size, the choice between the two methods is an important decision. Whether the timing of cash flows should be reflected in return measures depends on whether the portfolio manager is responsible for the timing of the cash flows. If she is responsible, then the money-weighted method should be used. In the case of mutual fund or pension fund managers who have no direct control of cash contributions and withdrawals, the time-weighted method is more appropriate. In the following three chapters we assume the time-weighted methodology.

Once the method for compounding returns is decided, the question of splitting multi-period returns into components (i.e., multi-period performance attribution) must be addressed. The difficulty arises from the fact that compounding is a nonlinear function and introduces interaction terms that must be allocated between different return components. For example, consider that the portfolio return is attributable to two components which both contribute 10% of return over two periods. The return of the first component is realized during the first period, and the return of the second component is realized over the second period. Time-weighted compounding will report total portfolio return of (1+10%) × (1+10%) – 1 = 21%. Each component contributes 10%, leaving 1% of total return that can be claimed by either component. A multi-period attribution system must adopt both return and outperformance compounding algorithms that retain the principles of additivity, completeness and fairness. Such algorithms are discussed in more detail in Chapter 72.

It is important that the frequency of the attribution system match the frequency of portfolio management decisions. If the attribution frequency is too low, as in the example above, part of the portfolio performance may remain unexplained. Conversely, if the attribution frequency is too high, the attribution model may attribute outperformance to portfolio management erroneously. Many fixed income portfolios are managed on a daily basis, especially with respect to their interest-rate exposures; therefore daily-frequency attribution models are commonly used for fixed income portfolios. Daily compounding generates the requirement for high-quality daily prices and analytics for all securities in a portfolio and its benchmark. Sophisticated attribution systems can be used as a magnifying glass for data quality. Any problems with the data are immediately shown in the quality of the results. An example of this is discussed later in the chapter.

Flexibility

A practical performance attribution system must reflect the decisions that a portfolio manager makes during the normal course of the investment process. With a wide diversity among portfolio managers also comes a wide diversity of styles that are often mutually exclusive. No single specification of a performance attribution can describe all managers' preferences. In order to be useful, the model must also satisfy the following requirements:

- Measure the risk factors corresponding to the portfolio managers' decisions
- Independently measure the contributions of each factor in the portfolio management process
- Closely follow the published returns of the fund, and its benchmark
- Be available in a timely manner

- Have sufficient adaptability to explain both short and long time periods

In short, it must be useful to the portfolio manager in explaining and refining her decisions, quantifying the effects of the investment process.

MATHEMATICS OF PERFORMANCE ATTRIBUTION

Performance attribution algorithms typically follow either a sector-based allocation or a factor-based allocation methodology. Both methods follow the same framework which expresses the total outperformance of the portfolio over a benchmark $R^P - R^B$ as the sum of several components. The contribution of each component is determined by a portfolio manager's decision to allocate a different exposure than the benchmark to a particular market or factor, and the performance of the market or the factor itself. In this section, we first discuss sector-based and factor-based attribution under this simple framework, and then introduce a hybrid model that blends the two and has the flexibility to support virtually all types of portfolios and portfolio management styles. We will develop the mathematical framework of performance attribution assuming a generic set of sectors and factors. In Chapters 71 and 72 we will see the application of this framework in the performance attribution of fixed income portfolios.

Sector-Based Attribution

In its simplest form, portfolio management versus a benchmark is modeled as a two-step process that consists of market weight allocation to various sectors and security selection within each sector. The classical performance attribution methodology is often referred as "Brinson model."[3] Portfolio return is the market value-weighted (w_s) sum of the individual sector returns, R_s:

$$R^P = \sum_s w_s^P R_s^P$$

Similarly, benchmark return is the weighted sum of benchmark sector returns:

$$R^B = \sum_s w_s^B R_s^B$$

This representation allows us to identify two key drivers of the total outperformance $R^P - R^B$: the differences in the sector allocations, $w_{s,}$ and the differences in the returns, R_s earned within each sector. The outperformance achieved by

3. Gary L. Brinson and Nimrod Fachler, "Measuring Non-U.S. Equity Portfolio Performance," *Journal of Portfolio Management*, 11, 3 (1985), pp. 73–76 and Gary L. Brinson Randolph. Hood and Gilbert Beebower "Determinants of Portfolio Performance," *Financial Analysis Journal*, 42, 4 4 (1986), pp. 39–44.

reweighting the sectors is called "Asset Allocation," and the outperformance due to the intrasector return differences is called "Security Selection." To make the decomposition of the total outperformance complete, we need to add a third term, the "Interaction" effect, the joint effect of asset allocation and security selection.

$$\text{Asset Allocation} \qquad \sum_s \left(w_s^P - w_s^B\right)\cdot R_s^B \tag{70-1}$$

$$\text{Security Selection} \qquad \sum_s w_s^B \cdot \left(R_s^P - R_s^B\right) \tag{70-2}$$

$$\text{Interaction} \qquad \sum_s \left(w_s^P - w_s^B\right)\cdot \left(R_s^P - R_s^B\right) \tag{70-3}$$

Interaction terms arise every time two factors contribute to outperformance through a non-additive function such as the product. Interaction terms are philosophically undesirable, since the stated goal of performance attribution is to credit agents separately for their contribution. Thus, we attempt to merge interaction terms into other outperformance components that can be uniquely attributed to a single agent. The criteria for consolidation are usually dictated by the order in which decisions are made, or the relative size of the interaction term.

The standard assumption is that asset allocation precedes security selection (i.e., the portfolio is managed in a top-down fashion), so it is common to fold the interaction term into the latter:

$$\text{Asset Allocation} \qquad \sum_s \left(w_s^P - w_s^B\right)\cdot R_s^B \tag{70-4}$$

$$\text{Security Selection} \qquad \sum_s w_s^P \cdot \left(R_s^P - R_s^B\right) \tag{70-5}$$

If, on the other hand, the expected returns of sectors in the portfolio are different than those in the benchmark (e.g., because of manager skill or leverage), then it might be more appropriate to fold the interaction term into asset allocation instead. As a result, asset allocation would be given by $\sum_s \left(w_s^P - w_s^B\right)\cdot R_s^P$ and security selection would be given by $\sum_s w_s^B \cdot \left(R_s^P - R_s^B\right)$. It is easy to see that in both cases, the outperformance breakdown is complete; i.e., the sum of the two components is equal to the total outperformance.

The above formulas would assign positive contribution to asset allocation outperformance to any overweighted sector with positive benchmark sector return. Thus, if all sectors have positive benchmark returns, overweighting the sector with the worst return would still be considered a good decision. This is intuitively wrong in most portfolios, as the weight allocated to such sector would be better used in sectors with higher returns. Therefore, instead of using the absolute benchmark sector return in the above asset allocation formula, one can use the sector return relative to the benchmark return (which represents the weighted average return of all benchmark sectors):

Asset Allocation $$\sum_s \left(w_s^P - w_s^B\right) \cdot \left(R_s^B - R^B\right) \qquad (70\text{-}6)$$

Security Selection $$\sum_s w_s^P \cdot \left(R_s^P - R_s^B\right) \qquad (70\text{-}7)$$

Notice that while the contribution of each sector to asset allocation changes, the total asset allocation outperformance remains the same as long as $\sum_s w_s^P = \sum_s w_s^B$.

The constraint that the sum of the portfolio and the benchmark sector weights are equal to one necessitates the comparison of the benchmark sector returns with the overall benchmark return. If leveraging is allowed, such that there is no constraint on each sector's weight, then each overweighted sector with a positive return should indeed have a positive contribution to outperformance. In such a case, we do not need to compare the return of each sector to the return of the benchmark and Eqs. (70-4) and (70-5) apply. In practice, however, leverage constraints do exist (usually dictated by risk constraints), and neither the benchmark return nor zero is a generally appropriate choice for the hurdle rate for each sector. In the following discussion, we will use the term R^H generically for the hurdle rate. This formulation describes both above models while allowing for extra flexibility. A choice of $R^H = 0$ gives the original Brinson model in Eqs. (70-4) and (70-5), while a choice of $R^H = R^B$ gives the model in Eqs. (70-6) and (70-7).

Recursive Allocation

Most large portfolios have many management layers by which allocation decisions are made successively. For example, the global strategist can specify the allocation into global markets, the U.S. strategist can determine the allocation to major asset classes in the United States (equities, bonds, commodities, etc.), the fixed income strategist can determine the allocations into the various sectors, and so forth.

In such a case, what we called security selection above contains not only security selection, but also further asset allocation, as well as security selection for each subsector. In fact, each sector can be considered as a smaller portfolio for which the above performance breakdown equations can be applied recursively. For this reason we will use the term "sector management" instead of "Security Selection," and we will reserve the term "security selection" for the last layer of management when no further sector decomposition occurs.

For each sector, its contribution to the sector management from the level above, $w_s^P \cdot \left(R_s^P - R_s^B\right)$, is recursively split into the following components:

Asset Allocation $$w_s^P \sum_r \left(\frac{w_r^P}{w_s^P} - \frac{w_r^B}{w_s^B}\right) \cdot \left(R_r^B - R_s^H\right) \qquad (70\text{-}8)$$

Sector Management $$\sum_r w_r^P \cdot \left(R_r^P - R_r^B\right) \qquad (70\text{-}9)$$

Typically, the benchmark sector return R_s^B is used as the hurdle rate as for the calculation of asset allocation to subsectors. In this fashion, we can keep decomposing sector management outperformance until we reach the last layer of portfolio management. Since at each level the decomposition is complete, the total outperformance decomposition is also complete. This algorithm has two of the three required properties of performance attribution: additivity and completeness. As we will see in the following discussion, it also has sufficient flexibility to be applied under different management structures such that it is considered to be fair, thereby satisfying all three requirements of performance attribution.

The fundamental advantage of the sector-based attribution methodology is its flexibility. The ability to analyze portfolio allocations along an arbitrarily specified market partition makes it possible to customize the model to fit many different types of portfolios and management styles. The main disadvantage of this approach is that it analyzes yield-curve and spread returns within the same market partition using market value weights, something that does not correspond to standard fixed income portfolio management practice.

Factor-Based Attribution

The "sector-based" attribution is gradually losing ground to a "factor-based" decomposition of the investment universe, where the return of the security in the portfolio/benchmark is decomposed into the contributions of common risk factors plus a residual. The residual represents the return not captured by the risk factors. The coefficients of the factors, α_k, are called loadings or sensitivities of the portfolio to each factor, f_k. Typically, the decomposition is linear and is represented as:

$$R^P = \sum_k \alpha_k^P f_k^P + \varepsilon^P$$

Such risk factors for fixed income securities include interest rates, implied volatility, spreads, etc., and the loadings are the corresponding sensitivities to the exposure of each factor (option-adjusted duration, partial (key-rate) durations, Vega, spread duration, and related measures). Factor-based attribution essentially entails the decomposition of outperformance to the contribution of each risk factor.

$$R^P - R^B = \sum_k \left(\alpha_k^P - \alpha_k^B\right) \cdot f_k^P + (\varepsilon^P - \varepsilon^B) \tag{70-10}$$

Pure factor-based attribution systems attempt to use a set of factors that can explain all of the systematic return of a portfolio. In this case the excess return is idiosyncratic and therefore quite small for a well-diversified portfolio. The disadvantages of this approach are that it does not attribute idiosyncratic returns of small portfolios to security selection decisions, and there is usually little flexibility in defining the risk factors. The latter shortcoming may be overcome with factor remapping,[4] which allows each portfolio manager to attain a personalized view of risk and return decomposition.

A Unified Framework for Performance Attribution

We will now combine the ideas we have developed in the preceding sections into a unified framework that blends the sector-based and the factor-based attribution. Models using this framework, such as the Barclays Capital Hybrid Performance Attribution model, are favored by portfolio managers since they can account for the complex management structures of large diversified portfolios. The framework offers enhanced flexibility in defining arbitrary hierarchical partitions along which sector allocation decisions are expressed. It allows the portfolio managers to achieve the best match to their investment decision-making process. It is a conceptually simple recursive algorithm that can be described in three steps: return splitting, factor return attribution, and recursive application. We explain these steps below.

Step 1: Return Splitting

The total return of the portfolio and the benchmark is split into the linear contributions of factors.[5]

$$R^P = \sum_k \alpha_k^P f_k^P \qquad R^B = \sum_k \alpha_k^B f_k^B$$

Note that residual is included here as one of the factors with a loading of one.

Step 2: Factor Return Attribution

The factors from step 1 are categorized as either common or allocated. We denote the set of common factors by C and the set of allocated factors by A and write the total outperformance as:

$$R^P - R^B = \left(\sum_{k \in C} \alpha_k^P f_k^P - \sum_{k \in C} \alpha_k^B f_k^B \right) + \left(\sum_{k \in A} \alpha_k^P f_k^P - \sum_{k \in A} \alpha_k^B f_k^B \right) \tag{70-11}$$

The outperformance from each factor is then handled separately. For each factor, we partition the investment universe into sectors[6] and decompose the outperformance from the factor.

$$\alpha_k^P f_k^P - \alpha_k^B f_k^B = \sum_s \alpha_{k,s}^P f_{k,s}^P - \sum_s \alpha_{k,s}^B f_{k,s}^B \tag{70-12}$$

---

4. António Baldaque da Silva, "Risk Attribution with Custom-Defined Risk Factors," *Barclays Capital Publications*, August 2009.
5. Successive valuation used for the return splits is discussed in Chapter 71.
6. A different partition may be used for each factor.

Outperformance from common factors is explained using bottom-up aggregation, namely via net exposures to a factor at each level of the aggregation. Furthermore, if a factor is truly common, where the factor return in the portfolio is identical to the factor return in the benchmark, then the contribution of the factor to portfolio outperformance can be written as:

$$\alpha_k^P f_k^P - \alpha_k^B f_k^B = \sum_s \left(\alpha_{k,s}^P - \alpha_{k,s}^B\right) \cdot f_{k,s} \tag{70-13}$$

This breakdown allows the performance of the portfolio due to the common factors to be categorized and aggregated to the portfolio level. In this way, a more detailed explanation of the factor and its impact to the total portfolio is possible than if the return were split between sectors. For example, exposure to the yield-curve is typically managed at the portfolio level by determining first the overall duration over/underweight vs. the benchmark and then determining where on the yield-curve to take the extra exposure. The strategy may be designed to take advantage of flattening or steepening in the yield-curve, and only measurement of these effects at the portfolio or sub-portfolio level is meaningful.

Outperformance from allocated factors is explained using the following allocation methods: absolute allocation and relative allocation. We discuss each below.

Unlike common factors, allocated factors may have different realizations for different securities or sectors even if they broadly capture the same type of risk exposure. For example, credit-spread, whose level depends on the particular securities within a sector, is a factor of this type. In the absolute allocation framework, the total portfolio exposure to each factor is determined by all sector managers. Each sector manager may take a different view as to the expected direction of each factor. In this case, asset allocation is solely determined by the net sector exposure to a particular factor:

$$\text{Asset Allocation} \quad \sum_s \left(\alpha_{k,s}^P - \alpha_{k,s}^B\right) \cdot f_{k,s}^B \tag{70-14}$$

$$\text{Sector Management} \quad \sum_s \alpha_{k,s}^P \cdot \left(f_{k,s}^P - f_{k,s}^B\right) \tag{70-15}$$

In the relative allocation framework, the total exposure to each factor is determined at the portfolio level (or the higher hierarchical level). The asset allocator subsequently determines the sector exposures to the factor subject to the constraint imposed by the portfolio exposure. Each sector may take a different view as to the relative movement of each factor against the overall benchmark factor return.

$$\text{Asset Allocation} \quad \alpha_k^P \cdot \sum_s \left(\frac{\alpha_{k,s}^P}{\alpha_k^P} - \frac{\alpha_{k,s}^B}{\alpha_k^B}\right) \cdot \left(f_{k,s}^B - f_k^H\right) \tag{70-16}$$

$$\text{Sector Management} \quad \sum_s \alpha_{k,s}^P \cdot \left(f_{k,s}^P - f_{k,s}^B\right) \tag{70-17}$$

$$\text{Top-Level Exposure} \quad \left(\alpha_k^P - \alpha_k^B\right) \cdot f_k^H \tag{70-18}$$

Notice that in the relative allocation framework, the factor hurdle rate f_k^H essentially becomes a common factor.

Step 3: Recursive Application

The sector management terms from top-down allocations, $f_{k,s}^P - f_{k,s}^B$, can be now decomposed separately using the above algorithm recursively.

At the last stage of the decomposition, in which a sector is not decomposed further into subsectors, the sector management term becomes security selection. The top-down decomposition can be applied one last time to break down the security selection outperformance of a sector into the contributions of individual securities. In this case the management term is typically zero, since the factor driving the return of the same security in the portfolio and the benchmark is the same.

An Example of Hybrid Performance Attribution

To illustrate how this algorithm can be applied in practice, consider a very simple model in which the return of a security is split into two components: the time return that is measured by the yield of the security and a market return that is measured as the duration of the security times the negative of its yield change. This decomposition may not be complete, so it is reasonable to assume the presence of a residual.

$$R_i = Y_i \, \Delta t - D_i \, \Delta Y_i + \varepsilon_i \tag{70-19}$$

The portfolio (or benchmark) return is the weighted average return of the securities in the portfolio (or benchmark). The summation extends over a universe defined by the union of securities in the portfolio and benchmark. Securities not present in either get correspondingly zero weight.

$$\begin{aligned} R^P &= \sum_i w_i^P R_i = \sum_i w_i^P Y_i \, \Delta t - w_i^P D_i \, \Delta Y_i + w_i^P \varepsilon_i \\ R^B &= \sum_i w_i^B R_i = \sum_i w_i^B Y_i \, \Delta t - w_i^B D_i \, \Delta Y_i + w_i^B \varepsilon_i \end{aligned} \tag{70-20}$$

Aggregation of yield and duration is the usual weighted average; however, yield changes must be aggregated using duration contribution weights to retain their natural interpretation.

$$\begin{aligned} Y^P &= \sum_i w_i^P Y_i \qquad Y^B = \sum_i w_i^B Y_i \\ D^P &= \sum_i w_i^P D_i \qquad D^B = \sum_i w_i^B D_i \end{aligned} \tag{70-21}$$

$$\Delta \mathrm{Y}^P = \sum_i \frac{w_i^P D_i}{D^P} \Delta \mathrm{Y}_i \qquad \Delta \mathrm{Y}^B = \sum_i \frac{w_i^B D_i}{D^B} \Delta \mathrm{Y}_i \tag{70-22}$$

We can now rewrite the portfolio and benchmark returns using top-level analytics:

$$R^P = Y^P \Delta t - D^P \Delta Y^P + \sum_i w_i^P \varepsilon_i$$
$$R^B = Y^B \Delta t - D^B \Delta Y^B + \sum_i w_i^B \varepsilon_i \tag{70-23}$$

Let us assume that time return (carry) and residual are allocated as common factors.

$$\text{Carry} \qquad (Y^P - Y^B) \cdot \Delta t \tag{70-24}$$

$$\text{Residual} \qquad \sum_i \left(w_i^P - w_i^B\right) \cdot \varepsilon_i \tag{70-25}$$

Market return is managed by allocating duration exposure $w_s^P D_s^P$ to a set of sectors and allowing managers to pick securities within each sector.

