Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

*Dr. Jane Case-Smith was soft spoken, thoughtful, and a brilliant scholar,
who consistently reinforced respect for children and their families.*

*She developed personal and professional relationships with each author, helping them
to produce chapters that would lead students, practitioners, and educators in their best practice.*

*Jane also believed strongly in using science as a foundation for intervention,
while never overlooking the art of therapy.*

*Her ability to integrate these two important aspects of occupational therapy will forever influence
the profession and help many children and their families participate in daily occupations.*

Her spirit is infused throughout the pictures and words of this book.

I dedicate this book to my friend Dr. Jane Case-Smith.

Preface

Organization

The current edition is organized into four sections to reflect the knowledge and skills needed to practice occupational therapy with children and to help readers apply concepts to practice. The first section describes foundational knowledge and includes chapters on theories and practice models, child and adolescent development, and family-centered care. In [Chapters 1 and 2](#) Dr. Case-Smith describes theories of child development and learning and specific models of practice used in occupational therapy. These theories and models of practice range from those that originated in psychology, education, and basic sciences to ones that were proposed and developed by occupational therapy scholars and practitioners. With this theoretic grounding, children's development of occupations is presented in two chapters: [Chapter 3](#) explains occupational development in infants, toddlers, and children, and [Chapter 4](#) describes how occupations continue to emerge and mature in youth and young adults. [Chapter 5](#) describes families, illustrates family occupations across the life span, discusses experiences of families who have children with special needs, and explains the importance of family-centered care.

The second section of the book begins with an explanation of the use of standardized tests, including how to administer a standardized test, score items, interpret test scores, and synthesize the findings. [Chapters 7 through 20](#) cover a variety of intervention approaches (e.g., motor control/motor learning, sensory integration, assistive technology). The authors describe interventions to target performance areas (e.g., hand skills) and occupations (e.g., feeding, activities of daily living, play, social participation). The chapters explain both the theory and science of occupational therapy practice and discuss practical issues that frequently occur in practice. Together these chapters reflect the breadth and depth of occupational therapy with children and adolescents.

The fourth section ([Chapters 21 through 30](#)) of the book describes practice arenas for occupational therapy practice with children. These chapters illustrate the rich variety of practice opportunities and define how practice differs in medical versus education systems and institutions. Only by understanding the intervention context and the child's environments can occupational therapists select appropriate intervention practices.

[Chapters 25 through 30](#) provide readers with intervention strategies for specific populations. For example, [Chapter](#)

[25](#) examines factors influencing a child's transition to adulthood. Other chapters illustrate how practitioners help children with visual impairments or blindness, autism, cerebral palsy, hand conditions, or trauma-induced conditions engage in occupations.

Distinctive Features

Although the chapters contain related information, each chapter stands on its own, such that the chapters do not need to be read in a particular sequence. Each chapter begins with key questions to guide reading. Case reports exemplify concepts related to the chapter and are designed to help the reader integrate the material. Research literature is cited and used throughout. The goal of the authors is to provide comprehensive, research-based, current information that can guide practitioners in making optimal decisions in their practice with children.

Distinctive features of the book include the following:

- Research Notes boxes
- Evidence-based summary tables
- Case Study boxes

Ancillary Materials

The *Occupational Therapy for Children and Adolescents* text is linked to an Evolve website that provides a number of learning aids and tools. The Evolve website provides resources for each chapter, including the following:

- Video clips with case study questions
- Additional case studies with guiding questions to reinforce chapter content
- Learning activities
- Multiple choice questions for students and faculty
- Resources (such as forms and handouts)
- Glossary

The Evolve learning activities and video clip case studies relate directly to the text; it is hoped that readers use the two resources together. In addition, readers are encouraged to access the Evolve website for supplemental information.

Acknowledgments

We would like to thank all the children who are featured in the video clips and case studies:

Adam	Emily	Luke	Peggy
Ana	Emily	Matt	Samuel
Annabelle	Faith	Micah	Sydney
Cameras	Isabel	Nathan	Teagan
Christian	Jessica	Nathaniel	Tiandra
Christina	Jillian	Nicholas	William
Eily	Katelyn	Paige	Zane
Ema			

A special thank you to the parents who so openly shared their stories with us:

Charlie and Emily Adams	Lori Chirakus	Sandra Jordan	Ann Ramsey
Robert and Carrie Beyer	Joy Cline	Joanna L. McCoy	Teresa Reynolds-Armstrong
Freda Michelle Bowen	Sondra Diop	Maureen P. McGlove	Tuesday A. Ryanhart
Nancy Bowen	Lisa M. Grant	Jill McQuaid	Julana Schutt
Kelly Brandewe	Ivonne Hernandez	Stephanie L. Mills	P. Allen Shroyer
Ernesty Burton	Shawn Holden	David J. Petras	Douglas Warburton
Ruby Burton	Luann Hoover	Theresa A. Philbrick	

We are very appreciative of the siblings and buddies who agreed to help us out:

Aidan	Robert
Lori	Todd and Keith
Megan	Tommy, Owen, and Colin

We thank all the therapists and physicians who allowed us to videotape their sessions and provided us with such wonderful examples:

Chrissy Alex	Katie Finnegan	Lisa A. King	Julie Potts
Sandy Antoszewski	Karen Harpster	Dara Krynicki	Ann Ramsey
Mary Elizabeth F. Bracy	Terri Heaphy	Marianne Mayhan	Suellen Sharp
Amanda Cousiko	Katherine Inamura	Taylor Moody	Carrie Taylor
Emily de los Reyes			

A special thanks to Matt Meindl, Melissa Hussey, David Stwarka Jennifer Cohn, Stephanie Cohn, and all the authors who submitted videotapes. Thank you to Emily Krams, Alicen Johnson, Brittany Peters, Katherine Paulaski, Kate Loukas, Scott McNeil, Jan Froehlich, MaryBeth Patnaude, Molly O'Brien, Keely Heidtman, Greg Lapointe, Caitlin Cassis, Judith Cohn, Jazmin Photography, and Michelle Lapelle. A special thanks to Mariana D'Amico, Peter Goldberg, and Carrie Beyer for all their expertise with videotaping. Jolynn Gower, Penny Rudolph, Tracey Schriefer, and Katie Gutierrez were instrumental in developing and completing this text and were

a pleasure with whom to work. Jane O'Brien would like to thank her family—Mike, Scott, Alison, and Molly—for their continual support. She would also like to thank her colleagues and students at the University of New England, all the authors, and Jane Case-Smith.

Jane Case-Smith thanks her family—Greg, David, and Stephen—for their support and patience. She also thanks her colleagues in the Division of Occupational Therapy, The Ohio State University, for their support. We both thank all the authors for their willingness to share their expertise and their labor and time in producing excellent chapters.

Contents

SECTION I Foundational Knowledge for Occupational Therapy for Children

1 An Overview of Occupational Therapy for Children, 1

Jane Case-Smith

CHAPTER

1

An Overview of Occupational Therapy for Children

Jane Case-Smith

KEY TERMS

Child-centered and family-centered practice	Therapeutic relationships
Strength-based approaches	Occupation-based models
Inclusion, integrated services, and natural environments	Ecologic models
Cultural competence	Assistive technology
Evidence-based practice	Environmental modification/universal access
	Consultation, coaching, and education

GUIDING QUESTIONS

1. Which concepts describe occupational therapy services for children and families?
2. How do occupational therapists use individualized, child-centered, and family-centered interventions and strength-based models?
3. How do occupational therapists use inclusive and integrated practices?
4. How do occupational therapists embrace diversity and value cultural differences?
5. How do occupational therapists use research evidence and science-based reasoning to make intervention decisions?
6. How does comprehensive evaluation guide clinical reasoning and lead to efficacious interventions?
7. What are the elements of the intervention process, and how do occupational therapy practitioners combine these elements to improve performance and participation of children and youth?
8. How are ecologic models that include task adaptation, environmental modification, and consultation/coaching used to promote the child's full participation in natural environments?

Occupational therapy practitioners develop interventions based on assessment of the occupations in which the child or youth engages, understanding of his or her natural contexts, and analysis of performance. When evaluating a child's performance, the occupational therapist determines how performance is influenced by impairment and how the environment supports or constrains performance. The occupational therapist also identifies discrepancies between the child's performance and

activity demands and interprets how to overcome or minimize those discrepancies. Analysis of the interrelationships among environments, occupations, and persons and the goodness-of-fit of these elements is the basis for sound clinical decisions. At the same time that occupational therapists systematically analyze the child's occupational performance and social participation, they acknowledge that the child's spirit and family's support highly influence the outcome.

This text describes theories, practice models, principles, and strategies that are used in occupational therapy with children. It presents evidence-based interventions designed to help children and families cope with disability and master occupations that have meaning to them. Although this theoretical and technical information is important to occupational therapy practice with children, it is childhood itself that creates meaning for the practitioner. Childhood is hopeful, joyful, and ever new. The spirit, the playfulness, and the joy of childhood create the context for occupational therapy with children. This chapter describes the primary themes in occupational therapy practice with children and adolescents that are illustrated throughout the text.

Essential Concepts in Occupational Therapy for Children and Adolescents

Using the research literature and their own expertise, the book's authors illustrate the role of occupational therapy with children and adolescents in specific practice areas and settings. Certain themes flow through many, if not most, of the chapters, suggesting their importance to occupational therapy. Four overarching themes ([Box 1-1](#)), briefly described in this chapter, are ubiquitous throughout practice and are well illustrated throughout the chapters of this book.

Individualized Therapy Services

A child or adolescent is referred to occupational therapy services because he or she has a specific diagnosis (e.g., autism or cerebral palsy) or because he or she exhibits a particular functional problem (e.g., poor fine motor skills or poor attention). Although the diagnosis or problem is the reason for therapy services, the occupational therapist always views the child or youth as a person first. Client-centered intervention has many implications for how the occupational therapist designs intervention. Primary implications of client-centered practice are listed in [Table 1-1](#).

TABLE 1-1 Principles of Client-Centered Intervention

Area of Intervention	Principles
Assessment	Child or adolescent and family concerns and interests are assessed in a welcoming and open interview. Child or adolescent and family priorities and concerns guide assessment of the child.
Team interaction	Child or adolescent and family are valued members of the intervention team. Communication among team members is child- and family-friendly. Relationships among team members are valued and nourished.
Intervention	Child or adolescent with caregivers guide intervention. Families choose level of participation they wish to have. Family and child or adolescent interests are considered in developing intervention strategies. When appropriate, intervention directly involves other family members (e.g., siblings, grandparents).
Life span approach	As child transitions to preadolescence and adolescence, he or she becomes the primary decision maker for intervention goals and activities.

BOX 1-1**Themes That Characterize Occupational Therapy Practice with Children and Adolescents**

Individualized therapy services

- Client-centered services
- Strength-based approaches
- Family-centered services

Inclusive and integrated services

- Natural environments
- Integrated services

Cultural competence

Evidence-based practice and scientific reasoning

As illustrated throughout the book, client-centered evaluation involves first identifying concerns and priorities of the child and family. Initially and throughout therapy services, occupational therapists prioritize and make specific efforts to learn about the child and family's interests, goals, daily routines, and preferred activities. What is important to the child and caregivers frames the goals and activities of the intervention. Fit of occupational therapy recommendations to family goals and interests is revisited throughout the intervention period to ensure that services are meeting the priorities of the child or adolescent and family.

Child-Centered Practices

As described by Law, Baptiste, and Mills,⁷³ client-centered occupational therapy is an approach to service that embraces a philosophy of respect for and partnership with people receiving services. Tickle-Degnen¹²⁸ further explains that practitioners form a therapeutic alliance with their clients in which they build rapport and collaborate to develop common goals and shared responsibility for achieving those goals. According to Parham et al.,⁹⁶ a primary feature of sensory integration intervention is “fostering therapeutic alliance.” They describe this alliance as one in which the occupational therapist “respects the child’s emotions, conveys positive regard toward the child, seems to connect with the child and creates a climate of trust and emotional safety”⁹⁶ (see [Chapter 9](#)). This relationship with the child is a priority for the occupational therapist and is believed to be instrumental to achieving positive intervention outcomes.

Philosophically, theoretically, and practically, client-centeredness is ubiquitous to occupational therapy interventions. This concept means that occupational therapists provide choices, allow the child or youth to make activity choices, and broadly consider the child’s culture and context when designing interventions. In child-centered practice, practitioners use activities that are meaningful to and preferred by the child, knowing that they engage the child’s efforts. Children are motivated to take on skill challenges that the occupational therapist embeds in preferred activities. It is also implied that the occupational therapist selects activities that are developmentally appropriate, suitable to the child’s environment, and aligned with the child’s expressed or understood goals.

Occupational therapists invite children and youth to participate actively in the evaluation process and goal setting using developmentally appropriate methods.⁸⁷ Measures have been developed to assess the child’s perspective on his or her ability to participate in desired occupations. For example, when using the Canadian Occupational Performance Measure (COPM), the family and child rate the importance of self-identified performance problems. By administering the COPM as part of the initial evaluation, the occupational therapist can prioritize the child’s goals and begin a collaborative relationship with the family. The Perceived Efficacy and Goal Setting System (PEGS) is another example of a measure that uses the child as the primary informant.⁸⁸ These assessments are explained further in [Chapters 11, 15, and 23](#). The information gathered from measuring children’s thoughts and feelings about their participation in childhood roles can complement results obtained from functional assessments. In addition, occupational therapists may consider gathering information about the child’s life satisfaction. Often the best strategy for gathering information about the child’s or adolescent’s interests and perspectives is to ask open-ended questions about his or her play preferences, favorite activities, best friends, special talents, and greatest concerns.

The occupational therapist monitors the fit of intervention activities to the child’s daily routines by asking parents and teachers. The occupational therapist seeks ways to adapt recommendations to match the child’s evolving interests and routines and to ensure that therapy is directed to current priorities of the child and family. Continually assessing which therapeutic activities are most appropriate given the child’s developmental levels, current performance, and interests, the practitioner

CASE STUDY 1-1 A Strength-Based Approach with a Child Who Has High Functioning Autism

Victor is a 10-year-old boy with high functioning autism. He has extraordinary visual perceptual skills and visual memory; he also has significant delays in social skills. In particular, he has difficulty knowing how to interact with his peers on the playground or in unstructured social activities. The therapist, Amy, suggests that he video record his peers when they are playing together or talking on the playground. Using these videos, Victor has examples of appropriate social interactions. He and Amy analyze the videos together, discussing how the children initiate and respond to social interaction; he practices some of the interactions with Amy. Amy encourages him to watch the examples of positive social interactions a number of times.

Using the videos, Victor makes and labels photographs of different examples of social interactions. With Amy's help,

Victor organizes the photographs into stories that he uses to learn how to engage with others socially. Amy also helps him organize the photographs into a social story; she creates a visual step-by-step procedure for initiating a social interaction.

The other children were interested in his videos and stories; they read the stories and praised Victor's skills in video recording and photography. His interest in and talents for photography resulted in a sequence of naturally occurring social interactions that allowed Victor to practice the social skills. By using a strength-based approach, he not only had used his talents to learn new skills, but also his peers recognized and appreciated his talent, establishing enhanced contexts for social participation.

selects activities that are most useful for obtaining the child and family's goals.¹²⁸

Strength-Based Approaches

Using holistic approaches, occupational therapists begin intervention by considering the strengths of a child or youth. With a full understanding of the child's strengths and interests, practitioners develop a plan to increase participation by building on those strengths. By identifying the positive aspects of a child's behavior and areas of greatest competence as well as performance limitations, the occupational therapist can access these strengths to overcome the challenges to participation. The strength-based model contrasts with the traditional medical model, in which the focus of intervention is on identifying the health or performance problem and resolving that problem. As explained in many chapters of this book, focusing on a child's performance problem does not always lead to optimal participation and improved quality of life. Because occupational therapists are concerned with a child's full participation in life activities, focusing solely on impairment narrows the vision of what the child can become and do.

Children and youth with disabilities often have unique strengths that are overlooked by professionals, but if these strengths are identified and encouraged, they can lead to increased participation. For example, a youth with high functioning autism may have excellent visual memory or analytic abilities. For this youth, cognitive approaches that engage the youth in problem solving and in determining how to structure social activities can help him overcome social skill limitations. For a child with spastic quadriplegia cerebral palsy who has a joyous sense of humor, encouraging his sense of humor in a social group can help to build peer supports and friendships that increase his participation in school activities.

As explained in numerous chapters, strength-based approaches can lead to increased self-efficacy and self-determination. When an occupational therapist acknowledges a child's strengths and competence, the child becomes more self-efficacious and motivated, and he or she may be more willing to take on performance challenges. A child with positive

self-efficacy is more likely to make repeated and sustained efforts to achieve his or her goals, despite lack of immediate success.⁷ Case Study 1-1 illustrates use of a strength-based approach with a child who has high functioning autism spectrum disorder. Chapter 12 explains how an occupational therapist's emphasis on strength-based approaches can facilitate increased self-determination and skills in self-advocacy in youth with disabilities. Identifying an adolescent's strengths can be particularly potent in interventions to promote social participation and friendship networks because it helps peers and family members recognize and acknowledge the adolescent's talents and interest and establish these as the basis for social interaction. Kramer and colleagues (Chapter 12) describe a community service program, EPIC Service Warriors, in which youth with disabilities serve others by cleaning up parks and making food at homeless shelters. This program expands the social networks of youth with disabilities, demonstrates a model of community inclusion, and changes the way these adolescents think about themselves. Envisioning roles for youth and adults with disabilities to serve others can enhance self-efficacy and change society's view of potential roles for people with disabilities.

A strength-based approach when offering parent supports and education is equally important. By identifying positive characteristics in the child, occupational therapists can help relieve parents' stress and can improve parents' engagement.^{49,121} Steiner¹²¹ found that when occupational therapists acknowledged the strengths of parents of children with autism (versus noting their deficits), parents demonstrated more positive affect and physical affection toward their child. When occupational therapists made positive statements about a child, parents repeated their statements and, less expected, demonstrated more playful behaviors and physical affection.¹²¹

Family-Centered Practices

In a family-centered approach, the occupational therapist is invested in establishing a relationship with the family characterized by open communication, shared decision making, and parental empowerment.¹² An equal partnership with the family

is desired, where each partner values the knowledge and opinions of the other.^{53,130} Trust building between professionals and family members is a first step in building a relationship. Demonstrating mutual respect, being positive, and maintaining a nonjudgmental position with a family appear to be important to establishing trust (see [Chapter 5](#)). Trust building can be particularly challenging with certain families—for example, families whose race, ethnicity, culture, or socioeconomic status may differ from that of the occupational therapist. These families may hold strong beliefs about child rearing, health care, and disabilities that are substantially different from those of the occupational therapist. However, establishing a relationship of mutual respect is essential to the therapeutic process.

Jaffe and Cosper ([Chapter 5](#)) explain that occupational therapists cultivate positive relationships with families when they establish open and honest communication and encourage participation of parents in their child's program to the extent that they desire. When asked to give advice to occupational therapists, parents stated that they appreciated (1) specific, objective information; (2) flexibility in service delivery; (3) sensitivity and responsiveness to their concerns⁸³; (4) positive, optimistic attitudes²⁴; and (5) technical expertise and skills.¹²

In a qualitative study in which 29 families were interviewed about their experiences in parenting a child with disabilities and working with the intervention systems, four themes emerged.⁴² (1) Parents need professionals to recognize that parenting a child with a disability is a “24/7” job with continual and often intensive responsibilities. (2) Both internal (coping and resilience) and external (e.g., extended family) resources are needed to raise a child with a disability; these should be bolstered and encouraged. (3) Parents ask that professionals respect them as the experts on their child. (4) Parents also ask that professionals accept their family's values. Although this study's qualitative findings do not constitute rigorous evidence of intervention effects, the findings concur with other descriptive studies of family-centered intervention. When combined, these studies suggest that respecting parents' knowledge of their child, acknowledging their resilience, accepting their values, and facilitating the building of a network of social resources are important components of family-centered intervention.⁴⁰

In [Chapter 22](#), on early intervention services, Myers, Case-Smith, and Cason explain methods for partnering with families. Recommended activities most likely to be implemented by and most helpful to the family are activities that are directly relevant to the family's lifestyle and routines. When interventions make a family's daily routine easier or more comfortable, the intervention can have an immediate positive effect and is more likely to be sustained and generalized to other routines and environments.

In a meta-analysis of family-centered practice in early intervention service, two types of family-centered services were identified: (1) services that fostered positive professional-family relationships and (2) services that enabled the family's participation in intervention activities.⁴⁰ In relationship building practices, occupational therapists actively listen, show compassion and respect, and believe in the family's capabilities. Occupational therapists enable and promote the family's participation by individualizing their services, demonstrating flexibility in meeting family needs, and being responsive to family concerns. Dunst, Trivette, and Hamby⁴¹ found that the provision of family-centered services was highly related to the family's

self-efficacy beliefs, parents' satisfaction with the program, parenting behaviors, and child behavior and functioning.

Inclusive and Integrated Services

Practitioners of occupational therapy are strong advocates for inclusion of all persons with disabilities. They embrace the vision that children and youth with disabilities fully participate in the community and take on roles to facilitate full participation. Inclusion of people with disabilities into communities involves transforming attitudes and assumptions, through education but primarily through demonstration that children and youth with disabilities can fully participate. To support inclusion of children and youth with disabilities in environments with children without disabilities, practitioners may recommend modifications to increase physical access, accommodations to increase social participation, or strategies to improve the child's ability to meet the performance and behavioral expectations. For example, occupational therapists often have roles in evaluating physical access in schools or jobs and recommending assistive technology or task modification. Occupational therapists have been leaders in promoting inclusion throughout their history,^{54,65} providing services that enable full inclusion of persons with mental, physical, and cognitive disabilities.

In current practice, legal mandates necessitate that services to children with disabilities be provided in environments with children who do not have disabilities. The Individuals with Disabilities Education Act requires that services to infants and toddlers be provided in “natural environments” and that services to preschool and school-aged children be provided in the “least restrictive environment.” The infant's natural environment is most often his or her home, but it may include any place that the family defines as the child's natural environment. This requirement shifts when the child reaches school age, not in its intent but with recognition that community schools and regular education classrooms are the most natural and least restrictive environments for services to children with disabilities. Inclusion in natural environments or regular education classrooms succeeds only when specific supports and accommodations are provided to children with disabilities. Occupational therapists are often important team members in making inclusion successful for children with disabilities. (This concept is discussed further in [Chapters 22](#) and [23](#).)

Early Intervention Services in the Child's Natural Environment

The Division of Early Childhood of the Council for Exceptional Children supports the philosophy of inclusion in natural environments with the following statement: “Inclusion, as a value, supports the right of all children, regardless of their diverse abilities, to participate actively in natural settings within their communities. A natural setting is one in which the child would spend time if he or she had not had a disability.”³⁶

As explained by Myers, Case-Smith, and Cason ([Chapter 22](#)), the philosophy of inclusion extends beyond physical inclusion to mean social and emotional inclusion of the child and family.^{26,131} The implications for occupational therapists are that they provide opportunities for expanded and enriched natural learning with typically developing peers. A natural environment can be any setting that is part of the everyday routine of the

FIGURE 1-1 When occupational therapy is provided in the child's home, the practitioners and child have easy access to practice of self-care activities.

child and family where incidental learning experiences occur.⁴² Intervention and consultation services can occur in a childcare center, at a grandmother's house, or in another place that is part of a family's routine. Social, play, and self-care learning opportunities in these environments are plentiful. [Figure 1-1](#) shows an example of a child's natural environment in which the occupational therapist could intervene.

When occupational therapy occurs in a natural environment such as the home, the intervention activities are embedded in naturally occurring interactions and situations. In incidental learning opportunities, the occupational therapist challenges the child to try a different approach or to practice an emerging skill during typical activities. The occupational therapist follows the young child's lead and uses natural consequences (e.g., a smile or frown, a pat or tickle) to motivate learning ([Figure 1-2](#)).

Research has shown that intervention strategies that occur in real-life settings produce greater developmental change than those that take place in more contrived, clinic-based settings.^{18,42} In addition, generalization of skills and behaviors occurs more readily when the intervention setting is the same as the child's natural environments.^{58,59}

Early intervention therapy services in natural environments require the occupational therapist to be creative, flexible, and spontaneous.⁴¹ The occupational therapist must accept and use the toys, objects, and environmental spaces in the family's home as those are most important and culturally relevant to the child's development ([Figure 1-3](#)). The occupational therapist must think through many alternative ways to reach the established goals and adapt those strategies to whichever situation is presented.⁵² Recognizing and accepting the family's uniqueness in cultural and child-rearing practices enables the occupational therapist to facilitate the child's participation in his or her natural environments.

Integrated Service Delivery Models

In school-based services, inclusion refers to integration of the child with disabilities into the regular classroom with support to accomplish the regular curriculum. [Box 1-2](#) lists the desired outcomes of inclusive school environments. In schools with well-designed inclusion, every student's competence in

FIGURE 1-2 A and B, Therapist and child rapport is demonstrated by sharing pleasure and clowning around.

BOX 1-2 Desired Inclusion Outcomes

- Children with disabilities are full participants in school, preschool, and childcare center activities.
- Children with disabilities have friends and relationships with their peers.
- Children with disabilities learn and achieve within the general educational curriculum to the best of their abilities.
- All children learn to appreciate individual differences in people.
- All children learn tolerance and respect for others.
- Children with disabilities participate to the fullest extent possible in their communities.

diversity and tolerance for differences increases. To promote the child's participation across school environments, occupational therapy practitioners integrate their services into multiple environments (e.g., within the classroom, on the playground, in the cafeteria, on and off the school bus). The occupational therapist's presence in the classroom benefits the instructional staff members, who observe the occupational therapy intervention. As explained by Bazyk and Cahill ([Chapter 23](#)), integrated therapy ensures that the occupational therapist's focus has high relevance to the performance expected within the classroom. It also increases the likelihood that adaptations and therapeutic techniques will be carried over into classroom activities,^{8,117,137}

FIGURE 1-3 The occupational therapist uses the child's own toys in the home to challenge and practice his or her emerging skills with the high probability that the child will continue to practice these skills.

and it allows the occupational therapist to link his or her goals and activities to the curriculum and the classroom priorities.

Children with disabilities benefit when therapy is provided as both direct and consultative services. Occupational therapists provide these services in the context of an interprofessional team, where communication about the child's strengths and limitations, expected performance, and contextual barriers and resources enables a cohesive plan and the likelihood of positive outcomes. Because children constantly change and the environment is dynamic, frequent team communication and planning are needed. With opportunities to interact directly with the child and experience the classroom environment, the occupational therapist can best support the child's participation and guide the support of other adults.

In a fluid service delivery model, therapy services increase when naturally occurring events create a need—for example, when the child obtains a new adapted device, when the child has surgery or casting, or when a new baby brother creates added stress for a family. Similarly, therapy services should be reduced when the child has learned new skills that primarily need to be repeated and practiced in his or her daily routine or the child has reached a plateau on therapy-related goals.

Models for school-based service delivery that offer the possibility for greater flexibility²¹ include block scheduling⁹⁹ and co-teaching.²² These models of flexible scheduling allow occupational therapists to move fluidly between direct and consultative services. In block scheduling, occupational therapists spend 2 to 3 hours in the early childhood classroom working with the children with special needs one on one and in small groups, while supporting the teaching staff (see [Chapter 22](#)). Block

scheduling allows occupational therapists to learn about the classroom, develop relationships with the teachers, and understand the curriculum so that they can design interventions that are easily integrated into the classroom. By being present in the classroom for an entire morning or afternoon, the occupational therapist can find natural learning opportunities to work on a specific child's goals. Using the child's self-selected play activity, the occupational therapist employs strategies that are meaningful to the child, fit into the child's preferred activities, and are likely to be practiced.¹¹⁹ During the blocked time, the occupational therapist can run small groups, coach the teacher and assistants,^{21,109} evaluate the child's performance, and monitor the child's participation in classroom activities.

Another integrated model of service delivery is co-teaching.^{31,37} This model emphasizes preventive approaches in that children at risk for disabilities as well as children in individualized education programs receive occupational therapy services. In this model, the occupational therapist and teacher plan and implement the sessions together. Collaborative planning allows interdisciplinary perspectives on student issues and behaviors; enables the occupational therapist to align interventions closely with the curriculum; and ensures that interventions can be feasibly implemented in the classroom, with consideration given to the teacher's goals and curricular expectations. Co-teaching models have been successfully implemented for handwriting programs, in which occupational therapists take on teaching roles while providing individualized supports and interventions for students who have handwriting difficulties.²³ Benefits of co-teaching are that occupational therapy services are embedded into the classroom instruction; students at risk receive more intensive instruction with individualized supports; and students with individualized education programs receive integrated services that support performance throughout their school day.

Cultural Competence That Embraces Diversity

To achieve full inclusion, all team members and systems must demonstrate cultural competence.²⁹ With increasing diversity within all communities, respecting and honoring the culture of the child and family are important to enable full inclusion and facilitate full participation. Cross-cultural competence can be defined as “the ability to think, feel, and act in ways that acknowledge, respect, and build upon ethnic, [socio]cultural, and linguistic diversity.”⁷⁹ Cultural competence in health care refers to behaviors and attitudes that enable an individual to function effectively with culturally diverse families.²⁹ Cross-cultural competence is salient to occupational therapists who work with children and youth given that:

1. Cultural diversity of the United States continues to increase.
2. A child's occupations, including social participation, are embedded in the cultural practices of his or her family and community.

Cultural Diversity in the United States

The diversity and heterogeneity of American families continue to increase each year. The latest census numbers¹³² show that the fastest growing populations in the United States are multiracial Americans, Asians, and Hispanics and that non-Hispanic white Americans will become a minority group within the next 3 decades. The United States has become a multicultural

FIGURE 1-4 A father bonds with his just-born son. (Photo © istock.com.)

nation, and today's children will become adults in this environment that is rich with cultural and racial diversity. In 2011, the United States was home to 74 million children. Of these, 53% were white, 14% were African American, 4.5% were Asian, and 23.5% were Hispanic.³

Diversity of ethnicity and race can be viewed as a risk or as a resource to child development.⁴⁵ Low birthrate, preterm delivery, and infant mortality are higher in African American families, suggesting that these families frequently need early childhood intervention programs. Race can also be a resource; for example, African American families are well supported by their communities and focused on their children (Figure 1-4). Studies also show that African Americans are child-centered and highly invested in child development.⁵⁵ Parents often perceive discipline and politeness as positive attributes and instill these in their children.¹³⁴ Children are taught to be obedient and respectful of adults. In addition, many African American families emphasize the importance of spirituality and religion.¹²⁶ Occupational therapists who work with African American families find many positive attributes in their family interactions and parenting styles. Families from other cultures, such as Hispanic families, have similar beliefs and child-rearing practices.¹⁰²

Poverty has a pervasive effect on children's developmental and health outcomes.²⁸ Despite overall prosperity in the United States, a significant number of children and families live in poverty. Although children younger than 18 years old represent only 23% of the U.S. population, they account for 34% of all people in poverty. Among all children, 45% live in low-income families, and approximately 20% live in poor families.⁶² In 2014, the Children's Defense Fund reported that 1 in every 5 children, or 16.1 million, was poor and that 40% of these lived in extreme poverty. These children are disproportionately black, American Indian, and Hispanic. Often these children live in families with a single parent. Families in poverty often have great need for, yet limited access to, health care and educational services.