If the top-level portfolio duration is not constrained and is completely determined by the choices of the sectors' net duration exposures, we should use the absolute allocation algorithm by setting $\alpha_k \leftarrow D$, $\alpha_{k,s} \leftarrow w_s D_s$, $f_{k,s} \leftarrow -\Delta Y_s$. The duration and yield change of each sector in the portfolio and the benchmark are calculated in the same weighted average fashion we discussed above. Since the asset allocation agent is free to determine the duration exposure of each sector, there is no hurdle rate and the total outperformance is solely distributed between asset allocation and security selection.

$$\text{Asset Allocation} \qquad -\sum_s \left(w_s^P D_s^P - w_s^B D_s^B\right) \cdot \Delta Y_s^B \tag{70-26}$$

$$\text{Security Selection} \qquad -\sum_s w_s^P D_s^P \cdot \left(\Delta Y_s^P - \Delta Y_s^B\right) \tag{70-27}$$

On the other hand, if the net duration of the portfolio is actively managed, we need to use the relative allocation method. In this case, we set the hurdle rate equal to the benchmark yield change.

$$\text{Asset Allocation} \qquad -D^P \cdot \sum_s \left(\frac{w_s^P D_s^P}{D^P} - \frac{w_s^B D_s^B}{D^B}\right) \cdot \left(\Delta Y_s^B - \Delta Y^B\right) \tag{70-28}$$

$$\text{Security Selection} \qquad -\sum_s w_s^P D_s^P \cdot \left(\Delta Y_s^P - \Delta Y_s^B\right) \tag{70-29}$$

$$\text{Top-Level Exposure} \qquad -(D^P - D^B) \cdot \Delta Y^B \tag{70-30}$$

APPLICATIONS OF PERFORMANCE ATTRIBUTION

Beyond its stated goal of attributing portfolio outperformance to the actions of agents, detailed and flexible performance attribution can bring clarity to the process of portfolio management by systematically exposing sources of risk and performance. By linking ex-post outperformance contributions to ex-ante views and management decisions, a manager can identify unanticipated sources of risk and return and adjust the management process accordingly. In addition, by providing the recursive decomposition of outperformance into the various contributing factors, it facilitates the discovery and correction of data errors that are not uncommon in large financial accounting systems. In the rest of this chapter we will illustrate such applications of performance attribution in the context of a particular portfolio.

Performance Attribution as a Portfolio Management Tool

Consider the following example. A portfolio manager has the mandate to track the Barclays Capital Global Aggregate G4 Index and has the latitude to implement certain market views in order to enhance the portfolio returns, as long as the standard deviation of portfolio minus benchmark returns (Tracking Error Volatility or TEV) stays below 40 bp per month. At a specific point in time, the manager is bullish on the Japanese yen, negative on the euro and neutral on the U.S. dollar and the British pound. She believes that global rates are falling. She has no sector views except in the U.S. markets, where she likes corporates but dislikes the securitized sector. According to her mandate and her views, she constructs a portfolio with the following characteristics:

- The portfolio has a 5% overweight (vs. the benchmark) in the yen, has a 5% underweight in the euro, and is flat in U.S. dollars and British pounds.
- The portfolio interest-rate option-adjusted duration (OAD) is about one year longer than that of the benchmark.
- Within the U.S. market, the portfolio has a 5% overweight in corporates, has a 5% underweight in securitized, and is flat in the U.S. Treasury and government-related sectors.

We created this portfolio in the POINT system then offered by Barclays and used the Global Risk Model in POINT to estimate the portfolio tracking error volatility relative to its benchmark as 32 bp per month. Since this is below the 40 bp per month risk budget the portfolio is acceptable.

We subsequently ran the POINT hybrid performance attribution model over one month and produced a detailed performance attribution report. This report begins by reporting the total portfolio and benchmark returns over the month (+188.7 bp and +150.0 bp, respectively) as well as their difference, +38.7 bp, the total portfolio outperformance (Exhibit 70-1). The report then proceeds to decompose the total outperformance into the contributions of the various portfolio exposures and market performance. The decomposition is hierarchical to allow the portfolio manager to first get a broad understanding of the sources of outperformance and then dive into the specific details. In Exhibit 70-2, we see a first decomposition of the portfolio total outperformance on a global level into three components: FX Allocation and Hedging (+28.3 bp), Local Market Allocation (–8.7 bp), and Local Market Management (+19.1 bp). In Exhibit 70-3, the Local Market Management component is further decomposed into contributions from Yield-Curve exposures (+20.6 bp), Asset Allocation (+0.2 bp), and Security Selection (–1.7 bp).

Outperformance from Currency Exposures

The +28.3 bp outperformance from FX allocation and hedges indicates that the manager's FX views were broadly correct. In Exhibit 70-4 we can see that, consistent to the manager's predictions, the yen rallied and the euro fell versus the U.S. dollar. The analysis also shows that the portfolio maintained a net exposure of +5% in the yen and –5% in the euro with little drift. In particular, the yen outperformed the U.S. dollar by 319.4 bp in the period, a figure that includes the change in the FX spot rate and the short-term interest rate differentials between the two currencies.[7] Since the yen is overweighted by 5% on average, a quick calculation estimates the outperformance contribution as 5% × 319.4 = +16.0 bp. This calculation is not exact, since the attribution model used in this example employs daily frequency and compounding as we have discussed previously. Such simple calculations are acceptable when the net exposure does not fluctuate significantly over the attribution period and will be used throughout this example. In this case the reported yen contribution of +16.1 bp in Exhibit 70-4 is within 1 bp of the result of simple calculation.

Similar analysis can be carried out for the underweight to weakening euro, which contributes outperformance of +12.0 bp. The fact that the British pound also weakened generates no outperformance because the portfolio net exposure to the British pound was designed to be zero. Finally, the completeness of FX outperformance decomposition is ensured by accounting for the interaction effect between FX and local returns. The cross-term is normally small. In this case, it is only +0.2 bp.

Outperformance from Allocation to Local Markets

Allocation to local markets evaluates a portfolio manager's decision to under-/overweight a local bond market. In this example its contribution is –8.7 bp. Exhibit 70-5 shows the major contributors to be the yen and euro markets. By attempting to overweight the yen and underweight the euro using cash instruments (i.e., without using FX forwards), the portfolio also took on an overweight in the yen local market and an underweight in the local euro-zone market. The yen market overweight is not a good decision since its local return over the deposit rate is only +64.2 bp, much lower than the benchmark local return over deposit of +164.1 bp. Therefore, it generates an underperformance that can be approximately calculated as (64.2 – 164.1) × 5% = –5.0 bp, as reported in the second to last column. The euro market underweight is not good either, since the local market had a return of +239.2 bp, significantly higher than the benchmark return of +164.1 bp. It results in an underperformance estimated as (239.2 – 164.1) × –5% = –3.8 bp. The actual contribution is –3.7 bp, as reported in the second to last column and together with the –5.0 bp of the yen market contribution fully explain the Local Markets Allocation outperformance component.

Separation of the FX and Local components of global markets allows the measurement of outperformance under several styles of management. In some portfolio management structures, the FX exposure of the portfolio is managed separately from the local market exposure of the portfolio using derivative instruments such as FX forwards. However, in our example, the exposures to the local markets might be thought as incidental to the manager's FX views and a result of

not properly differentiating the views on FX versus the views on the local market performance. In this case, it might make sense to combine the two contributions and allocate 28.3 – 8.7 = +19.6 bp of outperformance to the views on the currency markets.

Outperformance from Management of Local Markets

Once the allocation into each local market is determined, local market management measures how well the portfolio performed versus its benchmark within the same local market. From Exhibit 70-3, we already know that the dominant contributor is yield-curve exposures with +20.6 bp. Exhibit 70-6 offers more details by each local market.

We can see that positive yield-curve outperformance came primarily from the U.S. dollar and the euro markets, whereas the British pound curve exposure resulted in a loss of –11.5 bp. We also see that asset allocation was not a significant driver of performance. Security selection decisions within each local market were significant, although the net result across all currencies was small at –1.7 bp. In particular, the selections within the U.S. dollar and British pound portion of the portfolio contributed positively, +5.9 bp and +6.2 bp, respectively, but the selections within the euro portion of the portfolio negated these gains by contributing –13.3 bp.

Outperformance Due to Yield-Curve Exposure

Focusing on the large yield-curve outperformance contribution, the manager wants to understand how her directive to go long duration by one year globally was implemented, and analyze the impact on each individual market. Exhibit 70-7 shows the yield-curve outperformance breakdown for the U.S. dollar portion of the portfolio.

Source: POINT

Individual market reports are unscaled by the value of the holdings in each market in order to evaluate single-market managers on an equal basis. Looking at each market in absolute terms allows us to reveal useful information about the management within each market, even for markets that constitute a small portion of the overall portfolio and their contributions to total portfolio outperformance are not significant. To translate the absolute unscaled numbers contained in the local reports into their contributions to total portfolio outperformance, one has to multiply such numbers by the corresponding market weight in the portfolio. In this example, the currency weights can be found in the Global Outperformance by Currency report in Exhibit 70-6; they are 45.5% for the U.S. dollar, 23.2% for the euro, 25.6% for the yen, and 5.8% for the British pound market.

The yield-curve report in Exhibit 70-7 contains a lot of information, but the manager can quickly see that the U.S. Treasury curve experienced bull-flattening with long rates falling in excess of 40 bp (third column from the left). She can also see that the portfolio is generally long duration by about 0.5 years (4.66 vs. 4.18). This is consistent with the general desire to be long duration, and with rates generally falling, it creates outperformance. More precisely, the yield change at the average maturity point of the benchmark is –31.6 bp. Multiplied by the (negative of) the average duration overweight of 0.48 years results in approximately +15.2 bp of outperformance contribution. The daily algorithm calculates that this number is actually +14.6 bp (top of the second to last column) by taking into account that duration exposure fluctuated during the period. The total U.S. dollar curve outperformance, accounting for the re-shaping of the yield-curve and the contributions from carry, is calculated to be +24.6 bp. Most of the additional outperformance comes from a butterfly position on the curve, where an overweight of the 20 year point of about 1.36 years is partially offset with underweighting the 5-, 10-, and 30-year points. Since the 20-year point is the one with the largest yield drop (–48.7 bp), this butterfly position results in additional outperformance. The algorithm calculates and reports the excess contribution of each curve point separately.

The manager should be concerned that such a large component of total outperformance comes from an inadvertent position in the re-shaping of the U.S. curve (about +4.7 bp, estimated as the non-parallel U.S. curve outperformance 24.6 – 14.3 = +10.3 bp, times the U.S. dollar market weight of 45.5%) and should seek to control exposure to the various parts of yield curves more carefully.

Exhibit 70-8 displays the yield-curve reports for the other three currencies. The euro curve outperformance analysis is very similar to the U.S. dollar one. There is duration overweight of about 1 year, as well as a butterfly position. Like the U.S. dollar curve, the euro curve also bull-flattens, resulting in (unscaled) outperformance of +77.4 bp and a contribution to total outperformance of +17.9 bp (remember that the average portfolio weight of the euro market is 23.2%). The yen has an even bigger duration overweight, about 2.7 years, but the curve movement is not as dramatic, with average yields falling about 7 bp. The portfolio contains significant curve reshaping positions as well, with the 20-year

Source: POINT

point being overweighted by more than 3 years, while the 20-year point is underweighted by about 1.7 years. Nevertheless, the yen curve change is not sufficiently pronounced and generates only +11.8 bp of (unscaled) outperformance, contributing +3.0 bp to the total outperformance (the average portfolio weight of the yen market is 25.6%). The picture is completely different for the British pound. Here, the portfolio has a significant duration underweight of about 3.8 years, combined with a strong bull-flattening move of the British pound yield-curve (a yield change of –44.9 bp at the long end). This underweight results in a dramatic (unscaled) underperformance of –199.2 bp. The small average portfolio weight of the British pound market (5.8%) prevents this from being a major drag in the portfolio performance but even so its contribution to total outperformance is a significant –11.5 bp.

At this point, it should be clear to the portfolio manager that understanding and managing the detailed exposure to the yield-curve of each currency is of paramount importance for proper control of the portfolio performance. She may also decide that global curve management is so important that it has to be managed before any local allocation and management decisions are made. In this case, a different attribution algorithm must be used, one that excludes yield-curve outperformance from the Local Market Allocation and Local Management Components. A detailed discussion on this type of analysis can be found in Chapter 72.

Asset Allocation and Security Selection

The manager now shifts her attention to the remaining sources of outperformance. First, she wants to understand how her views on the performance of U.S. assets panned out. From the "Global Outperformance by Currency" report of Exhibit 70-6, she already knows that U.S. dollar asset allocation contributed –2.5 bp to total outperformance. Exhibit 70-9 displays the U.S. Dollar Asset Allocation report, where we can see that most of the underperformance is caused by the overweight to corporate bonds. Remember that all numbers in this page are un-weighted; that is, they have to be scaled by the 45.5% portfolio weight of the U.S. market allocation in order to convert them into contributions to total portfolio outperformance. In particular, the 5% overweight sought to U.S. corporate bonds during the portfolio construction is represented here as an overweight of 10.9% (30.9% – 19.8% = 11.1%, approximately equal to 5%/45.5%), and the –2.5 bp of underperformance is reported as –5.5 bp (approximately equal to –2.5 bp/45.5%). The corporate sector contributes –5.2 bp, something that can be explained by the significant underperformance of the corporate sector in the benchmark (–70.2 bp) relative to the benchmark itself (–22.0 bp). The approximate calculation results in 11.1% × (–70.2 + 22.0) = –5.35 bp, close to the –5.2 bp reported. The Treasury and government-related sectors have no contribution to asset allocation, as their weights are matched exactly between the portfolio and the benchmark, as designed. Finally, the securitized sector has minimal contribution to asset allocation, despite the significant underweight, because its performance (–19.0 bp) is close to that of the benchmark (–22.0 bp).

EXHIBIT 70-9

Source: POINT

The same report also lists the contribution of each sector to security selection. We see that once again, the corporate sector is the dominant contributor with +11.1 bp out of the total +13.0 bp of security selection in the U.S. dollar market. To further understand the sources of security selection outperformance, the manager studies the detailed U.S. Dollar Security Selection report displayed in Exhibit 70-10. This report lists the chosen securities in each sector and their excess-of-curve return. We can see that the manager responsible for security picks in the U.S. corporate sector has indeed picked mostly securities whose excess returns beat the benchmark. One notable exception is the 6.45% 2037 Comcast bond, which represents 10.1% of the portfolio holdings in this sector (an overweight of 10% versus the benchmark) and which experienced –280.0 bp of excess return (much worse than the benchmark, which lost only 70.2 bp).

To estimate the contribution of the bond to the security selection outperformance coming from U.S. corporate bonds, one must take into account the weight of the corporate sector in the U.S. portfolio, which is 30.7%, to get 30.7% × 10% × (–280.0 + 70.2) = –6.4 bp. After scaling by the 45.5% weight of the U.S. portfolio, we calculate the contribution of the particular Comcast bond to global outperformance as 45.5% × –6.4 bp = –2.9 bp. This is quite significant and highlights the importance of name selection in a portfolio with a relatively small number of positions.

The manager also takes a look at the details of security selection in the euro market, which, as reported in Exhibit 70-6, reduces the total outperformance by a significant 13.3 bp. The report in Exhibit 70-11 lists the security selection outperformance as –57.4 bp (which scaled by the market weight of the euro market of 23.2% is equal to –13.3 bp) and identifies Italian government bonds as the main culprits. The fact that, absent any specific direction otherwise, the euro government sector was constructed by mostly Italian government bonds, leading to significant underperformance because of sovereign credit deterioration in Italy, indicates that the manager should attempt to take control of country exposure within the euro sector.

By now, the manager has a good understanding of most major contributors to the outperformance of the portfolio and has also reached some useful conclusions regarding the management of a small global portfolio.

- Yield-curve exposure is the dominant risk factor and must be managed explicitly in each currency.
- It is not sufficient to manage yield-curve exposure using just the duration. Exposure to curve re-shaping must also be controlled carefully.
- It may make sense to manage yield-curve exposure globally and not allow it to be determined by local allocation and management decisions.
- Name risk is very significant in a small portfolio; exposure to corporate issuers must be scrutinized and questionable names should be excluded.
- Country risk in certain areas such as the euro-zone must be managed separately.

Further insight can be gained by using a mode of performance attribution in which returns and outperformance are fully decomposed using all available analytics from pricing models. In this model, any part of outperformance that cannot be explained by analytics is reported as residual. This Fully Analytical model will be explained in detail in Chapter 71. Using this model, we get the local management details shown in Exhibit 70-12.

Comparing it with the report of Exhibit 70-3 we see that Local Market Management Details panel has changed. While the yield-curve contribution remains at +20.6 bp, asset allocation is now –0.9 bp instead of +0.2 bp, and security selection is now –2.2 bp instead of –1.7 bp. New terms have appeared, in particular Implied Volatility with +0.9 bp contribution, Mortgage with –3.7 bp contribution, and Residual with a prominent +4.4 bp. The Fully Analytical model also offers more clarity into sources of outperformance beyond the yield-curve, allowing users to understand the sources of the various types of outperformance; it will be discussed in detail in Chapter 71. In this example we will review only the Euro Security Selection report shown in Exhibit 70-13. We can see that not only is the portfolio concentrated on Italian government bonds, but that it also contains bonds of very long maturity, further overweighting the entire European government sector in terms of spread duration exposure. This may lead the manager to draw yet another conclusion: The spread duration exposure of sectors with credit risk must be carefully controlled.

Performance Attribution as a Data Quality Tool

A comprehensive and detailed performance attribution system serves as a magnifying lens for data quality problems and allows users to pinpoint and correct such issues quickly.

Source: POINT

The report of Exhibit 70-13 shows that one particular Italian government bond (Issue IT0004513641) is almost single-handedly responsible for the entire reported residual. Indeed, it contributes +17.4 bp of residual to the euro portfolio, which, when scaled by the euro portfolio market weight of 23.2%, results in +4.0 bp of portfolio-level residual (out of the total of +4.4 bp reported in Exhibit 70-12). A diligent manager will promptly investigate such residuals. They may mean one of the following four things:

- Incorrect total returns. This can be caused by missing or incorrect prices, transaction errors, incorrect corporate actions, etc.
- Missing or inaccurate analytics produced in the security valuation process
- Attribution model deficiencies wherein certain contributing factors are not captured by the factor return decomposition
- Issues with the attribution algorithm or its implementation

All four are extremely important for the portfolio manager to know. Over time, model deficiencies will presumably be corrected, leaving data quality problems in the form of bad returns or bad analytics to be the primary cause of attribution residuals.

In the case of this portfolio, a quick investigation reveals that the offending bond had a coupon payment of 2.50% that has been recorded twice. The price of the bond on the coupon payment date was approximately 110; therefore, one would expect a residual of +227.3 bp at the bond level. Indeed, after taking into account the net weight of the bond, the residual contribution of the bond to the euro portfolio is 44.0% × (18.3% – 0.5%) × 227.3 = +17.8 bp, very close to the +17.4 bp of reported residual. Re-running the report after correcting the double entry produces a mostly identical report (Exhibit 70-14) to the one before (Exhibit 70-12), except that the return of the portfolio is lower by the correction amount (+4.2 bp), the outperformance is +34.5 bp instead of +38.7 bp, and the residual term has been reduced correspondingly from +4.4 bp to +0.2 bp.

Data problems have the potential to affect the quality of outperformance measurement of a portfolio significantly, as well as its breakdown to the various sources. Proper use of an analytics-based attribution platform can help identify and correct potential issues promptly.

KEY POINTS

- Performance measurement and attribution is an important function of the investment process. It helps bring clarity to the sources of portfolio risk and performance and identify the contributions of individual decision-makers.
- A successful performance attribution algorithm should satisfy three important requirements: additivity, completeness, and fairness.