Many families who are served by early intervention and special education systems are of low socioeconomic status. When families lack resources (e.g., transportation, food, shelter), their priorities and concerns orient to these basic needs. Responsive occupational therapists provide resources to assist with these basic needs, making appropriate referrals to

community agencies. They also demonstrate understanding of the family's priorities as these relate to the child's occupational performance goals and the family's participation in the community. Chapter 5 describes helpful practices for families with limited resources.

Influence of Cultural Practices on a Child's Development of Occupations

To support and improve a child's participation in the home, school, and community, occupational therapists need to understand the multitude of ways that cultural practices influence a child's occupations. Table 1-2 lists questions to elicit information about the cultural practices and values that may influence a child's development of occupations. For certain cultures, performance goals of interdependence may be more appropriate than goals for independence, particularly at certain ages. Cultural groups vary in their perception of giving and receiving help, communication styles, and child-rearing beliefs. The literature is replete with examples of the influence of culture on children's occupations.^{27,34,45,61,108}

Cultural values in families often influence their routines, daily activities, and expectations for child participation in family routines. For example, Middle Eastern families often do not emphasize early independence in self-care; skills such as self-feeding may not be a family priority until ages well beyond the normative expectations.¹¹⁵ Interventions to promote self-feeding during early childhood may not be a priority for Middle Eastern families. In Hispanic cultures, holding and cuddling are highly valued, even in older children.¹³⁸ Mothers hold and carry their preschool children. Recommending a wheelchair for a young child may be unacceptable to families who value close physical contact and holding.

In some cultures (e.g., Polynesian), parents delegate child-care responsibilities to older siblings. In established families, siblings care for the infants. Young children in Polynesian cultures tend to rely on their older siblings rather than their parents for structure, assistance, and support. Being responsible for a younger sibling helps the older sibling mature quickly by learning responsibility and problem solving.¹⁰⁸ Primary care by an older sibling is challenging when the younger child has a disability and needs additional or prolonged assistance.

Because the focus of occupational therapy is to enhance a child's ability to participate in his or her natural environment and everyday routines, the occupational therapist must appreciate, value, and understand those environments and routines. Recommendations that run counter to a family's cultural values are not likely to be implemented by family members and may be detrimental to the professional-family relationship. By asking open-ended questions, occupational therapists can elicit information about the family's routines, rituals, and traditions to provide an understanding of the cultural context.

A culturally competent occupational therapist demonstrates an interest in understanding the family's culture, an acceptance of diversity, and a willingness to participate in traditions or cultural patterns of the family. In home-based services, cultural competence may mean removing shoes at the home's entryway, accepting foods when offered, scheduling therapy sessions around holidays, and accommodating language differences. In center-based services, cultural sensitivity remains important, although a family's cultural values may be more difficult to ascertain outside the home.

TABLE 1-2 Cultural Values and Styles That Influence Children's Development of Occupations

Value or Style	Guiding Questions
Family composition	Who are the members of the family? How many family members live in the same house? Is there a hierarchy in the family based on gender or age?
Decision making	Who makes the decisions for the family?
Primary caregiver	Who is the primary caregiver? Is this role shared?
Independence/interdependence	Do family members value independence?
Feeding practices	Who feeds the infant or child? What are the cultural rules or norms about breastfeeding, mealtime, self-feeding, and eating certain foods? When is independence in feeding expected?
Sleeping patterns	Do children sleep with parents? How do parents respond to the infant during the night? What are appropriate responses to crying?
Discipline	Is disobedience tolerated? How strict are the rules governing behavior? Who disciplines the child? How do the parents discipline the child?
Perception of disability	Do the parents believe that the disability can improve? Do they feel responsible for the disability? Do family members feel that they can make a difference in improving the disability? Are spiritual forms of healing valued?
Help seeking	From whom does the family seek help? Does the family actively seek help, or do family members expect help to come to them?
Communication and interaction	Does the family use a direct or an indirect style of communication? Do family members share emotional feelings? Is most communication direct or indirect? Does the family value socializing?

Adapted from Wayman, K. I., Lynch, E. W., & Hanson, M. J. (1990). Home-based early childhood services: cultural sensitivity in a family systems approach. *Topics in Early Childhood Special Education*, 10, 65–66.

A culturally competent occupational therapist inquires about family routines, cultural practices, traditions, and priorities; demonstrates a willingness to accommodate to these cultural values; and integrates intervention recommendations into the family's cultural practices. The occupational therapist's appreciation of the influence of culture on children's occupations facilitates the development of appropriate priorities and the use of strategies that are congruent with the family's values and lifestyle.

In summary, occupational therapy services can be characterized as child-centered and family-centered, integrated into the natural environment of the child or youth, and culturally competent. These concepts guide the practitioner's decision making about which interventions and service delivery models are most appropriate. Clinical reasoning is also guided by the research evidence. As explained in the following section, occupational therapy interventions are grounded in occupation-based models that are supported by research evidence.

Evidence-Based Practice and Scientific Reasoning

Occupational therapists have fully moved into the era of evidence-based practice (EBP). Historically, practice techniques were handed down from practitioner to practitioner.⁵⁶ Beginning in the 1940s and 1950s, intervention strategies and activities were described in journals and textbooks; however, measures and data were rarely included in these descriptions. Occupational therapy was considered to be a "craft" in which the therapist viewed each client as unique and designed an intervention plan based on his or her experience and expertise. Although research was recognized to be important to the profession, the art of therapy and the uniqueness of each client were emphasized. In the second half of the twentieth century,

scholars in occupational therapy realized that professional reasoning needed to be guided by practice models. An understanding of critical reasoning and theory-based practice developed in the 1960s and 1970s.¹⁰⁶ At that time, theories of occupation,⁶⁷ play,¹⁰⁰ and sensory integration⁵ were organized into practice models and became widely accepted by the profession. These theory-based practice models, described by Parham⁹⁴ as "tools for thinking," were guided by hypotheses about how individuals perform occupations, develop occupational roles, and function in their environments.⁶⁶ These models included postulates on how interventions can improve occupational performance and function.¹⁰⁶ Although theory-based models resulted in more systematic clinical reasoning and improved coherence in intervention methods, the field had little evidence of its efficacy, and practitioners made decisions with mostly personal knowledge of intervention outcomes.

Beginning in the 1990s and continuing into the twenty-first century, the profession has been highly invested in evaluating intervention outcomes and in researching its practice models to establish evidence for their effectiveness.⁷⁴ In the past 25 years, researchers in occupational therapy and related professions have focused their efforts on creating trials and studies that examine the effectiveness of interventions. As a result, hundreds of efficacy studies on occupational therapy interventions for children have been published.^{70,98} Many of these studies are cited in the chapters of this book and are incorporated in the explanations of interventions.

With extensive availability of research on pediatric practice, competent practitioners read, appraise, and use this evidence when making clinical decisions about intervention. The Institute of Medicine defines health care quality as the extent to which health services are consistent with current professional knowledge.⁶⁰ However, despite wide agreement among professionals regarding the importance of EBP, studies have shown

BOX 1-3 Steps in Evidence-Based Practice**Step 1**

- Convert the need for information (about intervention effects, prognosis, therapy methods) into an answerable question.

Step 2

- Search the research databases using the terms in the research question.
- Track down the best evidence to answer that question.

Step 3

- Critically appraise the evidence for its:
 - validity (truthfulness)
 - impact (level of effect)
 - clinical meaningfulness

Step 4

- Critically appraise the evidence for its applicability and usefulness to your practice.

Step 5

- Implement the practice or apply the information.
- Evaluate the process.

that research findings are not routinely integrated into everyday practice.^{111,127} Barriers to implementing research findings fully into daily practice include practitioners' limited time to read and consume all the available evidence and lack of administrative support to develop systems for routinely using evidence in practice.

With the proliferation of published research related to pediatric occupational therapy,^{9,70} organizations, including the American Occupational Therapy Association, have supported the development of EBP guidelines.²⁰ EBP guidelines are developed by a group of experts who synthesize the research on a particular intervention or diagnosis to formulate recommendations for practice. These guidelines translate the research evidence to practice by making specific recommendations for evaluations and interventions that prioritize the recommendations using a grading system.^{48,92}

Hospitals and medical systems are aggressively promoting use of EBP guidelines to improve the consistency and effectiveness of medical intervention.¹ Schools and educational systems also are calling for research evidence to be used to guide educational practices and policies.¹¹⁸ Clinical guidelines enable efficient consumption of efficacy research; however, implementing the guidelines consistently also requires commitment, system and environmental supports, and consensus among the agency's or program's team. EBP clinical guidelines have been adopted by children's hospitals and medical systems as tools to promote quality improvement and patient outcomes.³⁰ When EBP guidelines are implemented within quality improvement processes, they also are embedded in existing processes that include monitoring and examining outcomes. Numerous steps are needed to ensure that use of EBP guidelines results in improved outcomes (Box 1-3).

Using evidence is part of the occupational therapist's scientific reasoning (Figure 1-5). With scientific reasoning,¹¹² the occupational therapist uses clinical guidelines that have

FIGURE 1-5 Scientific reasoning using evidence-based practice guidelines.

synthesized the research evidence, science-based knowledge about the diagnosis, and past experience in all steps of the assessment and intervention process. These resources are accessed, interpreted for the practice context and the child's and family's needs, and used to guide intervention. Case Study 1-2 describes using an EBP guideline in clinical decision making for a young child with autism spectrum disorder.

There are benefits to using the recommendations from EBP guidelines; they:

1. Are relevant because experts in the diagnosis or type of intervention determine the scope and methods for developing the recommendations.
2. Represent synthesis of current research that is appraised and evaluated.
3. Incorporate appraisal of available evidence by grading the recommendations based on the rigor of the research; these grades determine the importance and priority of the recommendations.
4. Represent the consensus of the experts.

Following clinical guidelines has the potential of increasing the consistency of practice and its efficacy. The likelihood of positive outcomes is high when occupational therapists (1) select EBP guidelines with optimal fit to their clientele and environment, (2) adapt the guidelines to fit their work environment, (3) modify them into user-friendly protocols, (4) examine and resolve barriers to implementation, and (5) establish systems to monitor their outcomes.¹⁹ All of the chapters in this book use research evidence in describing evaluation and intervention.

In summary, the occupational therapy process is grounded in research evidence. Occupational therapists select assessments with evidence of validity and reliability and interventions that demonstrate positive effects for performance and participation goals of relevance to their clients. The following sections briefly describe the occupational therapy process of evaluation and intervention as it is presented throughout the book.

Comprehensive Evaluation

The chapter authors recommend using a *top-down* approach to assessment—that is, the occupational therapist begins the

CASE STUDY 1-2 Using Evidence-Based Practice Guidelines for Restricted Eating in Autism Spectrum Disorder

Background

Meg, a school-based occupational therapist, initiated intervention for Rebecca, a 5-year-old girl with autism with highly restricted eating. Meg evaluated Rebecca and determined that she eats eight to nine foods throughout the day as snacks. She does not participate in mealtime with the family because she has a tantrum when foods that are not part of her diet are presented. Rebecca eats crackers, cereals, chips, noodles, and French fries, and she occasionally eats yogurt, milk, and cheese. She interacts with her caregiver using gestures and two-word sentences. She also uses jargon that does not have communicative intent. She is very skilled in computer tablet games, puzzles, and Lego blocks. She is independent in eating and dressing but continues to require some assistance with bathing, and she dislikes water and soap. Rebecca's parents have prioritized her eating as a first occupational therapy goal.

Meg accessed the BESt evidence statement from *Behavioral and oral motor interventions for feeding problems in children* (Cincinnati Children's Hospital and Medical Center, 2013) to guide her intervention planning. Listed in order of evidence strength, the following BESt recommendations seemed relevant, appropriate given Rebecca's age and behaviors, and feasible to implement at home and school. These recommendations were particularly applicable because Rebecca exhibited significant behavioral rigidity and stereotypic behaviors, and she did not appear to have sensory processing problems.

- It is recommended that the following behavioral interventions within a treatment package may be used to increase intake for children with feeding problems:
 - Differential attention
 - Positive reinforcement
 - Escape extinction/escape prevention
 - Stimulus fading
 - Simultaneous presentation
- It is recommended that a child (4 months to 7 years old) with feeding difficulties be exposed 10 to 15 times to a previously unfamiliar or nonpreferred food to

increase intake (Cincinnati Children's Hospital Medical Center, 2013).

An intervention was designed in which a nonpreferred food was placed on Rebecca's plate with her preferred foods twice a day. The teacher or occupational therapist implemented the intervention at school, and the mother implemented it once each day at home. The occupational therapist, teacher, or parent gave Rebecca praise and attention when she touched, played with, or tasted the nonpreferred foods. The occupational therapist and parent ate some of the nonpreferred food with her, modeling for her and having fun with that food. The same nonpreferred food was presented at least 10 times. The occupational therapist and parent used highly positive affect during the meal, and although Rebecca was allowed to eat her preferred foods, she was praised and reinforced only when she ate a nonpreferred food. The table was arranged to make escape very difficult, and she was encouraged to stay at the table.

In the first week, Rebecca did not eat any nonpreferred foods, but she touched and played with these foods (fruits, cream cheese, peanut butter, and pita bread). In the second week, she took several bites of nonpreferred foods each week, and by the third week, her regular diet had increased to 11 foods, including fruit, cream cheese, and peanut butter. Meg, the teacher, and Rebecca's mother recorded and tracked her eating and mealtime behavior each day to decide which foods to try and which reinforcement seemed most effective.

Summary

This guideline on feeding problems effectively improved Rebecca's eating and diet because:

- Rebecca's mother and teacher were invested in implementing mealtime interventions.
- The occupational therapist created a protocol from the feeding guideline that worked both at home and at school.
- The occupational therapist, teacher, and mother were committed to implementing the protocol consistently.
- A system for routinely assessing Rebecca's intake and behavior was developed and implemented.

Adapted from Cincinnati Children's Hospital Medical Center (2013). *Best evidence statement (BESt). Behavioral and oral motor intervention for feeding problems in children*. <<http://www.guideline.gov/content.aspx?id=47062&search=autism%2c+eating>> Accessed March 10, 2014.

evaluation process by gaining an understanding of the child's level of participation in daily occupations and routines with family, other caregiving adults, and peers. Initially, the occupational therapist surveys multiple sources to acquire a sense of the child's ability to participate and to develop an occupational profile for the child that includes his or her interests and priorities.³ Table 1-3 lists attributes of occupational therapy evaluation of children.

Ecologic Assessment

Ecologic assessment allows the occupational therapist to consider how the environment influences performance and to design interventions that are easily implemented in the child's

natural environment. By considering the child's performance in the context of physical and social demands, ecologic assessment helps to determine the discrepancy between the child's performance and expected performance (Figure 1-6). Ecologic assessment uses a top-down model that considers cultural influences, resources, and value systems of the child's environment. Bazyk and Cahill (Chapter 23) advocate for ecologic assessment of what the child "needs and wants to do across a variety of occupational performance areas and settings." In ecologic assessment, the occupational therapist considers the fit or match between the performance of the child or youth and the demands and expectations of the environment (e.g., in school-based practice, the relationship between the child's performance and the educational context and curriculum).

TABLE 1-3 Description of Comprehensive Evaluation of Children

Evaluation Component	Description of Occupational Therapist's Role—Tools, Informants
Occupational profile	Obtains information about child's developmental and functional strengths and limitations. Emphasis on child's participation across environments. Interview with parents, teachers, and other caregivers. Informal interview and observation.
Assessment of performance	Carefully assesses multiple areas of developmental performance and functional behaviors and underlying reasons for limitations. Standardized evaluations, structured observation, focused questions to parents and caregivers.
Analysis of performance	Analyzes underlying reasons for limitations in performance and behavior. In-depth structured observations, focused standardized evaluations.
Environment	Assessment and observation of environment, focused on supports and constraints of child's performance. Focused observations, interview of teachers and parents.

FIGURE 1-6 **A**, Cutting skills are assessed using the classroom art activity. **B**, The child's ability to access an instructional activity is assessed in the computer lab.

Two examples of standardized ecologic assessments are the School Function Assessment (SFA)³³ and the Participation and Environment Measure—Children and Youth (PEM-CY).³² Both of these assessments are comprehensive measures of children's functioning in the context of school, home, and community. As described in [Chapter 23](#), the SFA measures the child's performance in functional tasks that support participation in academic and social aspects of school. To rate the SFA, the teacher or occupational therapist judges the child's performance compared with the performance of other students in his

FIGURE 1-7 Through observation of writing activity at school, the occupational therapist gains an understanding of the child's performance and the accommodations and supports needed.

or her class or grade. Performance is rated in the natural context of the classroom. [Figure 1-7](#) shows an example of an activity observed to complete the SFA. As described in [Chapters 11](#) and [16](#), the PEM-CY assesses participation and environment across home, school, and community environments. The parent rates the frequency and intensity of participation of the child or youth in activities, defines whether or not he or she desires the level of participation to change, and identifies which features of the environment promote or constrain the child's participation. Both the SFA and the PEM-CY allow the occupational therapist to assess performance and context as they influence the child's participation.

To support adolescents preparing for employment, occupational therapists use ecologic assessment of the adolescent's performance as it relates to job tasks and work environments. Through in-depth task analysis and performance analysis, the occupational therapist identifies the skills required for the job tasks and the discrepancy between the task requirements and the youth's performance. If the team seeks to identify the student's interests and abilities as they relate to future community living, an ecologic assessment would take place in the community and the home. Cleary, Persch, and Spencer

(Chapter 25) explain ecologic assessment in which the demands of the environment and job tasks are compared with the person's skills and limitations to determine the fit between person and context. By identifying job and task demands that are too challenging for the client, the occupational therapist can focus intervention on specific performance skills and task or environment accommodations. Ecologic approaches allow occupational therapists to optimize job matching and to focus interventions where performance problems are most likely to occur.

Evaluating Context

Occupational therapists also evaluate the contexts in which the child learns, plays, and interacts. Evaluating performance in multiple contexts (e.g., homes, schools, childcare centers, other relevant community settings) allows the occupational therapist to appreciate how different contexts affect the child's performance and participation.

Contexts particularly important to consider when evaluating children include *cultural*, *physical*, and *social*. Assessment of cultural context was described in an earlier section. The physical space available to the child can facilitate or constrain exploration and play. Family is the primary social context for the young child, then peers and other adult caregivers become important in the social context at preschool and school ages. Few standardized assessments of context are available, and most often the occupational therapist evaluates physical and social contextual factors informally, guided by the following questions:

- Does the environment allow safe physical access?
- Are materials to promote the child's development and participation available?
- Does the environment provide an optimal level of supervision and adult assistance?
- Are a variety of spaces and sensory experiences available?
- Is the environment conducive to social interaction, and does it provide opportunities for social interaction?
- Are opportunities for exploration, play, and learning available?
- Is positive adult support available, readily accessed, and developmentally appropriate?

Practitioners evaluate how environmental and activity demands facilitate or constrain the child's performance. The family culture, lifestyle, parenting style, and values have a profound influence on the child's development, and an understanding and appreciation of this influence form a foundation for intervention planning. Chapters 3 and 4 explain how these variables influence the child's development of occupations. Using ecologic assessments to frame the evaluation and establish the priorities, the occupational therapist further assesses specific performance areas.

Analyzing Performance

With priorities identified, the occupational therapist completes a performance analysis to gain insight into the reasons for the child's performance limitations (e.g., neuromuscular, sensory processing, visual perceptual). This analysis allows the occupational therapist to refine the goals and to design intervention strategies likely to improve functional performance. Richardson (Chapter 6) describes the use of standardized assessments in analyzing performance. Assessment of multiple performance

areas is essential to understanding a child's strengths and limitations for developing a focused intervention plan to improve performance. Many of the chapters in this book describe the evaluation process and identify valid tools that help to analyze a child's performance and behavior. For example in Chapter 8, Case-Smith and Exner explain that comprehensive evaluation of fine motor (hand) skills includes assessment of developmental and functional skills (e.g., Bruininks-Oseretsky Test of Motor Proficiency [BOT-2], Bayley Scales of Infant and Toddler Development, Assisting Hand Assessment, work task performance) and analysis of performance components (e.g., range of motion, strength, sensitivity, stereognosis, visual motor integration). Evaluation also includes assessment of related performance components that may influence fine motor skills, such as postural stability, visual perception, or motor planning.

When a child exhibits evidence of sensory problems, the occupational therapist uses standardized parent report and observational measures to identify patterns of behavior and performance that infer sensory integration or sensory modulation difficulties. The practitioner interprets these patterns in the context of the original concerns and resources available to make recommendations for therapy services. Parham and Mailloux (Chapter 9) describe assessment of sensory integration and praxis skills as these influence a child's performance. Sensory integration and praxis are assessed using multiple standardized tests that are scored and analyzed to reveal performance patterns that infer specific sensory difficulties.⁴ Sensory processing difficulties (i.e., hyperreactivity and hyporeactivity) are often identified through parent report of the child's behaviors and sensory preferences (see Chapter 9).⁸⁴

In Chapters 11 and 12, measures of social participation are described. Assessment of social interaction skills often includes a parent's or teacher's report of the child's communication skills, behaviors (including disruptive behaviors), and social initiation and responsiveness as key features of social participation. The occupational therapist also analyzes individual performance factors that may influence social participation, such as nonverbal communication, social awkwardness, turn-taking, voice volume, interest in others, and understanding of non-spoken rules of social interaction.

Through comprehensive evaluation, the occupational therapist analyzes the discrepancies between performance, expectations for performance, and activity demands. He or she identifies potential outcomes that fit the child's and family's story. By moving from assessment of participation to analysis of performance and contexts, the occupational therapist gains a solid understanding of the strengths, concerns, and resources of the individuals involved (e.g., child, parent, or caregiver; family members; teachers). The occupational therapist also understands how to interact with the child to build a trusting and positive relationship.

Occupational Therapy Intervention Process

Much of this book describes interventions for children. Occupational therapists improve children's performance and participation (1) by providing interventions to enhance performance; (2) by recommending activity adaptations and environmental modifications; and (3) through consultation, coaching, and

FIGURE 1-8 Phases of the occupational therapy process. *The intervention phases are generally overlapping—that is, provided both concurrently and sequentially.

education roles. These intervention strategies complement each other and in best practice are applied together to support optimal growth and function in the child.

Interventions to Enhance Performance

This section illustrates the chapter themes that explain how the occupational therapist interacts with, challenges, and supports the child and develops interventions that promote and reinforce the child's participation. Occupational therapists understand that specific interventions or supports may be needed to enable a child to participate fully in learning activities or intervention sessions.

Children with motor limitations may need postural supports that promote alignment or provide additional stability to perform an activity optimally. Children with autism spectrum disorder may benefit from a visual schedule to orient them to the sequence of activities in which they are expected to participate. Figure 1-8 presents the phases of interventions and elements that characterize the goals and activities for each phase. Although illustrated as phases, occupational therapists typically provide the intervention goals and activities concurrently as well as sequentially.

Optimize Child's Engagement

The child's engagement in an activity or a social interaction is an essential component of a therapy session. This engagement funnels the child's energy into the activity, helps him or her sustain full attention, and implies that the child has adopted a goal and purpose that fuels his performance in the activity. When children are given supports that enable them to focus on and engage fully in a learning activity, they are more likely to

persevere and attempt challenging aspects of the activity. Children engage in an activity and sustain engagement when they are motivated to participate, share positive affect with others (peers and adults) involved in the activity, and respond to and initiate interaction.^{64,82} These elements promote learning.^{44,85,95,107} The child's readiness to engage and self-regulation are foundational to his or her readiness to learn or participate in a therapy session (see Chapter 9).⁸¹ Occupational therapists often facilitate a child's self-regulation of behavior—that is, promote attentive, focused, calm behavior—using sensory strategies, social-emotional supports, or cognitive cues. Teachers more frequently use cognitive strategies or cues to promote a student's focus, whereas occupational therapists often use physiologic or sensory approaches that consider the child's arousal level, sensory modulation, attention, and comfort within the learning or intervention environment. They also provide social-emotional supports (e.g., relate to the child on a personal level) to promote motivation, self-efficacy, and interest in participation (see Chapters 11 and 23).

Parham and Mailloux (Chapter 9) propose that soliciting the child's active engagement and tapping the child's inner drive are key features of the sensory integration intervention. Engagement is essential because the child's brain responds differently and learns more effectively when he or she is actively involved in a task rather than merely receiving passive stimulation. Children integrate their sensory experiences and make adaptive responses when they are actively and fully engaged in participating.⁵

Engagement can be difficult to obtain when the child has an autism spectrum disorder. Sensory strategies (e.g., strategies that apply deep touch or rhythmic movement) that elicit a physiologic response of pleasure can be particularly useful for

engaging a toddler or young child with autism spectrum disorder.^{81,107} These strategies—for example, hugging and giggling, singing and touching body parts, rolling together—are playful ways to initiate imitation, joint attention, and social interaction. Spitzer¹¹⁹ suggests that an occupational therapist can engage a child with autism by beginning with his or her immediate interest, even if it appears as nonpurposeful (e.g., spinning a wheel, lining up toy letters, lying upside down on a ball). The occupational therapist may begin with the child's obsessive interest (i.e., trains, letters, or balls) and create a more playful, social interaction using these objects. By engaging in the child's preferred activity, the occupational therapist can foster and sustain social interaction, at the same time making the activity more playful and purposeful. Hilton (Chapter 11) further describes these intervention strategies to support positive social participation outcomes.

In Chapter 10, Mandich, Wilson, and Gain describe how the occupational therapist uses cognitive strategies (i.e., Cognitive Orientation to Occupational Performance [CO-OP]) to engage the child and build his or her motivation to master everyday occupations. The occupational therapist and child identify a performance goal of interest to the child. By guiding the child to identify the performance problem and then a feasible goal and plan for reaching that goal, the occupational therapist encourages the child's own problem solving and investment in achieving that goal. Mandich and colleagues explain how engaging the child as a collaborator in the intervention process enhances the child's motivation, best efforts to improve performance, and sustained engagement. There is emerging positive evidence for use of cognitive strategies to engage the child and improve occupational performance in children with developmental coordination disorder, high functioning autism, and attention-deficit disorder.^{85,103,124}

Prepare the Child to Participate

Occupational therapists prepare the child to participate in multiple ways, according to the type of disorder the child exhibits and the context in which he or she is performing. When children have motor challenges, various strategies are needed to enable the child to participate fully and perform optimally. For children with neuromotor disorders, occupational therapists select and arrange activities and environment supports to optimize postural alignment, postural stability, and motor control. The occupational therapist selects a positioning device or seating that supports midline and upright spinal alignment, offers a firm base of support, and facilitates postural stability for optimal eye-hand and bimanual manipulation skills. For example, using a prone stander can enable functional positioning for using eyes and hands together to manipulate objects in a well-aligned, weight-bearing posture. Caregivers report that when adaptive seating that supports posture well and gives the child a biomechanical advantage is used, the child's participation in eating, self-care, play, and recreational activities increases.¹⁰¹ Chapters 7 and 19 explain the importance of biomechanical principles to position and support a child with neuromotor disorders for optimal participation in daily tasks and play activities.

Other therapeutic techniques are used to prepare a child with a neuromotor disorder to participate in intervention activities designed to increase strength and motor control. Coker-Bolt, Reidy, and Nabor (Chapter 28) describe use of electrical

stimulation to improve muscle activation to perform a fine motor activity. Electrical stimulation is used immediately before and sometimes during a functional activity to strengthen weak muscles (e.g., that are overpowered by the antagonist muscles), increase range of motion, or reduce spasticity (see Chapter 28). Another technique that can facilitate or inhibit specific muscle groups is kinesiology taping. Emerging evidence suggests that kinesiology tape, applied before and during performing fine motor activities, can support joints and improve alignment, improve circulation, and reduce pain.¹³⁵

Splinting can also be used to support weak joints and, when used to support wrist or thumb joints, can give the child a biomechanical advantage for increased strength and control in manipulation or tool use. Additional preparatory techniques using biomechanical and neuromuscular principles are discussed in Chapters 28, 29, and 30.

In the acute care setting for children following trauma, preparatory activities may focus on pain reduction, improving the child's physiologic stability, or preventing secondary problems from extended periods of immobility. In Chapter 30, Lowe, Sharp, Thelen, and Warnken describe preparatory methods for children who are in acute care units for spinal cord injury, burns, or traumatic brain injury. The occupational therapist may contribute to nonpharmaceutical strategies to reduce pain and to provide more comfort. In Chapter 24, Dudgeon, Crooks, and Chappelle describe interventions to prevent loss of skills and potential injuries in children hospitalized following acute trauma who are not yet sufficiently stable to participate in purposeful activities. Occupational therapists along with nursing staff use preventive measures, including splinting and positioning, to ensure that range of motion and skin integrity are maintained during acute care or until the child is sufficiently stable to participate in activities.¹³⁶

Establish a Therapeutic Relationship

The occupational therapist establishes a relationship with the child that encourages, supports, and motivates. The occupational therapist first establishes a relationship of trust (Figure 1-9).^{15,129} The occupational therapist becomes invested in the child's success and reinforces the importance of the child's efforts. Although the occupational therapist presents challenges and asks the child to take risks, the occupational therapist also supports and facilitates the performance so that the child succeeds or feels okay when he or she fails. This trust enables the child to feel safe and willing to take risks. The occupational therapist shows interest in the child, makes efforts to enjoy his or her personality, and values his or her preferences and goals. The child's unique traits and behaviors become the basis for designing activities that will engage the child and provide the just-right challenge.

To establish a therapeutic relationship, occupational therapists demonstrate a positive affect, show personal interest in the child, and seek opportunities for personal connection. The occupational therapist collaborates with the child to select an activity of interest, makes the activity fun and playful, and gives the child choices.^{11,14,119} Fostering a therapeutic relationship involves respecting the child's emotions, conveying positive regard toward the child, attempting to connect with the child, and creating a climate of trust and emotional safety (see Chapters 9 and 11). The occupational therapist encourages positive affect by attending to and imitating the child's actions

FIGURE 1-9 Conversation helps to establish the occupational therapist's relationship with the child. (Courtesy of Suellen Sharp.)

and communication attempts, waiting for the child's response, establishing eye contact, using gentle touch, and making non-evaluative comments. By choosing activities that allow the child to feel important and by grading the activity to match the child's abilities, the occupational therapist gives the child the opportunity to achieve mastery and a sense of accomplishment. Generally, the intrinsic sense of mastery is a stronger reinforcement to the child and youth with greater probability of sustained effects than external rewards, such as verbal praise or other contingent reward systems.⁶ The occupational therapist vigilantly attends to the child's performance during an activity to provide precise levels of support that enable the child to succeed. A child's self-esteem and self-image are influenced by skill achievement and by success in mastering a task (see [Chapters 2 and 3](#)).⁷ This concept is illustrated in many chapters.

Research evidence suggests that interventions in which the occupational therapist establishes a relationship with the child and emphasizes playful social interaction within the therapy session have positive effects on children's development.^{50,120,133} Studies of the effectiveness of relationship-based interventions have found that they promote communication and play,⁵⁰ social-emotional function,^{51,80,120} and learning.

The occupational therapist remains highly sensitive to the child's emerging self-actualization and helps the team and family provide activities and environments that support the child's sense of self as an efficacious person. Self-actualization,

as defined by Fidler and Fidler,⁴³ occurs through successful coping with problems in the everyday environment. It implies more than the ability to respond to others: self-actualization means that the child initiates play activities, investigates problems, and initiates social interactions. A child with a positive sense of self seeks experiences that are challenging, responds to play opportunities, masters developmentally appropriate tasks, and forms and sustains relationships with peers and adults. In therapeutic relationships, the occupational therapist focuses on fostering the self-actualization of the child or youth. Vroman ([Chapter 4](#)) defines self-esteem, self-image, and self-worth and explains how teenagers' self-concepts influence health and activity. In [Chapter 12](#), Kramer and colleagues describe how occupational therapists can support adolescents' participation in self-advocacy activities, leading to increased social participation and enhanced quality of life. In [Chapter 16](#), Loukas and Dunn discuss the importance of therapeutic relationships for fostering self-determination in adolescents with significant disabilities. The practitioner's therapeutic relationship with the child appears to be a consistent feature of efficacious interventions.⁶⁹

Use Occupation as a Means and an End

As illustrated throughout this text, occupation-based models are core to occupational therapy practice with children and youth. The profession is uniquely skilled in understanding the interaction of person, his or her occupations, and contextual influences on those occupations.¹⁰⁵ As stated by Law,⁷² "Occupational therapy focuses on enabling individuals and groups to participate in everyday occupations that are meaningful to them, provide fulfillment, and engage them in everyday life with others." For young children, play occupations serve as the means and the end for interventions, and playfulness is part of interventions across age groups.^{11,95} Occupation-based models emphasize the interaction of person, environment, and occupation; use purposeful activities with goals that are meaningful to the child (and family); and incorporate holistic methods that consider the child's sensory, motor, social-emotional, and cognitive abilities. Occupation-based approaches are well researched, and the evidence consistently supports positive effects on performance. In a systematic review of occupation-based therapy, Lee⁷⁷ found 29 outcomes studies that demonstrate positive effects across a wide variety of ages and populations. In a systematic review of occupation-based interventions for children, Kreider, Bendixen, Huang, and Lim⁷⁰ found that in almost a third (12 of 38) of the studies, the researchers focused on the child's participation in occupations within natural contexts using interventions that adapted the environment or used occupational task practice, demonstrating the importance of linking context, occupation, and person in pediatric occupational therapy research.

One occupation-based intervention with emerging evidence of effectiveness is CO-OP (see [Chapter 10](#)). CO-OP is a task-oriented, problem-solving approach that engages the child or youth in setting goals and planning strategies to improve performance. This approach was originally designed for children with strong cognitive skills and motor limitations to improve in motor tasks⁸⁵; however, it has been used more recently with children who have high functioning autism.^{103,104} This occupation-based approach has shown positive effects in multiple single-subject design studies.^{85,86,97,104}

Motor learning approaches are also task-oriented interventions, acknowledging the importance of engaging children in meaningful, purposeful activities to harness their motivation and full efforts (see [Chapter 7](#)). Whole activities with multiple steps and a meaningful goal (versus repetition of activity components) elicit the child's full engagement and participation. Repeating a single component (e.g., squeeze the Play-Doh or place pennies in a can) has minimal therapeutic value. By engaging in an activity with a meaningful goal (e.g., cooking or an art project), children use multiple systems and organize their performance around that goal. For example, if a game requires that a preschool child attend to a peer, wait for his turn, and correctly place a game piece, the child is developing the joint attention that he needs to participate in circle time or a family meal. Functional magnetic resonance imaging studies indicate that more areas of the brain are activated when individuals engage in meaningful whole tasks versus parts of tasks (see [Chapter 7](#)).⁶⁸ Children and youth participate for more extended time and stay engaged in skills practice when the activity is meaningful.⁴⁷ In addition, the quality of movement improves when the activity has meaning to the child.¹²² Research supporting functional, task-oriented approaches has consistently resulted in positive effects.⁸⁹

Occupation-based models are illustrated throughout the text, including interventions for feeding ([Chapter 14](#)), activities of daily living ([Chapters 15 and 16](#)), play ([Chapters 9, 17, and 22](#)), school tasks ([Chapters 18 and 23](#)), and work occupations ([Chapter 25](#)). Chapters on social participation ([Chapters 11, 12, 13, and 23](#)) also emphasize occupation-based approaches, often involving groups of children and youth engaging in meaningful activities that facilitate social interaction.

Provide a Just-Right Challenge

A child's active participation and efforts to achieve a task are elicited when therapeutic activities are at just the right level of complexity—that is, where the child not only feels comfortable and nonthreatened but also experiences some challenge that requires effort. An activity that is a child's "just-right" challenge has the following elements: the activity (1) matches the child's developmental skills and interests, (2) provides a reasonable challenge to current performance level, (3) engages and motivates the child, and (4) can be mastered with the child's focused effort.

Based on careful analysis of performance and behavior, the occupational therapist selects an activity that matches the child's strengths and limitations across performance domains. The analysis allows the occupational therapist to individualize the difficulty, the pace, and the supports needed for a child to accomplish a task. Generally, the occupational therapist selects highly adaptable activities that can be modified to increase or decrease the difficulty level based on the child's performance. To promote change in the child, the activity must be challenging and create a degree of stress. The stress is meant to elicit a higher level of response. [Figure 1-10](#) provides an example of an activity challenging to a child with sensory integration problems. The interactions of the occupational therapist and the child are like a dance: The occupational therapist poses a problem or challenge to the child, who is then motivated by that challenge and responds. The occupational therapist facilitates or supports the action to prompt the child to respond at a higher level. The occupational therapist gives feedback

FIGURE 1-10 A climbing wall activity challenged this child's motor planning, bilateral coordination, strength, and postural stability.

regarding the action and presents another problem of greater or lesser difficulty, based on the success of the child's response. Cognitive, sensory, motor, perceptual, or social aspects of the activity may be made easier or more difficult ([Case Study 1-3](#)). By precisely assessing the adequacy of the child's response, the occupational therapist finds the just-right challenge.

Parham and Mailloux ([Chapter 9](#)) explain that occupational therapy sessions typically begin with activities that the child can engage in comfortably and competently and then move toward increasing challenges. For example, the occupational therapist may initially provide a child who has gravitational insecurity (i.e., fear of and aversion to being on unstable surfaces or heights with immature postural balance) with therapy activities that begin close to the ground and provide close physical support to help the child feel secure during a game played while sitting on a ball. Gradually, in subsequent sessions, the occupational therapist designs activities that require the child to walk on unstable surfaces and to swing with his or her whole body suspended ([Figure 1-11](#)). These graded activities pose a just-right level of challenge, while respecting the child's need to feel secure and in control. This gradual approach is key to maximizing the child's active involvement and to eliciting and practicing higher level skills.

Myers, Case-Smith, and Cason ([Chapter 22](#)) suggest that occupational therapists design and employ play activities that engage and challenge the child across domains (e.g., activities

CASE STUDY 1-3 Grading an Activity: Challenging and Eliciting Full Participation

Aaron, a 10-year-old boy with autism, participated in a cooking activity with the occupational therapist and three peers. The children were proceeding in an organized manner—sharing cooking supplies and verbalizing each step of the activity. As they proceeded, Aaron had great difficulty participating in the task; the materials were messy, and the social interaction was frequent and unpredictable. He performed best when the activity was highly structured, the instructions were very clear, and the social interaction was kept at a minimum. To help him participate at a comfortable level, the

occupational therapist suggested that his contribution to the activity be to put away supplies and retrieve new ones. The other children were asked to give him specific visual and verbal instructions as to what they needed and what should be replaced in the refrigerator or cupboard. With this new rule in place, the children gave simple and concrete instructions that Aaron could follow. An important element of this strategy was that it included the support of his peers to elicit an optimal level of participation and could be generalized to other small-group activities involving Aaron and his peers.

FIGURE 1-11 Applying a sensory integration approach, the occupational therapist gradually introduced a child with gravitational insecurity to unstable surfaces and higher levels of vestibular input.

that are slightly higher than the child's developmental level in motor, cognitive, and social domains). When a task challenges both cognitive and motor skills, the young child becomes fully engaged, and the activity has high therapeutic potential for improving the child's developmental level of performance.

Provide Supports and Reinforcement That Encourage Practice

Research evidence cited throughout this book indicates that more intense intervention has greater positive effects on performance.^{35,46,125} One intervention, constraint-induced movement therapy (CIMT), has been shown to have strong positive effects (see [Chapter 8](#)). This intervention uses a specific protocol with a specific population of children. In CIMT, the non-affected hand and arm of a child with hemiparesis cerebral palsy is casted, and the child practices specific skills with the affected hand and arm. CIMT also provides an intensive dosage of therapy ([Figure 1-12](#)). The “shaping” intervention is provided 3 to 6 hours a day for 21 days. Across time, trials of CIMT have demonstrated improvement in the child's upper extremity movement and function.^{25,57,110}

Although this level of therapy is not typical and may be impractical in most situations, these research findings suggest that intensive services have clear benefit. Schertz and Gordon¹¹³

FIGURE 1-12 In constraint-induced movement therapy, the child's less involved arm was casted, and she received intensive therapy to build skills in the involved arm and hand.

conclude that intensive interventions that involve repeated practice and progressive challenge can produce positive changes in functional performance. O'Brien ([Chapter 7](#)) explains the importance of repeated practice in skill attainment. She notes that children learn new skills with frequent practice and various types of practice. Motor learning studies have shown that intense (blocked) practice is helpful when first learning a new skill but that the child also needs variable and random practice to generalize and transfer the newly learned skill to a variety of situations. When distributed practice (i.e., practicing a task

alternating with periods of rest) is compared with blocked practice, distributed practice results in superior long-term learning.¹³⁹

Research has also demonstrated that interventions in which the child is rewarded for performing well have positive effects.^{16,123} Burtner et al.¹⁶ demonstrated that children with cerebral palsy and typical children who practiced with 100% feedback consistently demonstrated better performance on a complex motor task compared with children who had intermittent feedback. Feedback may be more important when learning a complex skill versus a simple task.

Based on a behavioral model, most occupational therapy interventions include reinforcement of the child's efforts. This reinforcement can range from hugs and praises to more tangible objects, such as a prize or piece of candy. Occupational therapists often embed a natural reinforcement within the activity. For example, the occupational therapist designs a session in which a group of four 12-year-olds with Asperger's syndrome bake cookies. The natural reinforcement includes eating cookies and enjoying socialization with others during the activity. Positive reinforcement includes both intrinsic (e.g., feeling competent or sense of success) and extrinsic (e.g., adult praise or a treat) feedback. O'Brien ([Chapter 7](#)) explains that feedback can be most effective when it is given on a variable schedule, with initially high-frequency feedback that is lessened as the skill is mastered. External feedback appears to be effective when it provides specific information to the child about performance and when it immediately follows performance.¹¹⁶ In summary, research evidence supports that children's performance improves with intense practice of emerging skills and with a system of rewards for higher level performance.

Support the Child's Transfer of Newly Learned Skills across Environments

Occupational therapists carefully plan strategies for children to generalize newly learned skills. Recognizing that transfer of new skills to natural environments does not always automatically follow performance of that skill in an intervention session, occupational therapists plan multiple ways for children to practice new skills in various tasks. They also recommend supports for performance that will ensure success. To support the generalization of new skills, occupational therapists educate caregivers and teachers to support and reinforce that practice. They suggest strategies to support the child's practice of skills in a variety of tasks. For example, in [Chapters 24](#) and [30](#) on hospital-based practice, the authors describe how children in rehabilitation units after trauma spend a weekend at home before discharge so that they can try newly learned skills in their natural environments with the support of family members. Based on feedback from the visit home, the occupational therapist solves the problem of how to improve function in the home and school environments. Education and coaching methods are illustrated throughout the text; see [Chapters 22, 23, and 25](#) for examples of consultation to promote skill transfer. These methods are also briefly described in the sections that follow.

Many research-based interventions include specific components to help the child generalize newly learned skills. Often these are home programs carefully developed in collaboration with parents to ensure that they are a good fit. Novak⁹¹ describes the components of an effective home program. She defines a "partnership home program" as one that includes (1)

establishing a collaborative partnership between the parent, child, and occupational therapist; (2) establishing parent and child goals; (3) selecting therapeutic activities that focus on achieving family goals; (4) supporting parents to implement the program through education, home visiting, and progress updates; and (5) evaluating outcomes. These elements are important to promoting the child's ability to generalize emerging skills to home activities. Approaching home programs first as a partnership, checking progress and supporting parents throughout, has demonstrated efficacy for improving parent efficacy and the child's function.⁹³ In summary, occupational therapists thoughtfully promote skill transfer by strategizing how and when children can practice new skills in different environments, by planning with teachers and parents how to phase out supports that were available during the intervention sessions, and by recommending how to modify the environment to enable successful performance.

Activity Adaptation and Environmental Modifications

The emphasis of intervention is often on implementing adapted methods or applying assistive technology to increase the child's participation despite performance problems. The following sections and many of the subsequent chapters explain how occupational therapists use task adaptation, assistive technology, and environmental modification to improve a child's participation in home, school, and community activities.

Interventions Using Assistive Technology

Occupational therapists often help children with disabilities participate by adapting activities and applying assistive technology ([Figure 1-13](#)). [Chapter 19](#) provides an in-depth explanation of assistive technology. In [Chapter 15](#), Shepherd offers many examples of adapted techniques to increase a child's independence in self-care and activities of daily living.

Technology is pervasive throughout society, and its increasing versatility makes it easily adaptable to an individual child's

FIGURE 1-13 The occupational therapist designed an adaptive switch so that the adolescent can activate a blender. (Photo © [istock.com](#).)

needs. Low-technology solutions are often applied to increase the child's participation in activities of daily living. Adapted techniques can be used to increase independence and reduce caregiver assistance in eating, dressing, or bathing. Examples include built-up handles on utensils, weighted cups, elastic shoelaces, and electric toothbrushes (see [Chapter 16](#)). Low technology solutions can also be used to support participation in play activities.⁷¹ Adapted techniques for play activities may include switch toys, battery-powered toys, enlarged handles on puzzle pieces, or magnetic pieces that can easily fit together.

High-technology solutions are often used to increase mobility or functional communication. Examples are power wheelchairs, augmentative communication devices, and computers. High technology is becoming increasingly available and typically involves computer processing and switch or keyboard access (e.g., augmentative communication devices) (see [Chapter 19](#)). As stated by Schoonover and Argabrite Grove, "Assistive technologies may unlock human potential and optimize human performance throughout the life span and across contexts and allow individuals to assume or regain valued life roles." Occupational therapists frequently support the use of assistive technology by identifying the most appropriate device or system and features of the system. They often help families obtain funding to purchase the device, set up or program the system, train others to use it, and monitor its use. Occupational therapists also make themselves available to problem-solve the inevitable technology issues that arise.

The role of assistive technology with children is not simply to compensate for a missing or delayed function; it is also used to promote development in targeted performance areas. Research has demonstrated that increased mobility with the use of a power wheelchair increases social and perceptual skills (see [Chapter 20](#)).^{63,90} Based on synthesis of the research and expert consensus, Livingstone and Paleg⁷⁸ concluded that for children with minimal mobility, a power mobility device can promote overall development. When introduced to power mobility, children particularly improve in psychosocial function.⁷⁸

The occupational therapist selects assistive technology not only to enable the child to participate more fully in functional or social activities but also to enhance the development of skills related to a specific occupational area. The use of an augmentative communication device can enhance language and social skills and may prevent behavioral problems common in children who have limited means of communicating.¹⁷ For example, to develop preliteracy skills, a child who has a physical disability with severe motor impairments can access a computer program that simulates reading a book; to promote computer skills, the child can use an expanded keyboard ([Figure 1-14](#)). The computer programs used in schools to promote literacy, writing, and math skills with all children are particularly beneficial to children who have learning and physical disabilities. Because schools have invested in universal design and appropriate accommodations for all learners, many students with disabilities can access computer programs that promote their literacy and writing skills. In [Chapter 19](#), Schoonover and Argabrite Grove describe currently available technologies designed to promote children's functional performance.

Assistive technology solutions continually change as devices become more advanced and more versatile. Although an

FIGURE 1-14 A switch activates a computer program that simulates a storybook. (Photo © [istock.com](#).)

occupational therapist can extensively train a student to use power mobility, an augmentative communication device, or an adapted computer, the child's skills with the technology will not generalize into everyday routines unless parents, teachers, and aides are sufficiently comfortable with and knowledgeable about the technology. Because it is important that the adults closest to the child be able to implement the technology and troubleshoot when necessary, the occupational therapist educates them extensively about how to apply the technology and remains available to solve problems that inevitably arise. Often, it is necessary to talk through and model each step in the use of the technology. Strategies for integrating the technology into a classroom or home environment (e.g., discussing the ways the device can be used throughout the day) help to achieve the greatest benefit.¹⁷ All team members need to update their skills routinely so that they have a working knowledge of emerging technology.

In many school systems, the occupational therapist serves as an assistive technology consultant or becomes a member of a district-wide assistive technology team. Assistive technology teams have been formed to provide support and expertise to school staff members in applying assistive technology with students. These teams make recommendations to administrators on equipment to order, train students to use computers and devices, troubleshoot technology failures, determine technology needs, and provide ongoing education to staff and families. Use of assistive technology is particularly helpful to adolescents preparing for supported employment (see [Chapter 25](#)).

Technologic solutions are described throughout this text and are the focus of [Chapters 15, 19, 20, and 25](#). These chapters offer the following themes on the use of assistive technology:

- Assistive technology is carefully selected according to the individual abilities of the child or youth (intrinsic variables), task demands or desired activities, and environmental supports and constraints (extrinsic variables).
- Techniques and technology should be adaptable and flexible so that devices can be used across environments and over time as the child develops.

- Technology should be selected with a future goal in mind and a vision of how the individual and environment will change.
- The strategy and technology should be selected in consultation with all caregivers, teachers, and other professionals and adults who support its use.
- Extensive training, ongoing monitoring to adjust the technology for optimal use, and outcome evaluation should accompany the use of assistive technology.

In summary, assistive technologies have significantly improved the quality of life for persons with disabilities. Computers, power mobility, augmentative communication devices, and environmental control units make it possible for children to participate in roles previously closed to them.

In addition to assistive technology designed specifically for children with impairments, children and adolescents with disabilities also have more access to technology through universal access. The concept of universal access, now widespread, refers to the movement to develop devices and design environments that are accessible to everyone. When schools invest in universal access for their learning technology, all students can access any or most of the school's computers, and adaptations for visual, hearing, motor, or cognitive impairment can be made on all or most of the school's computers. Universal access means that the system platforms can support software with accessibility options and that a range of keyboards, "mice" (tracking devices), and switches are available for alternative access. The concepts of universal design and access are well illustrated in [Chapter 19](#).

Environmental Modification

To succeed in a specific setting, a child with disabilities often benefits from modifications to the environment. Goals include not only enhancing a child's participation but also increasing safety (e.g., reducing barriers on the playground) and improving comfort (e.g., improving ease of wheelchair use by reducing the incline of the ramp). Children with physical disabilities may require specific environmental adaptations to increase accessibility or safety. For example, although a school's bathroom may be accessible to a child in a wheelchair, the occupational therapist may recommend the installation of a handlebar beside the toilet so that the child can safely perform a standing pivot transfer. Desks and table heights may need to be adjusted for a child in a wheelchair. See [Chapter 15](#) for additional examples.

Environmental adaptations, such as modifying a classroom or a home space to accommodate a specific child with a disability, can be accomplished only through partnership with the adults who manage the environment. High levels of collaboration are needed to create optimal environments for the child to attend and learn at school and at home. Environmental modifications often affect everyone in that space, so the modifications must be appropriate for all children in that environment. The occupational therapist articulates the rationale for the modification and negotiates the changes to be made by considering what is most appropriate for all, including the teacher and other students. Through discussion, the occupational therapist and teacher reach agreement as to what the problems are.

With consensus regarding the problems and desired outcomes, often the needed environmental modification logically

follows. It is essential that the occupational therapist follow through by evaluating the impact of the modification on the targeted child and others. The Americans with Disabilities Act provides guidelines for improving accessibility to schools and community facilities.

Often the role of the occupational therapist is to recommend adaptations to the sensory environment that accommodate children with sensory processing problems.³⁸ Preschool and elementary school classrooms usually have high levels of auditory and visual input. Classrooms with high noise levels may be overwhelmingly disorganizing to a child who is hypersensitive to auditory stimulation. Young children who need calming techniques or quiet times during the day may need their own physical space in the corner of the room where they are allowed to "take a break" intermittently throughout the school day. The occupational therapist may suggest that a preschool teacher implement a quiet time with lights off to provide a period to calm children. Contextual modifications to accommodate a child who has sensory processing problems are described in [Chapters 9, 11, 13, and 22](#).

Other environmental modifications can improve arousal and attention in children. Sitting on movable surfaces (e.g., liquid-filled cushions) can improve a child's posture and attention to classroom instruction.¹¹⁴ The intent of recommendations regarding the classroom environment is often to maintain a child's arousal and level of alertness without overstimulating or distracting the child. Modifications should enhance the child's performance; make life easier for the parent or teachers; and have a neutral or positive effect on siblings, peers, and others in the environment. Owing to the dynamic nature of the child and the environment, adaptations to the environment may require ongoing assessment to evaluate the goodness-of-fit between the child and the modified environment and determine when adjustments need to be made.

In a study of children with sensory processing challenges, Dunn et al.³⁹ used an intervention in which occupational therapists made recommendations for changing the family's contexts based on analysis of the child's sensory processing and sensory characteristics of the environment. This contextually focused intervention resulted in improvements in children's participation and parent's sense of competence. Law et al.⁷⁶ also examined the effects of intervention that focused on adapting the environment to promote function for children with cerebral palsy. A 6-month period of context-focused therapy was as effective as traditional occupational therapy in improving function in self-care, mobility, and participation.⁷⁶ Ecologic approaches that focus on use of adaptive equipment, assistive technology, and environmental modification are often achieved through consultation, coaching, and education.

Consultation, Coaching, and Education Roles

Pediatric occupational therapy involves working intimately with caregivers and teachers to create opportunities for the child to participate optimally across environments. This aspect of service delivery is challenging and fulfilling because it requires a complementary skill set to assess, plan, implement, and evaluate the effects of parent and teacher consultation, coaching, and education.

Consultation and Coaching

Services “on behalf of” children complement and extend direct service delivery. Occupational therapists provide these indirect services by consulting with, coaching, and educating parents, assistants, childcare providers, and any adults who spend a significant amount of time with the child. Through these models of service delivery, the occupational therapist helps to develop solutions that fit into the child’s natural environment and promotes the child’s transfer of new skills into various environments.

In [Chapter 9](#), Parham and Mailloux explain that a first step in consultation is “demystifying” the child’s disorder.¹⁴ By explaining the child’s behaviors as a sensory processing problem to teachers and parents, occupational therapists foster a better understanding of the reasons for the child’s behavior (e.g., constant bouncing in a chair or chewing on a pencil), which gives adults new tools for helping the child change behavior. Reframing the problem for caregivers and teachers enables them to identify new and different solutions to the problem and often makes them more open to the occupational therapist’s intervention recommendations.¹³ For a situation in which a highly specific, technical activity is needed to elicit a targeted response in the child, teaching others may not be appropriate, and a less complex and less risky strategy should be transferred to the caregivers to implement. To implement routinely a strategy recommended by the occupational therapist, teachers and caregivers need to feel confident that they can apply it successfully.

A major role for school-based occupational therapists is to support teachers in providing optimal instruction to students and helping children succeed in school (see [Chapter 23](#)). Occupational therapists accomplish this role by promoting the teacher’s understanding of the physiologic and health-related issues that affect the child’s behavior and helping teachers apply strategies to promote the child’s school-related performance. Occupational therapists also support teachers in adapting instructional activities that enable the child’s participation and collaborate with teachers to collect data on the child’s performance. This focus suggests that, in the role of consultant, the occupational therapist sees the teacher’s needs as a priority and focuses on supporting his or her effectiveness in the classroom.⁵³ Consultation is most likely to be effective when occupational therapists understand the curriculum, academic expectations, and classroom environment.

Effective consultation or coaching also requires that the teacher or caregiver be able to assimilate and adapt the strategies offered by the occupational therapist and make them work in the classroom or the home. The occupational therapist asks the teacher how he or she learns best and accommodates that learning style.⁵³ Teachers need to be comfortable with suggested interventions, and occupational therapists should offer strategies that fit easily in the classroom routine. The occupational therapist and teacher can work together to determine which interventions would benefit the child and be least intrusive to other students.

Education Roles

Occupational therapists also educate administrators and policy-makers about the need to improve accessibility of recreational,

school, or community activities. They work directly with school curriculum committees to modify curriculum materials and develop educational materials that align with the core curriculum and use universal design. They educate the public to improve attitudes toward disabilities (see [Chapters 12](#) and [25](#)). By participating in curriculum revision or course material selection, occupational therapists can help establish a curriculum that meets required standards but has sufficient flexibility to meet the needs of children and youth with disabilities. Often a system problem that negatively affects one child is problematic to others as well. The occupational therapist needs to recognize which system problems can be changed and how these changes can be encouraged. For example, if a child has difficulty reading and writing in the morning, he or she may benefit from physical activity before attempting to focus on deskwork. The occupational therapist cannot change the daily schedule and move recess or physical education to the beginning of the day, but he or she may convince the teacher to begin the first period of the day with warm-up activities. The occupational therapist can educate teachers on the benefits of using a simplified, continuous stroke handwriting curriculum, which can benefit children with motor-planning problems but also benefit all children beginning to write. Education on accessible playgrounds can promote greater participation and safety on the playground for all children, regardless of skill levels.

Ecologic models recognize the powerful influence of home, school, and community environments on child and youth outcomes (see [Chapter 25](#)).⁷⁵ Occupational therapists educate others about and advocate for environments that are both physically accessible and welcoming to children with disabilities. With an extensive background on which elements create a supportive environment, occupational therapists can help design physical and social environments that facilitate participation of every child. To change the system on behalf of all children, including children with disabilities, requires communication with stakeholders or persons who are invested in the change. The occupational therapist needs to share confidently the rationale for change, appreciate the views of others invested in the system, and change and negotiate when needed.

A system change through education is most accepted when the benefits appear high and the costs are low. Can all children benefit? Which children are affected? If administrators and teachers in a childcare center are reluctant to enroll an infant with a disability, the occupational therapist can advocate for accepting the child by explaining specifically the care that the child would need, the resources available, the behaviors and issues to expect, and the benefits to other families.

Convincing a school to build an accessible playground or establish a completely accessible computer lab are examples of how a focused education effort can create system change. Occupational therapists are frequently involved in designing playgrounds that are accessible to all and promote the development of sensory motor skills. Another example is helping school administrators select computer programs that are accessible to children with disabilities (see [Chapter 19](#)). The occupational therapist can serve on the school committee that selects computer software for the curriculum and advocate for software that is easily adaptable for children with physical or sensory disabilities. A third example is helping administrators

and teachers select a handwriting curriculum to be used by regular and special education students. The occupational therapist may advocate for classroom instruction that emphasizes prewriting skills or one that takes a multisensory approach to teaching handwriting (see Chapter 18). The occupational therapist may also advocate for adding sensory-motor-perceptual activities to an early childhood curriculum. In Chapter 23, Bazyk and Cahill describe the role of occupational therapists in promoting positive behavioral supports to improve school mental health outcomes. These examples of proactive roles to create system change illustrate how occupational therapy practitioners take leadership roles in promoting participation of all children and youth, preventing disability among children at risk, and promoting healthy environments where all children and adolescents can learn and grow.

Summary

This chapter introduces the book by describing concepts that characterize occupational therapy practices with children. All chapters of this book emphasize evidence-based interventions for children and youth across practice settings. The occupational therapy process was briefly explained and is illustrated in depth in the subsequent chapters of the book. Occupational therapy practice with children has matured in recent decades from a profession that relied on basic theories and practice models to drive decision making to one that uses scientific evidence in clinical reasoning. A primary goal of this book is to define and illustrate the application of research evidence in clinical reasoning. The subsequent chapters expand on the basic concepts presented in this chapter by exploring the breadth of occupational therapy for children, explaining theories that guide practice, illustrating practice models in educational and medical systems, and describing interventions with evidence of effectiveness.

Summary Points

- Occupational therapists provide child-centered services to ensure that intervention is developmentally appropriate,

meaningful and motivating to the child, and well aligned with the child's goals.

- In family-centered services, occupational therapists develop positive relationships with families, demonstrate compassion, exhibit responsiveness and sensitivity, and foster parental self-efficacy.
- Occupational therapists advocate for inclusion and recognize the value of services within the child's natural environments.
- Collaborative models of services delivery, such as classroom-embedded services or co-teaching, allow occupational therapy services to be integrated into the child's goals for participating in the curriculum and functioning in the school environment.
- Culturally competent occupational therapists respect the child and family's culture and design services that demonstrate respect for the family's culture.
- Occupational therapists access, interpret, and use evidence to make clinical decisions; high-quality, efficacious intervention uses evidence-based practice guidelines.
- Occupational therapists use top-down, ecologic assessment with performance analysis to determine how context, task demands, and performance strengths and limitations influence the participation of the child or adolescent.
- The intervention process includes specific methods to prepare the child or adolescent for participating in intervention.
- Evidence-based occupation-based models include establishing a therapeutic relationship, using occupation as a means and an end, providing a just-right challenge, providing appropriate supports for and reinforcement of performance, and supporting generalization of newly learned skills to natural environments.
- Ecologic models that include application of assistive technology and environmental modifications increase the participation of the child or adolescent in activities for daily living, play, school functions, and work.
- Occupational therapists have important roles in consulting with, coaching, and educating caregivers, teachers, and other professionals who support the participation of children and adolescents with disabilities.

CHAPTER

2

Foundations and Practice Models for Occupational Therapy with Children

Jane Case-Smith

KEY TERMS

World Health Organization International Classification System Ecologic theories Person-environment-occupation model Client-centered and family-centered practice Strength-based approaches

Practice models Learning/acquisition Behavioral theories Cognitive orientation Social participation Motor learning/motor acquisition Neurodevelopmental Sensory integration Coaching/consultation Prevention and primary care

GUIDING QUESTIONS

1. What overarching theoretical concepts guide occupational therapy practice with children?
2. What are primary theoretical models that define children's *occupation and participation* in the context of the cultural, social, and physical environments?
3. How are ecologic theories used in occupational therapy?
4. What is meant by person-environment-occupation congruence?
5. What are the implications of client-centered and family-centered practice?
6. Which major practice models and principles guide occupational therapy practice with children?
7. How do occupational therapists make intervention decisions using specific theories, conceptual models of practice, and principles?
8. What is the research evidence for major theories and practice models used by occupational therapists?
9. Using practice examples, how do intervention activities derived from different theoretical approaches and practice models compare?