- A good attribution system should have a calculation and compounding frequency that corresponds to the dynamics of modern portfolio management. This normally means daily frequency for an actively managed fixed income portfolio.
- A good attribution system should have the flexibility to accommodate the wide range of portfolio management styles. The best attribution is an analysis that best matches the portfolio management decision-making process.

- Performance attribution algorithms typically follow either a sector-based allocation or a factor-based allocation, but neither is sufficient to cope with the complexity of modern portfolio management.
- Algorithms that combine the sector-based and the factor-based attribution have the flexibility to adapt to the particular management structure of most fixed income and equity portfolios.

CHAPTER

SEVENTY-ONE

PERFORMANCE ATTRIBUTION FOR PORTFOLIOS OF FIXED INCOME SECURITIES

Barclays

In contrast to the simple and opaque nature of equities, fixed income securities can be thought of as structured investments that promise to pay a stream of cash flows. The magnitude of cash flows can be fixed, or may depend on observable variables (e.g., realized inflation, principal prepayments of mortgage loans, or the price of the security itself for securities with call/put features). This quasi-formulaic nature of fixed income securities allows their present value to be expressed as a (generally stochastic) function of economic variables—most prominently interest rates and credit spreads—which can be calibrated to observed market prices of reference securities to generate a "pricing model." In other words, a pricing model is a function that expresses the present value of a fixed income security (or derivative contract) as a function of economic variables. This function can be also used to estimate the sensitivities of the present value to changes in the underlying variables. Such sensitivities, generically called *analytics* and known as *greeks* in the options world or *duration/convexity* in the bond world, can and are being used as loadings to the pricing factors driving returns during performance decomposition and attribution of fixed income portfolios.

In this chapter we discuss in detail how the performance of a portfolio of fixed income securities relative to a benchmark can be analyzed using the hybrid performance attribution algorithm described in Chapter 70. The hybrid methodology that combines factor-based attribution with the traditional Brinson method is particularly appropriate for fixed income securities whose return usually includes a significant component driven by a common factor, interest rates. In this chapter, we will focus on attribution over a single period only. As discussed in Chapter 70, a single period is one business day for the majority of fixed income systems. Methods for compounding single period attribution results over longer periods of time will be discussed in detail in Chapter 72.

This chapter was coauthored by Anthony Lazanas, António Baldaque da Silva, Chris Sturhahn, Eric P. Wilson, and Pam Zhong when they were employees of Barclays.

We begin the discussion by using a generic pricing model in order to split the return of a fixed income security into the contributions of the various factors driving the security return. We discuss in detail the treatment of the most important factors such as interest rates, implied volatility, and credit spreads. Two important asset classes with special characteristics, mortgage-backed securities and inflation-linked bonds, are discussed separately. We then show how the flexible hybrid attribution framework can be applied in several ways to accommodate various types of fixed income portfolios and styles of portfolio management.

In this chapter we restrict the analysis to single-currency portfolios. The complications arising from investing in multiple currencies will be discussed in Chapter 72. All performance attribution reports have been generated using the Hybrid Performance Attribution (HPA) model[1] as implemented in POINT, the portfolio analytics and modeling platform then offered by Barclays.

RETURN SPLITTING

Securities with deterministic cash flows are priced by discounting the cash flows off a reference yield-curve. When future cash flows are not known but can be reasonably predicted by modeling them as functions of economic variables (most commonly interest rates) and security characteristics, more complex statistical diffusion models are used. Such models produce a set of projected interest rate paths that are consistent with the current yield-curve and the market implied volatility of liquid interest-rate options. Projected cash flows on each path are discounted at the corresponding discount factors, and the present value of the security is calculated as the average present value across all interest-rate paths. In this case, the present value of a security is a function of interest rates, their implied volatility and possibly other variables in the model.

A pricing model produces the "model value" of a security. In the case of securities such as derivatives that are traded over-the-counter, the model value is usually used to mark-to-market positions in the security. When a security is publicly traded, its market price generally does not agree with the model price. To make them equal, model parameters are calibrated to match the market price. For example, in the case of bonds, this usually entails additional discounting of cash flows at a flat rate across all maturities. In the majority of models, in which cash flows are discounted at a risk-free reference yield-curve (the government or swap yield-curve in a particular currency), this additional discounting rate is the well-known option-adjusted spread (OAS), which captures the extra discounting required to account for credit, liquidity, and other types of risks. Analytics produced by such a model are therefore known as option-adjusted analytics.

1. For details of the model, see Anthony Lazanas, Chris Sturhahn, and Pamela Zhong, *The Barclays Hybrid Performance Attribution (HPA) Model* (Barclays Publications, October 2010).

Generically, a pricing model can be expressed with the following formula:

$$MarketValue = f\,(Time,\ YC,\ Vol,\ Other,\ OAS)$$

Here, *YC* stands for yield-curve, *Vol* for implied volatility, and *Other* for any other market factors or parameters that the pricing model is using.

For a single-currency portfolio, the analysis begins with splitting the return of each portfolio position into the contributions of various factors. Most pricing systems provide the first-order sensitivity of the market value of a position to the underlying risk factors. Sometimes second-order sensitivities to particular factors (such as interest-rate convexity) are also reported. Using these sensitivities, the return of a particular position is approximated as a linear combination of the contributions of each pricing factor, for example:

$$R \approx \frac{\partial f}{\partial Time}\Delta Time + \frac{\partial f}{\partial YC}\Delta YC + \frac{1}{2}\frac{\partial^2 f}{\partial YC^2}\Delta YC^2 + \frac{\partial f}{\partial Vol}\Delta Vol + \frac{\partial f}{\partial OAS}\Delta OAS$$

Although some pricing systems do provide additional sensitivities (e.g., spread convexity, or sensitivities to some of the "other" pricing factors such as prepayment speed for mortgage securities) most of the time the difference between the actual return of a position (as reported in the accounting system of the portfolio) and the above approximation is non-negligible. Such difference, usually referred to as *Residual*, is attributable to sensitivities to unaccounted model inputs and parameters, higher-order terms, cross-terms between factors, and very often in practice, data and calculation errors. Analyzing the residual and understanding whether it is legitimate or a result of data or calculation error is an important function of a performance attribution system. To help achieve that, sophisticated performance attribution systems use an alternative scenario-based decomposition of returns, which by design is complete, i.e., has no residual. The return splitting exercise in such systems has two stages:

Stage I: Scenario-based return decomposition into broad categories

Stage II: Analytics-based return decomposition into fine categories

In Stage I, the scenario decomposition of one-period return[2] begins with the market value of the position at the beginning of the period and then moves one parameter at a time to the end-of-period value until all of the parameters have changed and the end-of-period market value is obtained. At each step, the market value of the security is obtained by fully recalculating its market value by

2. As discussed in Chapter 69, attribution over longer periods of time requires compounding attribution results over smaller periods. The length of a single period should be consistent with the management style of the portfolio. Actively managed portfolios should use a short period, typically one day. Buy and hold portfolios should use longer periods such as one month or even one year. The algorithm we describe here can be applied for arbitrary period lengths. Nevertheless, bear in mind that using pricing analytics to manage exposure typically indicates an active management style which more often than not requires daily portfolio actions and therefore daily compounding of attribution results.

EXHIBIT 71-1

Typical Scenario-Based Return Decomposition

Surprise Return	The difference of actual cash flows and notional changes from model predictions
Time Return	The effect of elapsing time
Yield-Curve Change Return	The effect of changes in the yield-curve
Implied Volatility Change Return	The effect of changes in the implied volatility surface
Other Market Return	The effect of changes in any other market parameters
Spread Change Return	The effect of changes in the option-adjusted spread

changing one input parameter at a time. This stage divides the return into broad categories, as described in Exhibit 71-1.

Of course, this is not the only possible decomposition. Coarser or finer decompositions are also possible, but this particular one is a good compromise between computational complexity and informational content for most fixed income portfolios. In Stage II, the sensitivities of the security to various pricing model inputs (analytics) are used to decompose the return further. The combination of the two decompositions allows the residual to be split among the major return constituents providing more insight about its potential sources.

We will now discuss in more detail the various return constituents in the typical decomposition of Exhibit 71-1.

Surprise Return

Surprise return is relevant to securities whose cash flows and amount outstanding are not deterministic. For example, for mortgage-backed securities, it is prepayments that generate the random behavior of cash flows and amount outstanding; for inflation-linked securities, it is the dependence of cash flows on the reference inflation index. Security valuation models make assumptions about inputs to pricing models and use such projections to value securities until realized values are known. The return explained by running scenarios or using model analytics is the return that would be realized if the uncertain parameters were consistent with the model predictions. If the realized values of the parameters are different from the projected ones, the difference between the actual return and the return explained by the model is captured as surprise return.

Mortgage Prepayments Surprise Return

As an example, consider a mortgage-backed security that is trading at a price of 105 and zero accrued. The prepayment model projects a 2.4% prepayment over the next month (25% CPR), thus predicting a return due to prepayments of –11.4 bp.[3] If the actual prepayment is lower, say 1.3% (15% CPR) resulting in a prepayment return of –6.2 bp, the difference of +5.2 bp will be registered as prepayment surprise return. The model-expected –11.4 bp of prepayment return will be part of the time return component.

Inflation Surprise Return

As another example, consider an inflation-linked security that is trading at a price consistent with projected inflation for next month of 3.0%. If the actual inflation announcement is 3.5% it will give +4.2 bp[4] of inflation surprise return to account for the larger inflation accretion accumulated over the month relative to the projected inflation rate. This return is separate from any return resulting from presumably increased future inflation expectations caused by the higher-versus-expectations announcement. Such return is captured separately as inflation spread change as will be described below.

Time Return

Time return is the deterministic component of the return, i.e., the return predicted by the pricing model if market parameters remain unchanged.[5] For most fixed income securities, time return can be decomposed into yield-curve carry, spread carry, and volatility decay. Inflation-linked securities also have inflation accretion and inflation spread carry. These time return components can be measured using analytics, as we will describe in detail in the following sections.

Yield-Curve Change Return

Changes of interest rates affect securities returns primarily through the change of discount factors. In addition, some securities have cash flows that are modeled as functions of interest rates (mortgage-backed, floating-rate securities). The component of return that is due to the fluctuation of the yield-curve is captured by the yield-curve change return component. The exposure of the security value to the yield-curve is captured by its sensitivity to parallel shifts of the yield-curve, the option-adjusted duration (OAD), movements of a specified set of points (key-rate points) representing the yield-curve, the key-rate durations (KRDs), and its second-order sensitivity, option-adjusted convexity (OAC). In daily frequency

3. −11.4 bp = (par-105) * 2.4% / 105.
4. The exact calculation is (3.5%/12 – 3.0%/12) / (1 + 3%/12) = 4.16 bp
5. We discuss the definition of “unchanged” for the yield-curve later in this chapter.

attribution models the potential daily change of yields is limited (moves above 15 bp are very uncommon); therefore, the convexity contribution is typically much smaller than the duration contribution. For this reason, the effect of yield-curve convexity does not need to be explicitly measured.[6]

Yield-Curve Change Return Decomposition

How total yield-curve change return is broken down between duration and convexity depends to a large extent on the frequency at which the duration exposure of a portfolio is managed. In this example a daily frequency is assumed, consistent with the practice of the majority of portfolio managers. To understand the frequency implications, consider a portfolio with interest-rate duration of 5 and an interest-rate convexity of –2. Assume that over the two weeks, interest rates keep falling at 10 bp per business day for a total of 100 bp. The duration-convexity formula explains portfolio returns caused by changes in interest rates:

$$R^{\Delta YC} = -OAD \cdot \Delta r + \frac{1}{2} \cdot (OAC/100) \cdot \Delta r^2$$

where both the returns and the rates change are expressed in basis points.

Applying this formula for the entire two weeks results in the following:

Duration Return:	$-5 \times (-100) =$	+500 bp
Convexity Return:	$0.5 \times (-2/100) \times (-100)^2 =$	−100 bp
Total Return:		+400 bp

On the other hand, applying the formula daily generates quite a different breakdown. The daily algorithm must take into account additional complexities such as the duration drift of the portfolio, as well as compounding. It is not sufficient to simply calculate the daily duration and convexity return as $-5 \times (-10) = +50$ bp and $0.5 \times (-2/100) \times (-10)^2 = -1$ bp, respectively, and just aggregate over 10 days to get +500 bp duration return and –10 bp convexity return, for a total return of +490 bp. Instead, the daily duration drift of the portfolio due to falling interest rates must be estimated first. Using the definitions of duration and convexity, the duration change due to a change in interest rates can be estimated as:

$$\Delta OAD = (OAD^2 - 100 \cdot OAC) \cdot \Delta r/10{,}000$$

where duration and convexity have the usual units and change of rates is measured in basis points. Due to the high convexity of the portfolio, over the course of the 10 days the duration of the portfolio shrinks by about two years. In addition, both the total return of the portfolio and the contributions of duration and

6. For currencies with high volatility of yields, convexity can become a significant determinant even for daily returns. In such a case, it is straightforward to include convexity as an explanatory variable to the algorithm.

convexity must be compounded daily (see Chapter 72 for details). After both adjustments, the total return calculation and breakdown are as follows:

Duration Return:	+408 bp
Convexity Return:	–10 bp
Total Return:	+398 bp

The total return is very close to the one estimated by analytics at the beginning of the period, but the breakdown between duration and convexity is dramatically different. In the daily model, the convexity contribution is much smaller than the duration contribution.

Daily attribution models typically use only the key-rate durations to explain the contribution of yield-curve changes. Any yield-curve change return (as estimated by the scenario-based total yield-curve change return) in excess of what can be explained by the key rates captures the contribution of the yield-curve movements between the key-rate points, as well as the convexity and other second-order terms and can be reported separately.

Implied Volatility Change Return

Securities with optionality require reference implied volatilities to calibrate the interest rate diffusion pricing model. In the fixed income world, most models use the Black swaption implied volatility surface[7] as input and calculate the sensitivity of the security value to the changes in implied volatility with a single analytic, Vega, which is the price change of the security for a 1% parallel shift in the Black implied volatility surface. Vega does not capture the effects of non-parallel movements of the implied volatility surface or the effect of yield-curve moves on the diffusion parameters of the interest-rate diffusion model.[8] Clearly, it does not sufficiently represent the sensitivity of the security value to changes in implied volatility surface. Some advanced models are capable of generating partial Vegas, e.g., sensitivities to exposures at multiple points of the volatility surface, or, alternatively, to a vector of parameters that can be used to parametrically fit the volatility surface. In such cases a more detailed decomposition of implied volatility change return is possible.

7. Swaptions are options on interest-rate swaps that are being priced using an extension of the classic Black-Scholes model, see Fischer Black and Myron Scholes, "The Pricing of Options and Corporate Liabilities," *Journal of Political Economy* 83 (1973), pp. 637-654. The volatility input in the Black-Scholes model that is consistent with the market price of such swaptions is commonly referred to as *Black volatility*. Swaptions are specified with two parameters, the tenor of the option and the maturity of the underlying swap. Therefore, the set of swaptions traded in the market is represented with a two-dimensional matrix, hence the term *volatility surface*.

8. In the simple lognormal model, the stochastic component of the relative interest rate changes is proportional to a scalar, the log-normal (Black) volatility; therefore no dependence on interest rates exists. Other models that better capture the true behavior of interest rates make the stochastic term a function of black volatilities, as well as the level of interest rates or other model parameters.

If only parallel Vega is available, capturing the total effect of implied volatility changes through scenarios is imperative. The scenario-based implied volatility change return can then be decomposed into a parallel shift component that is equal to the product of Vega and the average volatility shift, and a remainder that contains the effects of nonparallel volatility movements as well as the effects of changes of other inputs and parameters used in the volatility model.

Other Market Return

Although yield-curve and implied volatility are the most important factors in the pricing models of most fixed income instruments, they do not capture every aspect of the cash flows, and more factors may be required. Securities or derivatives with cash flows that depend on external factors, such as prepayments or inflation levels, may use additional inputs to the pricing model. Changes in such inputs will generate return that is not attributable to yield-curve or implied volatility surface changes. The effects of the changes of all others factors are captured together as Other Market Return.

For example, the model-projected cash flows of mortgage-backed securities may depend on market mortgage rates, as well as additional model-specific parameters such as home price appreciation expectations or swap spreads. All of these parameters contribute to Other Market Return. The breakdown to the various factors follows an instrument specific algorithm and depends on the availability of specific analytics.

Spread Change Return

The effect of OAS changes to return is captured in the spread change return component. Sensitivity to spread movements is measured directly using both spread duration (OASD) and spread convexity (OASC). The large spread moves often observed in the market make it necessary to use spread convexity. The difference between the sum of spread return captured by OASD and OASC and the scenario-based spread return contributes to the residual return component.

Reporting the return split of individual securities and sectors in a portfolio and a benchmark is very useful for the portfolio manager as it provides a detailed understanding of the sources of exposures and returns in the portfolio. When reporting return splits, attribution systems may re-organize the various components of returns. In particular, the Barclays HPA model which we use for illustrations in this chapter, re-groups the return components along risk-factors as shown in Exhibit 71-2. Sample return splits for a few securities can be found in Exhibit 71-3.

OUTPERFORMANCE BREAKDOWN

Having split the returns in such detail based on analytical exposures to market factors, one might be tempted to proceed with bottom-up aggregation of outperformance per factor. However, neither does every portfolio manager use the factor approach to management, nor do all agree on which factors should represent portfolio risk. Many portfolios are managed by sectors or asset classes where top-down decomposition of outperformance is more appropriate, as the returns of the portfolio and the benchmark in each asset class or sector may differ. A flexible hybrid approach for performance attribution can be useful for both methods by allowing users to flexibly split total return into two parts: that driven by common factors for the entire portfolio and that in excess of common factors, which is further explained by asset allocation/security selection based on a user-defined hierarchical partition of the investment universe into sub-universes that we will refer to with the term "partition buckets."

Common components are explained by bottom-up aggregation as the difference of the exposure of the portfolio and the benchmark multiplied by the factor return. For example, yield-curve exposure is captured by duration, thus the outperformance explained by yield-curve movement would be the duration overweight of the portfolio (over the benchmark) multiplied by the negative of the yield-curve change. Excess of common or allocated components is explained by top-down decomposition using a user-defined hierarchical partition and the recursive algorithm discussed in Chapter 69, as will be detailed below.

This approach has the ability to accommodate different portfolio management styles. It also allows users to compare different ways of analyzing returns and outperformance and can lead to a better understanding of what drives portfolio outperformance. For example, many high-yield managers do not like to split total return into yield-curve, implied volatility, and spread components, citing the high negative correlation between yield-curve and implied volatility return versus spread return. Instead, they prefer to manage total return as a whole. And even when they do wish to separate out yield-curve return and manage the excess-to-yield-curve return, they usually do not rely on spread duration and spread convexity to measure their exposure. However, when spreads were very tight in 2005, many high-yield managers began experimenting with spread duration-based management.

While any return split component could be considered as a bottom-up common return component or as an excess return component that participates in the top-down allocation algorithm, the following three common configurations support most portfolio management decision-making structures: Total Return Model, Excess Return Model, and Fully Analytical Model.

The *Total Return Model* is the simplest model, where the total return is considered a single allocated factor. In other words, there is no common factor, and the total return is explained by top-down decomposition using market value weights and a user-defined security partition.

The *Excess Return Model* takes advantage of the return splitting algorithm to separate the factors contributing to return into common and allocated factors.