Occupational therapists have developed and used theory as the basis for professional practice for many years. Early developers of occupational therapy focused on the theories of occupation and the use of time.^{113,161} As stated by Meyer,

Our conception of man is that of an organism that maintains and balances itself in the world of reality and actuality by being

in active life and active use, i.e., using and living and acting its time in harmony with its own nature and the nature about it. It is the use that we make of ourselves that gives the ultimate stamp to our [being] (p. 64).¹¹³

Meyer posited that humans maintain rhythms of work, play, rest, and sleep that need to be balanced and that “the only way to attain balance in all this is actual doing, actual practice” (p. 64).¹¹³ Current practices with children build on many of the original concepts of the profession’s founders that children learn and develop through their participation in activities and occupations. Social engagement (with family and friends) enables children to develop a sense of belonging and self-esteem that contributes to health and well-being. Since the time of Meyer, occupational therapists have continued to develop models of practice based on an understanding of humans as occupational beings. They have also integrated the theories and science of psychology, neuroscience, and other disciplines into their practices. This chapter describes overarching theoretical concepts, practice models, and principles commonly used in occupational therapy for children and youth. The chapter also provides examples of evidence for the practice models.

In the first section, we explain five overarching theoretically based concepts or models common to occupational therapy practice: (1) occupation and participation as these relate to health; (2) ecologic theories and person-environment-occupation (PEO) models; (3) International Classification of Functioning, Disability, and Health (ICF); (4) client-centered and family-centered models; and (5) strength-based approaches. In the following sections, specific practice models that align with the conceptual theories are explained. These sections are organized by cognitive, social, motor, and sensory outcomes, recognizing that the models are used to attain various client goals across performance areas.

Occupational therapists make decisions and select strategies using their synthesized knowledge of practice theories, including evidence for those theories, their own experiences, and their perceptions of the client’s priorities. Through the use of theory, assessment, and professional reasoning, occupational therapists hypothesize and develop interventions to improve the performance and participation of children. Practice models and the theories from which they are developed provide a guide and rationale for occupational therapy intervention.

As noted earlier, *theoretically based conceptual models* for occupational therapy practice with children have defined practice since the profession’s inception¹¹³ and have evolved with

continual refinement over the ensuing decades.^{8,71,89,121} *Practice models* more specifically define interventions for different types of children and settings and guide the day-to-day delivery of occupational therapy services. A practice model provides occupational therapists with specific principles, methods, and guidelines for decision making when evaluating, planning, and implementing intervention.

This chapter also explains the research evidence for occupational therapy models of practice. Evidence-based practice models and interventions are ones that have been tested through research that examined the theory's inherent relationships or assumptions. Intervention practices are often tested in controlled studies with inference to original theory. Testing of theoretical propositions about practice (i.e., which interventions promote children's performance, participation, and well-being) allows the profession to refine, revise, or expand practice models.

Overarching Conceptual Models

This section describes the overarching theoretically based concepts and models that influence the profession's core focus on occupation and participation of children and youth with disabilities. Ecologic theories are described as the foundation for PEO models. The ICF and the occupational therapy practice framework² are essential models for understanding how the environment and occupation are determinants of an individual's health, societal participation, and well-being. Family-centered and strength-based approaches, as cornerstones for occupational therapy practice with children, are defined.

Occupation and Participation

Throughout the 1920s and into the 1930s, the focus of occupational therapy was the development of the idea of occupation as a cure for disease and disability. The occupations best suited to cure specific medical problems were identified. The original focus of the profession was on the fundamental activities of human life: "work and play and rest and sleep" (p. 8).¹¹³ Occupational therapists continue to use the principles of graded, purposeful activity and a balance of work, rest, and play as the basis for intervention methods.^{111,161} As originally conceived, occupation has a dual role in the profession: the focus of intervention and the medium through which occupational therapists intervene.

Because occupations are everyday activities, they may appear to be simple; occupations are the basic activities that people perform each day for self-care, to care for others, to be productive, and to enjoy life. Engagement in occupation is driven by an intrinsic need for mastery, competence, and self-identity. Dunton,⁵³ a founder of occupational therapy, expressed his belief that occupation is as necessary to life as food and drink. The definition of occupation becomes more complex with the inclusion of its meaning or purpose. The meaning and value of an occupation are determined by the individual's culture and values. Occupations have many layers, relate to and are defined by one's roles, and are central to the human experience.

Although the original focus was on the therapeutic effect of occupation on mental health, this focus shifted during and after the world wars as a result of the escalating demand for physical

rehabilitation of soldiers and veterans. In the 1960s through 1980s, new knowledge from neuroscience and increased understanding of critical reasoning promoted the development of a science-based profession. Emphasizing work and play as the contexts for developing competency, Reilly^{141,142} developed a theory of occupational behavior in which the individual inherently strives to develop and achieve skill mastery. Her view of occupational therapy, "that man through the use of his hands as they are energized by mind and will, can influence the state of his own health" (p. 2),¹⁴⁰ has inspired generations of practitioners. In the 1970s, Fidler and Fidler⁵⁸ focused on the importance of purposeful activity, or *doing*, in the development of self and the prevention of disability. Yerxa et al.¹⁹⁴ followed Reilly's work, stating that in "authentic occupational therapy," the occupational therapist commits to the client's goals, offers activity choices that are meaningful, and engages the client in meaningful and purposeful activity. Also building on Reilly's theories, Kielhofner and Burke⁸² developed a model of human occupation that incorporated a systems view of the nature of occupation. In the model of human occupation, the motivation for occupation, the routine patterning of occupations, skilled performance, and the influence of the environment systematically and continually interact. This model expanded the understanding of life roles and the powerful influence they have on daily life and health.

Wilcock described occupation as a "synthesis of doing, being, and becoming."¹⁸⁵ Humans need to use time in a purposeful way to develop and flourish.¹⁸³ Occupational science, using primarily qualitative methods of analysis, integrates social, cultural, and historical views of how people live and act in everyday life. Studies have explored the relationships among activity, participation, and health; social views of disability; and quality of life and human experience of persons with disabling conditions.^{72,185} Both physical and mental health can be strongly influenced by a person's engagement in meaningful occupations, and, conversely, the absence of meaningful occupation can have dire health consequences.¹⁸⁴

For children, occupation and doing enable skill development, personality formation, and self-identity development. Occupations are linked to roles and evolve over the life span. Children's occupations are largely determined for them in the beginning of life, and they gradually become more independent and more responsible for how they use their time and in which activities they participate. The shift in responsibility for and independence in daily occupations is often delayed, uneven, and less predictable for children with disabilities. Occupational science studies have promoted understanding of how occupations develop,⁷⁶ the complexity of engagement in occupation, and the relationship between occupation and human health.

Development of Occupations

During the 1960s and 1970s, occupational therapists working with children had a strong developmental perspective. These theories attempted to explain the functioning and growth of children and adolescents from an occupational therapy perspective. Llorens⁹⁹ identified a developmental practice model that focused on the physical, social, and psychological aspects of life tasks and relationships. She viewed the role of the occupational therapist to be one of facilitating development, assisting in the mastery of life tasks, and enabling children to cope with life expectations. Gilfoyle, Grady, and Moore⁶⁵ created a

spatiotemporal adaptation model that views development as a spiraling process, moving from simple to complex. Adaptation is a continuous process of interaction involving the individual, time, and space. This model became central to occupational therapists' views of child development and fostered the development of intervention models.

In recent years, occupational therapy researchers have suggested a dynamic system perspective of developmental processes.^{74,75} A child's occupational development is based on complex, reciprocal, and nonlinear relationships involving the child's innate characteristics and environmental factors. Children develop in the context of interpersonal and social opportunities (e.g., interaction with other children). They learn by observing others perform activities, through play with other children and adults, and through adults teaching and modeling for them. These social mechanisms are the catalyst for much of a child's learning. Building on the work of Vygotsky¹⁷⁸ and Bandura et al.,⁶ Humphry⁷⁵ posited that occupations develop through vicarious learning when observing others. For example, children learn through shared occupations, such as circle time or group activities in preschool.

In addition to vicarious learning in social situations, children learn directly by engaging in novel activities. Through new play activities, the child reorganizes learned skills, adapts skills on the basis of trial and error, and tries new actions to accomplish the activity. Fully engaging in an activity is an important catalyst to learning. To engage completely, the child must find the activity to be meaningful, fun, and challenging. These concepts about development of occupational performance imply that children learn in social contexts and that engagement in activity results in learning. Various adult roles are implicated by these concepts, including designing group activities, creating learning environments, modeling, encouraging, supporting, and guiding.

At the broadest level, communities invest in children's learning by developing programs, places, and opportunities for social engagement that enable children to participate in community life. Examples of community investment in children with diverse developmental needs include childcare centers that welcome the attendance of children with disabilities, play spaces that use universal design allowing all children to use them, and educational programs that encourage the participation of families with young children. Communities that invest in child development support human resources, childcare centers, educational programs, and spaces that encourage healthy development and learning in children of all abilities. These influences are explained further in the later section on ecologic theories and PEO models. Chapter 3 further explains developmental theories used in occupational therapy.

Participation of Children and Youth with Disabilities

The goal of an occupation-based model of practice is the child's achievement of optimal occupational performance and participation. Participation (i.e., being involved and sharing in activities)⁹¹ meets a basic human need and contributes positively to health.²³ What do professionals know about the participation of children with special needs? Children with special needs have lower rates of participation in ordinary daily activities.¹¹ Young adolescents with physical disabilities need supports to participate in household chores, cooking, and managing their laundry

(see Chapter 16).⁵⁷ Researchers have also documented that children with disabilities are more restricted in active recreation and community socialization activities.¹⁰ Numerous researchers have found that children with disabilities participate less frequently in community activities than children without disabilities.^{11,108} Specifically, Bedell and Dumas¹¹ found that children with acquired brain injury were most restricted in participating in structured community events, managing daily routines, and socializing with peers, and they were least restricted in physical mobility. Youth with cerebral palsy have fewer opportunities to participate in community activities compared with children without disabilities.^{96,156} In their systematic review of studies of leisure activities in children and youth with physical disabilities, Shikako-Thomas et al.¹⁵⁷ found that children with disabilities participate more in informal activities (e.g., activities that require little or no planning and are often self-initiated, such as reading or playing with toys) than in formal activities (e.g., activities with a formally designated coach or instructor, such as music or art lessons or organized sports). These researchers later found that adolescents with cerebral palsy spend most of their leisure time in sedentary, informal recreation, such as watching TV or listening to music (Research Note 2-1).

Australian¹⁰⁵ and Canadian⁹⁵ studies found an inverse relationship in children with disabilities between the amount

Picture Me Playing—A Portrait of Participation and Enjoyment of Leisure Activities in Adolescents with Cerebral Palsy

Shikako-Thomas, Shevell, Lach, Law, Schmitz, Poulin, Majnemer, the QUALA group (2013). This descriptive study by a Canadian group of researchers examined the level of participation and enjoyment in leisure activities among adolescents with cerebral palsy. Participants were 175 adolescents 12 to 20 years old with a range of cerebral palsy severity. The participants completed the Children's Assessment of Participation and Enjoyment (CAPE). Occupational therapists complete the Manual Ability Classification System (MACS) and the Gross Motor Function Classification System (GMFCS) from parent report.

Results: The adolescents reported that their most frequent activity was watching TV or a rented movie or listening to music. When with peers, the participants "hung out" or visited. Older adolescents (>15 years old) engaged in few recreational activities and completed them less often. Adolescents who were ambulatory and had high manual ability participated in more activities and at higher frequency than adolescents who were nonambulatory and had low manual ability.

Implications for Occupational Therapy

- Adolescents with cerebral palsy most frequently participate in informal, passive recreational activities such as watching TV or listening to music.

of physical activity and age, with a significant decline in active leisure participation from childhood to adolescence. Although healthy children are less physically active as adolescents, they continue to participate in a wide range of leisure activities. In contrast, adolescents with disabilities engage in fewer leisure and social activities, and their activities tend to be more often home-based than community-based.¹⁵⁷ These studies conclude that greater efforts among community organizations are needed to support the participation of children and youth with disabilities.

Community participation appears to vary by type of disability and is higher for children with functional communication and social behavior. The most important determinant of participation is adaptive behavior (i.e., can the child express needs, follow instructions, and interact appropriately?).¹³⁰ Children who have sustained traumatic brain injury and have behavioral problems or executive functioning impairments may have more difficulty in structured activities than children with cerebral palsy, who can more often fully participate in structured activities.¹³ Adolescents with autism spectrum disorder (ASD) have limited social participation as they transition into young adulthood; almost 50% do not receive phone calls from friends or are not invited to activities with friends.¹²⁸ Limited social participation often continues into adulthood; more than 50% of adults with ASD do not have close friendships.⁹⁸ See Chapters 4 and 12 for discussions of adolescent participation.

Both intrinsic (personal) and environmental (family and community) factors influence the diversity of activities and the intensity of participation. As noted earlier, intrinsic factors include communication skills, adaptive behavior, motor function,¹²⁹ personality, and social skills. Social participation appears to be most influenced by the child's conversational ability and functional cognitive skills.¹²⁸ Girls tend to participate more in arts and social activities, and boys participate more in group activities involving physical activity and sports.^{54,157} Family support can have a positive or negative effect. Children's activities may be restricted by family time constraints, financial burden, and lack of supportive mechanisms (e.g., babysitting).^{95,176} Participation for children with disabilities is positively influenced by high levels of family cohesion, high incomes, strong family coping skills, and low levels of stress.^{95,157} Parents of children with disabilities report that barriers to participation are access to the physical environment; the physical, cognitive, and social demands of the activity; attitudes; peer relations; and safety.^{11,13} Encouraging participation in the typical activities of childhood needs to be the major focus of pediatric occupational therapy. Bedell et al.¹³ recommended that occupational therapists advocate for modification of the physical and social environments for community activities in ways that support full participation by children and youth with disabilities. In her seminal article, Law⁹¹ defined occupational therapy intervention principles that promote participation in everyday life (Box 2-1).

Ecologic Theories

Human ecology is the study of human beings and their relationships with their environments. *Environments* are the contexts and situations that occur outside individuals and elicit responses from them, including personal, social, institutional, and physical factors. Environmental factors can facilitate or limit

BOX 2-1 Best Practice Principles of Occupational Therapy to Promote Participation in Everyday Life

Occupational therapy:

- Is evidence-based and client-centered.
- Focuses on occupations important to each person within his or her environment.
- Acknowledges the power of engagement in occupation.
- Recognizes the force of the environment as a means of intervention.
- Has a broad intervention focus.
- Measures outcomes of participation.
- Focuses on occupations important to each person within his or her environment.

From Law, M. (2002). Participation in the occupation of everyday life. *American Journal of Occupational Therapy*, 56, 640–649.

engagement in occupation. A concept prevalent in the human development literature and more recently in health care is person-environment congruence, or *environmental fit* (i.e., the congruence between individuals and their environments).¹⁶² Over the past 3 decades, occupational therapy scholars have stressed the importance of the interaction between individual and environment, and most occupational therapy models of practice embrace the importance of cultural, social, institutional, and physical environments in the transactional relationship between people and the environments in which they live, work, and play.^{46,82,93,192}

Psychologists who created theories and models about the relationship between humans and their environments that have influenced occupational therapy include Bronfenbrenner,^{18,19} E. Gibson,⁶³ and J. Gibson.⁶⁴ Bronfenbrenner¹⁸ developed an ecologic model to explain how social and cultural environments influence a child's development. In his model, interdependent relationships between a child and his or her social and cultural environments have an important influence on the child's outcomes. Different levels of social support and social interactions surround the individual, including informal (e.g., family and friends) and formal (e.g., occupational therapists and teachers). Levels of the environment are defined by their proximity to the individual—family is most important, then friends and extended family, and then the community and society. Children and their families interact with and are influenced by all levels of the social environment. Changes at any level of the environment influence a person's behavior. Throughout the course of life, a person constantly adapts to and influences changes in his or her social environment.

According to Bronfenbrenner's theories of social development,¹⁸ occupational therapists are part of a person's social environment, and the occupational therapist's influence on the systems that closely surround the child may be as important as direct interventions to the child. Although social contexts change over the life span, family, community, and societal interrelationships continue, influencing outcomes for the individual. The interdependence between a person and the social environment implies that occupational therapists expand intervention strategies to include families and communities.

Ecologic psychologists E. Gibson⁶³ and J. Gibson⁶⁴ considered the interdependence of a person with his or her

FIGURE 2-1 The infant uses sensorimotor play with mouth and hands to explore an object.

environment to be an explanation of *perceptual* development. E. Gibson⁶³ understood that manipulative play had a key role in the infant's cognitive development and that a child's intrinsically motivated exploratory actions lead to perceptual, motor, and cognitive development. She defined an *affordance* as the quality of an object or an environment that allows an individual to perform an action. Action and perception are tightly linked: the child's first actions are to gather new information about the environment, and those actions form the basis for perceptual development (the child's understanding of the environment) (Figure 2-1). "As new action systems mature, new affordances open up and new experiments on the world can be undertaken" (p. 7).⁶³ As explained by E. Gibson:

The young organism grows up in the environment (both physical and social) ..., one that imposes demands on his actions for his individual survival. To accommodate to his world, he must detect the information for these actions—that is, perceive the affordances it holds ... evolution has provided [the child] with action systems and sensory systems that equip him to discover what the world is all about. He is "programmed" or motivated to use these systems, first by exploring the accessible surround, then acting on it ... extending his explorations further. The exploratory systems emerge in an orderly way that permits an ever-spiraling path of discovery. The observations made possible via both exploratory ... actions provide the material for his knowledge of the world—a knowledge that does not cease expanding, whose end (if there is an end) is understanding (p. 37).⁶³

Successful adaptation to the environment occurs when a person matches his or her activities to the affordances of the environment or when the person modifies the environment to achieve successful completion of an activity. The Gibsons' theories emphasize the importance of understanding a child's development in the context of daily surroundings and activities. Occupational therapists are encouraged to provide activities (based on their understanding of the activity's inherent affordances) that allow a child to explore and learn about the environment, enabling achievement of the child's goals. In Figure 2-2, an infant shows motivation to explore objects within her environment.

FIGURE 2-2 The infant is motivated to explore her environment.

Person-Environment-Occupation Models

PEO ecologic theories gave rise to occupational therapy models that situate a child's participation in the context of his or her social, cultural, and physical environment. Occupational therapy practitioners are concerned not only with the child's performance in everyday activities but also the environmental influences that enable a child's engagement and participation in activities.¹⁸⁶ Occupational therapy practitioners recognize that health is supported and maintained when clients engage in occupations and activities that allow desired or needed participation in home, school, workplace, and community life.²

Most occupational therapy practice models explain the interaction of person, occupation, and environment, recognizing the premise that human performance cannot be understood outside of context.⁴⁶ In earlier models (e.g., person-environment-performance, person-task-environment¹⁴⁵), the focus of primary intervention is on the person, with relatively less emphasis on changing environments. Law et al.⁹³ developed the PEO model, which focuses equally on facilitating change in the person, occupation, or environment.

The PEO model was developed using theoretical foundations from the *Canadian Guidelines for Occupational Therapy*, environmental-behavioral theory, and theories about optimal experience as proposed by Csikszentmihalyi and Csikszentmihalyi.³⁷ Csikszentmihalyi³⁸ explained that optimal experience, or "flow," occurs when a person's activity is an optimal challenge for his or her skill level; the person is focused on his or her actions and goals; time passes without awareness; and the activity becomes an end in itself. The PEO model suggests that optimal fit of the activity (occupation) and environment to a person's goals, interests, and skills can lead to optimal participation and health. The PEO model outlines the concepts of person, environment, and occupation as follows⁹³:

- **Person:** A unique being who, across time and space, participates in various roles important to him or her.
- **Environment:** Cultural, socioeconomic, institutional, physical, and social factors outside a person that affect his or her experiences.
- **Occupation:** Any self-directed, functional task or activity in which a person engages over the life span.

FIGURE 2-3 A, Person-environment-occupation model. B, Person-environment-occupation analysis. (From Law, M., Cooper, B., Strong, S., Stewart, D., Rigby, P., & Letts, L. [1996]. The person-environment-occupation model: A transactive approach to occupational performance. *Canadian Journal of Occupational Therapy*, 63[1], 9–23.)

The PEO model suggests that occupational performance is the result of the dynamic, transactive relationship involving person, environment, and occupation (Figure 2-3, A). Across the life span and in different environments, the three major components—person, environment, and occupation—interact continually to determine occupational performance. Increased congruence, or fit, among these components represents more optimal occupational performance (Figure 2-3, B).

The PEO model can be used as an analytic tool to identify factors in the person, environment, or occupation that facilitate or hinder the performance of occupations chosen by the person. Using this model, occupational therapy intervention focuses on facilitating change in any of these three dimensions to improve occupational performance. Specific models of practice, as defined in later sections, can be used in conjunction with the PEO model to address specific performance limitations or environmental conditions that impede occupational performance.

Occupational Therapy Practice Framework and World Health Organization International Classification of Functioning, Disability, and Health

The American Occupational Therapy Association² occupational therapy practice framework and World Health Organization¹⁹³ ICF are essential frames of reference for occupational therapists. The practice framework defines the domain and process of occupational therapy and has been internationally adopted by occupational therapists to guide the scope and process of practice.² The ICF is a classification system for health and health-related domains. Recognizing that the experience of disability is a universal human experience, the ICF views human functioning at three levels: the body (structure and function), the person (activities), and society (participation) (Figure 2-4). It also includes the domain of environmental factors, which can have a significant influence on a person's functioning and health. The ICF model of functioning, disability, and health depicts the dynamic interaction between a person and his or her environment at all levels of functioning. An extension of the ICF, the International Classification of Functioning,

FIGURE 2-4 The International Classification of Functioning, Disability, and Health (ICF). According to ICF terminology, problems with body functions and structure are called impairments; activity limitations are difficulties in executing tasks or actions; and participation restrictions describe problems with involvement in life situations. (From World Health Organization [2002]. *Towards a Common Language for Functioning, Disability and Health: ICF*. Geneva: WHO.)

Disability, and Health for Children and Youth has been developed to address the unique concerns of developing children.¹⁰⁰ The American Occupational Therapy Association has acknowledged the strong connection between its practice framework and the ICF by establishing the domain of the profession as “supporting health and participation in life through engagement in occupation” (pp. 626–627).²

The classification of levels and definition of occupational therapy domains offer a framework for explaining top-down and bottom-up approaches. Although occupational therapists traditionally focused on underlying performance or performance impairments—that is, a “bottom-up” approach—more recently developed interventions follow a “top-down” approach that focuses on changing the environment and adapting activities to increase the child's participation.

The occupational therapist may design bottom-up interventions to reduce impairment (e.g., by increasing strength,

improving balance, or reducing social anxiety). The advantage of a bottom-up approach is that by gaining specific new skills, the child's higher level performance may generalize to a broad range of activities (e.g., increased motor coordination may improve the child's handwriting, typing, cutting, and buttoning). A top-down approach allows the occupational therapist to think about multiple aspects of the child's performance, including the environment, the routine, activity patterns, contextual supports, and opportunities for participation, bringing a broader lens to the child's restricted participation. When using a top-down approach, the occupational therapist recommends modifications to the environment (e.g., social supports or assistive technology) to enhance the child's participation. Practitioners often use both approaches or use them sequentially. Systems (e.g., medical versus educational), occupational therapy roles (e.g., consultant versus direct therapy), resources (e.g., to purchase technology or modify the environment), expected outcomes (i.e., improved performance or increased participation), and the individual child (e.g., age, level of disability) influence the type of approach used. Using the practice models defined later in this chapter, Table 2-1 gives examples of top-down and bottom-up assessments and interventions.

Occupational therapy measures align with the ICF and enable practitioners to assess children at multiple levels. The School Function Assessment (SFA) is a scale that reflects a top-down approach rating the child's function at two levels, activities and participation.³⁴ Similarly, the Participation and Environment Measure for Children and Youth (PEM-CY)^{12,31} assesses the effect of home, school, and community environments on children's participation. The PEM-CY identifies the factors that support or limit a child's participation across contexts, identifying factors that the family can modify to increase the child's participation.³² Both the SFA and the PEM-CY take a top-down approach that identifies the environments and tasks that can be modified to accommodate increased performance and participation in specific contexts. Chapters 8, 11, 13, 16, and 17 provide additional examples of interventions using a top-down approach that emphasize task and environment modification.

Child-Centered and Family-Centered Service

Client-centeredness has always been an essential tenet of occupational therapy. In pediatric occupational therapy the client is

TABLE 2-1

Examples of Occupational Therapy Assessments and Interventions Categorized by the World Health Organization International Classification of Functioning, Disability, and Health (ICF) and the American Occupational Therapy Association Occupational Therapy Practice Framework*

Type of Approach	ICF Level	Occupational Therapy Practice Framework Domain	Assessment Examples	Intervention Example
Bottom-up	Body function and body structures	Client factors: Values, beliefs, and spirituality Body functions Body structures	Range of motion Muscle strength Motor coordination (Bruininks Oseretsky-2; M-Fun) Sensory processing (Sensory Processing Measure) Visual perception (Motor Free Visual Perception Test)	Biomechanical interventions, active range of motion Shaping and practice of motor skills Sensory integration intervention Action imitation Motor planning activities
	Activity and participation	Performance skills Performance patterns	School function (School Function Assessment; School AMPS) Self Care (PEDI-CAT; Wee-FIM) Social skills (Social Skills Rating Scale) Leisure and recreation (Children's Assessment of Participation and Enjoyment; Pediatric Activity Card Sort)	Handwriting interventions Self-regulation strategies Visual schedules for increasing activities of daily living Social skills groups Eating interventions Peer modeling
Top-down	Environmental and personal factors	Context and environment Activity demands	Environmental assessment (Home Observation for Measurement of the Environment [HOME]) Family preferences	Consult with school in developing a playground Recommend a Social Story for going to a restaurant with family Fit child in ultra-lightweight wheelchair for sports activities Modify work space for job internship

*Data from American Occupational Therapy Association. (2014). Occupational therapy practice framework: Domain and process (3rd ed.). *American Journal of Occupational Therapy*, 68(Suppl.1), S1–S48. <http://dx.doi.org/10.5014/ajot.2014.682006>; World Health Organization. (2001).

expanded to encompass the family in recognition that child and family are inextricably linked. In services for children and youth, this focus shifts from the parents of the young infant to the individual youth as he or she matures in decision making and self-determination. Client-centered occupational therapy practice emphasizes the importance of activities that are meaningful to the child, match the child or family's goals and priorities, provide choice, and elicit intrinsic motivation. During the past 30 years, families of children with disabilities have increased their roles in determining and implementing services for their children. Families have been leaders in promoting family-centered service, a philosophy of service provision that emphasizes the central role of families in making decisions about the interventions their children receive. Challenged by the changes in the health services field and an increased demand by consumers for involvement in the services they receive, health care providers have made great strides in implementing family-centered service.

The term *family-centered service* arose from early intervention programs. Three important concepts define the rationale for family-centered service: (1) parents know their children best and want the best for their children; (2) families are different and unique; and (3) optimal child functioning occurs in a supportive family and community context. Chapters 5 and 22 further explain the rationale for and application of family-centered practice.

In family-centered service, the family's right to make autonomous decisions is honored. The relationship between the family and professionals is a partnership in which the family defines the priorities for intervention and, with the service providers, helps direct the intervention process.⁵² In working with families, service providers emphasize education to enable parents to make informed choices about the therapeutic needs of their child. Comprehensive education about services and community resources can help families understand the disability, acquire tools to manage behavior, and develop strategies for obtaining community resources. In family-centered practice, intervention is based on the family's visions and values; service providers recognize their own values and do not impose them on the family. The family's roles and interests, the environments in which the family members live, and the family's culture make up the context for service provision. Individualization of both the assessment and the intervention processes is essential to family-centeredness. Intervention is viewed as a dynamic process in which clients and parents work together as partners to define the therapeutic needs of the child with a disability. Services are designed to fit the needs of the family, rather than forcing the family to fit the needs of the service providers or the intervention policies already in place. DeGrace explains that occupational therapy intervention needs to fit into a family daily routine because how a family participates in daily routines "defines who that family is and plays a key role in determining its health" (p. 348).⁴¹ Because each family is unique, practitioners need to ask about and learn how each family defines its routines, habits, and values and to adapt their services to this family-constructed definition. The overriding goal of intervention is to empower families by enhancing their capacity to manage the care of their child, to participate fully in desired roles and activities, and to pursue desired family goals.^{48,50}

The later section on coaching and consulting conceptual models defines approaches that occupational therapists use to

support families in problem solving and transfer therapy activities into family routines. Other examples of family-centered practice include helping families find social supports and network with other families¹⁴ and supporting families in gathering needed resources.⁶⁹

Parenting roles are strengthened and outcomes are improved when service providers solicit and value parental participation.⁴⁸ Increasing evidence in the literature indicates that interdisciplinary, family-centered services for children with disabilities lead to increased family satisfaction and may lead to greater functional improvement in children with disabilities.^{106,149} Parents are less likely to act on behalf of their child when practitioners are unresponsive to the family's needs, are paternalistic, or fail to recognize and accept family decisions.⁵¹ In a qualitative study of families participating in early intervention, parents asked for flexibility in how services are delivered. Parents vary in the extent to which they are willing and able to participate in interventions; it is inappropriate to give parents responsibilities for delivering intervention unless this model fits their preferences and abilities to manage.⁷⁰

Intervention programs and occupational therapy practice need mechanisms for families to provide feedback about their experience and satisfaction with services. The findings of a large survey distributed at Canadian children's rehabilitation centers indicate that parental satisfaction with service is primarily determined by the family-centered culture of the organization and by parental perceptions of family-centered service.⁹⁴ Family satisfaction with services also decreases feelings of distress and depression and improves feelings of well-being.⁸³ Using qualitative methods, Hiebert-Murphy et al.⁷⁰ confirmed previous findings that families desire professionals who work collaboratively to identify and meet the family's goals. Occupational therapists enhance the effectiveness of their services when they practice from a family-centered perspective.

Strength-Based Approaches

A child's motivation, attitude, and self-perception are core to his or her initiative to attempt new skills and responsiveness to environmental demands. The relationship between learning and other affective components is complex. It is widely accepted that children's motivation to perform occupations is influenced by their perceptions of self-efficacy, regardless of whether these perceptions are correct.¹⁰ Learning and competence are also enhanced through positive and supportive relationships.^{88,150} When children experience success in learning situations, they gain perceived competence and internal control, gain support from significant others, and show pleasure at mastering the task. The assumption is made that with success, a child is more likely to seek new optimal challenges.⁶ The corollary of this theory is that a child who experiences repeated failure begins to avoid challenges and is less likely to seek new learning situations.

In a strength-based approach to intervention, the strengths of the child and family are identified and become the building blocks for skill development and optimal participation. At the foundation of a strength-based approach is the belief that children and families have unique talents and skills that often are not recognized by professionals.⁵⁵ Implied in this approach is a positive, respectful relationship between the child and family and the occupational therapist. A focus on child and family

resources and strengths and building on a positive therapist-client relationship imply different approaches to performance deficits. For example, a child with ASD who is cognitively proficient but is nonverbal may benefit from alternative methods of communication, rather than a focus on developing speech. A child with cerebral palsy who has communication and social competence but few functional fine motor skills may best participate in school by using a “buddy” whom he or she directs to perform required motor tasks.

A strength-based approach means that the occupational therapist:

1. Recognizes the strengths of the child or youth and accesses strengths to attain new levels of participation.
2. Gives the child or youth meaningful choices.
3. Collaborates with the child or youth in defining intervention goals.

Therapy goals that focus only on the child’s deficits and missing skills miss the opportunity to use the child’s strengths to promote function and participation. Strength-based approaches lead to increased self-determination. When children feel self-efficacious, they are motivated to try harder and to improve performance; they take initiative in attempting new activities and have greater facility to problem solve when they meet barriers. Self-efficacy beliefs contribute to motivation in several ways. A child with self-efficacy tries harder to attain a goal, expends more effort, perseveres in the face of difficulties, and is willing to try again when failing.¹⁰

Occupational therapists need to be aware of the importance of emphasizing a child’s strengths, providing successful learning opportunities, and supporting the child or youth in challenging situations. Child strengths known to promote growth and participation include strong self-esteem, positive mental

health, and positive communication skills.^{9,181,182} Other child attributes that are associated with positive outcomes include intelligence, emotion regulation, temperament, coping strategies, and attention.¹⁷² Children and youth who can effectively process information and problem solve can use these abilities in adverse situations.⁸⁴ Children who can regulate their emotions can monitor and modify the intensity and duration of their emotional reactions, enabling them to function better at school and in social relationships. An easygoing temperament is also a protective factor because it may evoke more positive attention from adults. Coping skills are also important because children with strong coping skills can moderate the impact of a difficult situation.¹⁹⁰

The family, extended family, and environment can provide supports and resources that enhance the child’s ability to cope with challenges and optimize the child’s participation. Table 2-2 lists protective factors in the social environment that foster optimal child development. Family resources such as love, nurturance, and a sense of safety and security increase the child’s resilience. Attributes of the family that influence positive outcomes include family cohesion and harmony. Researchers have shown that a high-quality relationship with at least one parent, characterized by high levels of warmth and openness and low levels of conflict, is associated with positive outcomes across level of risk and stages of development.¹⁰²

Protective factors in the community also contribute to the child’s development. These are specified in Chapter 4. Neighborhood quality, youth community organizations, quality of school programs, and after-school activities all can influence a child’s ability to cope with risk factors and overcome adversity.¹⁷² Attributes of the social environment that promote resilience include extended social support and availability of external

TABLE 2-2 Protective Factors in Families and Communities That Promote Health and Well-Being in Children

Protective Factor	Strategies That Promote Parenting Roles to Enhance the Child’s Well-Being
Nurturing and attachment	Emphasize bonding and attachment throughout childhood. Support fathers in nurturing roles. Encourage play, particularly pretend and creative play. Support families in using positive discipline methods.
Knowledge of parenting and child development	Encourage parents to guide and reinforce appropriate child behaviors. Model desirable behaviors. Recommend nonpunitive disciplinary techniques.
Parental resilience	Teach or recommend stress management techniques. Suggest community resources and supports, such as faith communities. Participate in programs that offer family-to-family help. Suggest community supports for mental health if these are indicated. Guide, model, and encourage problem solving.
Societal connections	Help family overcome transportation, childcare, or other barriers to participate in a social network. Encourage the parent to join a parent’s group or play group.
Concrete supports for parents	When appropriate, link parents with community leaders or disability groups to organize support and advocacy. Give parents suggestions on how to advocate for their interests and needs.
Social and emotional competence of children	Teach or model responsive interactions with the child. Praise the parents’ nurturing behaviors; acknowledge the child’s assets and positive traits. Encourage the parents to share their child with extended family and friends.

Adapted from U.S. Department of Health and Human Services, Administration for Children and Family, Child Welfare Information Gateway. *Protecting Children/Strengthening Families* (n.d.). <<https://www.childwelfare.gov/preventing/preventionmonth/factors.cfm>> Accessed January 3, 2014.

resources. Environmental factors, such as family-centered service delivery, acceptance of community attitudes, supportive home environments, and mentoring relationships with adults, have been shown to have a positive influence on child development.^{178,182} The concepts discussed in this section share the common goal of promoting participation in social and physical roles, enhancing quality of life, and increasing self-efficacy. Figure 2-5 shows the theoretical constructs and intervention principles described in this section that promote an individual's self-efficacy and self-determination.

Conceptual Practice Models Specific to Performance Areas

Most conceptual practice models used by occupational therapists who work in pediatrics are concerned with change,

specifically enhancement of children's behaviors, skills, and life participation. This section describes practice models that form intervention principles and guide practice in the following areas: (1) cognitive performance, (2) social participation, (3) sensory and motor performance, (4) task and environment adaptation, and (5) coaching and consultation. Practice models can be used across and within different *phases of intervention*: (1) preparation—interventions to promote self-regulation, sensory modulation; (2) behavioral change and skill development; and (3) generalization or transfer of learning. See Figure 2-6 for examples of practice models appropriate for different phases of intervention.

Cognitive Performance

Occupational therapists apply learning theories and principles when teaching children basic life skills, often embedding

FIGURE 2-5 Relationship of theoretical constructs to a common goal of self-determination and self-efficacy.

FIGURE 2-6 Examples of practice models and principles that can be used in phases of intervention.

learning concepts into the child's daily routine and natural contexts. Learning is the acquisition of knowledge, skills, and occupations through experience that leads to a permanent change in behavior and performance. Learning to perform at higher levels and adapting to performance difficulties reflect neuroplasticity (i.e., the ability of the central nervous system [CNS] to adapt to and assimilate novel information or tasks). Learning theories foundational to occupational therapy practice models include behavioral theories and social cognitive learning. This section includes a description of the cognitive orientation to daily occupational performance approach, in which a child or youth uses cognitive (and metacognitive) skills to establish goals and apply learning techniques to overcome functional deficits.

Behavioral Theories

The past 60 years have witnessed tremendous progress in the field of learning theories. Early learning theorists, such as Thorndike, emphasized the association between a behavior and the resulting reward or punishment as a simple explanation of behavioral change. More than 60 years ago, Skinner¹⁵⁹ developed learning theories based on his belief that the environment shapes all human behaviors and that behaviors may be randomly emitted in response to an environmental stimulus. Learning occurs when a person tries a behavior that worked in a previous situation and the behavior is reinforced by environmental consequences that follow. Learning can also occur when a person exhibits an involuntary, reflexive response to an environmental stimulus and is subsequently reinforced by a consequence. This sequence—stimulus situation, behavioral response, and environmental consequence—constitutes a *contingency of behavior*, the mechanism by which the environment shapes behavior.

Through natural occurrences in the environment, a child's adaptive behaviors are reinforced, and behaviors that are not adaptive are ignored or punished.¹⁶⁰ The Skinnerian concept that became fundamental to interventions for children is *instrumental* or *operant learning*, or the use of reinforcement to modify behavior. Behavior is strengthened and maintained when it results in positive reinforcement (rather than punishment). If reinforcement is absent (i.e., not given and therefore negative), positive behaviors may be extinguished. Behavioral interventions are explained further in [Chapters 13](#) and [15](#).

Applied behavior analysis has been well developed in the fields of education and psychology. Applied behavioral interventions primarily use operant conditioning in highly controlled environments in which an occupational therapist or teacher gives the child an instruction and rewards the child for an appropriate response (reinforcement). Components of the approach are in-depth analysis of behavior to understand when and why a behavior occurs and development of strategies to modify the targeted behavior. The child is presented with a stimulus that prompts a new behavior that is rewarded or reinforced. Prompting and reinforcement are repeated until the behavior is learned.¹²² Extensive research has confirmed that when particular behaviors result in specific, consistent consequences, these behaviors are learned.³³

Occupational therapists using operant conditioning techniques can help a child achieve a higher level of performance or to refine an existing skill through a process called *shaping*.¹³⁶ Shaping involves breaking down a complex behavior into

components and reinforcing each component of the behavior individually and systematically until it approximates the desired behavior ([Box 2-2](#)). Although this technique is structured, the occupational therapist implements shaping techniques into the child's play, and play activities are used to motivate the child's actions ([Figure 2-7](#)).

BOX 2-2 Example of Shaping Techniques

Shaping is a systematic process of progressive acquisition of a new behavior through performance of successive acts that collectively represent a more advanced skill. In this process, the occupational therapist (1) defines behavior as a series of incremental steps or parts, (2) prompts and cues the child to demonstrate the steps, and (3) rewards each successive approximation of the skill. Shaping is appropriate for multi-component skills that have a developmental progression in which the skills can be divided into steps and a progression in performance can be elicited. It is implemented within the child's play activities and within natural interaction. The small steps can be modeled, cued, or prompted. The child's responses and actions are immediately reinforced. During this repetition, a higher level skill is prompted and when performed it is reinforced.

For example, 5-year-old Anne has left hemiparesis with limited reach and grasp in her left arm. The occupational therapist initiated building a castle with large Lego pieces. She initially positioned the castle so that Anne used her left hand to place blocks on the left side and at midline. The occupational therapist praised her successful placement of blocks, encouraging her to build a taller and bigger castle. Seeing repeated successes in block placement, the occupational therapist moved the castle to a position that required Anne to reach with her left hand across midline. As the castle grew bigger, Anne had to reach overhead with her left hand, at which time the occupational therapist provided physical support at her left shoulder with continued positive verbal reinforcement. Because overhead movement was an emerging skill, Anne and the occupational therapist practiced this movement repeatedly before moving on to another activity.

FIGURE 2-7 In this example, the child selected the activity (finger painting) and the medium (shaving cream). The occupational therapist reinforces the child's efforts to reach overhead with praise and touch.

TABLE 2-3**Comparison of Discrete Trial Training and Incidental Teaching in Early Childhood Programs**

Discrete Trial Training	Incidental Teaching
Occupational therapist plans highly structured sessions with planned stimulus and reward.	Occupational therapist plans a loosely structured session with environment designed to elicit specific responses, but directives are not used.
Occupational therapist gives instructions to direct the child's actions.	Child initiates and paces the activity.
The training session is generally one-on-one in a clinic or the home.	The session generally takes place in the classroom, childcare center, or home, in the child's natural environment.
The same stimuli are used repeatedly.	A variety of stimuli selected from the natural environment is used.
Occupational therapist uses artificial reinforcers and often the same reinforcers.	A variety of reinforcers selected from the natural environment is used.
	The goal is that these reinforcers be available to the child without the presence of the occupational therapist.

Adapted from Cowan, R. J., & Allen, K. D. (2007). Using naturalistic procedures to enhance learning in individuals with autism: A focus on generalized teaching within the school setting. *Psychology in the Schools, 44*, 701–715.

In recent years, learning and behavioral theories used with young children have evolved into approaches that can be applied broadly across settings. Applied behavioral interventions are successful in developing skills; however, skills learned in an isolated setting, as in discrete trial training, do not always generalize into new or higher level behaviors across all settings. Educators have developed behavioral approaches that also use Skinner's framework of instrumental (operant) learning and can be implemented in the child's natural environment to teach children adaptive behaviors that generalize across environments.⁸⁷ Educators in early childhood programs have advocated for naturalistic teaching procedures that can be implemented in minimally structured sessions in various locations and contexts with a variety of stimuli. Although educators and occupational therapists who used naturalistic teaching procedures hold the same developmental goals for children as professionals who use classical behavioral theory, their procedures tend to be more flexibly structured, incorporate peers, and use naturalistic conditions and reinforcers.³⁵ Two types of these naturalistic learning procedures, incidental teaching and pivotal response training, are frequently used by occupational therapists with young children in early childhood programs and are described subsequently. A third evolution of behavioral theories, positive behavioral supports, uses functional behavioral assessment to identify antecedents to behavior that can be removed from or modified with the environment. Positive behavior supports are implemented school-wide by teams of teachers, aides, and occupational therapists to promote positive student behavior and prevent harmful, inappropriate behavior. This preventive model is described in [Chapter 23](#).

In *incidental teaching*, a play environment is created to stimulate the young child's interest and curiosity. It is important that toys used be developmentally appropriate and include both novel and familiar toys. The goal is for the child to select an activity and spontaneously begin to play. The occupational therapist builds on the child's play selection by expanding the play scenario so that it becomes more challenging or creates a problem for the child to solve. The occupational therapist may cue the child to perform a different action and reward the child for attempting more challenging actions. These teaching sessions take a different approach than behavioral interventions, which use discrete trial training in which the child is given

specific directives and rewarded for a specific response. [Table 2-3](#) compares incidental teaching and discrete trial training.

Pivotal response training is also a naturalistic teaching and learning approach used with young children.⁸⁶ The goal of pivotal response training is to teach children a set of pivotal behaviors believed to be central to learning. The desired outcomes of pivotal response training include increasing (1) the child's motivation to learn, (2) attention to learning tasks, (3) persistence in tasks, (4) initiation of interactions, and (5) positive affect.¹⁰⁷ Procedures that are used in pivotal behavioral training are similar to procedures used in incidental teaching with emphasis on methods to promote generalization of learning. When applying pivotal response training, the occupational therapist gives the child a choice in play materials, uses natural reinforcers, intersperses mastered tasks with learned tasks, and reinforces attempts at new learning ([Figure 2-8](#)).³⁵

Social Cognitive Theories

In general, social cognitive theory explains learning that occurs in a social context. The initial acquisition of highly complex and abstract behaviors was difficult for learning theorists to explain until the advent of the social cognitive theory proposed by Bandura et al.⁶ Children learn by observing the behavior of others.⁷⁵ This learning may not be immediately observed in behavior but becomes part of the child's general understanding of the world. In contrast with the behaviorists, who believe that all learning produces behavioral change, social cognitive theorists believe that learning can occur without observable behavioral changes. A child can learn by observing the behavior of others, such as subtle nonverbal gestures that are used in conversation. These are observed and stored in memory and may not be demonstrated by the child until a much later time, when the child may exhibit similar gestures but with his or her own unique style.

In social cognitive theory, people determine their own learning by seeking certain experiences and focusing on their own goals. Children do not simply learn random elements from the environment; they direct their own learning and are goal-oriented in what they learn. Social cognitive theorists also believe that children learn indirectly by observing how their peers' behaviors are rewarded or punished. Direct reinforcement is not always needed when learning new behaviors.¹²⁷

FIGURE 2-8 A-C, Challenging tasks are interspersed with mastered tasks.

These principles do not always apply in the case of children with ASD, for whom learning often needs to be more explicit, structured, and directed.

With some exceptions, children frequently learn by observing the consequences of behaviors of individuals around them. Learning that occurs when observing the behaviors of others also depends on the child's goals, interests, and relationship to the observed individual. Children's learning increases when they are given an incentive to learn a new behavior (e.g., an anticipated valued outcome or reward). Learning is also promoted when the child establishes his or her own goals, is given opportunities to work on those goals, and evaluates whether the goal was accomplished. When children set their own goals, they direct their behavior in a specific way; they are more likely to persist in the behavior to achieve the goal; and they are often more satisfied with the outcome. Practice models that use social cognitive and cognitive theories are described in the next section.

Cognitive Approaches

Cognitive approaches are “top-down” or occupation-based approaches because the emphasis in occupational therapy is on assisting the child to identify, develop, and use cognitive strategies to perform daily occupations effectively. These models build on Bandura's research⁶ supporting the importance of self-efficacy and establishing goals to motivate individual achievement.

In cognitive approaches, the occupational therapist designs interventions to increase a child's repertoire of cognitive strategies and improve the child's ability to select, monitor, and evaluate his or her use of these strategies during the performance of a task. The inherent assumption is that improved performance results from the dynamic interaction of the child's skills with the parameters of the task in the context in which it needs to be performed. The child discovers, applies, and evaluates cognitive strategies during task performance in his or her typical environments.¹¹⁹

In a cognitive model of practice, the occupational therapist identifies and uses a global problem-solving strategy, which provides a consistent framework within which the child discovers specific strategies applicable to tasks that he or she either needs or wants to perform. This global strategy is based on the five-stage problem-solving structure first outlined by Luria.¹⁰¹ Using occupational therapy terminology, these steps include (1) task analysis, (2) anticipation of the child's difficulties, (3) exploration and selection of task-specific strategies, (4) application of a strategy to the task, and (5) evaluation of the strategy's effectiveness.¹¹⁸ The occupational therapist guides the child to develop his or her own cognitive strategies based on the problems encountered during tasks. The task-specific strategies a child discovers are unique to him or her.

Using cognitive skills to assess his or her performance, identifying successful and unsuccessful actions, the child learns to become more efficient in functional activities. The occupational therapist supports the child's goals and self-evaluation. The occupational therapist can also cue, prompt, or model the task, aligning these supports to the child's goals. The atmosphere in the therapy session is one of acceptance and support for taking risks. Although the child guides the selection of activities, the occupational therapist is always aware of the generalization and task-specific strategies that the child needs to learn and creates opportunities for the child to discover these.^{119,138}

Because the selection of tasks is critical to the approach, a client-centered tool must be used that allows the child to identify goals for intervention. An appropriate goal-setting instrument for use with children older than 9 years of age is the Canadian Occupational Performance Measure⁹⁵; for children 5 to 9 years old, the Perceived Efficacy and Goal Setting system can be used.¹²⁰ The cognitive approach is probably not a suitable model of practice for children younger than 5 years old because of its emphasis on the development of metacognitive skill and knowledge.

One of the key features of a cognitive model of practice is the way in which the occupational therapist helps the child explore strategies, make decisions, apply strategies, and evaluate their use. The occupational therapist does not give instructions. Rather, occupational therapists use questions to help children (1) discover the relevant aspects of the task, (2) examine how they are currently performing the task, (3) identify where they are getting "stuck," (4) creatively think about alternative solutions, and (5) try out these solutions and evaluate them in a supportive environment. When a strategy is found to be helpful, the occupational therapist uses questions to help the child "bridge" or generalize the strategy, eliciting from the child other times and situations in which that strategy may apply.¹³⁸

In recent years, a particular cognitive approach, the Cognitive Orientation to daily Occupational Performance (CO-OP),¹³⁷ has been developed and researched systematically (see Chapter 10). The CO-OP approach is most appropriate for children who demonstrate cognitive strengths and a range of performance problems. The components include (1) working with the child to establish the goals, (2) analyzing performance, (3) identifying cognitive strategies to use, (4) guiding the child to discover solutions to the performance problem, (5) enabling the child to improve performance relative to the goal, and (6) promoting generalization and transfer. The child is asked to apply a global executive strategy, "Goal, Plan, Do, Check,"¹¹² to guide his or her problem solving. CO-OP has

been successfully applied to children with developmental coordination disorders,^{15,180} attention-deficit/hyperactivity disorder, traumatic brain injury,¹¹⁷ and high functioning autism.¹²⁸

Evidence is accumulating that CO-OP is effective at enabling skill acquisition and that it results in generalization and transfer of learned skills.¹³⁸ A randomized clinical trial comparing CO-OP with an equivalent number of sessions of direct skill training found that although children in both groups improved and achieved motor goals, the gains in the CO-OP group were greater; long-term maintenance both of the motor goals and of the cognitive strategies was significantly stronger in the CO-OP group, which led parents to report greater satisfaction with this treatment approach.¹¹⁵

Various cognitive strategies have been identified that seem to be helpful when using CO-OP to remediate occupational performance difficulties. Videotape analysis has been used to identify systematically and describe some of these strategies.¹⁰⁹ Verbalization and repetition of the strategy, "Goal, Plan, Do, Check"¹¹² to guide problem solving appears to be important to maintaining goal-directed action. In addition, specific strategies seem to be useful for improving performance, including verbal self-guidance (child talks himself or herself through the motor sequence), feeling the movement (drawing attention to an aspect of the sensation of movement as it is performed), motor mnemonic (labeling a body position or motor sequence), body position (verbalizing or directing attention to the body position or body parts relative to the task), and task specification (discussing specific parts of the task or actions to change the task).¹⁰⁹ Chapter 10 summarizes the research on the CO-OP approach with various diagnoses.

In summary, occupational therapists who use a cognitive model of practice (1) focus on the occupations a child wishes to perform rather than on foundational skill building; (2) use a general problem-solving framework that guides the child to discover, select, apply, and evaluate the use of specific cognitive strategies; (3) use process questions to increase the child's awareness of the use of strategies during the performance of daily tasks; and (4) plan for transfer and generalization of the strategies that the child has learned.^{118,138}

Social Participation

Occupational therapists use various psychosocial approaches when working with children and adolescents experiencing problems in occupational performance because of social, emotional, or behavioral issues or difficulties with relationships. Several of these approaches, such as a cognitive approach or the compensatory and environmental approach, were described in the previous section. These approaches are grounded in theories that focus on the development of self, on family and peer relationships, and on the aspects of the social and cultural environment that influence each of these. Although the number of occupational therapists who work with children with chronic mental health issues is relatively small, all occupational therapists who work in pediatrics use the concepts of psychological and social development implicitly and explicitly because developing the ability to maintain relationships with peers and significant others is an essential part of the occupational performance of childhood and adolescence.

Several chapters (e.g., Chapters 11, 12, and 23) describe the models of practice that focus on social behavior and the

development of self. Personal attributes, such as temperament, self-esteem and self-efficacy, problem-solving ability, and social skills, are considered important determinants of healthy functioning. Environmental influences on behavior and social development suggest the need to consider the expectations and social elements of the home, school, and community environments and to recognize the importance of friends in a young person's life.

Given the complex nature of behavior and social relationships, occupational therapists often draw on numerous intervention approaches to promote a child's social skills and peer relationships. The occupational therapist's knowledge of normal behavior, vulnerabilities associated with particular disabilities, attachment, coping skills, and compatibility of temperaments may guide intervention with a parent-child dyad (see Chapter 3). Cognitive-behavioral strategies may be used by occupational therapists to help young people who are depressed or socially withdrawn develop strategies that encourage participation in social situations (see Chapters 11 and 12).

Coping Model

The coping model addresses psychosocial function, uses cognitive-behavioral strategies, and is congruent with the PEO model.^{189,194} Occupational therapists who use this model emphasize the use of coping resources that enable the child to meet challenges posed by the environment. The goal is to improve the child's ability to cope with stress in personal, social, and other occupational performance areas. When children are successful in coping with their own personal needs and the demands of the environment, they feel good about themselves and their place in the world. Coping strategies are learned, and children build on previous successful experiences in coping with environmental expectations.¹⁹⁴

All children experience stress when faced with physical, cognitive, and emotional challenges. When these challenges are successfully met by the child's inner resources and caregiving supports, the result is a sense of motivation, learning, and mastery. Stress can evoke negative feelings when the child's resources are poorly matched to the environment's demands.

Developmental skills and competence are the internal resources a child brings to a task. Often a child with disabilities is placed in situations that match the child's chronologic age (e.g., a preschooler play group) but not necessarily the developmental age. When environmental demands do not match developmental skills (e.g., to sit quietly and attend), children experience stress and generally seek external coping supports.

Parents and other primary caregivers are the most significant external resources for coping in the child's early years.¹⁸⁹ Parents buffer the child's exposure to stress, make demands, model coping behaviors, encourage and assist the child in coping efforts, and give contingent feedback. Environmental supports are the spaces and materials available to the child and may include adapted equipment and technology associated with comfort and functional support.

The child successfully copes with new challenges when (1) he or she has underlying resources that enable a successful response to an environmental demand or new situation; (2) human supports are provided to facilitate his or her performance (e.g., the occupational therapist gives the child a visual or verbal cue); and (3) environmental supports are provided

that enable the child to feel safe and comfortable, be attentive and engaged, and feel calm and organized (e.g., a classroom that is quiet and well organized and that has a comfortable lighting level and temperature). The occupational therapist continually evaluates whether the child's skills (internal resources) and environmental supports (external resources) are adequate to meet the demands of the activity. When the child exhibits ineffective coping strategies, the occupational therapist adjusts the task demands and provides more human or environmental support to enable the child to succeed in his or her coping efforts. Table 2-4 provides examples of interventions using the coping model (Figure 2-9).¹⁸⁹

Social Play Interactions

When working with young children, occupational therapists often foster social skill development in play interactions. Occupational therapists establish developmentally appropriate play activities that promote sharing, fun, and creativity. To support the play of children with disabilities, peer models with higher level skills and similar interests are selected to participate. The occupational therapist offers support to the play activity without being directive. Social play interventions reflect theories about play occupations, child development, and behavioral interventions. One practice model, the Early Start Denver Model (ESDM),⁴⁰ which targets toddlers and preschoolers with ASD, is based on principles from Pivotal Response Training⁸⁵ and developmental, relationship-based intervention.⁶⁷ ESDM practices and principles are defined in Table 2-5. ESDM is implemented in the toddler's natural environment (preschool setting or home), and occupational therapists can use the principles in play activities, group eating activities (snack time), or throughout the child's daily routines. ESDM is child-centered, meaning that the occupational therapist selects a play activity known to be of interest to the child, shares control of the play by selecting objects that are appropriate choices for the child, models and reinforces specific child actions, and sequences activities to increase the challenge. Every social interaction is considered to be a teaching opportunity in which the occupational therapist is modeling, cueing, reinforcing, and supporting generalization. Whether ESDM is implemented in an early childhood program or at home, the parents are important participants. Parents are taught the same interaction techniques (see Table 2-5) to promote the child's social development and to manage difficult or undesired behaviors.

Early studies of ESDM provided in the classroom resulted in improved symbolic play and social communication.¹⁴⁶ With success in improving social competence using therapist-child interactions, Vismara and Rogers¹⁷⁷ developed a parent-coaching model for ESDM, demonstrating that parents can be trained to implement ESDM with fidelity. After this pilot study, a randomized controlled trial of home-based ESDM resulted in positive effects for children with ASD 18 to 30 months old.¹⁴⁶ The intervention comprised sessions in the home led by the occupational therapist twice a day (average 15 hours/week), and parents were asked to use ESDM strategies throughout the day. These strategies included consistent use of positive affect during interpersonal exchanges with the child, responsivity and sensitivity to child cues, and developmentally appropriate communication. Imitating the child's actions is a strategy that encourages interaction. After 2 years of home-based intervention, children who received ESDM improved more than

TABLE 2-4 Principles of the Coping Model and Examples of Interventions

Coping Model Principles	Intervention Examples
Occupational therapist grades or modifies the environmental demands to ensure that they are congruent with the child's adaptive capabilities.	The environment of a child with attention-deficit/hyperactivity disorder is adapted by reorganizing materials to reduce visual demands and enhance visual attention. For a child with ASD, a picture board is organized that indicates the sequence of activities in the preschool day to promote easy transitions between activities.
Occupational therapist designs intervention activities to enhance the child's internal and external coping resources. Intervention focuses on the child's resources, including coping style, physical and affective states, developmental skills, human supports, and material and environmental supports. The occupational therapist fosters a positive sense of self and can involve the child in activities that promote self-efficacy.	For older children, the occupational therapist can facilitate group discussions of personal goals and plans for reaching these goals. Personal social skills may be emphasized by practice of social skills in the context of games with peers. Activities that emphasize group skills, such as problem solving, sharing, and communication, can help older children develop improved personal social skills that can be generalized to school and extracurricular activities.
Occupational therapist provides appropriate, contingent responses to the child's coping efforts. Timely, positive, and explicit feedback to coping efforts helps the child experience a sense of mastery. Feedback that effectively enhances coping efforts emphasizes self-directed, purposeful behaviors. The occupational therapist supports child-initiated activity and provides feedback that encourages the extension and elaboration of emerging skills.	When the child with ASD initiates a social interaction with peers, the occupational therapist cues and encourages the peers' responsiveness and promotes the interactions by showing interest and promoting the "fun" of the play activity. When a child with dyspraxia initiates a puzzle but cannot fit the pieces, the occupational therapist gestures to indicate the correct placement or suggests a game of turn-taking so that the therapist can model correct puzzle piece placement for the child.

FIGURE 2-9 A and B, Therapist guides child through a yoga routine. She encourages the child to perform the yoga routine learned in therapy daily to reduce stress and improve his physical agility and coordination.

TABLE 2-5 Principles of the Denver Model

Principle	Description
1. Occupational therapist helps the child modulate arousal, affect, and attention.	Often using sensory input, occupational therapist may provide input to calm or regulate the child, increase arousal, engage the child's attention, or eliminate distraction.
2. Occupational therapist uses positive affect.	Occupational therapist attempts to modulate arousal through deep pressure, vestibular, or tactile input so that the child is in an alert, attentive state. Occupational therapist models fun, laughs, smiles, and makes full eye contact when possible.
3. Occupational therapist models and encourages turn-taking and dyadic engagement.	Occupational therapist selects activities that allow turn-taking and sharing. Occupational therapist models turn-taking, demonstrates reciprocity. The child's turn-taking and reciprocity are reinforced.
4. Occupational therapist responds sensitively and immediately to the child's communication and gestures.	Occupational therapist reads and acknowledges the child's cues, including gestures or utterances. Occupational therapist may respond empathetically, may imitate child's behavior; occupational therapist clearly acknowledges any attempt that the child makes to communicate.
5. Occupational therapist creates multiple and varied communication opportunities.	Occupational therapist models communication with gestures, expressions, and speech. Occupational therapist uses developmentally appropriate language.
6. Occupational therapist scaffolds the child's skill practice and elaboration of new skills.	Occupational therapist encourages child to perform new skills in various activities. Occupational therapist encourages practice of new skills using different materials and in a variety of settings.
7. Occupational therapist uses developmentally appropriate language and communication.	Occupational therapist gestures, uses 1- to 2-word sequences. Occupational therapist carefully selects simple language and combines language with gesture. Occupational therapist emphasizes pragmatics, i.e., facial and body expressions that accompany language.
8. Occupational therapist supports the child's transitions.	Occupational therapist helps the child shift attention from one activity to another. Occupational therapist uses visual schedules, visual cards, or social stories to help child with the transition.

children who received community intervention in cognitive ability, language, and adaptive behaviors.¹⁴⁸

In a later study, using a sample of young children, aged 12 to 24 months, Rogers et al.¹⁴⁹ examined the efficacy of a brief period of ESDM (12 weeks) provided at a lower dosage (1 hour/week) of parent training. Occupational therapists coached parents in using ESDM techniques, and parents were responsible for providing the ESDM intervention. A comparison group received community-based interventions. Child outcomes for the group receiving ESDM provided by the parents were not significantly different from outcomes for children who received community-based interventions; however, the parents developed strong alliances with the primary occupational therapist. Developmental gains during the 12 weeks related to the number of intervention hours received and the child's age (younger children improved more). Coaching models that ask parents to implement the intervention may have varied effects that are influenced by family culture, time, work schedules, values, priorities, and resources.

Another child-centered, play-based intervention model that occupational therapists use, reciprocal imitation training (RIT),⁷⁷ appears to benefit social skill development in young children with ASD. This intervention, led by the occupational therapist and implemented by the parent, emphasizes parent-child joint attention and imitation in naturalistic play. The occupational therapist contingently imitates the child's actions and describes them for the child to reinforce their meaning or models variations of the child's actions.⁷⁸ To teach social imitation, the occupational therapist prompts the child to imitate

his or her actions. In a randomized controlled trial, young children (27 to 47 months old) with ASD who received RIT improved more in spontaneous, social use of imitation and in elicited imitation skills than a control group.⁷⁸ In RIT, the occupational therapist selects play activities that are developmentally appropriate, fun, and interesting and that embed natural social opportunities. Within these well-designed play activities, the occupational therapist can use opportunities to enhance the child's social skills by imitating his or her actions; responding to, reinforcing, and expanding the child's communicative cues and gestures; and scaffolding interactions between peers. These interventions have evidence of efficacy for promoting social competence, joint attention, and communication skills in young children with ASD.^{77,78}

Peer-Mediated Approaches

Learning to interact positively with peers is an important social skill that is typically acquired during early childhood. Peer relationships are also inherently of value in promoting healthy social-emotional development. Interventions to promote peer interaction are commonly implemented in early childhood programs and are often used with children who have ASD. Peer-mediated interventions involve a typically developing peer interacting with a targeted child and combine behavioral and social-behavioral theories. The peer is trained to serve as a model and to encourage interaction and reinforce the targeted child's actions. The occupational therapist encourages these peer-to-peer interactions in routine activities and play interactions that occur naturally during the preschool day. A

practitioner trains the peer by introducing the peer to the targeted child, explaining what is expected of him or her, practicing with the peer, and prompting the peer to interact with the child.⁶⁶ For example, an occupational therapist may prompt the peer to invite the targeted child to play, offer to share, or offer help. The occupational therapist carefully selects a peer to interact with the targeted child and trains the peer to engage with that particular child, giving the peer information about the targeted child's interests and how best to initiate and sustain an interaction.