Returns from common factors are explained by bottom-up aggregation using appropriate analytic weights (e.g., OAD, Vega, market beta, and the like.). For fixed income portfolios yield-curve and/or implied volatility are typically considered as common factors. Returns from other factors (excess-over-common factor returns) are explained by top-down decomposition as in the Total Return Model.

The *Fully Analytical Model* is the most detailed model. It takes full advantage of the return splitting algorithm and the hybrid allocation algorithm, where each factor can be explained either by the top-down or the bottom-up aggregation using appropriate weights.

The following sections discuss these different types of models in more detail.

TOTAL RETURN MODEL

The Total Return model is the most basic performance attribution model and follows the classical, sector-based, asset allocation/security selection framework. It is appropriate for portfolios whose managers make decisions solely based on the total returns of the securities. A typical usage is a portfolio whose managers are allocating the capital based on their views of the sector and security returns, rather than risk factors. The model is generic in that the allocation buckets can be defined via a user-defined partition using any of the hundreds of security attributes available. Allocations such as geography, size, and momentum can be used, essentially mimicking factor-based allocation. The partition should be defined to mimic the management structure of the portfolio.

The Total Return model uses the relative allocation method of the top-down decomposition algorithm as explained in Chapter 70, where sector market value weight w_s is the allocation weight $\alpha_{k,s}$, total return of sector s is the only factor return $f_{k,s}$, and total return of the benchmark is the hurdle rate.

Asset Allocation $$w^P \cdot \sum_s \left(\frac{w_s^P}{w^P} - \frac{w_s^B}{w^B} \right) \cdot \left(TR_s^B - TR^B \right) \qquad (71\text{-}1)$$

Sector Management $$\sum_s w_s^P \cdot \left(TR_s^P - TR_s^B \right) \qquad (71\text{-}2)$$

Top-Level Exposure $$(w^P - w^B) \cdot TR^B \qquad (71\text{-}3)$$

Absent leverage, the top-level weights of the portfolio and the benchmark are both equal to one, so the top-level exposure term is always zero.

Let us now re-visit the attribution example of Chapter 69 to illustrate how results change according to the attribution model used. We remind the reader that in Chapter 69 we analyzed the outperformance of a multi-currency portfolio versus the Barclays Global Aggregate G4 Index over a period of one month. Here, we will focus only on the U.S. Dollar portion of the portfolio, which achieved a +32.1 bp outperformance[9] versus the U.S. Dollar portion of the index.

Using the Total Return model and assuming that the asset allocation universe consists of the major asset classes in the U.S. Dollar fixed income markets, the total portfolio outperformance is split into +18.9 bp of asset allocation and +13.2 bp of security selection as shown in Exhibit 71-4.

The contribution of each asset class to both asset allocation and security selection is calculated based on the total return of each asset class in the portfolio and the benchmark using Eqs. (71-1) and (71-2) and reported in Exhibit 71-5.

The corporate sector contributes +7.4 bp to the outperformance, since it has been overweighted by about 10.9% (portfolio average weight: 30.7%, benchmark average weight: 19.8%) and its performance in the benchmark (+196.1 bp) is much higher than the performance of the benchmark itself (+129.8 bp). The approximate[10] calculation yields 10.9% × (196.1 – 129.8) = +7.2 bp, close to the +7.4 bp reported. The contribution to security selection is also shown and captures the performance advantage of the portfolio versus the benchmark, weighted by the portfolio weight of each sector. For the corporate sector, this calculation yields 30.7% × (107.9 – 196.1) = –27.1 bp, close to the –27.3 bp reported.

The analysis above assumed that asset allocation occurs only at the major asset class level (Treasuries, Government-Related, Corporates, Securitized, and Cash). It is likely that within each major asset class a second level of allocation to asset class subsectors will occur. For example, within the Securitized sector further allocation to the Residential Mortgages (RMBS) sector, the Commercial

9. This number can be approximated from the reported numbers in Exhibit 70-6 of Chapter 70 as the ratio of the outperformance contribution of the U.S. Dollar portfolio (+14.6 bp) divided by the U.S. Dollar portfolio weight (45.5%). The calculation is not exact because the weight of the dollar portfolio fluctuates over the monthly attribution period.

10. The calculation is approximate because the algorithm used by the Barclays HPA model that generated this report employs daily compounding. This calculation would be exact for single-day results.

Mortgages (CMBS) sector, the Asset-Backed (ABS) sector, and Covered Bonds may be desirable. As discussed in the previous chapter, a flexible attribution algorithm should support multiple decision levels. In our example, we introduce a second level of asset allocation by using asset class subsectors as defined by the Barclays Global Aggregate Index classification scheme. In this case the Total Return model applied recursively reports a dramatically different breakdown between asset allocation and security selection as reported in Exhibit 71-6. Asset allocation shrinks from +18.9 bp to +2.9 bp, while security selection grows from +13.2 bp to +29.2 bp.

Intuitively, the finer the partition used for asset allocation the more emphasis is put on asset allocation decisions versus security selection decisions. In the limit, if the buckets of the asset allocation partition are individual securities, then the entire outperformance is reported as asset allocation. Conversely, if the asset allocation partition contains only one bucket, the entire outperformance is reported as security selection. Notice though that the transition between the two limits is not monotonic since individual partition buckets may contribute positively or negatively to both asset allocation and security selection. Such flexibility to define the asset allocation levels used in the breakdown of total outperformance is an important characteristic of an attribution system as it can support multiple styles of portfolio management. It is important that the partition used for performance attribution corresponds to the decision structure used for the management of a particular portfolio.

To understand the differences between single-level and two-level asset allocation, examine the two-level asset allocation details shown in Exhibit 71-7. In the Level 1 report, there are two columns for asset allocation, a top-level one (labeled simply Asset Allocation) which is identical to the asset allocation from the simple partition (+18.9 bp) and a Further Allocation column that captures subsequent allocation decisions (–16.0 bp). Their sum is +2.9 bp, the asset allocation reported in the summary report. Level 2 reports illustrate the details of the asset allocation into subsectors within each of the major asset classes. Asset classes for which no subsectors are defined (such as Treasuries and Cash) do not get Level 2 reports and do not contribute to Further Allocation.

Source: POINT

Let us focus again on the corporate sector, which shows –8.6 bp of underperformance contribution from Further Allocation. Its Level 2 decomposition table explains why: the portfolio had a large overweight to financial institutions, an underweight to industrials, and no allocation to utilities. While both industrials and utilities outperformed the corporate benchmark, financials had a lower performance of +157.0 bp than the +196.1 bp of the aggregate corporate sector. Therefore, all three sectors have negative contribution to outperformance, with the largest (–5.1 bp) coming from financial institutions. Once again, this can be approximated with the recursive application of Eq. (71-1) as follows: 30.7% × (80.4% – 38.5%) × (157.0 – 196.1) = –5.0 bp close to the –5.1 bp reported. The security selection numbers represent security selection within each sub-sector.

EXCESS RETURN MODEL

The Excess Return model uses the return splitting algorithm to extract common factor returns from the total return and considers the remainder as excess return. In the fixed income world, portfolio managers like to manage their exposures to common factors such as the movement of the yield-curve and implied volatility surface separately from their other investment decision choices. For example, consider a manager who chooses to hedge the overall exposure to the yield-curve and makes investment decisions purely based on expectations of excess-to-curve returns. In this case, she would like to see the total outperformance breakdown into yield-curve and excess return so that she can assess the effectiveness of the hedge, as well as the asset allocation/security selection choices separately.

The outperformance due to exposure to common factors, which we will discuss in detail below, is explained by bottom-up aggregation. The excess return outperformance is explained by top-down decomposition using the relative allocation model of the the previous chapter, with sector excess returns and sector market value weights as in the Total Return model.

Asset Allocation $$w^P \cdot \sum_s \left(\frac{w_s^P}{w^P} - \frac{w_s^B}{w^B} \right) \cdot \left(ER_s^B - ER^B \right) \tag{71-4}$$

Sector Management $$\sum_s w_s^P \cdot \left(ER_s^P - ER_s^B \right) \tag{71-5}$$

Top-Level Exposure $$(w^P - w^B) \cdot ER^B \tag{71-6}$$

Once again, if neither the portfolio nor the benchmark is leveraged, the top-level weights are equal to one and the top-level exposure term is equal to zero.

Exhibit 71-8 shows the outperformance breakdown when using the Excess Return model and the two-level asset allocation in the previous example. The left-hand side table shows the results when only interest rates are treated as common return factors. Most of the outperformance (+24.6 bp) comes from the yield-curve exposure. Asset allocation is responsible for –2.2 bp and security selection for

EXHIBIT 71-8

+9.7 bp. The right-hand side table shows the results when, in addition to interest rates, implied volatility is also treated as a common factor. The Implied Volatility term contributes +1.9 bp to outperformance, altering the asset allocation contribution to –4.0 bp and the security selection contribution to +9.6 bp.

Outperformance Due to Yield-Curve Exposure

As discussed at the beginning of this chapter, the pricing framework for most fixed income securities essentially amounts to projecting future cash flows and discounting them at projected paths of interest rates. Government, swap, or municipal AAA interest rate yield-curves can be used as the reference yield-curve, depending on the type of the security.

The yield-curve contribution to outperformance includes yield-curve change, the effect of interest rate changes, and yield-curve carry, the effect of the change of yield-curve discount factors or interest rate-related projected cash flows with the passage of time assuming that rates stay unchanged. There exist two different philosophies with respect to the definition of what constitutes a change in interest rates, and they result in different breakdowns between yield-curve carry and yield-curve change; however, the total yield-curve effect (their sum) is identical under both methodologies.

Methodology I: Rolling on Forwards

A yield-curve is deemed unchanged if the rates realize the values implied by the forward rates in the previous period. For example, if we look at an unchanged yield-curve one month into the future, the one-year rate is equal to the one-month forward one-year rate calculated from today's yield-curve. In this methodology, a yield-curve change is calculated with respect to the projected forward rates, and carry always accrues at the short rate.

This method is not very popular (particularly among cash investors) because it introduces significant complexity in the estimation of yield-curve change return—the most important component of fixed income returns. In addition, forward rates are not particularly good predictors of the realized path of interest rates, further reducing the appeal of this method.

Methodology II: Parallel Translation

A yield-curve is deemed unchanged if the level and shape of the yield-curve remains unchanged. For example, if we look at an unchanged yield-curve one month into the future, the one-year rate is equal to the one-year rate in today's yield-curve. In this methodology, a yield-curve change is calculated with respect to today's yield-curve, and carry accrues at a different rate for each cash flow.

Further, the representation of the yield-curve (e.g., par rates, zero rates, forward rates) is important and affects the breakdown of total yield-curve return between carry and change. If instantaneous forward rates are used to represent the yield-curve, then each cash flow accrues carry at a rate equal to the forward rate corresponding to the cash-flow date. Securities with deterministic cash flows accrue carry at a rate equal to the average of the forward rates corresponding to the date of each cash flow, weighted by the present value of each cash flow. Unfortunately, the forward rate representation is not very popular since forward rates are not directly observable in the market. Investors prefer the better understood zero or par rates to represent a yield-curve. Under both representations, the calculation of the curve carry of a set of cash flows is complicated. From the discussion above it is evident that the breakdown of yield-curve return and outperformance into curve carry and curve change is somewhat subjective. Portfolio managers should have the flexibility to choose a methodology that is consistent with their style of management.

Since interest rate yield curves are infinite-dimension objects, we need to represent them with a finite set of parameters. The simplest method is to choose a small discrete set of yield-curve points (key-rate points) dispersed along the yield-curve. The premise is that the dynamics of the yield-curve can be represented with the dynamics of the key rates with a high degree of accuracy. Intermediate yield-curve points are assumed to move as a linear combination of the moves of adjacent key rates. A typical set of key rates used includes the 6-month, 2-year, 5-year, 10-year, 20-year, and 30-year points for most currencies. Other curve points that also appear are the 1-month, 3-month, 1-year, 3-year, 7-year, 12-year, 15-year, 25-year, and 40-year points. Some managers prefer to represent the curve using factors that are defined as linear combinations of curve points. The prototype for such representation is the level-slope-butterfly set of factors, a representation implied by the principal component analysis of yield-curves. The choice of yield-curve representation depends on the type of yield-curve exposure a portfolio is taking as well as the capabilities of the underlying analytics system.

Although the key rates or level-slope-butterfly representation of the yield-curve is highly accurate from a risk perspective (captures more than 99% of its variance), there may be deviations from a return perspective, especially if a small number of points are used. Indeed, there are periods where, for example, the three-year U.S, Treasury rate moves very differently than what is implied from the two-year and five-year rates. Analytics (key-rate durations) explain the bulk of yield-curve outperformance. Scenario-based outperformance calculations are used to capture any residual outperformance from intermediate yield-curve points and convexity.

Yield-Curve Carry

As discussed above, yield-curve carry calculations are complex even for bullet securities under par- or zero-rate representation of yield-curves. An approximation method for the calculation of yield-curve carry, called the Curve Matching Portfolio (CMP) method, can be used to simplify these calculations.

The basic idea is to define a set of par and/or zero-coupon reference bonds whose yield-curve carry can be easily computed analytically, and then construct a carry-matching portfolio of such bonds for each portfolio or benchmark security. The matching algorithm attempts to create a portfolio that earns the same yield-curve carry as the security.

Matching par bonds are made to have a coupon equal to the par key rate of the corresponding maturity and a price of par (100). The payment frequency and day count convention match those used for yield-curve construction. As a result, all matching par bonds on the day of construction have an option-adjusted spread of zero by construction. Zero-coupon bonds do not pay coupons, but have yields matching the zero rates for maturities matching each point.

A curve matching portfolio consisting of reference bonds and cash is created for each security in the portfolio and benchmark such that the cash-flow profile of the portfolio matches the one for the bond. Since dealing with bond cash flows (which are often nondeterministic) is generally difficult, some algorithms use key-rate durations to represent the concentration of cash flows around each key-rate point. Therefore matching the key-rate durations of the curve-matching portfolio and the bond is an approximate way to match their cash-flow profiles and thus the curve carry. Cash is added or subtracted from the matching portfolio to make sure that it has the same present value with the bond. The amount of cash needed to replicate any particular bond can vary according to the duration profile and price of the bond. For example, if only par bonds are used in the matching portfolio of a bond with a higher coupon than the current par rate, leverage must be used in the matching portfolio (borrowing at the short rate to fund the future cash flows) to match the cash-flow profile of the bond. This leads to a negative amount of cash in the matching portfolio.

A common choice for the set of matching reference bonds is to use one par or zero bond per key-rate point. The weights of each reference bond (and cash) are aggregated over all positions in the portfolio and benchmark. Let us represent with ω_j^P and ω_j^B weights allocated to reference bond and cash in the curve-matching portfolio of the portfolio and benchmark, respectively, with j spanning all key-rate points and cash. If we approximate the carry return of each reference bond and cash as its yield (by definition the corresponding key rate level) multiplied by the attribution period length $y_j \Delta t$, the yield-curve carry outperformance can be broken down per key-rate point contribution as $\sum_j \left(\omega_j^P - \omega_j^B\right) \cdot y_j \cdot \Delta t$. If we define the average portfolio or benchmark yield as the average of all key rates using the CMP portfolio weights, the above formula can be re-written as $\left(y_{avg}^P - y_{avg}^B\right) \cdot \Delta t$. The excess yield-curve carry contribution of each key rate over the average carry can be defined, but the sum over all key rates will be zero.

Generally, yield-curve carry can be broken down using the following equations:

Outperformance from average carry $$\left(y_{avg}^P - y_{avg}^B\right) \cdot \Delta t \tag{71-7}$$

Key rate contributions $$\sum_j \left(\omega_j^P \left(y_j - y_{avg}^P\right) - \omega_j^B \left(y_j - y_{avg}^B\right)\right) \cdot \Delta t \tag{71-8}$$

If the average yield is set to zero for both portfolio and benchmark, then the average carry term is zero and the yield-curve carry outperformance is attributed to each key rate. If the average yield is calculated using the CMP weights for portfolio and benchmark, then the average carry is equal to the total carry contribution and the sum of the excess key rate contributions is equal to zero. Other choices for the average yield are also possible.

Yield-Curve Change

Yield-curve change outperformance is a result of duration profile differences between the portfolio and the benchmark and the change in the yield-curve. The scenario-based return decomposition described earlier is used to compute the total yield-curve change return and hence the outperformance. Then, by using the analytics (OAD and KRDs), the total yield-curve change outperformance is decomposed further into a parallel shift component, a curve reshaping (at the key-rate points) component, the rest of yield-curve contribution, and the effects of convexity.

The outperformance from parallel yield-curve shift is computed by applying the bottom-up aggregation, using key-rate durations as loadings and key rate changes as factors. Similar to yield-curve carry, the notion of an average yield change (parallel shift) can be used to control how the yield-curve change outperformance is distributed between the key rate contributions and the parallel shift term.

Outperformance from avg. parallel shifts $$-(OAD^P - OAD^B) \cdot \Delta y_{avg} \tag{71-9}$$

Outperformance from reshaping $$-\sum_j \left(KRD_j^P - KRD_j^B\right) \cdot (\Delta y_j - \Delta y_{avg}) \tag{71-10}$$

If the average yield change is set to zero, the yield-curve change outperformance will be attributed to each key rate separately. If the average yield change is set equal to an appropriately defined parallel shift, the key rate terms capture the outperformance in excess of the parallel shift, i.e., the yield-curve reshaping effect on outperformance.

Since we represent the shape of the yield-curve by key-rate points, there will always be a small fraction of yield-curve change outperformance not captured by the above methodology, as explained at the beginning of this section. Exhibit 71-9 illustrates the change not captured by the key rates.

This final piece of the yield-curve change outperformance, calculated as the difference between total yield-curve change return from the scenario-based decomposition and the sum of the average parallel shift and reshaping return, includes the change in excess of key rates as well as return from convexity and other higher-order terms.

Exhibit 71-10 displays a yield-curve attribution report as produced by the Barclays HPA model.[11] The total yield-curve outperformance of +77.4 bp is broken into +2.9 bp of curve carry and +74.4 bp of curve change. Each is further broken down into an average curve contribution, the excess-to-average contributions of each key-rate point and the rest of the curve and convexity effect. The key rate levels and their changes over the attribution period (one month in this example) as well as the portfolio exposures in terms of curve matching portfolio weights and key-rate durations are displayed to help users better understand the reported outperformance breakdown.

To illustrate how this can be done we will focus on curve carry. The average yield of the portfolio and the benchmark are calculated as the yield of the corresponding yield-curve–matching portfolios. Since the portfolio is longer than the benchmark (as indicated by its higher duration) in an upward sloping yield-curve, its average yield is higher than the benchmark (2.030% versus 1.698%).

Source: POINT

The corresponding average yield-curve carry contribution can be approximated[12] using Eq. (71-7) as the excess yield of the portfolio times the elapsed time of one month, (2.030% – 1.698%) × (1/12) = +2.8 bp, close to the +2.9 bp shown. The additional contributions of key-rate points can be estimated using Eq. (71-8). For example, the 2-year point contributes approximately [39.5% × (0.771% – 2.030%) – 37.4% × (0.771% – 1.698%)] × (1/12) = –1.3 bp, close to the –1.4 bp shown.

Outperformance Due to Implied Volatility Exposure

For fixed income securities with optionality, pricing models are typically calibrated to reflect the Black swaption implied volatility surface prevailing in the market. Therefore, changes in implied volatility create returns on the embedded option that must be attributed correctly in performance attribution. Similar to how the contribution of yield-curve changes are measured, both scenario- and analytics-based calculations are used to break down the contribution of implied volatility changes to outperformance. The outperformance due to exposure to implied volatility is typically calculated in terms of volatility decay, parallel shift of the implied volatility surface, and surface reshaping.

Volatility Decay

Volatility decay captures the change in option value due to the lapse of time. The return from volatility decay is difficult to capture exactly, as it requires re-simulating interest rate paths and pricing securities using two separate time variables (one for diffusion and the other for discounting). However, volatility decay return can be approximated by subtracting all other components of the total time return, such as yield-curve and spread carry. Outperformance due to volatility decay is the difference between the weighted average volatility decay return of the portfolio and the benchmark.

Implied Volatility Change

The outperformance due to implied volatility change is a result of the difference in volatility exposures of the portfolio and the benchmark and the change in the implied volatility surface. The exposure to parallel shift is measured by Vega, and the parallel shift return is equal to Vega multiplied by the average implied volatility change over the entire surface. The implied volatility surface reshaping return, as well as additional terms that represent other parameters entering the fitting of the implied volatility surface can be calculated as the scenario-based total implied volatility return minus the return from the parallel shift.

Exhibit 71-11 shows a sample implied volatility report[13] produced by the Barclays HPA model. Volatility outperformance is broken down into the contributions of the major asset classes in the portfolio and benchmark.

---

12. Remember that these formulas hold for attribution over a single period while the example goes over a month using a daily compounding attribution algorithm.

13. The portfolio and benchmark in this report are the U.S. dollar portions of the global portfolio used in the example in the previous chapter.

Source: POINT

The report contains the initial implied volatility level and its change over the attribution period for each asset class.[14] In this example, implied volatility exposure occurs only in the government-related, corporate, and securitized sectors. The ability of an issuer to call a bond and the prepayment option of mortgage-backed securities give issuers of such bonds optionality, therefore long exposure to implied volatility. Conversely, holders of such bonds are short volatility, as the negative exposure numbers indicate. By being long the corporate and short the securitized sector, the portfolio is implicitly underweighted volatility in the corporate sector and overweighted volatility in the securitized. Since on average implied volatilities increased 5.71% during this month, the corporate sector contributes negatively to parallel volatility outperformance (–0.6 bp), and the securitized sector contributes positively (+6.6 bp). Overall, the portfolio is long volatility since the volatility exposure of the securitized sector is much bigger than that of the corporate and government-related sectors. The total parallel volatility change outperformance contribution is +6.2 bp. The total contribution of changes in the implied volatility surface is calculated from the return splits scenarios, as described above. From that, the surface reshaping (net of the parallel shift) contribution as well as the effects of other parameters and factor of the volatility model are calculated as –3.8 bp. Finally, a net long volatility portfolio will suffer loss of return because of volatility decay. In this case, it has been calculated to be –0.5 bp. Putting it all together, the total contribution of implied volatility to the outperformance of the dollar portfolio is calculated to be +1.9 bp.

FULLY ANALYTICAL MODEL

The Fully Analytical model offers the flexibility to match the increasing diversity in portfolio management structures. It takes full advantage of the return splits by isolating returns from each factor individually. The model can accommodate either bottom-up aggregation or top-down decomposition, depending on how the factor exposures are managed in the portfolio. It is suitable for portfolios with multiple asset classes, as they often have exposures to different market risk factors. For example, consider a portfolio consisting of corporate bonds, mortgage-backed securities, and inflation-linked bonds. While all of these securities are exposed to changes in interest rates and possibly implied volatility, mortgage securities have additional exposure to prepayment risk and mortgage spreads, and inflation-linked securities have additional exposure to their reference

14. Although in this report the average volatility of each bucket is reported to be the same, generally each security is exposed to different points of the volatility surface. It is difficult to estimate a single point representing the reference point for each security hence this report is using the simplistic approach where all securities are exposed to the same point for parallel shift calculations. Since the total effect of implied volatility changes is captured using scenario-based returns breakdown this choice only affects the breakdown between the average volatility change and the reshaping components.

inflation indices. Similar to how the yield-curve risk is managed, managers of mortgage and inflation-linked securities tend to manage these additional risk factors separately. The ability to break down outperformance due to specific factor exposure can be very valuable to the managers for explaining the impact of their portfolio decisions.

Furthermore, the Fully Analytical model allows portfolio managers to use measures other than market value as allocation weight. This is particularly useful for managers who allocate their capital to various sectors based on risk exposures rather than market values. For instance, a manager taking views on sector spread movement may think of over/underweight in terms of option-adjusted spread duration (OASD). In the credit space, the concept of duration-times-spread (DTS) has been gaining traction in recent years as an alternative measure of spread risk exposure.[15] As a result, credit portfolio managers may prefer to use OASD or DTS as allocation weight in performance attribution.

For illustrative purposes here, we will use the Fully Analytical model with the following choices: Yield-curve and implied volatility are considered common factors and their outperformance contribution is explained using bottom-up aggregation as previously described. The outperformance from mortgage and inflation factors as well as residuals are also explained using bottom-up aggregation and the details of their decomposition is described in the following sections. These factors are calculated per security and can be aggregated to buckets of the selected partition. Outperformance from spread is calculated in a top-down fashion using analytics-based exposure weights for spread change outperformance but market value weights for spread carry outperformance, as described in detail below.

Outperformance Due to Spread

Outperformance from spread is explained using top-down decomposition into asset allocation and security selection per user-defined hierarchical partition or sector. All three components of spread outperformance (carry, spread duration, and spread convexity) are decomposed separately using the top-down decomposition algorithm. Spread carry outperformance is decomposed by applying the absolute allocation algorithm using market value weights and carry returns. We consider two different methods for the decomposition of the spread change outperformance: top-level and sector-level.

Top-Level Spread Model

The top-level spread model assumes that there is a decision to over/underweight the spread duration exposure of the portfolio against the benchmark at the portfolio

15. See Arik Ben Dor, Lev Dynkin, Patrick Houweling, Jay Hyman, Erik van Leeuwen, and Olaf Penninga, *A New Measure of Spread Exposure in Credit Portfolios* (Barclays Publications, February 2010).

level (top level). Subsequent decisions to allocate spread duration exposure to various sectors are made relative to the portfolio spread duration. This implies that allocation weight is measured by the ratio of the spread duration contribution of each sector ($w_s OASD_s$) over the portfolio spread duration. In other words, we apply the relative allocation method of the top-down algorithm of Chapter 69 using $\alpha_k \leftarrow OASD$, $\alpha_{k,s} \leftarrow w_s OASD_s$, $f_{k,s} \leftarrow -\Delta OAS_s$ and $-\Delta OAS^B$ as hurdle rate.

$$\text{Asset Allocation} \quad -OASD^P \cdot \sum_s \left(\frac{w_s^P OASD_s^P}{OASD^P} - \frac{w_s^B OASD_s^B}{OASD^B} \right) \cdot \left(\Delta OAS_s^B - \Delta OAS^B \right) \tag{71-11}$$

$$\text{Security Selection} \quad -\sum_s w_s^P OASD_s^P \cdot \left(\Delta OAS_s^P - \Delta OAS_s^B \right) \tag{71-12}$$

$$\text{Spread Duration Mismatch} \quad -(OASD^P - OASD^B) \cdot \Delta OAS^B \tag{71-13}$$

Here, the Top-Level Exposure term has been renamed Spread Duration Mismatch.

Sector-Level Spread Model

In contrast to the top-level model, the sector-level model assumes no such spread duration decision at the portfolio level. Instead, each asset allocation decision is made without any top-level restriction. In this case, the appropriate allocation weight is the absolute, rather than relative, spread duration contribution. Furthermore, the hurdle rate is set to zero, as sector views are expressed on the absolute (rather than relative) changes in sector spreads. In other words, the absolute top-down decomposition is applied using $\alpha_{k,s} \leftarrow w_s OASD_s$ and $f_{k,s} \leftarrow -\Delta OAS_s$.

$$\text{Asset Allocation} \quad -\sum_s \left(w_s^P OASD_s^P - w_s^B OASD_s^B \right) \cdot \Delta OAS_s^B \tag{71-14}$$

$$\text{Security Selection} \quad -\sum_s w_s^P OASD_s^P \cdot \left(\Delta OAS_s^P - \Delta OAS_s^B \right) \tag{71-15}$$

Exhibit 71-12 shows the USD Local Management outperformance decomposition of the U.S. Dollar portfolio discussed earlier in this chapter using the Fully Analytical model with either top-level or sector-level spread duration management. We assume two-level allocation of spread exposure, first to major asset classes and then to subsectors of each asset class. In both models a new category, Mortgage,[16] has appeared and is responsible for –8.2 bp of outperformance. In both models, the security selection contribution is +9.3 bp. The difference comes from the treatment of spread duration exposure. The top-level model treats it as a portfolio-level decision (essentially a common return factor) contributing –1.8 bp of outperformance under the label Spread Duration Mismatch, while asset allocation is listed as +5.0 bp. The sector-level model makes spread duration exposure

16. We will discuss this term in more detail below.

part of the allocation decision and essentially combines the two terms, reporting asset allocation of +3.2 bp.

Exhibit 71-13 contains the Asset Allocation report to major asset classes (first level of allocation) using the sector-level model. Outperformance from asset allocation and security selection from each partition bucket is displayed, along with other useful information such as OAS and the changes in OAS, OASD, OASC, and market value weights.

The asset classes with the biggest contribution to spread change asset allocation outperformance are securitized with +4.4 bp and corporate with –1.7 bp. These numbers can be explained as follows. The securitized sector has an underweight of –0.3 years in terms of spread duration (0.8 years versus 1.1 years as seen in the top panel), while benchmark spreads in this sector widened 15.9 bp. Note that since we use the sector-level model, the hurdle rate is zero; therefore, we do not need to compare the spread widening of each sector with that of the benchmark. The approximate calculation estimates the contribution as –0.3 × –15.9 = +4.8 bp, relatively close to the +4.4 bp shown.

Spread carry contributes +1.5 bp to asset allocation, coming mostly from the corporate sector, which has high spread (+186.5 bp versus +57.1 bp for the benchmark) and is market value overweighted (30.7% versus 19.8%). The approximate calculation is (30.7% – 19.8%) × (186.5 – 57.1) × (1/12) = +1.2 bp.

EXHIBIT 71-12

Outperformance Breakdown Using the Fully Analytical Model

Fully Analytical Model (Top-Level) Outperformance Details		Fully Analytical Model (Sector-Level) Outperformance Details	
Yield-Curve	24.6	Yield-Curve	24.6
Implied Volatility	1.9	Implied Volatility	1.9
Asset Allocation	5.0	Asset Allocation	3.2
Security Selection	9.3	Security Selection	9.3
Spread Duration Mismatch	–1.8	Mortgage	–8.2
Mortgage	–8.2	Residual	1.3
Residual	1.3		

Source: POINT

Columns for further allocation[17] representing the contribution of spread exposure allocation to subsectors are also included.

Exhibit 71-13 also provides information to confirm the USD spread duration mismatch term from the top-level model (Exhibit 71-12, left panel). Indeed, the portfolio is slightly longer than the benchmark in terms of spread duration (4.7 versus 4.5 years), and benchmark spreads widened by 8.3 bp on average. Multiplying the spread overweight by the negative of the benchmark spread change yields $+0.2 \times (-8.3) = -1.7$ bp close to the –1.8 bp shown in Exhibit 71-12.

Mortgage Factors

The present value of mortgage-related securities depends on additional factors such as prepayments and mortgage rates. Some common additional factors are described below.

Prepayment Surprise Outperformance

Securities involving prepayments are priced using model predictions of future cash flows. Over a month, the realized prepayment rate is generally different from the one predicted by the model. The difference gives rise to a return component that is not captured by analytics; this return can be computed separately as Prepayment Surprise return. In the Global Aggregate G4 index, which is the benchmark in this example, prepayments are recognized on the first of the month based on a predicted rate (which, if different from the model-predicted one, will generate surprise return). Over the course of the month, the actual prepayment rate can be more accurately predicted and used to adjust the returns, leading to more days where the surprise return is non-zero. Once the actual rate is known and returns are adjusted to reflect it, no more surprise return for that particular month will occur. Note that portfolio accounting conventions with respect to recognizing realized prepayments may vary. If they are different from the benchmark conventions, the attribution system will report prepayment surprise outperformance that is not economic but accounting in nature.

Mortgage Spread Change Return

A common factor that affects the cash flows of all mortgage securities is the difference between the model-implied mortgage rate and the actual mortgage rate observed in the market. This difference is called the mortgage spread and the

17. It is interesting to note that further allocation must use the relative spread duration allocation model, since the spread duration of each major asset class has been determined at the first level of allocation. The spread duration allocation to subsectors must be consistent with the pre-determined spread duration of the asset class.

price sensitivity of a security to this spread is the mortgage spread duration. The return due to mortgage spread change is usually estimated with a first order approximation as the product of the mortgage spread duration and the negative of the change in the mortgage spread, i.e., $-MtgRtDur \cdot \Delta MtgSpread$. The outperformance is the difference between the weighted average mortgage spread return of the portfolio and the benchmark.

Other Mortgage Factors

A number of other parameters such as home price appreciation projections and swap spreads may also be used in mortgage pricing models. In the scenario-based return splits, all such parameters are accounted for in Other Market Return scenario. For mortgage securities, the difference between the other market return and the mortgage spread return captures the return from factors for which no analytics are available. If this difference is significant, it is an indication that additional analytics are required to better understand the sources of risk and performance of mortgage securities under the particular valuation model.

Exhibit 71-14 displays a portion of a detailed position-level outperformance contribution report for the U.S. Dollar portfolio discussed earlier in this chapter. The contribution of each position is broken down per factor. Outperformance components that are allocated in a top-down fashion such as spread carry and spread change are listed under "Security Selection." Components aggregated in a bottom-up fashion such as mortgage factors and residual are listed under "Other." Exhibit 71-14 is focused on the securitized sector, which is solely responsible for the –8.2 bp of underperformance attributable to mortgage factors. This report can be very useful to help managers drill down to the position level and understand the drivers of outperformance per individual factor.

Inflation Factors

Inflation-linked securities have cash flows linked to a specified price index. For example, the principal and interest payment of U.S. Government Inflation-Linked bonds (TIPS) are linked to the Consumer Price Index for All Urban Consumers (CPI-U), non–seasonally adjusted. The value and the return of inflation-linked securities depend on realized inflation as well as on expectations of future inflation during the lifetime of the security.

The analysis of the risk and performance of inflation-linked securities is subject to debate. One school of thought prefers to treat them as independent of nominal interest rates and express risk and performance as a function of real rates (nominal rates minus inflation expectations). In this type of analysis, the return of inflation-linked securities comes from changes of real rates, as well as time return, which is a combination of real rate carry and realized inflation accretion.

Another school of thought prefers to decompose real rates into the difference of nominal interest rates and inflation expectations such that nominal interest rate risk and contribution to outperformance is accounted consistently

Source: POINT

across all types of bonds. The numbers shown below are calculated following the latter approach.[18] Inflation expectations are captured by a negative discounting spread (similar to OAS), which is called inflation spread. The return of inflation-linked securities is explained by changes in nominal interest rates and inflation spreads. The time return is captured by the nominal interest rate carry reduced by the negative inflation spread carry and increased by realized inflation accretion. Since realized inflation is announced only once a month, an assumption about the projected inflation of the current month is required to ensure smooth daily inflation accretion. When realized inflation is announced, it is generally different from projected inflation, producing a return that cannot be otherwise accounted for. This kind of return of inflation-linked securities is called inflation surprise and is accounted separately. Inflation surprise return is also present when current month inflation projections change.

Exhibit 71-15 shows the Fully Analytical model's security return splits for the Barclays Inflation Linked US TIPS index for the period from July 16, 2010, to August 13, 2010. These dates correspond to the CPI-U announcement dates for the index level as of the end of June and July, respectively; therefore, the index should show a realized inflation return equal to the rate of inflation realized during July (but only becoming known on August 13).

The total return of the index was +169.9 bp, with the majority coming from nominal interest rates exposure (+27.7 bp carry and +184.6 bp of yield-curve change). Inflation related return was negative at –40.6 bp, most of it coming from falling inflation expectations (captured under inflation spread change as –29.7 bp). Inflation accretion during July was –3.0 bp, indicating that at the beginning of the month, the market actually expected a small amount of deflation at an annualized rate of $-0.03\% \times 12 = -0.36\%$. The positive inflation surprise of +5.3 bp indicates that the realized inflation was actually positive, although quite low. The total realized inflation return is +2.3 bp, the sum of inflation accretion (at the market expected rate) and inflation surprise. From that, July realized annualized inflation can be calculated to be approximately $+0.023\% \times 12 = +0.28\%$. Indeed, the CPI reading for June was 217.965 and the one for July 218.011, implying an inflation rate for July of $218.011/217.965 - 1 = 2.11$ bp or +0.25%. The inflation spread carry term of –13.1 bp reduces the yield-curve carry of +27.7 bp that was credited to the index due to exposure to nominal rates. The difference of the two can be thought of as the carry earned by the index due to exposure to real rates, i.e., nominal rates reduced by inflation expectations.

Another interesting thing to note is that inflation expectations did not fall uniformly across all maturities. Indeed, short bonds exhibited positive inflation spread return, indicating increasing inflation expectations over the next three years or so. This is also the case for very long bonds, with the 30-year bond showing increasing inflation expectations. Inflation expectations fell only for bonds

18. This approach is detailed in Anthony Lazanas and Jeremy Rosten, *Risk Modelling and Performance Attribution for Inflation-Linked Securities* (Lehman Brothers Publications, October 2005).

with maturities between 3.5 and 20 years. This indicates that inflation portfolio managers need to pay more attention to the term structure of expected inflation exposure and use more detailed analytics that provide partial sensitivities to the inflation term structure.

SELECTING AN APPROPRIATE ATTRIBUTION MODEL

From the above discussion, it should be clear that many variants of attribution models exist and that a portfolio manager must choose one that best corresponds to the decision structure during portfolio management. The results from several models applied to the U.S. dollar–denominated portion of the portfolio/benchmark from the previous chapter are summarized in Exhibit 71-16. All models assume two-level asset allocation, first to major asset classes and then to subsectors of each asset class.

Essentially, models differ with respect to what factors of return are managed at the portfolio level via allocations of appropriate exposures (factor-based management) and which component of return is managed via allocation to sectors and security selection within each sector (sector-based management).

Each successive model brings one additional common factor. The Excess of Yield-Curve model introduces yield-curve exposure as a common factor; the Excess of Yield-Curve and Implied Volatility model introduces implied volatilities; the Fully Analytical model with sector-level allocation of spread exposure

EXHIBIT 71-16

Outperformance Contributions Using Various Models

	Total Return	Excess of Yield-Curve	Excess of Yield-Curve and Vol	Fully Analytical (Sector-Level)	Fully Analytical (Top-Level)
Total	32.1	32.1	32.1	32.1	32.1
Yield-Curve		24.6	24.6	24.6	24.6
Implied Volatility			1.9	1.9	1.9
Spread Duration Mismatch					–1.8
Asset Allocation	2.9	–2.2	–4.0	3.2	5.0
Security Selection	29.2	9.7	9.6	9.3	9.3
Mortgage				–8.2	–8.2
Residual				1.3	1.3

introduces all other factors for which there exist explanatory analytics (mortgage factors only, in this particular portfolio) as well as residual; and the Fully Analytical model with top-level allocation of spread exposure introduces top-level spread duration as a common factor.