Karasi et al.⁷⁹ taught peers to how to engage children with ASD, 6 to 11 years old, on the playground by asking them to play. The peers were taught strategies to support social interaction with children who appeared to be having difficulty making friends (the targeted children were not specifically identified to the peers). The children who received the peer supports decreased their solitary play and demonstrated increased engagement in games and conversation. Although teachers reported the children in the peer-mediated intervention showed increased social participation, the children did not report more friendships, suggesting that additional supports are needed to create and sustain friend relationships. Peer-mediated interventions have also resulted in children with ASD interacting in closer proximity and sustaining play for longer periods.³⁰ Based on a synthesis of research on peer-mediated interventions, Goldstein et al.⁶⁶ recommended that a consistent peer be used, that the strategies taught to the peer be simple to learn, and that the occupational therapist encourage peer interactions throughout the day. A combination of strategies may be needed to produce optimal results, including combining peer-mediated strategies with social stories, visual cueing, or specific verbal scripts.

Social Skills Training

As described in the previous section, young children can learn social skills through well-designed play interactions with adults and peers. When older children continue to have delayed social skills, they may benefit from structured social groups designed to promote positive peer interactions and appropriate social behaviors. Social skills groups are based on learning and acquisition theories, self-efficacy theories, and occupation models. Social skills groups allow young people to master social communication in a safe and supportive environment. Goals for social skills groups vary according to the types of children involved and the context for the group. Occupational therapists may include strategies to promote emotional regulation; modeling and reinforcing specific social behaviors (e.g., greetings, introducing oneself, asking for a favor); or discussing dating, friendships, and online relationships. Occupational therapists create occupation-based groups, in which members share a goal and activities that focus on a theme. Activities that provide an appropriate context for the development of social-emotional skills encourage positive peer interaction; allow for modeling, sharing, and reciprocal interaction; are creative rather than competitive; and enable give and take that can lead to relationship building. The occupational therapist models for group members, encourages interactions, maintains a safe atmosphere, monitors behaviors to prevent inappropriate or escalating behaviors, and collects data on members' social behaviors. See [Table 2-6](#) for examples of venues for social groups.

Social skills training groups have shown positive effects with school-age children and adolescents with autism. Gutman, Raphael-Greenfield, and Rao⁶⁸ implemented a weekly small-group intervention with children with high functioning autism. This intervention emphasized motor imitation as a key element of social behaviors and focused on the children role playing specific social skills, practicing the skills with peers, and learning both the verbal and the nonverbal aspects of social interaction. The children were paired with a social partner with similar but higher level social skills to practice targeted social behaviors in the school setting and later in the community. Using a multiple baseline design, all of the participants improved in their targeted social behaviors, making the greatest gains in the first 7 weeks. The Program for the Education and Enrichment of Relational Skills (PEERS) social group intervention was developed to promote social skills in adolescents with ASD.⁹⁰ In the highly structured PEERS intervention, occupational therapists teach specific social skills; group members practice and receive feedback about their performance; and repetition is reinforced through homework. Social cognitive techniques are used through discussion of the role playing and by members identifying their own social etiquette rules. The PEERS intervention includes the parents, who meet separately to discuss the content that their adolescent is learning. Using standardized scales of social responsiveness and social behaviors, the PEERS intervention resulted in improvement in social awareness, social cognition, communication, and social motivation. Friendship skills improved after the 14-week session and at follow-up.⁹¹ Social skills groups with adolescents can also promote improvement in initiating, maintaining, and closing conversations.¹⁷ Groups that meet regularly and allow relationships to develop can improve self-esteem and confidence.¹⁷ Social networks have been shown to help a person establish positive attitudes, improve self-esteem, and develop moral and social values.

Other occupational therapy studies have identified the interactive, protective factors in child, family, and social environment that support social participation of children with brain injuries. Bedell, Cohn, and Dumas¹⁰ described a "Building Friendship Approach" in which collaborative student-centered school teams (student, school personnel, family, and friends) identify strategies to improve the social opportunities of students with brain injury. The team helps the student generate his or her own solutions and set goals to improve his or her social opportunities. This approach appears to be effective, but the outcomes need to be monitored to ensure that they are maintained. When occupational therapists embed well-designed, interactive, and meaningful activities that facilitate reciprocity and creativity, social skills groups can enhance social participation and social emotional competence in children and youth.

Sensorimotor Performance

From infancy through childhood, sensorimotor systems develop rapidly, resulting in competent and coordinated sensorimotor performance. Children move constantly in direct response to the environment or on their own initiative, and by exploring, manipulating, and moving through the environment, a child quickly attains competent motor skills. When children, such as children with cerebral palsy or developmental coordination disorder, demonstrate motor delays or impairment, occupational therapists have key roles in supporting the development

TABLE 2-6 Occupational Therapy Social Skills Groups to Improve Social Participation and Peer Relationships

Therapeutic Activity	Description	Targeted Group
Yoga dyads	Occupational therapist provides yoga sessions for small groups. Children hold hands and cooperate with a partner to perform yoga poses and actions. They experience touch, movement, and mindfulness in a group setting. Emphasis on movement, balance, breathing, meditation.	School-age children with behavioral problems; children at risk who experience increased stress (e.g., disadvantaged homes).
Arts and crafts groups	Occupational therapist develops arts and crafts groups, often related to holidays, seasons, or school themes. These groups work together cooperatively, sharing materials and conversation. Usually they work together to create one product.	School-age children with low social skills; can include children with Asperger's syndrome, children with behavioral problems, children at risk.
After-school groups	Occupational therapist organizes after-school groups. These meet to plan projects and events. Social participation is modeled and encouraged. The groups are organized to promote turn-taking, sharing of ideas, and joint activities. These groups generally have themes that can be determined by the group (e.g., sharing information on favorite music bands).	Middle school or high school youth with delayed social skills; can include youth Asperger's syndrome, high functioning autism, intellectual impairment.
Cooking groups	Occupational therapist embeds cooking groups into weekly therapy sessions. These groups often plan a meal, budget the meal, shop for the food items, prepare the meal together, and then eat together.	Middle school or high school youth with delayed social skills; can include youth with high functioning autism or intellectual impairment.
Special interest clubs	Occupational therapist leads the development of a club in middle school or high school that supports the special interests of a targeted cohort of youth. Examples of special interests are video or music, extreme Legos, weird animals and reptiles, cartoons, and comedy.	Youth or young adults with autism or intellectual impairment who have low social participation and no or few friends.

of sensorimotor skills. Chapters 7, 8, and 9 describe motor development, diagnoses that involve the sensorimotor systems, and interventions that are helpful in remediating sensorimotor problems. This section describes five primary theories and practice models that guide evaluation and intervention to promote sensorimotor performance: (1) dynamic systems theory, (2) motor learning, (3) biomechanical models, (4) neurodevelopmental therapy (NDT), and (5) sensory integration therapy (SIT).

Dynamic Systems Theory

Dynamic systems theory¹⁶⁶ contrasts with a hierarchical model of neural organization, originally thought to explain how movement developed.⁶² This theory proposes that the CNS functions with flexible and dynamic organization and that the control of movement is distributed among many elements of the CNS rather than vested in a single hierarchical level.¹⁷⁴ It follows that the CNS controls groups of muscles (not individual muscles) and that these groups can potentially change motor behavior without CNS control. Motor control can emerge spontaneously from relationships among kinematics (muscles) and biomechanics (joints and bones) that naturally limit the degrees of freedom of movement, implying that the motor system is self-organizing.

Dynamic systems theorists emphasize that learning not only occurs in the brain but also reflects body and environment variables that constantly change and simultaneously influence each other.¹⁷³ In this theoretical approach, instead of viewing

behavior (e.g., sensorimotor skills) as predetermined in the CNS, systems theory views motor behavior as emerging from the dynamic cooperation of the many subsystems in a task-specific context. It implies that all factors contributing to motor behavior are important and exert an influence on the outcome by either facilitating performance or constraining it. It also implies that a child's actions organize and reorganize over time into a series of dynamically stable behavioral patterns (i.e., occupations). Although a child acquires a specific skill, performance of the skill varies based on the social and physical variables in the environment. The child performs the skill flexibly based on his or her goal and fluctuating internal variables (e.g., fatigue, arousal, motivation) and external variables (e.g., parental encouragement, perceived desired goal, comfort and safety of the environment).⁶⁰

Dynamic systems theory is an ecologic approach that assumes that a child's functional performance depends on the interactions of the child's inherent and emerging skills, the characteristics of the desired task or activity, and the environment in which the activity is performed. System variables that facilitate learning and drive a child's transition from one level to another change over time.^{20,166} Physical growth and biomechanics may be highly important for motor learning in infancy, whereas experience, practice, and motivation may be more influential in the learning of motor activities in an older child.¹⁶⁵ Self-organization is optimal in a functional task that has a meaningful goal and outcome. Most functional tasks (e.g., eating and drinking) elicit a predictable pattern of

movement; the task itself can organize the movements attempted. These features suggest that dynamic systems theory aligns well with occupational therapy.

Research in dynamic systems theory has focused on explaining the ways new skills are learned.^{56,167,168} The learning of new movements or ways of completing an activity requires that previously stable movements be broken down or become unstable. New movements and skills emerge when a critical change occurs in any of the components that contribute to motor behavior. These periods of change are called *transitions*. Motor change in young children is envisioned as a series of events during which destabilization and stabilization of movement take place before the transitional phase movement becomes stable and functional.¹³⁶

The period of instability that occurs in a transitional phase is seen as the optimal time to effect changes in movement behavior. The sequential transitional stages are as follows¹³⁶:

1. Variability in motor performance increases. The child experiments with different movement patterns.
2. Through these exploratory movements, the child determines which pattern is the most adaptive.
3. The child selects the movement that is most adaptive, the movement that meets his or her goals given environmental demands and constraints (e.g., which pattern makes it easiest to rise from sit to stand given the effects of gravity

and available supports). During this phase, the child repeatedly practices the new movement pattern.

In children with impairments such as cerebral palsy, constraints hinder the emergence of motor functions. Such *constraints* are limitations imposed on motor behaviors by the child's physical, social, cognitive, and neurologic characteristics. The constraint that traditionally has received most attention is the integrity of the CNS; less frequently, other biomechanical constraints are considered, such as biomechanical forces, muscle strength, or a disproportionate trunk-to-limb ratio. *Environmental constraints* include physical, social, and cultural factors not related to a specific task. One example of a physical constraint is a suboptimal surface for the child's activity (e.g., a soft, unstable couch or inclined surface); a social constraint could be a parent's lack of reinforcement of the acquisition of motor behaviors. *Task constraints* are restrictions on motor behavior imposed by the nature of the task. Established motor behaviors may be altered by specific task requirements. For example, when faced with the task of crawling on rough terrain, infants may alter motor behavior by straightening the knees and "bear walking." When a child reaches for a ball, the ball's size influences the shape of the child's hand and the approach taken (e.g., one hand versus two). The unique features of these tasks have shaped the child's motor behavior. See Table 2-7 for a list of dynamic systems theory principles.

TABLE 2-7

Principles of Dynamic Systems Theory Applied to Motor Development

Dynamic System Theory Principle	Application to Motor Development
Sensory perception and motor systems are coupled. These systems continually interact in learning new motor skills. The infant's perceptions guide his or her movements, which create the infant's perception of the world.	Haptic sense, discrimination of the physical properties of objects through touch, is acquired through object manipulation. Sensory information is gained as the infant's fingers move over the object's surfaces.
Functional synergies are the basis of motor behavior. Movement synergies are based on kinematic (e.g., muscles) and biomechanical (e.g., joints) constraints and are the basic units that control movement. The basic units of motor behavior are functional synergies or coordinated structures rather than specific muscle actions. These functional synergies are "soft"—assembled (i.e., they are highly adaptable and highly reliable).	Similar synergies are used for eating and drinking that involve shoulder internal rotation and adduction, elbow extension followed by flexion, forearm pronation followed by slight supination, and neutral wrist position. This functional synergy is also used with slight modification in combing one's hair and cleansing face and teeth. This is a stable but flexible synergy.
Transition to new movement patterns involves exploration, selection, and practice phases. The infant or child first explores many different patterns and exhibits high variability in movement. The infant then selects an optimal pattern to achieve his or her goal. This pattern is practiced and becomes more adaptable to various environmental demands.	When first learning to eat with a spoon, the infant exhibits various patterns with the spoon, including banging, stabbing, and waving. The infant then selects a functional pattern that successfully meets the environmental demand (e.g., the toddler learns to supinate the forearm when bringing the spoon to mouth so that the food reaches the mouth rather than spilling down the chest). This adaptive pattern is repeatedly practiced as the toddler insists on always self-feeding.
The infant's unique motor patterns are the result of input from multiple systems that interact in dynamic ways both to facilitate and to constrain movement. Behavior is multiply determined, and children develop in context. Behavior is determined by an integrated system of perception, action, and cognition. These elements are integrated over time to form a child's unique developmental trajectory.	The pattern an infant uses to reach for an object is determined by many variables. Variables that may influence reaching include biomechanical and kinematic factors such as weight of his or her arm, stiffness of joints, strength, and eye-hand coordination. However, the reaching pattern is also influenced by how successful the child was in previous reach and grasp (did the object move before the child could obtain it?), how motivated the child is to attain the object, general energy level, and curiosity.

Dynamic systems theory has many similarities to the emerging occupational therapy theories that focus on person, environment, and occupation relationships. This theory is explained further in [Chapter 7](#).

Occupational therapists approach intervention with a child by first gaining an understanding of the environmental, family, and child factors that influence the performance of specific activities. From the literature that discusses the application of systems theory or dynamic systems theory to occupational therapy intervention, the following principles emerge:

- Assessment and intervention strategies must recognize the inherent complexity of task performance. The most useful assessment strategy is to develop a “picture” or “profile” of the ways performance components and environmental and task factors affect performance of the tasks the child wants to accomplish. Assessment of only one or a few components (e.g., balance, mood, strength) is not likely to lead to the most effective identification of constraints.
- The focus of assessment and intervention is on the interaction of the person, the environment, and the occupation. Therapy begins and ends with a focus on the occupational performance tasks a child or youth wants to, needs to, or is expected to perform. When a child shows readiness and motivation to attempt a task or activity, the focus of intervention on that particular activity can effect changes in his or her performance.⁹⁵
- The therapy process focuses on identification and change of child, task, or environmental constraints that prevent the achievement of the desired activity. Some of these factors may be manipulated to enhance the functional motor task or goal; others may be managed by providing the missing component during the execution of the task. Parts of activities can be changed (e.g., different toy sizes, different position for child or activity).
- Activities should be practiced in various environments that can facilitate completion of the task and promote the flexibility of movement patterns. Activities incorporated into the child’s daily routine provide opportunities for finding solutions for functional motor challenges ([Figure 2-10](#)).
- When preparing therapeutic activities, the occupational therapist identifies playful activities that appear to motivate the child, are developmentally appropriate, match the child’s and family’s goals, provide a challenge to current skills levels, and match an expected or hoped for outcome.
- With intervention through the systems approach, the focus on changing environments and occupations is at least as great as the focus on changing the inherent skills of the child or adolescent. Intervention is best accomplished in natural, realistic environments.
- The accomplishment of complete occupations, not parts of them, is emphasized. The goal in therapy is to enable a child to accomplish an identified activity, rather than promote change in a developmental sequence or improve the quality of the movement.
- Therapeutic effect and positive outcomes are determined by the child’s engagement in the activity, the match between the intervention activities and the child’s skill levels, the meaningfulness of the activity, the amount of practice, and the opportunities to transfer and generalize the newly learned skill to a variety of contexts. Positive effects relate to how well the interventions enable the child to perform

FIGURE 2-10 For written work at home and at school, the child uses a slant board to promote improved posture and grasp of the pencil. A weight on the pencil provides added proprioceptive input.

well across his or her natural environments given age and role expectations.

Research on interventions based on dynamic systems theory is beginning to emerge. In a study of 55 children receiving either functional therapy based on dynamic systems theory or therapy aimed at developing “typical” movement patterns, Ketelaar et al.⁸⁰ found that children in the functional therapy group demonstrated significantly more functional skills (mobility and self-care). Law et al.⁹⁷ and Darrah et al.³⁹ developed an intervention model, context therapy approach, for children with cerebral palsy using dynamic systems theory to guide the therapy principles. Context therapy is a functional, task-oriented, activity-focused, top-down approach to assessment and intervention. Occupational therapists explicitly manipulate characteristics of the task and the environment to achieve the goals (i.e., therapy activities are not directed toward changing the child’s performance). Underlying this approach is the tenet of the dynamic system that motor behavior is organized around functional tasks and goals. The occupational therapist encourages the parents and child to develop their own solution to an environmental challenge. Primary roles of the occupational therapist and parents are to eliminate barriers to the child’s function, enabling greater participation. Another tenet of dynamic systems theory is that new motor behaviors are learned by experimenting with different actions that can accomplish a new goal. The new skill or performance goal that a child is attempting or exploring becomes an appropriate intervention focus. Occupational therapists help the child accomplish the new goal by modifying environment barriers and adapting the task to make goal accomplishment possible.³⁹

In a randomized controlled trial that compared context therapy with child-focused therapy, preschool children improved equally; effect sizes for self-care and gross motor

function pre to post were large for both groups. This study demonstrated that children with cerebral palsy can improve in performance when intervention focuses on modifying tasks and the environment to promote function and goal achievement.⁹⁷ These findings validate the theoretical concept of dynamic systems theory as a basis for intervention principles and strategies.

Motor Learning and Skill Acquisition

Motor learning as a model of practice focuses on helping the child achieve goal-directed functional actions. It may initially appear to be a skill-building approach because the focus is on the acquisition of skills involved in movement and balance. However, motor learning is an occupation-based approach because it is directed toward the search for a motor solution that emerges from an interaction of the child with the task and the environment.

When a child is learning a new functional task, a general movement structure is brought into place that takes into consideration the relationship involving the child's movement capabilities, the environmental conditions, and the action goal. When the task is performed repeatedly, these correspondences become more refined, and the goal is achieved more successfully. Specific processes, such as muscle contraction patterns, stabilization and positioning of joints, and response to gravity and other forces, are only crudely organized at first. However, with continued practice, these become more organized and fine-tuned.⁶¹ These patterns are called *movement synergies*, or *coordinative structures*, and they represent the child's preferred strategy for solving a task in the most energy-efficient way.¹⁶⁵

Children with motor programming and motor control deficits often have difficulty establishing the timing and sequencing of functional synergies. Task and activity demands may vary, and each of these dimensions is relevant to the way in which tasks are learned. These characteristics of a task determine which motor learning strategies are used to improve performance.

1. *Simple-complex.* Simple tasks, such as reaching for an object, require a decision followed by a sequenced response. Complex tasks, such as handwriting, require the integration of information from a variety of sources and the application of underlying rules that guide performance.
2. *Open loop–closed loop.* In an open-loop task, a motor program is put into place before the action begins and is not modified during the performance of a task. An example of an open-loop task is throwing a ball. In a closed-loop task, the child continues to monitor and respond to feedback that he or she receives intrinsically from the body and extrinsically from the environment. An example of a closed-loop task is cutting out a shape using scissors.¹
3. *Environment changing–environment stationary.* The difficulty of learning a task is tremendously influenced by the extent to which the task is predictable. When the environment is changeable or variable, the child has to learn the movement and learn to monitor the environment to adapt to change. Running on rough terrain and playing soccer are examples of tasks in which the environment is constantly changing. This concept is not to be confused with the open-loop and closed-loop features of the task previously described. Brushing the teeth and playing the piano are tasks during which the child must monitor sensory feedback (closed loop), but the environment remains stationary.¹⁶³

4. *Task characteristics.* The ease or difficulty of learning a task depends on the match between the way the task is presented and the preferred learning style of the child. Some children learn best through auditory or visual methods; others prefer movement and touch.

Different types of feedback contribute to the motor learning process.¹⁹⁶ Feedback is *intrinsic* when it is produced by the child's sensory systems and is inherent in a task. An example of intrinsic feedback is information available to the child through vision, proprioception, sensation, or kinesthesia. The occupational therapist observing the child's performance provides two types of *extrinsic* feedback: *knowledge of results* and *knowledge of performance*.¹²⁴ In *knowledge of results*, the occupational therapist provides information to the child about the relationship between the actions and the goal. For example, a child who is throwing a basketball toward the hoop may be told that the ball is not going high enough and is missing the hoop. To provide extrinsic feedback that allows *knowledge of performance*, the occupational therapist emphasizes the pattern of movement and its relationship to achievement of the task. In the same example, the child may be told that he is not extending his arms far enough before releasing the ball. In both cases, the occupational therapist's feedback focuses on the outcome of the action, not on the child's effort. These terms are explained further in Chapter 7.

Research on the scheduling, frequency, and amount of feedback that best promote learning can guide application of motor learning theories.^{164,190} Studies have shown that immediate extrinsic feedback may prevent the learner from paying attention to the intrinsic sources of feedback that are always available, such as vision and proprioception. This lack of attention to intrinsic feedback may make the learner dependent on information from the person providing instruction.¹⁵⁵

Few research studies have focused on the effect of different types of feedback on task performance in children experiencing occupational performance difficulties. However, research investigating motor learning principles in children with movement difficulties has suggested that they may not solve movement problems in the same way that adults do. Sullivan et al.^{164,196} found that children perform best when they receive constant and immediate feedback compared with reduced and intermittent feedback, which is shown to improve performance in adults. Extrinsic sources of feedback that focus a child's attention on specific aspects of the task and on important sensory cues may be important.

Another important concept in motor learning is the influence of different types of practice on learning and performance.¹⁵⁸ Although we know that task practice results in learning, research findings differ in regard to whether practice of the *whole task* or practice of *task components* results in optimal learning. The benefits of practicing either the whole task or parts of the task may depend on the inherent goals of the task. If coordination or timing of the parts is important to the task, whole-task practice is more effective for learning.¹⁰⁴ Examples of these continuous types of tasks are walking, swinging at a ball, and bicycling. If a task contains distinct parts that can be performed in a serial manner, these can be practiced as parts of the task. A child learning to don his jacket can be taught how to zip it as a first step. Most occupations involving movement are a combination of continuous and discrete tasks (Figure 2-11). Consequently, doing the whole task must follow

FIGURE 2-11 This activity of threading a string through hooks to create a design involves eye-hand coordination, dexterity, and control of arm in space (strength). It requires multiple steps to achieve a completed product.

learning its parts. For example, in learning to ride a tricycle, the child can focus on learning to pedal separately from steering, but he or she must then combine them.

Another important consideration in planning practice sessions is the use of random versus blocked practice. During random practice, the environmental conditions vary slightly each time; blocked practice involves drilling the task over and over in the same way. In most cases, random practice produces better learning because practice in variable contexts allows the child to solve a slightly different movement “problem” every time.

Some of the key techniques that occupational therapists use in this model of practice are giving verbal instructions and demonstrating movement strategies. Verbal instructions focus on the relationship between the child and the objects in the environment and emphasize key movement features directly related to achievement of the functional goal (Figure 2-12).⁶¹ Physical or manual guidance can be helpful during the initial teaching of a movement because it may clarify the goal, guide selective attention, and help the child organize and plan the movement. Researchers stress that guidance or facilitation of movement should be removed as soon as possible, arguing that the occupational therapist rapidly becomes part of the environment, which alters the performance context and the intrinsic feedback available to the child.⁶¹

Motor learning researchers^{126,161,191} recognize that learning has occurred when there is evidence of a relatively permanent change in the child’s ability to respond to a movement problem or to achieve a movement goal. The learning of a new motor skill needs to be evaluated through tests of retention and transfer, not just immediate changes in performance.¹⁰³ Occupational therapists who use a motor learning model of practice

FIGURE 2-12 A and B, The occupational therapist emphasizes the child’s understanding of relationships among objects in achieving functional goals.

must create opportunities for the child to demonstrate learning during a subsequent therapy session (retention), on a closely related task (transfer), or in a different setting (generalization). Case Study 2-1 and Table 2-8 apply motor learning concepts and compare motor learning with adaptation approaches.

Occupational therapists use theories about motor learning to promote development in areas of function that involve learning complex skills and behaviors. Self-care and handwriting are examples of areas of occupational performance to which occupational therapists have applied a motor learning approach. Researchers and practitioners have advocated for acquisitional and motor learning approaches to help children achieve handwriting competence (see Chapter 18). Many remedial or practice-based handwriting programs are commercially available. Several studies have demonstrated that the use of acquisitional principles by occupational therapists and educators in

CASE STUDY 2-1 Reggie; Cerebral Palsy

Reggie is a 5-year-old girl who has cerebral palsy with moderate quadriplegia. She has difficulty controlling the movement of her arms and hands and functions at Manual Ability Classification System (MACS) level III (to manipulate objects, she needs help to prepare and modify activities). Isolated finger movements are limited. Reggie walks short distances using a walker. With limited arm strength, she can wheel her wheelchair only 4 to 5 feet. She has no other form of independent

mobility. Her parents have set current goals for Reggie that include participation in dressing tasks and drawing and cutting skills in kindergarten activities. They also would like her to become more independent in mobility because she currently needs personal assistance to travel to the playground, cafeteria, and bus. Goals include increased participation and independence in dressing, drawing, cutting, and mobility.

TABLE 2-8 Occupational Therapy Evaluation and Intervention

Problem Definition and Intervention Goals	Description of Intervention	Expected Outcome
Motor Learning Theory Reggie lacks the motor skills needed to perform motor tasks through her day. Often the feedback she receives from movement is negative (e.g., she fails to reach her goal). Goals include that Reggie will: • Pull up her pants and fasten with minimal assistance. • Orient and don her shirt with moderate assistance in buttoning. • Cut a straight line using regular Fiskars scissors independently • Push her manual chair 20 feet without taking a break.	The intervention for Reggie focuses on improving coordination and strengthening her upper extremities. The occupational therapist identifies specific movement patterns that become the focus of intervention and whole task-related action to practice. To enhance dressing performance, she decides to practice in Reggie's bedroom in a large chair with arm rests and a firm seat. Easy clothing is selected first, and practice is repeated. Then Reggie practices with a variety of pants and shirts; she also attempts to don and doff clothes when sitting on the bed. Both the occupational therapist and the mother reinforce her efforts with praise. To improve her cutting and mobility skills, the occupational therapist selects the kindergarten classroom. The occupational therapist provides cueing and guidance during cutting with feedback on how to hold the scissors and paper. Reggie first cuts a strip of paper into small pieces and then cuts a large piece of paper. To practice mobility, Reggie practices wheeling her manual chair in the hallway. The occupational therapist encourages her, gives her cues to move in a straight line, and times her as if in a race.	Reggie's strength and coordination improve. Her endurance improves. She dresses with less caregiver assistance. She uses scissors to cut straight lines. Her wheelchair mobility improves. Reggie's intrinsic motivation improves because she is more independent and successful in these activities. Her parents are less anxious about her entering first grade and are satisfied with the gains that she has made in dressing and mobility.
Adaptation of Task and Environment The demands of Reggie's kindergarten classroom and home environment surpass her abilities. Task demands are often higher than her current abilities. She would benefit from adapted equipment or technology to enhance her function. Goals include that Reggie will: • Pull up her elastic band pants with Velcro fastener independently. • Orient and don her open neck sweatshirt independently. • Cut a straight line using adapted scissors independently. • Use a joystick to maneuver her power wheelchair independently from her classroom to the playground.	The occupational therapist and family focus on selecting and trialing adapted equipment and technology. The occupational therapist recommends types of clothing that are easier to don, and the family selects attractive clothing that they think Reggie will enjoy wearing. The occupational therapist practices with Reggie's new clothing and instructs the family in how to support her donning and doffing until she becomes independent. The kindergarten class has different adapted scissors available. The occupational therapist first selects loop scissors for Reggie to use in cutting activities. After practicing with straight-line cutting, the occupational therapist gives Reggie spring-release scissors to use in cutting activities. The occupational therapist encourages the family to consider power mobility as an optimal way for Reggie to explore her environment, become independent in mobility, and manage the longer traveling distances required in elementary grades. They select a power chair with joystick. The occupational therapist trains Reggie to use the joystick to drive her chair. Together they practice in a range of natural environments.	The adaptation approach improves Reggie's function and participation at home and school. With the adapted clothing and scissors and power wheelchair, her participation is markedly improved. She becomes almost completely independent in dressing, easing the parent's burden in preparing her for school. She participates in arts and crafts activities, cutting simple shapes with straight lines. With her power wheelchair, she moves independently in the school environment. The family engages in more community activities because Reggie is more independent in mobility.

a positive, interesting, and dynamic learning environment promotes the development of handwriting.⁴³ Further research is needed to determine the effectiveness of this approach with children who have challenges in sensorimotor and occupational performance.

To summarize, an occupational therapist using a motor learning model of practice:

1. Analyzes the movement synergies the child uses to achieve the functional action goal.
2. Considers the child's stage of learning and determines how best to facilitate the provision of both extrinsic and intrinsic feedback to improve the efficiency of the movement.
3. Provides opportunities for optimal practice of the goal and encourages practice in the natural environment.
4. Emphasizes practice of whole tasks, massed or distributed, according to the skill to be learned, child's developmental level, and context.
5. Establishes an activity that provides both intrinsic and extrinsic feedback. When appropriate, the occupational therapist provides knowledge of results and knowledge of performance by praising the child and giving specific information about the child's performance.
6. Promotes independent performance and decision making as soon as possible and evaluates whether the motor learning has been acquired, transferred, and generalized.¹⁹⁵

Biomechanical Approaches

Biomechanical approaches require the understanding of anatomy and physiology related to posture and movement and the mechanics (i.e., kinetics and kinematics) that define movement. Through biomechanical approaches, occupational therapists use an understanding of the internal and external forces that act on and affect the body—that is, the musculoskeletal system. Specifically, occupational therapists analyze the relationships between musculoskeletal systems and body function to optimize body (trunk and neck) alignment as a basis for the child or youth to move and control extremities.

Joints and posture can be in poor alignment or misalignment when a child has low or high muscle tone, paralysis, or significant weakness. When muscles do not support joints, the forces of gravity or forces from the weight-bearing surface can create misalignment.²⁹ Poor alignment of joints affects movement, and when alignment is not corrected, contractures or deformity can result.