Flexibility is a very important feature of attribution algorithms. Portfolio management styles differ, and an attribution platform must have sufficient richness so that a model representing each management style can be chosen. In addition, running multiple versions of the performance attribution algorithm may help portfolio managers reveal exposures that they have been implicitly taking and help them improve their management process.

KEY POINTS

- The total return of a security can be broken down to the contributions of various risk factors such as yield-curve, volatility, spread, mortgage, and inflation—based on the variables used in the pricing model for that security type.
- Various models can be applied to allocate these components of return in different ways to correspond to the management structure of a portfolio.
- The Total Return Model considers all return as a single allocated factor and divides the difference in performance versus a benchmark into allocation to sectors and sector performance using market value weightings.
- The Excess Return Model extracts common factors, such as yield-curve and volatility, and allocates outperformance from excess return using a top-down algorithm into asset allocation and security selection. Relative performance from common factors is determined using bottom-up aggregation.
- The Fully Analytical model allows any return split component to be extracted as a common factor for bottom-up aggregation. Alternative weights, such as spread duration, can be used in allocation calculations to provide a risk-weighted view.
- It is most effective to choose a primary performance attribution model that matches the management structure of the portfolio. This provides a more effective evaluation of the performance due to exposure to the factors used in the decision-making process.

CHAPTER

SEVENTY-TWO

ADVANCED TOPICS IN PERFORMANCE ATTRIBUTION

Barclays

The principles of performance attribution are outlined in Chapter 70 and a detailed attribution analysis for fixed income portfolios is discussed in Chapter 71. This chapter explores topics that more complex portfolios or analysis may encounter in practice. In particular, we start looking at the attribution exercise in a multicurrency context. Given the fact that the majority of multicurrency portfolios have some type of foreign exchange (FX) hedging overlay, being able to accurately separate the performance due to active FX positions from that due to hedging is a complex but important exercise. Another important topic discussed in this chapter concerns the treatment of returns and outperformance due to the use of derivatives or leverage in the portfolio. Their presence may change the nature of the basis used to define returns, so we discuss in more detail how to change the analysis in order to maintain the integrity of the performance attribution. This chapter finishes with the discussion of other practical considerations that performance attribution exercises often encounter. These include issues such as multi-period compounding, transaction handling, and missing or incorrect input data.

MULTICURRENCY ATTRIBUTION

In the previous chapter, we used performance attribution to examine the portfolio at the local market level, that is, associated with a particular currency market. Multicurrency portfolios add an additional layer of complexity to the portfolio management structure. For instance, there may be decisions made at the global level to determine capital allocation across different local markets or the FX exposures to those markets. In this section, we describe in more detail how one can decompose total global outperformance in terms of FX allocation, local market allocation, and local market management.

This chapter was coauthored by Anthony Lazanas, António Baldaque da Silva, Chris Sturhahn, Eric P. Wilson, and Pam Zhong when they were employees of Barclays.

To study the FX component of the portfolio's return, we need to define first the base currency of analysis, the currency in which we define the portfolio's return. Note that by definition, securities denominated in the base currency do not have FX exposure or return.

FX Return Splitting

Since most portfolio managers prefer to manage FX risk separately from all other risk exposures, the first step in return splitting of non-base-currency-denominated securities is to separate the FX component of return from the local component of return. The base currency total return of security i (${}^{b}R_i$) can be expressed in terms of its local currency return (R_i) and the spot FX return of the currency in which the security is denominated, F_i.[1]

$$ {}^{b}R_i = F_i + R_i F_i + R_i \tag{72-1} $$

Here, we assume that all positions with cash flows or dependencies on interest rates in multiple currencies (such as FX swaps, FX forwards) have been decomposed into legs that have exposure only to the market parameters of a single currency. Note the presence of a cross-term that is the product of the FX return and the local currency return. This can be accounted separately, but in most cases it is combined with the FX return under the assumption that the FX return is typically much larger than local currency returns. While this is generally true for fixed income securities, it may not be true for portfolios that invest in asset classes with higher volatility, such as equities or commodities.

To separate the performance due to FX exposures from the performance due to local management, we need to include the cash deposit return of each currency in the FX return.[2] Indeed, a cash investment in any foreign currency will earn the FX return plus the local cash deposit return over the attribution period, R_i^{depo}, without incurring any local risk.

$$ {}^{b}R_i = \left(F_i + R_i^{depo}\right) + R_i F_i + \left(R_i - R_i^{depo}\right) \tag{72-2} $$

The total return of the portfolio can then be written as the sum of returns from "local markets" that correspond to the first allocation layer of a multicurrency portfolio. Although single-currency markets provide the natural breakdown

1. This formula is applicable to fully funded securities only. When leverage is present, such as in derivatives, it needs to be adjusted appropriately.
2. Brian D. Singer, and Denis S. Karnosky, "The General Framework for Global Investment Management and Performance Attribution," *Journal of Portfolio Management* (Winter 1995), pp. 84–92.

for FX returns, there is no reason to impose the same breakdown for local returns. In fact many managers allocate local return exposure to markets based on geography, asset class, or industry, rather than currency. We will denote the local return allocation markets with *m* and we will generally assume that they are not necessarily single-currency markets. Single-currency markets will be denoted with *c* and will be used for the allocation of the FX component of return, as well as the cross term.

$$ {}^{b}R^{P} = \sum_{c} {}^{b}w_{c}^{P} \cdot \left(F_{c} + R_{c}^{depo}\right) + \sum_{c} {}^{b}w_{c}^{P} R_{c}^{P} F_{c} + \sum_{m} {}^{b}w_{m}^{P} \cdot \left(R_{m}^{P} - R_{m}^{depo,P}\right) \quad (72\text{-}3) $$

The three terms in Eq. (72-3) correspond to FX, FX/local cross-term, and local returns, respectively. Here, ${}^{b}w_{c}^{P}$ and ${}^{b}w_{m}^{P}$ represent the "base-currency portfolio market value weights," i.e., the market value of positions in currency *c* or market *m* over the market value of the portfolio, both expressed in base currency units. Note that within single-currency markets the cash deposit rate return and the FX return are the same for all securities and therefore the same for the portfolio and the benchmark. However for a generic market *m* that may span several currencies, the cash deposit rate return $R_{m}^{depo,P}$ is defined as the weighted average return over all market securities. Since the composition of the market generally differs across portfolios and benchmarks we need to use the designation *P* to identify a specific portfolio.

FX Hedging

FX hedging—the overlay of FX derivatives with the intent to change the FX exposure profile of a portfolio without affecting its local markets exposures—is a common practice in multicurrency portfolios. It enables managers to disentangle the portfolio construction process between the FX experts and the local market managers. The most common instruments used for hedging are FX forwards, typically with short tenors (e.g., one month) and rolled regularly. Longer tenors are sometimes used to reduce rolling costs.

Despite the intent to leave the local exposures unchanged, in practice FX hedging instruments have side effects that must be accounted for in a complete attribution framework. In what follows we detail two such effects.

Exposure to Local Interest Rates

Ideal FX hedges earn the cash rate in each currency and have zero interest rate duration. In practice, FX hedging instruments do have exposure to the short end of local interest rate curves. This effect is highlighted during market crises, when short rates exhibit significant volatility. Typically, this return is considered part of the hedging return, as it comes from an unintended exposure to local rates through the instruments used to hedge the portfolio and is not part of the local rates strategy decisions.

Cash Balance Effect

As FX rates fluctuate, the mark-to-market of FX forwards becomes nonzero, essentially representing a cash balance (positive or negative). Unless such cash balance is reinvested regularly, it represents an unintended allocation to cash (which is equivalent to leveraging if the balance is negative). This effect can be significant and needs to be highlighted in performance attribution. To that end, one possible solution is to capture this effect explicitly as the difference of the actual portfolio return minus the hypothetical return that would be achieved if the FX hedges cash balance were reinvested daily in the portfolio. Similar to the exposures to local rates, this effect should also be reported as part of the hedging return.

Once these side effects have been accounted for, the effect of FX hedges is restricted to the FX component of the total return and the cross-term; the local component of return remains unchanged.

Outperformance from FX Allocation and Hedging

FX outperformance is defined as the part of total outperformance that is due to fluctuations of the exchange rates between the base currency and all non-base currencies present in the portfolio or the benchmark. The first two terms of Eq. (72-3), pure FX and the FX/local cross-term, contribute to FX outperformance. We look at them separately in what follows.

Let's denote the effective portfolio exposure to each spot FX rate after hedging with ${}^{b}h_c^P$ and the benchmark one with ${}^{b}h_c^B$. Then, we can represent the *pure FX outperformance* contribution to the portfolio outperformance as follows:

$$^{FX}R^P - {}^{FX}R^B = \sum_c {}^{b}h_c^P \cdot \left(F_c + R_c^{depo}\right) - \sum_c {}^{b}h_c^B \cdot \left(F_c + R_c^{depo}\right)$$

We can now apply the relative allocation model of the top-down decomposition algorithm described in Chapter 70 to get the hedged FX allocation as:

$$\sum_c \left({}^{b}h_c^P - {}^{b}h_c^B\right) \cdot \left(F_c + R_c^{depo} - R_b^{depo}\right) \tag{72-4}$$

To derive Eq. (72-4), we specifically set the following variables using the notation from Chapter 70: $\alpha_{k,s} = {}^{b}h_c$, $\alpha_k = \sum_c {}^{b}h_c = 1$, $f_{k,c} = F_c + R_c^{depo}$ and $f_k^H = R_b^{depo}$. The allocation in Eq. (72-4) is typically used to measure pure FX allocation. However, a similar decomposition can be made to the FX outperformance without the hedges. The unhedged FX allocation would be:

$$\sum_c \left({}^{b}w_c^P - {}^{b}w_c^B\right) \cdot \left(F + R_c^{depo} - R_b^{depo}\right) \tag{72-5}$$

Let's now discuss the *FX-local cross-term return*. For simplicity, let's focus only on the portfolio and split it into the original portfolio (P, with weights w) and the portfolio of hedges (H, with weights w–h). As per Eq. (72-3), we know that the portfolio cross-term return is $\sum_c {}^b w_c^P R_c^P F_c^P$. However, the hedge portfolio H pays the deposit rate R_c^{depo} in each currency. Therefore, the net return for the hedged portfolio ($P + H$) is:

$$\sum_c \left({}^b w_c^P R_c^P - \left({}^b w_c^P - {}^b h_c^P\right) \cdot R_c^{depo}\right) \cdot F_c^P$$

We can therefore see that hedges do contribute to the cross-term between FX and local returns. The contribution of the FX-local cross-term return to the outperformance of a portfolio versus a benchmark is calculated as:

$$\sum_c \left({}^b w_c^P R_c^P - {}^b w_c^B R_c^B\right) \cdot F_c^B + \left(\left({}^b w_c^P - {}^b h_c^P\right) - \left({}^b w_c^B - {}^b h_c^B\right)\right) \cdot R_c^{depo} \cdot F_c^B \qquad (72\text{-}6)$$

Since this term is the product of two returns, its size is usually smaller than either of the two. However over time, the contributions of the cross-term can accumulate (similar to a convexity term) and become significant relative to the local and FX returns. Moreover, the FX cross-term can be a significant component of total return when FX and local returns have opposite signs and similar magnitudes. For example, if FX return is +5% and local return is –4%, the total return is 5% – 4% + 5% × –4% = 0.80%. Without the cross-term the total return would have been 1.00%, so the cross-term of –0.20% reduces total return by 25%. In the extreme, if the two returns are opposite but equal in magnitude, the entire total return is due to the cross-term. While in the majority of the cases the FX/local cross-term is insignificant, it is preferable to account for it explicitly.

In addition to the first two terms of Eq. (72-3) we just explored, the local return and market value effects of the hedging instruments, as well as their trading returns, should be accounted for separately. This allows us to separate any returns from the hedging instruments from the local returns and outperformance that we explore in the next stage of attribution.

Outperformance from Allocation to Local Markets

After the contributions of FX exposure and hedging are taken out, the remaining outperformance is given by:

$${}^L R^P - {}^L R^B = \sum_m {}^b w_m^P \cdot \left(R_m^P - R_m^{depo,P}\right) - \sum_m {}^b w_m^B \cdot \left(R_m^B - R_m^{depo,B}\right) \qquad (72\text{-}7)$$

There are many different ways to decompose this outperformance into the contributions of the various decision-makers. The most straightforward is to assume that the first decision layer is the allocation of market value exposure to various local markets. After this, each local market is managed separately versus a corresponding benchmark. We can apply the top-down decomposition algorithm from Chapter 70 to define the local market allocation outperformance as:

$$\sum_{m}\left({}^{b}w_{m}^{P}-{}^{b}w_{m}^{B}\right)\cdot\left(\left(R_{m}^{B}-R_{m}^{depo,B}\right)-\left(R^{B}-R^{depo,B}\right)\right) \tag{72-8}$$

And the local market management outperformance as:

$$\sum_{m}{}^{b}w_{m}^{P}\cdot\left(\left(R_{m}^{P}-R_{m}^{depo,P}\right)-\left(R_{m}^{B}-R_{m}^{depo,B}\right)\right) \tag{72-9}$$

Specifically, we use the following notation from Chapter 70 to construct the equations above $\alpha_{k,s}={}^{b}w_{m}$, $\alpha_{k}=\sum_{c}{}^{b}w_{m}=1$, $f_{k,s}=R_{m}-R_{m}^{depo}$ and $f_{k}^{H}=R^{B}-R^{depo,B}$. Note that this breakdown is equivalent to the *Total Return model* presented in the previous chapter.

If each local market contains securities denominated in the same currency then Eq. (72-9) is simplified to $\sum_{c}{}^{b}w_{c}^{P}\cdot\left(R_{c}^{P}-R_{c}^{B}\right)$. The local outperformance within each currency $R_{c}^{P}-R_{c}^{B}$ can then be decomposed using the general methodology and any of the models described in the previous chapter. If on the other hand local markets span across currencies, then only the *Total Return Model* (see Chapter 71) is directly applicable for the analysis of local market management outperformance. The use of models that require a reference interest-rate curve for the analysis is not straightforward.

Factor-Based Local Markets Allocation

Market value-weighted allocation to markets hides many of the complexities of the decision process of investing across markets. Indeed, allocation of exposure to local markets consists of the aggregation of exposure to each risk factor that drives market returns, such as yield-curve, implied volatility, spreads, and so forth. To better quantify how much risk is taken in a particular local market, we can describe the allocation decision using the appropriate exposure to each risk factor, e.g., interest rate duration for yield-curve, Vega for implied volatility, and spread duration for spreads, etc.

Following the methodology described in Chapter 70, we can rewrite Eq. (72-7) by decomposing local returns into the contributions of risk factors as follows:

$$\begin{aligned}{}^{L}R^{P}-{}^{L}R^{B}=&\sum_{k}\sum_{m_k}{}^{b}w_{m_k}^{P}\alpha_{k,m_k}^{P}f_{k,m_k}^{P}-\sum_{m}{}^{b}w_{m}^{P}R_{m}^{depo,P}\\&-\left(\sum_{k}\sum_{m_k}{}^{b}w_{m_k}^{B}\alpha_{k,m_k}^{B}f_{k,m_k}^{B}-\sum_{m}{}^{b}w_{m}^{B}R_{m}^{depo,B}\right)\end{aligned} \tag{72-10}$$

As implied by the notation m_k, each factor may use a different set of local markets. We can now separate local outperformance into allocation, management, and leverage using different weights for each factor. Specifically, the outperformance due to allocation is:

$$\sum_k \left(\sum_{m_k} \left({}^b w^P_{m_k} \alpha^P_{k,m_k} - {}^b w^B_{m_k} \alpha^B_{k,m_k} \right) \cdot \left(f^B_{k,m_k} - f^H_k \right) \right) - \sum_m \left({}^b w^P_m - {}^b w^B_m \right) \cdot R^{depo,B}_m \tag{72-11}$$

While the one due to management is:

$$\sum_k \left(\sum_{m_k} {}^b w^P_{m_k} \alpha^P_{k,m_k} \cdot \left(f^P_{k,m_k} - f^B_{k,m_k} \right) \right) - \sum_m {}^b w^P_m \cdot \left(R^{depo,P}_m - R^{depo,B}_m \right) \tag{72-12}$$

Finally, the top-level allocation, or leverage, can be represented as:

$$\sum_k \left(\sum_{m_k} {}^b w^P_{m_k} \alpha^P_{k,m_k} - \sum_{m_k} {}^b w^B_{m_k} \alpha^B_{k,m_k} \right) \cdot f^H_k \tag{72-13}$$

Example: Curve Allocation to Local Markets

As an example of the decomposition we just described, consider a portfolio manager that centrally manages the global interest-rate positioning of the portfolio. In this context, we can use the above methodology to separate the local performance of a portfolio into a global curve allocation and excess (of global curve) outperformance. The portfolio manager can use key rate durations to control her exposure to the former and market value weight to control exposure to the latter. We will select the local markets for the decomposition of global interest rates outperformance in a way that each market c corresponds to a unique interest-rate curve. Most of the time this decomposition is equivalent to single currency markets decomposition, yet occasionally this is not the case. For example, it might be preferable to use individual country government curves when analyzing a portfolio of euro-denominated bonds. This methodology allows us to answer successively:

- What was the contribution of the global duration position of the entire portfolio (Global Duration Mismatch)?
- What was the contribution of taking interest rate exposure (sovereign exposure) outside of our reference currency (Local Curve Advantage)?
- What was the contribution of taking other risk exposure in each currency (Excess of Curve Allocation)?

In this example, we will further separate the curve return into two components, a *curve carry* and a *curve change* return. To account for *curve carry* in a way that is consistent with Eq. (72-7), we subtract the deposit return from the outperformance of curve carry. The carry exposure to each individual key-rate point i in each curve c is constructed using the curve-matching portfolio (CMP) weights $\omega_{c,j}$ as described in the previous chapter. The idea behind the CMP is to represent each bond in the portfolio or benchmark as a portfolio of "par bonds" whose curve carry is easy to compute analytically. We can then calculate the carry associated with the portfolio or benchmark using the carry of the corresponding CMP. Let us also denote the curve carry return from each individual key-rate point with $R_{c,j}^{carry} = y_{c,j}\Delta t$. From Eqs. (72-11) to (72-13), using the transformations $\alpha_{k,m_k} = \omega_{c,j}$, $f_{k,m_k} = R_{c,j}^{carry} - R_c^{depo}$ and setting the hurdle rate equal to the excess carry return of a reference currency (typically the base currency of the analysis) $f_k^H = R_{ref,j}^{carry} - R_{ref}^{depo}$, we get the following decomposition.

The local curve carry allocation is given by

$$\sum_c \sum_j \left({}^b w_c^P \omega_{c,j}^P - {}^b w_c^B \omega_{c,j}^B \right) \cdot \left(\left(R_{c,j}^{carry} - R_c^{depo} \right) - \left(R_{ref,j}^{carry} - R_{ref}^{depo} \right) \right) \tag{72-14}$$

The local curve carry management by

$$\sum_c \sum_j {}^b w_c^P \omega_{c,j}^P \cdot \left(\left(R_{c,j}^{carry} - R_c^{depo} \right) - \left(R_{c,j}^{carry} - R_c^{depo} \right) \right) = 0 \tag{72-15}$$

And the global curve carry over deposit as

$$\sum_c \sum_j \left({}^b w_c^P \omega_{c,j}^P - {}^b w_c^B \omega_{c,j}^B \right) \cdot \left(R_{ref,j}^{carry} - R_{ref}^{depo} \right) \tag{72-16}$$

Note that since c represents a single interest-rate curve, the carry return at each key-rate point and the deposit rate return are uniform across all securities and therefore the same for the portfolio or the benchmark. In this case the curve carry management is zero by construction. Further, if we do not use a reference curve, then the global curve carry term also becomes zero and the global curve carry outperformance is simply broken down per curve and key-rate point as follows:

$$\sum_c \sum_j \left({}^b w_c^P \omega_{c,j}^P - {}^b w_c^B \omega_{c,j}^B \right) \cdot \left(R_{c,j}^{carry} - R_c^{depo} \right) \tag{72-17}$$

We now turn to the second component of the curve return, the *curve change* return. The outperformance due to curve change is decomposed similarly using key-rate durations as allocation weights and the negative of the key-rate yield change as return, i.e., $\alpha_{k,m_k} = KRD_{c,j}$, $f_{k,m_k} = -\Delta y_{c,j}$ and $f_k^H = -\Delta y_{ref,j}$.