Methods for achieving joint alignment include passive range of motion, active range of motion, and strengthening. Achieving joint alignment may require that muscles or ligaments are relaxed or stretched; that joints are held in position by an external means, such as a splint or positioner; or that muscles around the joint are strengthened to maintain correct alignment. Gravity and its effects on weak muscles or low postural tone need to be considered when positioning or seating a child because gravity can negatively affect posture. Appropriate alignment of the trunk that includes a stable neck and trunk with the head directly over the pelvis allows the eyes to scan and visualize the environment, the mouth and throat structures to eat and breathe safely, the eyes to visualize hands and the hands to come to midline, and the pelvis to support an upright trunk that allows controlled arm movement through full range of motion.

Biomechanical principles are important when designing seating systems for a wheelchair or other positioner, making a splint or cast, or positioning a child for a functional task. Principles for attaining correct postural alignment when seated have been established; these are described further in [Chapter 20](#). General guidelines for selecting appropriate seating that allows optimal function (i.e., coordinating eyes and hands, reaching, eating) include the following:

1. The head aligns over the shoulders that align with the pelvis.
2. The hip angle is approximately 90 to 95 degrees. The pelvis is secured with a strap.
3. The trunk is at midline with symmetric weight bearing on buttocks.
4. The arms are forward toward midline and can move freely.
5. Muscle tone is sufficiently relaxed to allow movement of the head and extremities.
6. The feet are supported, and the legs are well supported.

Often biomechanical approaches are combined with other practice models (e.g., motor learning). Biomechanical approaches are often preparatory for interventions that promote functional performance (see [Figure 2-6](#)). When alignment has been achieved, skill building, strengthening, and practice of functional tasks become easier for the child. Range of motion exercises and splinting are often helpful techniques for hand trauma or hand surgery. The use of biomechanical approaches in hand therapy is described in [Chapter 29](#).

Neurodevelopmental Therapy

NDT may follow biomechanical approaches and targets children with cerebral palsy. Also similar to and expanding biomechanical approaches, NDT focuses on attainment of normal postural reactions that promote normal movement.¹⁶ Although this intervention approach continues to focus on problems in postural control and motor coordination, as seen in cerebral palsy, the principles underlying the treatment approach have expanded to include motor learning and dynamic systems theories. In addition, NDT principles have shifted to recognize the importance of the environment and to place more emphasis on activities that are clearly functional and meaningful to the child.⁷³

When using this approach to evaluate a child, the occupational therapist analyzes the child's movements to identify missing or atypical musculoskeletal elements that create functional limitations. These missing elements become one focus of intervention and are used to select the developmental level of therapeutic activities. Therapeutic handling is integral to the NDT approach and is used to facilitate postural control and movement synergies and to inhibit or constrain motor patterns that, if practiced, would lead to secondary deformities and dysfunction.⁷³ An occupational therapist applying NDT strategies focuses on changing movement patterns to achieve the most energy-efficient performance for the individual in the context of age-appropriate tasks.

As the occupational therapist manually guides and handles the child in the context of an activity, these elements are always combined with the child's active participation. With the occupational therapist's guidance, the child practices sequences of movements in slightly different ways to reinforce learning of the task. This practice is important for making a movement strategy functional and automatic. Occupational therapists

emphasize quality of movement (e.g., accuracy, quickness, adaptability, fluency). Although therapeutic handling remains an integral part of NDT, practitioners use many treatment methods, “manipulating the individual task or the environment in order to positively influence function” (p. 63).⁷³

Acknowledging that NDT principles have changed over the years to incorporate theories of motor learning and dynamic systems theory, clinical evaluation studies of the NDT approach (many of which were completed >10 years ago) have raised questions about its efficacy. Comparison studies of the NDT approach for children with cerebral palsy have been conducted over the past 30 years. In these studies, the NDT approach has been compared with functional therapy,¹⁵⁴ infant stimulation,¹³¹ Vojta therapy, and differing intensities of therapy.^{92,110} The results of these trials have been mixed, with two demonstrating no difference,⁹³ two supporting NDT,^{110,154} and two supporting alternative treatments.¹³¹ The more rigorous randomized clinical trials have generally produced results that do not support the efficacy of the NDT approach.¹³⁵

A systematic review of NDT concluded that “the preponderance of results ... do not confer any advantage to NDT over alternatives to which it was compared” (p. 789).²¹ The only consistent effect of NDT that was statistically significant was an immediate effect on range of motion. In contrast to NDT methods, the motor-based interventions that produce meaningful improvements in functional outcomes for children with disabilities incorporate three essential elements: (1) intensive task repetition, (2) progressive challenges to the learner with increasing difficulty, and (3) the presence of motivators and rewards.¹⁵³ Novak et al.¹²⁵ completed a systematic review on interventions for cerebral palsy and concluded that NDT was not a recommended intervention for children with cerebral palsy. However, despite lack of evidence on efficacy,^{125,153} NDT remains a widely used approach with children who have cerebral palsy and CNS dysfunction affecting motor performance. Because the conceptual basis of NDT has evolved over the past decade, a first step in additional research on its efficacy would be to operationalize the new concepts into treatment protocols that can be measured and replicated for research purposes. Despite this recommendation, many of the principles of NDT are widely implemented and appear to be helpful; core concepts and specific principles of NDT may be integrated into other approaches. For example, key concepts on the importance of postural stability to functional movement suggest that good alignment and positioning are beneficial when a child with cerebral palsy performs fine motor play activity.

Sensory Integration Therapy

The theory of sensory integration, together with the intervention approach derived from that theory, grew from the work of Ayres.³ Ayres developed her theory in an effort to explain behaviors observed in children with learning difficulties based on neural functioning. Specifically, she hypothesized that some children with learning difficulties experience problems in “organizing sensory information for use.”³ She named this neural process *sensory integration*.

Much of Ayres’ work and that of her colleagues was devoted to the development of evaluation tools that could clearly identify individuals with sensory integrative problems. The Sensory Integration and Praxis Tests (SIPT) are the result of this work.⁵ Included in this area of identification and evaluation are

numerous studies aimed at describing different subtypes of sensory integrative problems (see Chapter 9 for a summary). Parham and Mailloux (Chapter 9) identify five sensory integrative patterns based on behavioral observation and assessment beyond the SIPT: (1) sensory modulation problems, (2) sensory seeking behavior, (3) sensory discrimination and perception problems, (4) vestibular-bilateral functional problems, and (5) praxis problems.

Although these disorders overlap, each suggests a specific type of intervention. The work of Dunn and Brown⁴⁵ identifying children with a sensory modulation disorder has shown that these children have patterns of poor registration of sensation, are hypersensitive to stimuli, avoid certain sensations, or seek particular inputs. These sensory processing patterns may be present in children with various developmental disorders, and they are often described in children with ASD.^{7,170} Evaluation tools for identifying sensory processing problems in children and adults are widely used by occupational therapists.^{52,54,116}

Ayres³ also developed interventions that she believed would help to resolve sensory integration problems. She proposed an intervention approach based on assumptions drawn from neuromaturation theory and systems theory. Neuromaturation concepts, such as hierarchical organization of cortical and subcortical areas, developmental sequence of learning and skill acquisition, and neural plasticity, are essential to an understanding of the mechanisms of sensory integration. Systems theory also underlies sensory integration because the focus is on the child seeking sensory input and using adaptive behavior as an organizer of the input. Intervention sessions are playful and child-directed. The occupational therapist and child collaborate to select activities that are of interest to the child and provide a “just-right challenge” to the child’s skill level (Figure 2-13). SIT seeks to provide the child with enhanced opportunities for controlled sensory input, with a particular emphasis on vestibular, proprioceptive, and tactile input, in the context of

FIGURE 2-13 The child’s selection of jumping into a ball pit helps to meet his need for proprioceptive input.

meaningful activity. In intervention, the occupational therapist facilitates an adaptive response, which requires the child to integrate the sensory information (Figure 2-14). Sensory integration is hypothesized to improve through this process. SIT is widely used by occupational therapists. In a survey of occupational therapists working with children with autism, 99% of the occupational therapists reported using sensory integration techniques with their clients.¹⁷⁹ See Case Study 2-2 for an example of a child with developmental coordination disorder and Table 2-9 to compare sensory integration intervention and the CO-OP approach.

Many authors have proposed intervention programs specifically to address sensory modulation disorders.^{151,188} Sensory modulation difficulties can limit a child's participation in activities of daily living, and this is often the case for children with ASD. Sensory integration strategies are often integrated into interventions that promote play and activities of daily living, including eating¹⁷¹ and sleeping.¹⁴³ In addition, primary autism interventions, such as Floortime⁶⁷ and ESDM,⁴⁰ have adopted sensory integration principles. Sensory strategies can promote a child's self-regulation and optimal arousal level, allowing engagement in interaction, attention to activity, and learning from social contexts (see Figure 2-6).

FIGURE 2-14 The child exhibits an adaptive response by pulling on the rope to control her movement through space.

Research of sensory integration intervention with various diagnoses has been published. The original research of Ayres and later Miller, Coll, and Schoen¹¹⁴ demonstrated benefit with children with learning disabilities and sensory processing disorder (see Chapter 9). Early work by Ayres⁴ and others⁸ reported positive changes resulting from SIT for outcomes such as motor, academic, and language performance. Studies in the late 1980s and the 1990s evaluated the efficacy of sensory integration intervention using more rigorous methods, including randomized controlled trials. Using meta-analysis techniques, Vargas and Camilli¹⁷⁵ concluded that children who received SIT improved in performance, particularly educational and motor outcomes, compared with children who received no therapy. When sensory integration intervention was compared with alternative therapies, the outcomes were no different across groups.

In the past decade, a group of scholars examined the research literature on sensory integration to develop a fidelity measure for sensory integration intervention.^{132,133} Based on a comprehensive review of the research literature, observation of master clinicians, and critique by master clinicians, the fidelity measure defines the active ingredients or core elements for sensory integration intervention. The fidelity measure has been used in more recent trials (Table 2-10).

Studies using rigorous methods have shown positive effects of sensory integration interventions. In a randomized trial comparing sensory integration intervention with an activity protocol or no treatment, Miller et al.¹¹⁴ assigned children with sensory modulation disorders to one of three groups. The children in the sensory integration group and the activity group received intervention twice a week for 10 weeks, and the control group children were placed on a waitlist for intervention. Children in the sensory integration intervention group made significant gains on goal attainment scaling and in attention and cognitive and social performance as measured by the Leiter International Performance Scale. Other measures of child behavior, sensory processing, and electrodermal reactivity improved in the sensory integration group but did not differ when the sensory integration group was compared with the activity and control groups.¹¹⁴

Trials of SIT have focused on effects for children with ASD. In two randomized controlled trials with young children with ASD, one examined the effects of clinic-based SIT compared with usual care,¹⁵² and one examined SIT effects compared with a fine motor activity intervention.¹³⁴ Both trials used the Ayres sensory integration fidelity measure (see Table 2-9)¹³³ to standardize the intervention procedures. Following 6 weeks of SIT or fine motor activities, Pfeiffer et al.¹³⁴ found that the children with ASD who received SIT improved more in their individualized goals (as measured by Goal Attainment Scaling) and

CASE STUDY 2-2 John; Developmental Coordination Disorder

John is an 8-year-old boy with developmental coordination disorder. As an infant, he was delayed in development of motor skills, and as a preschooler, he was described as clumsy and awkward. At 8 years old, he rarely participates in physical activities with his peers. He has great difficulty in learning new motor tasks and motor planning complex motor tasks.

He has struggled to learn handwriting. He is in second grade, and key issues for the teacher are (1) his handwriting is illegible and his written work is highly disorganized, and (2) he does not participate in recess activities but stands on the side watching the other children play.

TABLE 2-9 Core Elements of Sensory Integration Therapy

1. Ensures physical safety	Occupational therapist anticipates physical hazards and attempts to ensure that the child is physically safe through manipulation of protective and therapeutic equipment and the therapist's physical proximity and actions.
2. Presents sensory opportunities	Occupational therapist presents the child with 2 of 3 types of sensory opportunities—tactile, vestibular, and proprioceptive—to support the development of self-regulation, sensory awareness, or movement in space.
3. Helps child to attain and maintain appropriate levels of alertness	Occupational therapist helps the child to attain and maintain appropriate levels of alertness and an affective state that supports engagement in activities.
4. Challenges postural, ocular, oral, or bilateral motor control	Occupational therapist supports and challenges postural control, ocular control, or bilateral development. At least 1 of these types of challenges is intentionally offered: postural challenges, resistive whole-body challenges, ocular-motor challenges, bilateral challenges, oral challenges, projected action sequences.
5. Challenges praxis and organization of behavior	Occupational therapist supports and presents challenges to the child's ability to conceptualize and plan novel motor tasks and to organize his or her own behavior in time and space.
6. Collaborates in activity choice	Occupational therapist negotiates activity choices with the child, allowing the child to choose equipment, materials, or specific aspects of an activity. Activity choices and sequences are not determined solely by the occupational therapist.
7. Tailors activity to present just-right challenge	Occupational therapist suggests or supports an increase in complexity of challenge when the child responds successfully. These challenges are primarily tailored to the child's postural, ocular, or oral control; sensory modulation and discrimination; or praxis developmental level.
8. Ensures that activities are successful	Occupational therapist presents or facilitates challenges that focus on sensory modulation or discrimination; postural, ocular, or oral control; or praxis in which the child can be successful in making an adaptive response to challenge.
9. Supports child's intrinsic motivation to play	Occupational therapist creates a setting that supports play as a way to engage the child fully in intervention.
10. Establishes a therapeutic alliance	Occupational therapist promotes and establishes a connection with the child that conveys a sense of working together toward one or more goals in a mutually enjoyable partnership. Relationship of occupational therapist and child goes beyond pleasantries and feedback on performance such as praise or instruction.

From Parham, L. D., Roley, S. S., May-Benson, T. A., Koomar, J., Brett-Green, B., Burke, J. P., et al. (2011). Development of a fidelity measure for research on the effectiveness of the Ayres sensory integration intervention. *American Journal of Occupational Therapy*, 65, 133–142.

demonstrated fewer autistic mannerisms; the groups did not differ in adaptive behaviors or sensory processing. In the trial by Schaaf et al.,¹⁵² children with ASD received 10 weeks of SIT or usual care. Children in the SIT group improved more in individualized goals and required less caregiver assistance in self-care and social functions. In a systematic review of sensory interventions for children with ASD, Case-Smith, Weaver, and Fristad²⁵ concluded that SIT results in “meaningful positive effects” on individualized goals and overall moderate effects on parent-reported and teacher-reported assessments.

Qualitative research has explored parents' perceptions of change in their children and in themselves as a result of occupational therapy that used sensory integration intervention.^{27,28} Parents reported positive changes in their children's social participation, perceived competence, and self-regulation. The parents valued the new understanding of the child's behavior and used this perspective to support and advocate for the child more effectively. Ayres' work has had a significant impact on occupational therapy practice with children and has led to an increased sophistication and rigor in the scholarly work accomplished in the field of occupational therapy.

Task and Environment Adaptation

Occupational performance is successful when the demands of the task, the skills of the child, and the features of the

environment are congruent. When the skills of the child or youth do not meet the demands of the task in the environment, occupational performance becomes less successful. Most of the models of practice in occupational therapy, particularly with children who are developing, focus on increasing the child's performance and participation; however, often the task and environment are modified or adapted to optimize participation. The adaptation approach can be combined with remedial intervention or may be the focus of occupational therapy services.

To implement an adaptation approach, the occupational therapist first completes an in-depth task and environment analysis. This analysis identifies the following:

1. What is the goal of the task, and what are the task demands?
2. Which performance components required for the task are difficult for the child, and which is the child unable to perform?
3. How can the task or environment be modified to increase the child's function?
4. Which resources, technologies, and methods are needed to enable the child to accomplish this task (or the goal of the task)?

The goal of the adaptation model of practice is to modify the demands of the task and environment so that they are congruent with the child's ability level. Adaptations may involve modifying the occupation so that it is easier to perform, using assistive technology devices, or changing the physical or social

TABLE 2-10 Occupational Therapy Evaluation and Intervention

Problem Definition and Goals	Description of Intervention	Expected Outcome
Cognitive Orientation to Occupational Performance		
Services are provided by the school-based occupational therapist. Through a discussion with John about his handwriting and his participation in playground activities, the occupational therapist identifies his frustration with his performance and his feeling of isolation that he is limited in participating in physical activities with his peers. Together they establish two goals: John will: • Improve his handwriting so that his teacher and his parents can read his stories. • Improve the neatness of his paper to earn a gold star from the teacher. • Participate in playground activities 4 of 5 days.	Based on an analysis of John's handwriting, the occupational therapist targets letter formation and letter alignment. She and John agree to work on handwriting together by making picture books about his pets. Throughout the sessions, the occupational therapist guides him in letter formation. Together they select the handwriting aids that help him most. They select a pencil grip and an alphabet strip. They also practice on paper with highlighted lines. They agree to make two copies of the book, the first one just for practice. John is motivated to make his pet book neat and readable. The occupational therapist also analyzes his performance on the playground and determines that his difficulty with motor coordination creates anxiety in using the equipment, and he is embarrassed to use the equipment in front of his peers. The occupational therapist gets permission for John to practice using the playground equipment with her at times other than recess. They practice on simple and then more difficult equipment. The occupational therapist models for him and sometimes cues him, but she does not often offer praise as his achieving the motor tasks is sufficient (intrinsic) reinforcement.	Having followed the Goal, Plan, Do, Check strategy, the occupational therapist asks John if he is pleased with his pet book. He indicates to the occupational therapist which supports were most helpful and which he would like to continue to use. John realizes that he needs to practice his handwriting and to take his time when writing. The teacher is pleased with his improvement in handwriting legibility. The occupational therapist and John check his participation on the playground. He prefers to stay with the swings, which are easiest to use. The occupational therapist and he agree that the swings are a good activity for recess. Later in the school year, they will create a new goal to use other pieces of playground equipment.
Sensory Integration Intervention		
Services are provided by a clinic-based occupational therapist. John appears to have a sensory integration disorder, specifically somatosensory dyspraxia. This means that his somatosensory perception (touch and movement) is limited; he does not receive accurate or sufficient feedback from movement to learn new motor skills easily. His coordination will improve if his sensory integration improves and he gains increased perception of his body's movement. The goals for therapy: John will: • Increase the accuracy of his tactile and proprioceptive perception as measured on the Sensory Integration and Praxis Tests (SIPT). • Demonstrate improved motor planning skills as measured on the Bruininks Oseretsky Test of Motor Proficiency (BOT-2) and the Evaluation Tool of Children's Handwriting	Based on the results of the SIPT, John shows low tactile discrimination and very low praxis skills. Intervention focuses on enhancing sensory integration of the tactile and proprioceptive systems and improving motor planning. The occupational therapist provides a sensory-rich environment with a variety of swings, unstable surfaces, crawling surfaces, and equipment that provides deep pressure. She and John collaborate in selecting activities that are fun but challenging, and the occupational therapist offers supports and guidance as needed for John to master the activities. Although the occupational therapist allows John to repeat fun activities, she also changes the activities so that they are more challenging. She often asks John if he can think of ways to make the activity harder. Together they plan activities that simulate the playground equipment at school so that he becomes more proficient and confident in performing these activities. To improve motor planning, the therapist devises obstacle courses for him to complete in the clinic. They spend some of the session practicing visual motor integration activities, such as games and handwriting practice.	John's scores on the SIPT and the BOT-2 improve. At the end of 6 months, he scores within normal limits on many of the subtests. His improvement in sensory integration and motor planning translates to his participation and performance at school. His handwriting improves and becomes more legible. His family helps him generalize skills that he gained in occupational therapy by taking him to the playground twice a week. With this support in generalizing his new skills, John participates with his peers on the playground equipment at school.

environment.³⁶ Often when children have significant impairments, task modification is needed to maximize the child's participation. For example, a child with cerebral palsy may require an adapted spoon and cup to eat dinner with his family. A child with autism may require a picture exchange card system to communicate his need to use the bathroom.

When skills are insufficient to enable performance, task adaptation is used to modify the demands of a task to bring it to the competence level of the child. An example in school-based practice would be adapting the writing surface by using a slant board so that the child's written work is more easily visualized and the child's hand and arm posture are supported in a posture that promotes writing. A child with a learning disability may be able to complete a page of arithmetic problems when the font is enlarged and the paper has a color tint.

Often adaptive equipment or assistive technology is used to modify or adapt the task. Campbell, Milbourne, and Wilcox²² view assistive technology as a bridge or mediator between the skills that a child can currently perform and the requirements of the task. Assistive technology may be as simple as adaptive brushes or crayons that allow a preschool child to participate in art activities. A wide variety of assistive technology devices can enable children with significant motor impairments to access their environment better. For example, assistive technology devices can help position the child to perform an activity (e.g., a prone stander) or provide postural support (e.g., wheelchair straps). "High-tech" technology is also available to provide a method for written communication (e.g., a laptop computer) or augmentative communication (e.g., a device for synthesized speech). Chapters 15, 19, and 20 describe assistive technology devices that use this approach to increase children's participation in their natural environments.

With children, the compensatory approach often complements other approaches that focus on skill building. Methods for adapting tasks are selected not only so that the child succeeds at a particular task but also to promote skills in similar tasks and in other environments. For example, a child with poor drawing skills can create a picture using peel-off stickers of animals. Although this adaptation allows him or her to create a picture more easily than drawing with markers, peeling off and placing the stickers provide practice of fine motor skills—specifically, bilateral coordination, isolated finger movements, spatial relations, and use of force. Practice in these skills may generalize to other art activities, and the easy success the child achieves when using colorful animal stickers may encourage him or her to attempt other art activities.

More recent research has used adaptation approaches as the primary occupational therapy intervention to optimize the child's function and participation. Research by Law et al.,⁹⁷ described in the section on dynamic systems theory, and Dunn et al.,⁴⁷ described in the next section, demonstrates the effectiveness of interventions that focus on adapting activities and the environment to enhance the child's participation.

Coaching and Consultation Models

Virtually all occupational therapy interventions for children involve coaching and consulting. Theory-based conceptual models guide how occupational therapists approach and implement these aspects of practice. Service delivery using coaching and consultation is particularly relevant for preventive

interventions; they also support generalization or transfer of new skills (see Figure 2-6). Often, but not always, these approaches to service delivery are provided in combination with direct interventions. The role of occupational therapy in prevention is emerging and promises to be an important part of practice.

Coaching models have evolved in recent years into essential elements of health care service delivery and therapeutic intervention. Coaching models vary in educational and medical models of service delivery, reflecting philosophical differences, top-down versus bottom-up approaches, and the targeted goal (health, development, function, relationships). Fundamental to coaching models are theories of self-efficacy and family-centered approaches.^{48,49} The positive outcomes of coaching are that parents can identify their own solutions; parents can fully participate in intervention; and parents' competence increases.⁴⁷

Coaching and Consulting Models in Early Childhood and Educational Settings

Researchers and practitioners have advocated for the use of coaching models in early intervention and early childhood programs.⁴⁹ Coaching can be defined as a reciprocal process between a coach (occupational therapist) and learner (parent), comprising a series of conversations focused on child outcomes that allow the learner to discover his or her own solutions for achieving the agreed outcomes. In coaching, the practitioner recognizes that when clients are informed and make their own decisions, they are more likely to participate fully, to maintain participation over time, and to be satisfied with services. It is an interactive process that supports the parents' observations and reflections about the child's behaviors. Because it is built on trust, respect, and open communication, this interaction facilitates the development of a therapist-caregiver relationship that sustains the intervention process and increases caregiver competence and satisfaction with services. An occupational therapist can apply the following steps in the coaching process: (1) use reflective statements and questions to invite parents to discuss the child's problem or desired goal; (2) guide the parents to become more aware of the problem and possible reasons for the problem; (3) help the parents analyze the problem; (4) suggest possible alternative solutions or guide the parent into identifying solutions; (5) identify with the parent an action, then encourage and support that action; and (6) ask questions to guide the parent in identifying potential outcomes that would determine goal achievement.⁴⁷ Coaching principles are listed in Table 2-11 and are described further in Chapter 22. Case Study 2-3 presents a brief example of coaching.

Coaching strategies have been used to promote parent-child interaction in home visits of early intervention professionals.¹⁰⁷ They have also been used to support parents in providing teaching opportunities to their children. Education and occupational therapy researchers have found positive effects when implementing coaching models.^{47,169} Coaching of teachers has resulted in positive outcomes for classroom management and teachers' support of student social-emotional development.^{24,144} Teaching children with ASD self-management of behavior allows them to be more self-directed, self-reliant, and independent and less dependent on external supervision.¹⁸⁷ Self-management is considered to be a pivotal skill that can generalize to adaptive behavior and promote autonomy for

TABLE 2-11 Coaching Principles and Examples

Coaching Principle	Explanation	Example
Coaching is a voluntary process based on collaborative relationship.	It is important that the professional does not approach the relationship with a sense of power over the family. The focus is on potential outcomes and not fixing a problem.	The occupational therapist asks: How would you like me to help you? What goals for your child are important to you?
The process involves small steps toward positive change.	Small steps are important. When problems arise, these can be reframed as opportunities for change.	The occupational therapist praises small accomplishments, helps the parent recognize the child's progress, even if it is short of the hoped-for outcome.
Occupational therapist creates opportunities for the learner to master new competencies.	Occupational therapist can suggest that the parent practice a new skill in different settings and context. This allows problem solving when context-specific problems arise.	The occupational therapist suggests that the parent try a strategy that was successful at home in the community. The occupational therapist suggests that the mother teach her spouse the strategy as way of reinforcing her learning.
Occupational therapist provides ongoing support and encouragement.	This support and trust enhances the positive relationship between the coach and parent.	Rather than giving the parent solutions, the occupational therapist guides the parent into identifying solutions and may give the parent additional resources.
Occupational therapist and parent together analyze situations and problem solve solutions.	Ideas and resources are shared. This process leads to self-discovery of solutions and establishes where more support is needed.	The occupational therapist asks: What happened when you tried ... ? What changes would you make the next time? What have you learned from this process?
Occupational therapist and parent reflect on the outcome of the strategy.	The parent and occupational therapist review experiences, discuss what worked, check perceptions, and analyze strategies.	The occupational therapist asks for the parent's perceptions of outcome. The occupational therapist asks about the parent's satisfaction with the child's outcome and the coaching process.

CASE STUDY 2-3 Examples of Coaching in School-Based Practice

Michael is struggling at school to fulfill his role as a student successfully because he has high functioning autism spectrum disorder (ASD). Michael struggles with his academic occupations because he becomes anxious in social situations, requires high structure to engage in academic activities, and has limited social skills. His social participation is characterized by interest in his peers but limited ability to read the social cues of his peers and anxiety about initiating a social interaction.

Thom, the occupational therapist, evaluates the school activities in which Michael is expected to participate and determines what personal and environmental factors are influencing his performance. School occupations with high social

interaction become the focus of intervention; for example, Thom helps the teacher structure the classroom environment to allow for nonsocial activities to be interspersed with social activities. Thom coaches Michael to use strategies that help him interpret social cues and gestures and make appropriate social responses. Thom creates opportunities for him to interact with peers in safe and structured environments. Scaffolding the child's participation in social activities with peers at school is likely to develop skills that generalize to other opportunities for social participation. This brief example illustrates intervention principles that enable participation of children in everyday occupations (see [Research Note 2-1](#)).⁹⁰

children with high functioning ASD.⁸⁷ To promote self-management of behavior, the occupational therapist meets with the child or youth to develop a plan and to identify goals. The occupational therapist and child determine how and when the targeted behaviors will be recorded and how positive behavior will be rewarded. The occupational therapist and child meet regularly to evaluate behavior and progress, and the occupational therapist provides rewards; this process is faded as the child becomes more independent, and behaviors become consistent.¹⁸⁷

Most occupational therapy interventions for children include a coaching or consultation component with direct intervention, making it difficult to separate the effects of consultation versus direct intervention. However, a few studies have examined consultation or coaching as the primary intervention model. In a comparison study, Dreiling and Bundy⁴⁴ found that consultation services were equal in effectiveness to direct services. Dunn et al.⁴⁷ examined the effects of a contextual intervention in which occupational therapists coached parents to develop strategies that supported participation of their children with sensory

processing problems. The occupational therapists provided home-based reflective coaching to support parent problem solving. Ten sessions of coaching resulted in improved child participation as measured on the Canadian Occupational Performance Measure and based on individualized goals. In addition, the parents who participated in the contextual intervention improved in self-efficacy, resulting in gains that were well above normative data for parent self-efficacy. In addition, occupational therapists using context intervention³⁹ apply coaching and consultation methods. Context intervention is a strength-based approach specifically designed to enhance parents' competence to problem solve and adapt task and environment barriers that limit the child's participation.⁹⁷ The occupational therapists encourage the parents to find solutions, using a trial-and-error approach to discovering what works best. In this intervention, the occupational therapists make specific recommendations for adapting tasks and environment, collaborate with families to implement the modifications, and are open to parent suggestions to ensure that the adaptations are congruent with the family's daily routine.

Coaching and Consultation in Medical Settings

Medical models of coaching focus on shifting the power from health professional to the client or family and recognizing the family's stage of readiness to change behavior. Core constructs for the coaching models that have been developed in medical systems follow the theories of Prochaska¹³⁹ on behavioral change and self-management—the therapist's coaching methods follow the family's readiness for behavioral change. The continuum of readiness is (1) precontemplation, (2) contemplation, (3) preparation, (4) action, and (5) maintenance. This continuum is relevant to the occupational therapist giving a family a home program, asking the parents to implement specific strategies or change their routine. Without considering this continuum, occupational therapists may overwhelm parents, may be unrealistic in their expectations, or may not provide sufficient resources to enable participation of parents in their child's intervention. The factors that influence behavioral change or a parent's readiness to participate in intervention include:

1. The pros and cons for the desired behavior change.
2. Self-efficacy or confidence in their ability to change.
3. Cognitive process including self-image.
4. Social norms for expected behavior.
5. Behavior process such as making a commitment.
6. Social resources available to support behavioral change.

Interventions focused on prevention and primary care frequently use consultation models of service delivery. For example, interventions to prevent skin ulcers in children in wheelchairs focus on coaching families to support the child's activity level, encourage the child to spend time out of the wheelchair, maintain the cushion and seating supports, and encourage weight shifts during sedentary activity.⁸¹ Occupational therapy programs to prevent weight gain in children with diabetes and to maintain activity levels for children with asthma also involve primarily family consultation and coaching.⁴² More recently developed coaching models that use telehealth technology have increased the range of occupational therapy services available to families with limited access to services.²⁶

Occupational therapists, nurses, and physicians have successfully used coaching and consultation models to promote

self-management of treatment for children with diabetes and asthma.⁵⁹ Occupational therapists can coach families on healthy lifestyles and healthy habits to help them manage these chronic conditions. In a study to promote parents' management of their child's asthma, Nelson et al.¹²³ used the transtheoretical model of behavioral change. The coaches assessed the parents' level of readiness and motivation to change and adjusted the coaching to match each stage. Parents made significant progress in moving forward in their stage of readiness. Parents were more engaged and made greater progress when contacts with the coaches were frequent and consistent.¹²³ The transtheoretical model of behavioral change is useful when parents face a sudden change in their child's health status (e.g., a head injury) and they are unprepared for the major changes in their daily routine and home environment that are necessary to accommodate a child with significant medical problems or disability. Using this frame of reference can guide how the occupational therapist coaches the parent, which information and resources to provide to the parent, the pace of coaching, and the level of support needed for transfer of care from the rehabilitation professionals to the family. Coaching is a strength-based and family-centered model of service delivery with the potential to build self-efficacy and self-determination in families and children.