Under this setting the local yield-curve change allocation is

$$-\sum_c \sum_j \left({}^b w_c^P KRD_{c,j}^P - {}^b w_c^B KRD_{c,j}^B \right) \cdot \left(\Delta y_{c,j} - \Delta y_{ref,j} \right) \tag{72-18}$$

And the local yield-curve change management is

$$-\sum_c \sum_j {}^b w_c^P KRD_{c,j}^P \cdot \left(\Delta y_{c,j} - \Delta y_{c,j} \right) = 0 \tag{72-19}$$

Finally, the global duration mismatch is

$$-\sum_c \sum_j \left({}^b w_c^P KRD_{c,j}^P - {}^b w_c^B KRD_{c,j}^B \right) \cdot \Delta y_{ref,j} \tag{72-20}$$

Once again, within a specific curve interest rate changes are the same for all securities and therefore for the portfolio and the benchmark. This causes the management term to be zero. In addition, if no reference curve is specified, then the global duration mismatch becomes zero as well and the global curve change outperformance is simply broken down per curve and key-rate point as follows:

$$-\sum_c \sum_j \left({}^b w_c^P KRD_{c,j}^P - {}^b w_c^B KRD_{c,j}^B \right) \cdot \Delta y_{c,j} \tag{72-21}$$

Once outperformance from interest-rate curve exposures has been accounted for, the remaining return, i.e., the return in excess of FX and curve return can be explained using a different set of local markets using the same methodology discussed above in the "Outperformance from Allocation to Local Markets" section.

Global Curve Allocation in Practice

To illustrate the concepts just developed, let's consider the following example. A U.S. dollar-denominated portfolio is managed against the Barclays Global G4 Treasury Index, an index consisting of government bonds from four currencies, U.S. dollar, euro, Japanese yen, and British pound. The manager is allowed to make the portfolio deviate from the index in order to express views that in her opinion will produce superior returns. In this case, the manager believes that the euro will strengthen versus the U.S. dollar and at the same time U.S. rates will rise while euro rates will fall. She wants no active exposure to the yen market. Finally, to minimize sovereign risk she prefers to concentrate exposure within the euro-zone to the strongest economies in the region.

The portfolio is constructed in line with the above views as follows:

- The portfolio is long euro (against the U.S. dollar, the base currency of the portfolio).
- The portfolio uses six-month FX forwards selling Japanese yen against the U.S. dollar to bring the portfolio yen exposure in line with that in the benchmark.

- The portfolio is net long interest-rate duration in euro-denominated securities and net short interest-rate duration in U.S. dollar–denominated securities.
- The portfolio overall interest rate duration is neutral against the benchmark.
- In the euro-zone, only bonds from AAA-rated countries are included in the portfolio.

The major portfolio exposures are summarized in Exhibit 72-1.

Exhibit 72-2 shows the breakdown of the portfolio outperformance versus the benchmark for a period of one month. The total outperformance is +10.5 bp. It is broken down by currency, with U.S. dollar being the top contributor at +15.5 bp. It is also broken down by type of exposures, where we see that FX positioning contributed +14.3 bp, and allocation to local markets (including interest rate exposures) contributed +6.5 bp, while local management within each currency market had a negative contribution of –10.3 bp. As expected, most of the FX Allocation outperformance came from the exposure to the euro (+14.4 bp), indicating that the manager's view regarding a strengthening euro was correct. The breakdown also shows a small contribution from hedging effects under Japanese yen, +0.1 bp. As discussed previously, the six-month JPY/USD FX forwards contributed to non-FX return in two ways: (1) They were exposed to the short end of the yen and U.S. dollar yield-curve movements; and (2) over the attribution period they accumulated nonzero market value and therefore created a cash balance effect. Both effects are captured in the non-zero hedging effects outperformance. The yield-curve allocation outperformance is +3.1 bp, with U.S. and the euro-zone contributing +14.9 bp and –12.0 bp, respectively. From this perspective and for this

period, the views the manager had regarding the movements on the yield-curve played well for him regarding the U.S. dollar, but against him regarding the euro. The local market allocation in excess of the yield-curve totals +3.4 bp. Finally, local management pulled back the overall outperformance. Security selection in the euro-zone, in particular, contributed –11.1 bp to total outperformance.

Let us first look into the FX allocation outperformance in detail (Exhibit 72-3). In line with the fund manager's view, the euro strengthened, producing +306.1 bp of FX plus cash deposit return in excess of the base currency (U.S. dollar) cash deposit return. Since the euro had an average overweight of 4.6% during this period, it contributed +14.8 bp of FX outperformance. This number can be approximated as the product of the average overweight times the excess return of the currency, i.e., $4.6\% \times 306.1 = +14.1$ bp. The number does not tie out exactly with the +14.8 bp outperformance reported in Exhibit 72-3 because in the attribution system it is calculated daily and then compounded taking account of any fluctuations in the exposure. In Exhibit 72-3 one can also observe that FX hedging of the yen exposure cost +8.5 bp of outperformance since the yen also appreciated during this period. However, the reverse could be true should the yen weaken against the U.S. dollar. The return coming from the hedged FX Allocation outperformance for the Japanese yen is close to zero. This shows that the manager was able to implement into the portfolio one of his goals: reduce significantly any volatility related to exposure to the yen.

EXHIBIT 72-3

FX Allocation Outperformance Breakdown by Currency[3]

Currency Market	FX Rate Begin	FX Rate End	Excess over Base Depo	Average Market Value (%)			Unhedged FX Allocation	Hedged FX Allocation	FX / Local Cross Term

Source: POINT

Next, we look more carefully into the global yield-curve outperformance (see Exhibit 72-4). The portfolio curve carry outperformance is almost flat at –0.1 bp. Most of the outperformance comes from portfolio duration positioning. During the period, yields rose for all G4 curves. However, on a relative basis, euro yields rose less than U.S. dollar yields. Without changing the portfolio overall interest rate duration, the portfolio picked up +3.2 bp of outperformance. This was achieved by going short the interest-rate duration in the U.S. (+16.3 bp) while long duration in the euro-zone (–13.1 bp). Overall, the duration decisions played in favor of the manager. Japanese yen and British pound markets contributed little as their durations have been purposely kept neutral to the benchmark.

The outperformance contributions in Exhibit 72-4 have been calculated using Eqs. (72-17) and (72-21) and taking into account the detailed key-rate exposures of the portfolio in each currency. For the purposes of this example we simplify these equations assuming that the portfolio curve exposure is distributed evenly across all key-rate points. In this case the following simplifications can be made:

$$\sum_c \sum_j \left({}^b w_c^P \omega_{c,j}^P - {}^b w_c^B \omega_{c,j}^B \right) \cdot \left(R_{c,j}^{carry} - R_c^{depo} \right) \approx \sum_c \left({}^b w_c^P - {}^b w_c^B \right) \cdot \left(\overline{R_c^{carry}} - R_c^{depo} \right), \text{ and}$$

$$-\sum_c \sum_j \left({}^b w_c^P KRD_{c,j}^P - {}^b w_c^B KRD_{c,j}^B \right) \cdot \Delta y_{c,j} \approx -\sum_c \left({}^b w_c^P OAD_c^P - {}^b w_c^B OAD_c^B \right) \cdot \overline{\Delta y_c}$$

Here $\overline{R_c^{carry}}$ and $\overline{\Delta y_c}$ represent the average curve carry return and average yield change in each curve.

For example, the average euro yield is about 3.1%, which implies a carry-over deposit return[4] of 23.4 bp over the attribution period (one month). The contribution of the euro market value overweight to curve carry outperformance can be estimated as the market value overweight times the average carry over deposit return, i.e., (34.4% – 29.8%) × 23.4 bp = +1.1 bp. The contribution of the euro duration overweight to curve change outperformance can be estimated as the product of the duration overweight times the negative of the average yield change, i.e., (2.33 – 1.88) × (–28 bp) = –12.6 bp. This is close but not equal to the reported –13.1 bp because of the simplification above as well as the compounding effects over the attribution period. A detailed key-rate level report can be used to gain more insight into the numbers. It is interesting to note that the portfolio market weights in some currencies reported here are different than the ones reported in Exhibit 72-3. In particular, the U.S. dollar weight was 24.1% in Exhibit 72-3 but is now reported as 21.6%; the yen weight was 34.5% but is now reported as 37.0%; the euro and British pound weights are unchanged. This is because the market value of the JPY/USD forwards has been excluded from the local analysis

4. Euro deposit rate is about 0.3% during the period. Its monthly carry over deposit return can be estimated as (3.1% – 0.3%) / 12.

EXHIBIT 72-4

since such positions are considered FX hedges. The contribution of the cash balance effect is captured in the *hedging effects* category of outperformance as discussed above.

If we analyze the performance by currency as in Exhibit 72-4, we may penalize the fund manager unfairly for the large negative outperformance coming from the Euro exposure. An alternative way to analyze the global curve outperformance is to use a reference curve, as presented in Eqs. (72-14), (72-16), (72-18), and (72-20). This is done in Exhibit 72-5, using the U.S. dollar yield-curve as the reference curve. Although the total curve outperformance remains the same, the breakdown among currencies has changed.

For example, Japanese yen now contributes negatively to the curve carry outperformance. Although the yen has a positive carry over deposit return of +9.1 bp over the month, this return is lower than the U.S. dollar (reference) carry over deposit return of +20.4 bp. Therefore, an overweight in a relatively underperforming currency results in an underperformance. The global carry outperformance can be approximated with the formula

$$\left(\sum_c {}^b w_c^P - \sum_c {}^b w_c^B\right)\cdot\left(\overline{R_{ref}^{carry}} - R_{ref}^{depo}\right)$$

This approximation is always zero since the sum of the weights over all curves of an (unleveraged) portfolio or benchmark is equal to 1. However, since the actual calculation is using exposures at each key-rate point, the exact global carry outperformance may be non-zero.

The euro shows now a *positive* contribution to the curve change outperformance due to better performance relative to the U.S. curve. Its contribution to curve change outperformance is now estimated as – (2.33 – 1.88) × (28 bp – 35 bp) = +3.2 bp, close to the +3.1 bp reported. As concluded before, the manager decision regarding global curve positioning had an overall positive performance for the portfolio during this period. The U.S. curve—being the reference curve—does not contribute to outperformance. The global duration contribution can be estimated using the formula $-(OAD^P - OAD^B)\cdot\overline{\Delta y_{ref}}$, i.e., – (6.46 – 6.47) × 35 bp = +0.3 bp, close to the +0.1 bp reported.

After the yield-curve outperformance has been accounted for, the excess of yield-curve return is split into allocation and management components. Although in general a different set of markets can be used, in this example we will use the same G4 markets used for the curve decomposition. Exhibit 72-6 shows the details of this breakdown. Overall, the allocation of exposure to the four markets has contributed positively (+3.4 bp) with the exposure to the euro market contributing most of it (+2.3 bp). This number can be approximated as the overweight of the euro market times the excess return of the euro market in the benchmark relative to the overall benchmark, i.e., 4.6% × (67.9 bp – 22.5 bp) = +2.1 bp. On the other hand, the local management of excess to curve return in the euro market has not been successful, contributing –9.8 bp to outperformance. The approximate calcu-

lation yields 34.4% × (40.5 bp − 67.9 bp) = –9.4 bp. This underperformance can be understood by looking at more detailed issuer-level reports as presented in the previous chapter,. In this example, it turns out that the lower-rated EU countries experienced much bigger spread tightening during the period. The concentration in the strongest economies in the region may reduce the portfolio long-term risk, but during this particular period contributed to loss of performance.

DERIVATIVES AND LEVERAGE

Derivative instruments are widely used across asset classes as both hedges and means to express market views. Their payoffs are tied to changes in the values of underlying securities, and their market values do not generally represent the size of the actual exposure to risk factors. In this section, we discuss how a performance attribution model may handle derivative instruments in order to maintain the intuitive and meaningful nature of the results.

Returns and Basis

Returns of derivative instruments can be difficult to measure. The market value of a contract is typically small (or sometimes zero) compared with its notional exposure, and the standard definition of return—profit/loss (P&L) divided by market value—can result in extremely large (or even infinite) values. For example, the market value of instruments that are marked-to-market daily, such as Treasury futures, is guaranteed to be zero at the end of the day, resulting in a theoretically infinite return. To maintain the notion of return as a P&L per unit of investment, we seek to use a denominator that represents the size of the position in terms of its exposure. We refer to this quantity as the "return basis" or simply "basis." One should define an appropriate return basis for each derivative type of interest. Usually, the basis is set equal to the notional amount, although in many cases special rules are used to define the basis in a bond-equivalent way.

To complicate the issue of derivatives further, the standard methodology of multi-period return compounding cannot be applied. Consider the following definition of single- and multi-period returns, where PL_t and R_t are the P&L and return over the period (t–1, t). The portfolio return is given by

$$R_t = \frac{PL_t}{MV_{t-1}}$$

And the multi-period return is:

$$R = \left(\prod_{t=1}^{T} \left(1 + R_t\right) \right) - 1$$

By using market value as a basis for the return and compounding it with the above formula, we get an intuitive relationship between the market values at t = 0 and t = T, and the return over the period (0, T).[5]

$$MV_T = MV_0\left(1+R\right)$$

Changing the basis to a quantity that is not proportional to the market value will annul this property. This is more evident when returns are large. As an exaggerated example, consider a futures contract that is marked-to-market daily and therefore always has zero market value. A reasonable basis for returns for a position in this contract is the notional amount invested. Suppose the notional amount is \$1,000 and that over two days, the contract produces a mark-to-market P&L of –\$500 and \$1,000, respectively. Using the notional amount as the basis of returns, the returns for the two days are –50% and +100%, respectively. Using the chain rule to compound returns yields zero return over the two days: $(1-50\%)\times(1+100\%)-1=0\%$. Obviously, this is not consistent with the positive P&L of \$500 produced over the two days. Such effects are always present when compounding returns using a basis that is different from the market value of the position; however, their effect is much smaller when the magnitude of returns is small. To avoid such nonintuitive results, one should make appropriate adjustments to the compounding of returns of derivative securities—something out of the scope of this chapter.

Returns for Portfolios and Sectors Containing Derivatives

The return of each individual derivative contract is defined using its basis as described above. However, in typical portfolios, these contracts coexist with cash securities. When we analyze partitions of the portfolio, such as sector or rating, that contain both cash and derivative securities, it is still typical to use market value as the denominator for all returns and weights.[6] Nevertheless, the presence of the derivatives imposes some changes into the analysis.

Let's define the leverage ratio for each security, β_i, to be the basis divided by the market value of the security. Then the leveraged weight of the security is the product of the market value weight and the leverage ratio, $w_i\,\beta_i$. The return of the portfolio or sector can then be written as the leveraged weighted sum of the deleveraged return of each security:

$$R^P = \sum_i \frac{PL_i^P}{MV^P} = \sum_i \frac{MV_i^P}{MV^P}\frac{basis_i^P}{MV_i^P}\frac{PL_i^P}{basis_i^P} = \sum_i w_i^P \beta_i^P R_i^P$$

5. We assume that the portfolio has no significant cash flows. When such cash flows do occur, the above formula does not hold.

6. Net (or gross) basis and gross market value could also be used as the denominator for the entire portfolio when analyzing highly leveraged or long-short strategy funds.

Although this transformation does not change the return, notice that the leveraged weights are no longer constrained to sum to 1 when derivatives are present in the portfolio.

$$\sum_i w_i \beta_i \neq 1$$

Therefore, when we seek to explain the contribution of each instrument to the security selection outperformance of each bucket (the last step of the top-down decomposition—see the previous chapter.), derivatives give rise to an additional term of outperformance that comes from the implicit leverage they introduce. The example below illustrates this issue.

Example: Leverage from Derivatives and Security Selection Outperformance
Consider a bucket with a single credit security A experiencing excess of curve return of +10%, while the corresponding benchmark bucket has two equally weighted securities, the one in the portfolio A and another one B returning 0%. The total return for that bucket in the benchmark is therefore +5%. Let us also assume that the market value weight of this bucket in the portfolio is 20%; therefore, its contribution to security selection would typically be calculated as 20% × (10% – 5%) = 1.0%. The contribution of security A to security selection is calculated as 20% × (100% – 50%) × (10% – 5%) = 0.5%, and the one of security B is 20% × (0% – 50%) × (0% – 5%) = 0.5%.

Now assume that the portfolio also contained a short protection credit default swap on the issuer of bond A with a return basis equal to the market value of A, essentially doubling the exposure to the issuer of A. Let us assume that the default swap is at-the-money, i.e., its market value is zero, and that it also experiences a return of +10% (using notional as the return basis). Since the market value of the portfolio bucket remains the same but its P&L doubles, the return of the sector is now reported as +20%, and the security selection term becomes 20% × (20% – 5%) = 3.0%. Notice that the market value weight of the bond remains 100% and that the default swap also has a weight of 100% (return basis over market value of the bucket). Bonds A and B contribute to security selection 0.5% exactly as before. The default swap contributes 20% × (100% – 0%) × (10% – 5%) = 1.0%. The contributions of the three securities to security selection sum to 2.0%, leaving 1.0% of security selection unexplained.

This comes from the leverage introduced to the bucket. Indeed, the sum of securities weights in the portfolio is 200%, whereas in the benchmark it is 100%. This causes an outperformance of 20% × (200% – 100%) × 5% = 1.0%, completing the decomposition of security selection. This term was introduced as the "top-level exposure" for the excess return model in Chapter 71 (see Eq. (71-6)).

Typically, in the presence of derivatives, this top-level term can be reported as a separate line item for each bucket–bucket leverage, and folded into the security selection term. Alternatively, it can be reported as leverage at the portfolio level.

A General Framework for Leverage

Leverage complicates portfolio returns calculations and comparison to the benchmark. Furthermore, there are different means to achieve leverage, and the decision to employ it can occur at any level of the portfolio management decision structure. For instance, cash borrowing can be used to leverage the entire portfolio, while derivatives can be used to leverage specific sectors. The latter case can be further distinguished into a decision made by an asset allocator or by a sector manager. Below, we outline an analytical way to account for leverage in a consistent framework with the one discussed in Chapter 70.

We expand the concept of leverage ratio as introduced before and apply it to the entire portfolio. We assume that a "funded" market value—generally different from the actual market value—can be defined for the portfolio, partition buckets, and individual securities, and serve as the *basis* for the calculation of unleveraged returns. The ratio of the returns basis to actual market value is the leverage ratio of the portfolio.

$$R^P_{leveraged} = \frac{basis^P}{MV^P} \cdot \frac{PL^P}{basis^P} = \beta^P R^P$$

We can also recursively break down the portfolio return into the contributions of its various sectors by appropriately defining the leverage ratio of each sector:

$$R^P_{leveraged} = \sum_s \frac{PL^P_s}{MV^P} = \sum_s \frac{MV^P_s}{MV^P} \cdot \frac{basis^P_s}{MV^P_s} \cdot \frac{PL^P_s}{basis^P_s} = \sum_s w^P_s \beta^P_s R^P_s$$

Using similar terminology for the benchmark, the total leveraged outperformance can be expressed as a function of leverage ratios and unleveraged returns as:

$$R^P_{leveraged} - R^B_{leveraged} = \beta^P R^P - \beta^B R^B = \sum_s w^P_s \beta^P_s R^P_s - \sum_s w^B_s \beta^B_s R^B_s$$

We will now consider the different ways to break down the total outperformance into contributions from asset allocators and sector managers. It is worthwhile to note that when leverage is allowed, there is no limit to how much exposure managers can allocate to sectors or securities. Consequently, it no longer makes sense to compare sector returns against a hurdle rate (as discussed in Chapter 70) to determine the contribution from asset allocation decisions.

Separate Allocation of Market Weight and Leverage of Each Sector

In this case, each sector is given a market value budget, but sector managers are free to take leverage within their sectors. Separate agents determine the market value allocation and the leverage in each sector. The simple asset allocation/sector management equations can be readily applied in this case. The comparison of sector returns of the portfolio and the benchmark occurs on a leveraged basis. In this case, the outperformance from leverage decisions is embedded in the sector management term. Specifically, the asset allocation would come as

$$\sum_s \left(w_s^P - w_s^B\right) \cdot \beta_s^B R_s^B \tag{72-22}$$

And the sector management as

$$\sum_s w_s^P \cdot \left(\beta_s^P R_s^P - \beta_s^B R_s^B\right) \tag{72-23}$$

Allocation of Total Exposure to Sectors

Alternatively, leverage can be determined by the asset allocator instead of the sector managers. In this case, a single agent decides the total exposure[7] to the unleveraged return of each sector. Once again, the asset allocation/sector management equations can be applied, but we now need to use total exposure instead of market value as the allocation weight. In this case, the outperformance from leverage decisions is embedded in the asset allocation term. The asset allocation is

$$\sum_s \left(w_s^P \beta_s^P - w_s^B \beta_s^B\right) \cdot R_s^B \tag{72-24}$$

While the sector management comes as

$$\sum_s w_s^P \beta_s^P \cdot \left(R_s^P - R_s^B\right) \tag{72-25}$$

In general, we can assume that leverage decisions are made at both the portfolio and the sector levels. A top-level manager may determine the total portfolio leverage (relative to the benchmark), and an asset allocator may subsequently determine the total exposure to each sector. Therefore, if total leverage is determined at the portfolio level, then the allocation of total exposure to each sector is constrained by the portfolio leverage decision and must be measured relative to that. Instead of using the absolute total exposure as the allocation weight, we now need to use the relative total exposure (total exposure divided by the portfolio/benchmark leverage). We also need to use a hurdle return, as exposure at the sector level is partially constrained.

In this scenario the outperformance decomposition has some extra terms, as shown below. The asset allocation outperformance can be derived as

$$\beta^P \sum_s \left(\frac{w_s^P \beta_s^P}{\beta^P} - \frac{w_s^B \beta_s^B}{\beta^B}\right) \cdot \left(R_s^B - R^H\right) \tag{72-26}$$

7. The total exposure is defined here as market weight times leverage.

While the sector management comes as

$$\sum_s w_s^P \beta_s^P \cdot \left(R_s^P - R_s^B\right) \tag{72-27}$$

The top-level leverage is

$$\left(\beta^P - \beta^B\right) \cdot R^H \tag{72-28}$$

If we do not assume that leverage aggregates linearly, i.e., generally $\beta^P \neq \sum_s w_s^P \beta_s^P$ and $\beta^B \neq \sum_s w_s^B \beta_s^B$ in order to keep the decomposition complete we need to add an additional term, that we call "diversification."

$$\left(\sum_s w_s^P \beta_s^P - \beta^P \frac{\sum_s w_s^B \beta_s^B}{\beta^B}\right) \cdot R^H \tag{72-29}$$

If we assume no leverage in the benchmark, the diversification term becomes

$$\left(\sum_s w_s^P \beta_s^P - \beta^P\right) \cdot R^H$$

Moreover, this term is zero if the leverage is aggregated linearly; that is,

$$\beta^P = \sum_s w_s^P \beta_s^P, \quad \beta^B = \sum_s w_s^B \beta_s^B$$

However, there are situations where we may not want the leverage to aggregate linearly. As an example, suppose that betas are defined based on risk. Then, if the different sectors are not perfectly correlated, the beta of the portfolio would tend to be smaller than the sum of the individual sector betas. This is due to the well-known risk diversification effect, hence the name for this term. In this case, the leverage creates a diversification effect with positive returns for our portfolio as long as the hurdle rate return is positive.

Handling leverage is a generalization of the top-down decomposition algorithm described in Chapter 70, where unleveraged returns are the factor returns, leveraged weights are the factor loadings, and we assume linear aggregation of leverage (so that the diversification term vanishes). This analysis is also similar to the one regarding the decomposition of the spread related outperformance, described in Chapter 71.

Special Handling of Certain Derivative Types

Often, derivatives are used to manage a specific type of risk exposure and are not meant to participate in the general asset allocation/security selection portfolio management framework. We already encountered this issue earlier in this chapter, while discussing how to handle the role of currency derivatives as FX hedging instruments. A similar situation arises with interest-rate derivatives as instruments of managing interest-rate risk only. In both cases we have to account for the return that is not tied to their primary hedging function and for the implicit cash allocation that occurs when derivative instruments used as hedges acquire market value between rebalancing dates. On the other hand, credit derivatives are typically used along with cash instruments to manage exposures to sectors and issuers; therefore, they do participate in asset allocation and security selection. Depending on the portfolio and level of analysis, we may want all these different effects to be captured and reported separately. Below, we discuss in more detail issues arising from the handling of common derivatives and the treatment typically adopted.

Currency Derivatives

FX forwards are typically used as FX hedging instruments. In this case, their return and outperformance contributions should not be allowed to affect the local (excess of FX) outperformance analysis. As discussed previously in this chapter, the easiest way to achieve this is to remove them completely from the analysis of non-FX outperformance. However, removing FX hedges from the local analysis introduces two side effects that have to be explicitly accounted for. First, the non-FX return of FX hedges must be recorded. Such return can be non-negligible in periods of market crisis or whenever hedges with longer tenors are being used. Second, since FX hedges are not being rolled daily, they accumulate market value, which represents an allocation to cash, if positive, or leverage, if negative. This effect—called earlier the "FX hedging cash balance effect"—contributes to outperformance and should be appropriately recorded.

Interest Rate Derivatives

Derivatives designed to hedge or gain exposure to interest rate factors are typically overlays onto a portfolio after the core positions are chosen. These instruments, such as government bond futures and interest rate swaps, typically affect the curve return of the portfolio but have little effect on the excess return over the yield-curve. Typically, they are used in portfolios that lend themselves to attribution models that treat curve outperformance separately (e.g., the excess return model discussed in Chapter 71). In these models, interest rate derivatives should only contribute to the curve outperformance, which is a common factor, and they should be removed entirely from the decomposition of the allocated factors. Two portfolios identical except for the use of interest rate derivatives should have the same asset allocation and security selection returns.

Similar to currency hedges, the removal of interest rate derivatives from the asset allocation/security selection outperformance analysis introduces a cash-balance effect if the market value of such derivatives is non-zero. Indeed, a positive market value indicates an implicit allocation to cash, whereas a negative market value indicates implicit borrowing and, therefore, leverage. Further, exchange-traded derivative instruments may incur return that cannot be explained by their curve exposures. For example, Treasury futures frequently trade at a spread to their theoretical fair value. Changes in this spread result in return that cannot be explained by interest rate movements. However, this return should be accounted for and reported as a side effect of interest rate hedging.

Credit Derivatives

In contrast to currency and interest rate derivatives, credit default swaps (CDS), credit index default swaps (CDX or iTraxx), and total return swaps (TRS) are primarily used to manipulate exposure to excess (over curve) return factors. Typically, these instruments are included in the regular asset allocation/security selection decomposition. Single issuer credit default swap instruments have small interest-rate exposure that does contribute to the yield-curve outperformance, but their primary exposure is to the credit factor of the underlying issuer. The performance of credit default swap indices should be explained by exploding them into their single-issuer constituents. The constituents are then included in the asset allocation/security selection decomposition, ensuring that the correct weights and returns are used to reflect the actual exposure to each partition bucket. The basis of returns for credit derivatives is not their market value. As a result, they generate bucket leverage, as discussed previously.

FROM THEORY TO PRACTICE

In order to be of any practical use, a performance attribution system must deal with a significant number of special situations that arise in day-to-day portfolio management. Such issues include missing security prices or analytics, bad prices or analytics, intra-period transactions, settlement conventions, pricing discrepancies between the portfolio and its benchmark, and so on. Below, we discuss some of these issues.

Return and Outperformance Compounding[8]

Multi-period arithmetic total return is compounded by taking the product of the single-period total returns:

$$R = \left(\prod_{t=1}^{T} \left(1 + R_t\right) \right) - 1$$

As discussed in Chapter 70, a general framework of performance attribution begins with the splitting of a single-period total return into the contributions

8. For an introduction to multi-period attribution and compounding see Chapter 70.

of various factors, $R_t = \sum_k \alpha_{k,t} f_{k,t}$. This leads to the question of how the return splits should be compounded so that the sum of the compounded return splits remains equal to the compounded total return. This is necessary to satisfy the additivity and completeness requirements of attribution.

One way to accomplish this is the following: Let us designate with $\hat{R}_k$ the multi-period compounded factor return. Setting $\hat{R}_k$ equal to the single-period factor return, $f_{k,t}$, scaled by the compounded portfolio value at the beginning of the period, i.e.,

$$\hat{R}_k = \sum_{t=1}^{T} \alpha_{k,t} f_{k,t} \prod_{s=1}^{t-1} \left(1 + R_s\right), \qquad \text{where} \qquad \prod_{s=1}^{0} \left(1 + R_s\right) \equiv 1 \tag{72-30}$$

guarantees the additive decomposition of total multi-period return, i.e., $R = \sum_k \hat{R}_k$. This decomposition algorithm is fairly straightforward and has the properties of additivity and completeness, but what about fairness?

Consider a simple example with two factors and two periods. Let us assume that both factors contribute 20% return, but factor A does so in the first period and has zero return in the second period, while factor B has zero return in the first period and 20% return in the second period. The total portfolio return is therefore (1 + 20%) × (1 + 20%) – 1 = 44%. According to the algorithm above, the contribution of the first factor is not scaled because it occurs in the first period and remains at 20%; the contribution of the second factor is scaled by the portfolio value at the end of the first period (1.20) so it becomes 24%. Although one could argue that the decomposition is unfair—as it favors the second factor which contributed returns after the first factor—the notion that later returns and contributions can be affected by the earlier performance of the portfolio as a whole is generally accepted as a fair practice.

In addition to the total return and return splits compounding, any multi-period attribution algorithm also needs to address the compounding of outperformance. In the context of simple factor-based performance attribution models the above algorithm can be readily applied:

$$R^P - R^B = \sum_k \left(\hat{R}_k^P - \hat{R}_k^B\right)$$

However, in the context of a general attribution model where the categories to which outperformance is decomposed to may depend both on the portfolio and the benchmark (e.g., asset allocation or security selection), such simple decomposition is not possible and more complex algorithms must be used.

Since single-period performance attribution provides a complete, additive, and fair decomposition of single-period outperformance, most compounding algorithms seek to define scaling coefficients for each period, such that the sum of the scaled single-period outperformance is equal to the total multi-period outperformance.[9]

$$R^P - R^B = \sum_t \beta_t \left(R_t^P - R_t^B\right)$$

Once β_t is determined, it can be used to scale every outperformance component (e.g., yield-curve, asset allocation, security selection, etc.) because of the additivity and completeness properties of single-period performance attribution.

One commonly used approach in practice is the optimized linking coefficient approach.[10] The basic idea behind this approach is to seek coefficients that avoid extreme values under most scenarios. Indeed, if not carefully defined, such coefficients can become zero or attain very high values distorting the outperformance decomposition and making it unfair. The value of β_t in the optimized-linked method is determined as follows:

$$A = \frac{\left(R^P - R^B\right)/T}{\left(1 + R^P\right)^{1/T} - \left(1 + R^B\right)^{1/T}}$$

$$C = \frac{R^P - R^B - A\sum_{t=1}^{T}\left(R_t^P - R_t^B\right)}{\sum_{t=1}^{T}\left(R_t^P - R_t^B\right)^2}$$

$$\beta_t = A + C\left(R_t^P - R_t^B\right)$$

Transactions

Return and outperformance calculations require special treatment of transactions. Security transactions that usually settle on a forward basis create “intra-period” returns as well as “unsettled” positions. It is important to recognize intra-period return separately because it does not participate in the decompositions previously discussed. It is also important to make the distinction between settled and unsettled positions because only the settled positions earn carry.

Intra-Day Return

Daily attribution models compound returns and outperformance using end-of-day market-closing prices. However, the models should allow users to enter transactions that occur during the day at the actual transaction prices, which can be quite

9. The exact nature of the algorithm that should be used to link the results of a multi-period attribution has been the subject of intense debate in the performance attribution literature. The entire Fall 2002 issue of the *Journal of Performance Measurement* was devoted to this topic.

10. Jose Menchero, “An Optimized Approach to Linking Attribution Effects over Time,” *Journal of Performance Measurement* (Fall 2000), pp. 36–42.

different from the closing prices of the traded security used to calculate daily returns. This flexibility guarantees that the returns of the portfolio, including trading activities, are captured accurately. The difference between the trade price and the closing price should be captured and reported separately as "Trading" return. Further, the return contribution from intra-day trading activities, which is not captured by the end-of-day portfolio snapshots, must also be accounted for and reported as "Intra-Day Trading" outperformance.

Unsettled Positions

Most security transactions settle on a forward basis, i.e., both cash and the security are exchanged some days in the future. For example, corporate securities transactions settle after three business days (T+3), while most government securities settle after one day (T+1). Certain mortgage-backed securities (TBAs) have special settlement rules as they settle on a specific day each month. A comprehensive attribution model should allow transactions to settle on any forward date.

While buyers of a security are exposed to its clean price fluctuations (market risk) immediately after the transaction, they do not begin earning the coupon return of the security (more accurately, the yield or time return of the security r^{carry}) until after the settlement date. Instead, they keep earning the yield on the cash (r^{cash}) that they have promised to pay on the settlement date. Therefore, an unsettled position in a portfolio is earning a return equal to $r^{cash} + r^{price}$, while the same security in an index, always settled, is earning $r^{yield} + r^{price}$. The return $(r^{cash} - r^{yield}) \cdot \Delta t$, where Δt is the time to settlement, constitutes real outperformance (usually negative) that must be accounted for. Conversely, when the portfolio sells the position, it is earning the security yield (instead of cash) until the sell settlement date, making back any yield lost when the security was bought. These effects should be captured by the outperformance algorithm and reported for each model as carry outperformance.

Handling Inconsistent or Missing Data

Security prices used to compute returns of benchmark indices may be different from what portfolio managers use to mark their positions.[11] For any outperformance decomposition to be meaningful, it is important for the price and, hence, the return of the same security to be consistent in both universes. In most cases, managers would want to use their own prices to compute their portfolio returns. In general, we should use the security returns from the portfolio by default. However, since the total return of the benchmark index typically needs to be consistent with the published number, the algorithm should allow for the pricing difference effect to be reported as a separate source of outperformance.

When there are missing prices during the attribution period, the system can either exclude the securities from the analysis entirely or imply prices if that is

11. This is not uncommon for less liquid securities.

deemed reasonable. During the period with missing prices, one can use last available analytics and market changes to imply prices so that daily outperformance can be computed. This approach is particularly useful if prices for the beginning and end of the period are available so that the correct return over the attribution period is known.

KEY POINTS

- Multi-currency portfolios add an additional layer of complexity to the portfolio management structure. An attribution algorithm normally needs to decompose the global total outperformance into FX and local market allocations, as well as local management.
- Being able to accurately separate the performance due to active foreign-exchange (FX) positions from that due to the hedging effects is a complex but particularly important task in any multi-currency attribution system.
- Factor-based local market allocation, such as duration-based global curve allocation, quantifies better the risk and return in a particular market than the market-value weighted local markets allocation.
- Derivatives change the nature of the basis used to define returns. They often require special treatment in order to obtain intuitive and meaningful attribution results.
- Return and outperformance compounding is an important task in order to ensure the additivity and completeness properties for any multi-period attribution.
- A complete attribution system should be able to handle intra-day transactions, unsettled positions as well as missing and inconsistent prices.

INDEX

ABOUT THE EDITOR

Frank J. Fabozzi is editor of *The Journal of Portfolio Management* and co-editor/cofounder of *The Journal of Financial Data Science*. He is Professor of Finance at EDHEC Business School. Over the past 35 years, he has held various professorial positions at MIT, Yale, Princeton, Carnegie Mellon University, and New York University. He is a trustee of the BlackRock fixed income complex. He has authored more than 120 books and more than 200 articles in peer-reviewed journals. He is the CFA Institute's 2007 recipient of the C. Stewart Sheppard Award and the CFA Institute's 2015 recipient of the James R. Vertin Award. He was inducted into the Fixed Income Analysts Society Hall of Fame in November 2002. He has earned the designations of Chartered Financial Analyst (CFA) and Certified Public Accountant (CPA). His *Conversations with Frank Fabozzi* for Portfolio Management Research is a fortnightly series of interviews of some of the investment industry's most renowned practitioners. He received his BA and MA in economics in 1970 from The City College of New York where he was elected to Phi Beta Kappa and received a PhD in economics in 1972 from the City University of New York. In 1994 he was awarded an Honorary Doctorate of Humane Letters from Nova Southwestern University.

ABOUT THE ASSISTANTS TO THE EDITOR

Francesco A. Fabozzi is a doctoral student in data science at Stevens Institute of Technology. He is the managing editor of *The Journal of Financial Data Science* and has worked as a research associate at NYU's Courant Institute in the Department of Mathematical Finance. He is the Associate Director of Data Science for the CFA Institute's Research Foundation and serves on the Curriculum Board of the Financial Data Professionals Institute (FDP Institute). He interned at AQR in the firm's machine learning group. Francesco is the coauthor of *The Fundamentals of Institutional Asset Management* and *Asset Management: Tools and Issues*. He has assisted in the authoring of *Global Financial Markets*, and his research has been published in the *Journal of Financial Econometrics* and *The Journal of Portfolio Management.* He earned a BA in economics in 2018 from Princeton University and an MS in financial analytics in 2019 from Stevens Institute of Technology.

Steven V. Mann is a Distinguished Professor Emeritus at the Moore School of Business at the University of South Carolina, where he was a member of the finance faculty for 31 years. He is the coauthor of four books (*Introduction to Fixed Income Analytics, Measuring and Controlling Interest Rate and Credit*

Risk, Global Money Markets, and *Floating Rate Securities*). His articles on fixed income securities and derivatives have appeared in the *Journal of Business*, *Journal of Banking & Finance*, *Journal of Corporate Finance*, *Journal of Derivatives*, and *Journal of Portfolio Management*. Winner of more than 20 teaching awards, he was a well-known lecturer at dealer firms and banks for more than two decades. He earned a doctorate in finance from the University of Nebraska and a master's and undergraduate degree from the University of Missouri.