Summary

Occupational therapists who provide services to children and youth use theory-based practice models. These models originated in the fields of psychology, education, and medicine and have been adapted using the lens of occupation and occupational therapy. They provide a framework for clinical decision making and reasoning. They also guide occupational therapists to consider the child, his or her occupations, the environment, and the interactions of these elements. Practitioners recognize that theories are overlapping and complementary. To meet the individual needs of the children they serve, they use theoretical concepts specific to certain problems as well as in combination. Occupational therapists apply different practice models as the child grows and experiences different contexts. Research studies have examined the effectiveness of practice models, assessing their benefits and for whom they are most beneficial and investigating how they should be staged across the life span. Research evidence has helped occupational therapists in refining practice models and using them appropriately in various contexts.

Summary Points

- Occupational therapy practice models have evolved from learning, development, occupation, and ecological theories.
- Outcomes of occupational therapy interventions include children's engagement in occupations—meaningful, goal-directed activities and participation across a balance of life activities.
- Ecological theories explain the influence of the environment on human behavior and function. Environment fit is the congruence between individuals and their environments, and optimal congruence allows for optimal participation.

- The person-environment-occupation model explains the dynamic, transactive relationship of person, environment, and occupation across the life span.
- The International Classification of Functioning, Disability, and Health and the occupational therapy practice framework define the relationships among body structures and functions, activities, and participation, suggesting that health directly relates to participation.
- Occupational therapy practice is child-centered, family-centered, and strength-based; these concepts are directly linked to enhancing self-efficacy and self-determination.
- Occupational therapy interventions based on behavioral theories, such as shaping, incidental teaching, pivotal response training, motor learning, and social skills training, use performance analysis, apply learning principles, access the natural environment and play activities, promote practice and repetition, challenge mastered skills and support emerging skills, and provide positive reinforcement.
- Cognitive-behavioral interventions, such as CO-OP, use a collaborative, strength-based approach to establish goals with the child, analyze performance, identify strategies to reach goals, guide the child in discovery of solutions for performance problems, enable the child to improve performance relative to goals, and promote generalization.
- Interventions to promote social behaviors and participation often use social play, occupation-based social groups, and peer-mediated models. There is positive evidence for use of these models with children and youth with ASD.
- Interventions to improve motor skills use dynamic systems theory and motor learning principles to identify the variables that influence the child's sensorimotor performance, focus on goals that allow reorganization of performance, identify contexts and activities optimal for sensorimotor practice, apply multiple dimensions of reinforcement, and specifically design strategies to promote generalization.
- Occupational therapists use collaborative models of coaching and consultation to promote parents' sense of competence, self-efficacy, and partnership in promoting child outcomes. These models are useful in preventive interventions for children with chronic health problems and are beneficial to families who are responsible for managing their child's health care and intervention long-term.

CHAPTER

3

Development of Childhood Occupations

Jane Case-Smith

KEY TERMS

Stages of cognitive development	Attachment
Zone of proximal development	Emotion regulation
Scaffolding	Risk and resiliency
Neuromaturational theory	Self-determination and self-efficacy
Dynamical systems theory	Cultural practices
Perceptual-action coupling	Occupations within cultural, social, and physical contexts
Functional synergies	Development of play occupations
Temperament	

GUIDING QUESTIONS

1. What are historical and current theories of child development?
2. How do a child's unique characteristics influence skill development?
3. Using an occupational therapy perspective, how do occupations develop?
4. How do individual biologic systems and cultural, social, and physical contexts contribute to a child's occupational performance in the first 10 years of life?
5. How do child performance and contextual variables contribute to the development of play?

An understanding of child development is foundational knowledge for pediatric occupational therapists. Researchers from many disciplines, including medicine, psychology, anthropology, education, sociology, and occupational therapy, have contributed to the literature on human development, and the different perspectives they provide should be woven into a holistic and comprehensive understanding of how children become adults.

Occupational therapists ask *what* developmental changes occur in children and *how* children develop their unique personhood. The answers to these questions provide essential knowledge for evaluating children and for determining the appropriate materials, activities, and environments to support children's skill development and participation in their communities. They are also interested in how human occupations develop over the life span.

This chapter focuses on child development theories, with emphasis on concepts that have emerged in the past 3 decades. The first section discusses concepts that explain how children develop and which variables and interactions influence developmental outcomes. In the second part of the chapter, a model for the development of childhood occupations is applied to children's development of play in the first 10 years of life. [Chapter 4](#) describes the development of preadolescent and adolescent occupations in the second decade of life.

Developmental Theories and Concepts

Developmental theories have guided education and therapy for children with developmental disorders for the past 60 years. Researchers of the 1930s and 1940s identified a sequence of skill maturation that defined the steps of normal development. Gesell and colleagues⁵²⁻⁵⁴ and McGraw⁹⁶ assumed that normal development followed a specific skill sequence that reflected maturation of the central nervous system (CNS). These scholars believed that the sequence of motor, cognitive, social-emotional, and language skill development was relatively unaffected by the infant's experiences. The sequence of normal development is an important frame of reference for creating developmental assessment tools that identify children with disabilities. Gesell and Amatruda⁵³ believed that variations in the normal sequence of development indicate CNS dysfunction. Identifying children with developmental deficits or significant delays remains an important role of physicians, nurses, occupational therapists, and others who provide early intervention services. Since the 1940s, theories of child development have evolved from observational and longitudinal research that identify the stages of child development and define key developmental milestones to studies that reveal the complexity of child development as it relates to cultural, physical, and social environments. This section describes theories that relate primarily to (1) cognitive development, (2) motor development, (3) social-emotional development, (4) self-identity and self-determination development, and (5) ecologic models.

Cognitive Development

In contrast to the first theories of child development that proposed a predetermined step-by-step process,^{9,53} scholars and researchers in the twentieth century understood that child development was influenced by the child's cultural, social, and physical contexts. They explained that development can be

represented by a pyramid, meaning that new skills are built on foundational abilities.^{62,109} The concept of a pyramid suggested that each new stage builds on specific foundational skills. Children move between more advanced or more primitive behaviors in different contexts, and new behaviors depend on not only neurologic maturation but also the demands, challenges, supports, and learning opportunities in the environment.⁸¹

Interplay of Intrinsic and Environmental Factors

One of the first scholars to describe this interactive nature of cognitive development was Jean Piaget. Piaget¹⁰⁹ expanded our understanding of a child's maturation by emphasizing that development occurs through the interaction between the environment and the child's innate abilities. Children adapt and grow developmentally through social and physical relationships. Piaget¹⁰⁹ introduced the idea that children are intrinsically motivated to learn from their surroundings and that they act on, rather than simply react to, their environment. Beginning in infancy, children develop *cognitive structures*, or *schemas*, to represent objects, events, and relationships in their minds.⁹⁸ Piaget emphasized the maturation of cognitive structures that enable the child to understand the environment, language, and social action. Every interaction is an opportunity either to assimilate new knowledge into existing structures or to adapt existing structures to accommodate new information. The influence of the environment on the child's development changes as the child becomes increasingly able to assimilate the complexities of physical and social events.

Piaget documented the child's maturation through stages of sensorimotor exploration to the acquisition of symbolic thought and formal cognitive operations. The developmental stages follow a predictable sequence but vary to the extent that they reflect genetic endowment and the child's experiences. Children's cognition matures from the simple to the complex, from the concrete to the abstract, and from personal to worldly concerns. Piaget specified four maturational levels or periods of cognitive function—sensorimotor, preoperational, concrete operational, and formal operational^{46,86,97,98}—that lead to the cognitive maturity of adulthood. Through these stages, children develop mental representations of the world that they use to understand and respond to events. The culmination of these levels is a person who has values, goals, and purpose (i.e., has become an occupational being). At the present time, most child researchers agree that the child is an active learner but do not view development in discrete stages.

This interplay between the child's abilities and his or her experience can be appreciated in the early development of tool use. Children at 8 to 10 months of age can manipulate two objects and can move an obstacle to reach an interesting or novel object (sensorimotor stage). By 12 months, infants can relate an object to other objects, in addition to relating the objects to themselves. At this stage, infants use a stick to rake in an object out of reach and place objects into containers (sensorimotor). By 18 months of age, infants begin to use trial-and-error to solve problems (preoperational). At 24 months of age, children no longer exclusively need physical manipulation to solve problems and begin to demonstrate use of mental manipulation (preoperational).^{96,110,111}

Research studies in the 1990s demonstrated that cognitive structures develop at earlier ages than Piaget assumed; they also

demonstrated that child development has more continuity and integration across the stages of development.^{21,46} At 1 month of age, infants demonstrate the ability to associate learning from one sensory system with another sensory system. For example, they recognize objects with their eyes that they previously felt in their mouths.⁹³ Researchers found that 9-month-old infants can remember an event 1 week after it happened.⁹⁹

Problem solving also appears to develop earlier than believed; developmental studies show that toddlers can manipulate and use tools and can solve problems such as how to grasp and use a spoon. After grasping a spoon awkwardly, children 9 to 14 months old can adjust the spoon's orientation to get the food into the mouth.⁹⁶ Children 19 months old can plan how to grasp and orient the spoon to get the food before acting, avoiding the use of an awkward grasp that required adjusting. At 19 months of age, children can solve problems without physical manipulation and trial-and-error to handle a tool accurately. By this age, the child can scoop food, fill the spoon, and correctly angle it toward the mouth,⁷¹ signifying the early emergence of tool use.

Scholars have critiqued and expanded Piaget's original theories to appreciate fully how the environment influences development. For example, Piaget's theories lack full appreciation of the influence of culture, society, and technology on development of children. Current occupational therapy theories consider these variables to have important roles in a child's development.^{11,150} In addition, Piaget's theories did not address the development of emotions and did not have a coherent explanation for individual differences, individuality, or variability.^{46,97} The importance of variability has been highlighted in the work of other psychologists^{133,136} and by occupational therapy researchers.⁷⁴

An understanding of Piaget's theory is important to occupational therapists who provide interventions for children. Regardless of the therapeutic approach used in treatment, the occupational therapist interacts with a thinking child who is continually learning from his or her environment. It is essential that the selection and structure of an activity be in accordance with the child's cognitive development.

Influence of Social Interaction on Learning

Following Piaget, another developmental theorist, Vygotsky,¹⁴³ proposed new concepts that explained how children learn through interacting with their environment. Similar to his predecessors (e.g., Gesell, Piaget), he understood that genetics has unequivocal influence on development; however, Vygotsky theorized that the child develops by internalizing the social interactions that he experiences. Social interaction has a fundamental influence on the child's development of cognition and language. A child's cognitive processing first requires the assistance of another being within a social interaction before the child can mentally process on his or her own. Cognitive processing is a social process before it is an internal process, and a child's development and learning are critically dependent on social interaction. Learning is essentially culturally determined, and culturally valued activities are the context of a child's development.¹⁴³

Vygotsky defined a "*zone of proximal development*" to explain how learning occurs through social interaction. The zone of proximal development is "the distance between the

actual developmental level as determined by independent problem solving and the level of potential development as determined through problem solving under adult guidance or collaboration with more capable peers” (p. 86).¹⁴³ What a child can achieve and learn with the assistance of another is the zone of proximal development and defines the area in which adults can work with the child to promote the child’s development and independence in a particular skill.¹⁴³ What children can do with the assistance of others may be more indicative of their mental development than what they could do independently. When presented with a *just-right* challenge (e.g., a task that is slightly more difficult than the tasks the child has currently mastered), the child generally attempts and succeeds in this challenge, learning the next step in skill development.

The mechanism through which children learn in social interaction is termed *scaffolding*—the support provided by caregivers and teachers. Scaffolding performance within the child’s zone of proximal development is the process by which an occupational therapist supports or guides a child’s actions to improve competence. Appropriate guidance is the just right amount of support that enables the child to perform at a higher level. When using scaffolding to facilitate the child’s learning, the adult gradually decreases the amount of support provided such that the child performs more independently. Through this process, actions that are externally supported become internalized. The child’s help-seeking in an activity can be as important to his learning as receiving assistance. By asking questions and help-seeking, the child becomes more self-directed in his learning. When the occupational therapist understands a child’s zone of proximal development and perceives methods for scaffolding his learning, the therapist can design an optimal activity to promote the child’s learning.

When an adult creates a learning opportunity that is an optimal balance between the child’s existing skills and the challenge of the task, the adult can model language and behavior to help the child progress. Vygotsky’s emphasis on the interactions between a child’s learning, his or her environment, and the type of instruction provided was a precursor to many of the system models that influence learning theory today.

Vygotsky and many subsequent developmental theorists have examined how human development transpires through a dynamic interplay involving the child and the child’s cultural, social, and physical environments. For example, rates of development appear different according to the family’s economic status,^{16,89} cultural groups, and generations,¹⁶ in part because of differences in nutrition and childcare practices. In human development research, the emphasis currently is on the variations expressed by individual infants and on how human systems and environmental constraints contribute to these variations.

Motor Development

Neuromaturation

In neuromaturation theory, the essential sequence in which children attain developmental milestones is linear and consistent across children. Skills emerge sequentially according to the maturation of CNS structures.^{41,100} Brainstem structures develop first, as evidenced by the reflexive responses of the

newborn (e.g., automatic grasp, asymmetric tonic neck reflex) that are controlled by neural pathways originating in the brainstem. Cortical structures appear to develop later, as evidenced by the coordinated and planned actions of the child. The infant’s increasing control of action and skill indicates not only development and myelination of the midbrain and cortical structures but also simultaneous inhibition of brainstem control of movement. Using neuromaturation theory, motor development is explained by the following principles:

1. Movement progresses from primitive reflex patterns to voluntary, controlled movement. In newborn and young infants, motor reflexes provide the first methods of interaction with the environment (e.g., reflexive grasp) and are essential to life (e.g., the sucking and swallowing reflexes). Because early reflexive movements serve functional needs, the newborn appears surprisingly competent. These reflex patterns subside as balance, postural reactions, and voluntary motor control emerge (i.e., when the infant learns to roll, sit, creep, stand, and walk).
2. The sequence and rate of motor development are consistent among infants and children. The developmental scales of Gesell and Amatruda,^{53,75,76} Bayley,¹⁰ and others are based on a typical rate and sequence of development. By assuming that the sequence of milestones (i.e., major motor accomplishments) is constant and predictable, the normative developmental sequence can be used to diagnose neurologic impairment and disability.¹⁰
3. Low-level skills are prerequisites for certain high-level skills. Infants develop motor control in a cephalocaudal direction, with head control maturing first, followed by trunk control sufficient for independent sitting, and, finally, pelvic control sufficient for standing and walking (Figure 3-1).

In assuming a hierarchy of CNS function, the neuromaturation theory limits our understanding of how a child learns

FIGURE 3-1 Infants play in supported standing for extended periods, gaining postural stability and balance when holding onto a stable surface.

to act in the environment. In particular, this theory does not explain how children learn new motor skills and ignores that the CNS has vast plasticity that allows humans to adapt to their environments. Gottlieb⁶³ defines plasticity as a fusion of the child and the environment. Through both experience and development, new structures (e.g., cellular) and functions (e.g., performance) emerge. The child's experiences produce new neurologic connections and structural changes, and development of the relationships among components is important. Acknowledgment of the system's plasticity places the focus on the child's potential for change and on the contextual features that promote or limit a child's performance. Using current research models,^{58,60,133,134} occupational therapists and others recognize that multiple variables at different levels influence the child's skill development. The child learns occupations through interaction with his or her environment rather than through the emergence of a predetermined scenario reflecting neuro-maturational principles.⁷²

Dynamical Systems Theory

Dynamical systems theory refers to performance or action patterns that emerge from the interaction and cooperation of many systems, both internal and external to the child.¹³⁴ In the context of child development, performance patterns emerge from the interaction of an individual's systems and performance contexts as the child strives to achieve a functional goal.^{94,95,103} The dynamical systems theory is useful in describing how specific motor and process skills develop.

Humans are complex biologic systems comprising many subsystems (e.g., motor sensory, perceptual, skeletal, and psychological subsystems). These subsystems are in constant flux, interacting according to the task at hand and conditions in the environment. The child's actions during the performance of a task are the result of the subsystems' interaction with each other and with the environment.¹³⁰ These individual systems come together and self-organize in a coordinated way to achieve the child's goal.¹³¹ For example, initially a child is interested in exploring the sensory characteristics of a toy. As the child reaches for the toy, grasps it, and brings it to midline in hand-to-hand play and then finally to the mouth, the child's attention and cognitive focus are not on planning each of these actions. Instead, they are on assimilating the toy's actions and perceptual features (Figure 3-2).

Longitudinal studies reveal that children demonstrate unique trajectories of development and that variations in functional performance among children persist into adulthood. Thelen, Corbetta, and Spencer¹³⁵ demonstrated the uniqueness of motor development in a study of reaching in 4- and 5-month-old infants. Each 5-month-old infant was able to reach toward an object, but the patterns demonstrated were unique. Some infants demonstrated a slow, cautious first approach to the object, whereas others made ballistic arm movements in an attempt to reach it. Although all first reaches tended to be circuitous, the amount of correction made to obtain the object, the speed at which the attempt was made, and the angle at which arms were held differed across infants. These investigators concluded that the development of reaching represented more than development of eye-hand coordination; rather, in the simple act of reaching and grasping an object, the infant demonstrated (1) motivation to obtain the object, (2) ability to localize the object in space, (3) understanding that the

FIGURE 3-2 The infant explores a toy, assimilating its action and perceptual features.

object was reachable, (4) planning of the reach trajectory, (5) correction of the movement as the hand approached the toy, (6) lift and stabilization of the arm in space, and (7) successful grasp of the object. How a 5-month-old infant manages all of these components to reach and grasp a toy successfully varies among infants and for different reasons. Reach and grasp, as an example of developmental skill, is best understood as the outcome of the interaction of multiple systems, intrinsic and extrinsic to the child.

In a similar way, between 8 and 10 months of age, most infants acquire the motivation to be independently mobile. The need to self-initiate movement from place to place emerges as an important task, or goal, to accomplish. This goal reflects the infant's curiosity about the environment, a desire to explore space, and a determination to reach a specific play object. Although mobility becomes a common goal for the infant toward the end of the first year, the method used to achieve that mobility varies greatly. Some infants roll to another space in the room, whereas others scoot on their buttocks in a sitting position. Some infants push backward while lying in a prone position, and others creep forward to explore their environment. How the infant achieves mobility is influenced by many contributing body systems (e.g., strength, coordination, and sense of balance and movement).

Conditions in the environment also influence an infant's mobility (e.g., the surfaces on which the infant plays, the encouragement provided by caregivers, and the way in which the task is presented). The infant's energy level, motivation, and curiosity about the environment influence when independent mobility is achieved. In addition to the factors that influence the maturation of mobility skills, becoming mobile influences the development of skills in other performance domains. When an infant achieves mobility, he or she becomes more independent in initiating a social interaction or in seeking help. Independent mobility contributes to the acquisition of

social skills, self-determination, problem solving, and motivation to explore. A child learns perceptual skills, spatial relations, form perception, and object relations by moving through the environment.

Perceptual Action Reciprocity

Perception and action are interdependent and inextricably linked. This relationship is particularly observed in infants and is useful in understanding motor development. An individual's perception of the environment informs action, and the individual's actions provide feedback about movement, performance, and consequences in the environment. Initially, many of the child's actions are exploratory in nature—the child moves fingers over the surfaces of objects to learn their shape, texture, and consistency. The child waves an object in the air to hear the sounds it makes and feel its weight. These actions help the child perceive sensory and perceptual features (affordances) of objects. *Affordance* is the fit between the child and his or her environment.^{57,59,61} The environment and objects in it offer the child opportunities to explore and act. This action is based on what the environment affords as well as the child's perceptual capability to recognize affordances in that environment. For example, colorful noise-making toys afford manipulation because they have movable parts and rounded surfaces and fit easily into an infant's hand. Learning about affordances entails exploratory activities. Individual finger movements, thumb opposition, hand-to-hand transfer, and eye-hand coordination are facilitated by the physical characteristics of the toy.

Manipulation in the infant initially is guided by visual, tactile, and kinesthetic input.^{114,123} Exploration of objects begins with visual exploration and mouthing.¹¹⁵ By 6 months of age, infants prefer exploring with their eyes and hands.¹¹⁴ Fingering and manipulation skills increase substantially between 6 and 12 months of age, enabling infants to gather more precise information about objects. By 12 months of age, infants detect object properties with increasing specificity and learn to adjust their exploratory action.¹ For example, to perceive the consistency of a soft, squishy object, a child squeezes it, and to perceive the texture of velvet or corduroy, the child runs the fingers back and forth over it.

Through object manipulation, the child develops haptic perception (i.e., an understanding of shape, texture, and mass of objects). Table 3-1 explains perceptual-action reciprocity in the development of object manipulation. Bushnell and Boudreau¹⁹ propose that specific motor skills are required to

develop haptic perception. They note that infants learn to identify an object's sensory qualities (e.g., texture, consistency, temperature, contour) only when they develop the motor skills to explore each different sensory quality. For example, an infant does not accurately discriminate texture until he or she can explore texture by moving the fingers back and forth (at about age 6 months). The infant also cannot discriminate hardness until 6 months, when he or she can tighten and lessen the grip while holding an object.¹⁹ Because configural shape requires that two hands be involved in exploring an object's surfaces, children typically cannot accurately perceive shape until 12 months of age. By 2½ years, children can identify common objects through their haptic sense, and by 5 years, children recognize common objects using active touch (without vision).²⁵ By 5 years, the child has also fully developed in-hand manipulation skills,¹⁰⁷ suggesting that haptic perception develops in association with the child's development of manipulation skills. Maturation of haptic perception and manipulation underlies the child's ability to use tools for written communication (e.g., handwriting and keyboarding) and activities of daily living.

Functional Performance: Adaptive and Flexible

As mentioned, the infant begins life with few constraints on performance, which permits the greatest variability in the system for the generation of spontaneous movements. This variability permits flexibility for exploration of the environment and rapid perceptual and cognitive learning. The infant quickly selects functional synergistic movement patterns. For example, from birth, the infant demonstrates a pattern of hand-to-mouth movement (e.g., for self-calming by sucking on a fist) (Figure 3-3). Only minimal adaptive changes are made in this synergistic pattern (shoulder rotation and horizontal adduction, elbow flexion and forearm pronation, followed by supination and neutral wrist position) as the child learns to self-feed with various utensils.

Because synergies that enable tool use are softly assembled around the goal of the task at hand, they are stable but flexible units. Synergies have specific consistent characteristics, such as the sequence of movements and the ratio of joint movement, which can be adjusted to accommodate each new situation. This *adaptable stability* is a hallmark of normal movement.²⁹ Soft assembly is critical to allow the child to act in changing and variable environments. It also allows the child to explore and select a response to the environment because his or her

TABLE 3-1 Perceptual-Action Reciprocity in the Development of Perceptual and Object Manipulation Skills

Age	Perceptual Skill	Object Manipulation Skill
<6 months	Visually explores and mouths objects	Brings object to mouth
6-12 months	Explores object textures by moving fingers back and forth	Begins to extend and move fingers together
	Explores objects with eyes and hands	Fingers and manipulates objects
	Discriminates hardness of object	Can tighten and loosen grip while holding an object
12 months-3 years	Adjusts manipulation according to the object property	Moves an object from hand to hand
	Perceives object shape by moving between hands	Uses two hands to manipulate object
>3 years	Identifies common objects using haptic perception (active touch)	Begins to demonstrate in-hand manipulation skills
		Uses dynamic grasping patterns

FIGURE 3-3 Hand-to-mouth movement is observed throughout the first year, first for sensory exploration of the mouth and hand and then as a feeding behavior. (From Henderson, A., & Pehoski, C. [2006]. *Hand function in the child: Foundations for remediation* [2nd ed.]. St. Louis: Mosby.)

response patterns are variable and flexible.¹³¹ See Figure 3-4 for examples of fluid exploration of objects and a child exploring and manipulating shapes.

The functional synergies that characterize a child's development of occupations are highly adaptable and reliable. The child self-organizes these synergies around tasks and goals, and his or her first goals are embedded in and organized around play (as described later in this chapter).

How does a child learn new performance skills? Although learning new skills is not limitless and is constrained by biologic and contextual factors, human development is believed to have relative *plasticity*.⁸⁵ This concept has importance to occupational therapists, who provide intervention services designed to change and promote children's performance. Gottlieb⁶³ defines plasticity as a fusion of the organism (the child) and the environment (including its cultural, physical, and socioeconomic characteristics).⁶⁴ Individual development involves the emergence of new structural (e.g., cellular) and functional (e.g., body systems) components. The child's experiences produce new neurologic connections (i.e., new associations) and structural changes (e.g., physical growth), and the relationships among components, not the components themselves, are most important to development. Acknowledgment of the system's plasticity places the focus on the child's potential for change and on the contextual features that promote or limit the child's performance.

Stages of Motor Learning

How does motor competence develop during childhood? Children generally pass through three stages of learning to acquire a new skill.^{59,111,136} The first stage involves *exploratory activity*. The first year of life is primarily a period of sensorimotor exploration. Exploration occurs naturally in all human beings, generally when an individual is presented with a new object or task. Through exploration, a child learns about self and the environment. In this stage, the child experiments with objects and activities using different systems, new combinations of perception and movement, and new sequences of action. In this exploratory stage or when challenged by a new and difficult task, a child tends to demonstrate primitive movement. New

challenges tend to elicit lower levels of skills because these can be accessed more easily than the child's highest level skills, which demand more energy and effort.⁶⁶ By using lower level skills to address new problems, the child can focus on perceptual learning about the task before beginning to use higher level skills, which ultimately allow more success in performing the task. Gilfoyle, Grady, and Moore⁶² noted that when children are first challenged with a new and difficult performance task (e.g., a first step), they use primitive movement patterns (e.g., balance by stiffening the legs and trunk) before progressing to integrated skill.

In the second stage of learning, *perceptual learning*, the child begins to use the feedback and reinforcement received from his or her exploration. In this transitional stage, the child exhibits more consistency in the movement patterns used to accomplish tasks. Because this second stage is a phase of perceptual learning, certain actions that were tried initially are discarded as ineffective. Interest in the activity remains high as perceptual learning continues and is inherently motivating and meaningful to the child. In this stage, the child appears focused on learning and attempts activities multiple times. The child may fluctuate between higher and lower levels of skill. Connolly and Dalglish³³ found considerable variability when toddlers attempted to use a spoon. Greer and Lockman⁶⁸ found similar variability when 3-year-olds attempted to use a writing tool. See Figure 3-5 for an example of a transitional marker grip. At times, the children grasped the tool using an adult gripping pattern, and at other times, they used a primitive, full-hand grasp. Mature patterns are selected more often as children enter the third stage of skill learning.

In the third stage of learning, *skill achievement*, the child selects the action pattern that works best for achieving a goal. The pattern selected is comfortable and efficient for the child. Selection of a single pattern indicates both perceptual learning and increased self-organization. During this end stage of learning, the child demonstrates flexible consistency in performance. He or she uses the same pattern and approach to the task but easily adapts the pattern according to task requirements. High adaptability is always characteristic of a well-learned task. Another attribute of learned performance is the use of action patterns that are orderly and economical. Children continue to practice performance when given opportunities in the environment. The third stage of learning leads to exploration of new and different activities; a child's learning continues into new performance arenas, expanding his or her occupations (Figure 3-6).

For most children, new experiences and new learning are sought and are a source of pleasure. Learning occurs when children seek opportunities for skill development; it also occurs when children adapt to the natural environment and daily activities in which they participate. Ayres^{3,4} explains that children make adaptive responses to the environment. An adaptive response is one in which the child responds to an environmental change in "a creative or useful way" (p. 14).⁴ These adaptive responses allow skill mastery and help to organize the child's CNS. An adaptive response helps to integrate the child's sensory and perceptual systems to respond more skillfully to new challenges to the sensory system. For example, once an infant can pull herself up to her mother's lap to ask to be held, she no longer needs to cry to solicit her mother's attention.

FIGURE 3-4 The child's movement patterns in exploring objects and the environment are variables and flexible.

Social-Emotional Development

Theories on temperament, attachment, and emotion regulation explain how a child's social-emotional behaviors develop and how social-emotional function affects performance across domains. These theories explain individual differences among children based on genetic endowment and social environmental influences.

Emotions play an important part in the child's appraisal of his or her experience and in the child's readiness for action in response to contextual change. Emotions relate to how a child evaluates the meaning of an experience in relation to his

or her goals. If a child engages in an activity with the goal of succeeding but does not, the child may become disappointed or frustrated. If a child engages in an activity simply to participate and without expectation for success, he or she may experience pleasure regardless of success. Emotions and temperament influence the child's interest in attempting new activities, the amount of effort demonstrated, and attempts to engage others. These variables influence how a child approaches an activity (e.g., joyfully, reluctantly) and influence its social nature (e.g., whether the child solicits the involvement of others).

FIGURE 3-5 The child experiments with writing utensil grasping patterns.

Temperament

Temperament reflects relatively stable traits that influence how individuals process and respond to the environment. These characteristics contribute to personality and everyday functioning. The child's temperament is an important determinant in how well a child matches the caregiver and the caregiving environment.⁸⁶ Temperament also influences the child's style of social interaction. Nine areas of temperament have been identified: (1) activity level, (2) approach or withdrawal, (3) distractibility, (4) intensity of response, (5) attention span and persistence, (6) quality of mood, (7) rhythmicity, (8) threshold of response, and (9) adaptability. Each of these areas contributes uniquely to the child's preferences, interests, and style in forming social relationships and responding to the social environment.¹³⁷

Taken together, these areas of temperament have their own continuum. Extreme temperament levels are associated with

FIGURE 3-6 The infant's learning demonstrates high adaptability. The third stage of learning leads to exploration of new and different activities, expanding learning into new occupations.

problematic behaviors, and moderate levels are related to easy and appropriate behaviors. Children who exhibit extreme temperament characteristics (e.g., children who are highly active, moody, or irritable) have been identified as *difficult*. The difficult child may not fit with the expectations and schedules of caregivers. Others with happy moods and moderate intensity of response are considered *easy*. A child with an easy temperament may easily establish routines (exhibiting regular sleep/wake cycles) and have positive moods and may have a better fit with caregivers. A match of parent and child temperament can facilitate strong attachment, just as a mismatch can create difficulties in attachment.

TABLE 3-2 Emotion Regulation Development

Phases	Approximate Ages	Characteristics	Examples
Neurophysiologic modulation	Birth to 2-3 months	Modulation of arousal, activation of organized patterns of behavior.	Infant can self-soothe (e.g., with nonnutritive sucking) or respond quickly when soothed by parents. May be fussy, calm. Different routines of awake/sleeping cycles.
Sensorimotor modulation	3-9 months	Behavior depends on social or environmental stimuli or events.	Infant derives pleasure from sensorimotor play; infants seek sensory exploration. Some infants have difficulty modulating sensory behaviors (e.g., may be sensory seeking).
Control	12-18 months	Behavior demonstrates awareness of social demands. Toddler demonstrates compliance and self-initiated monitoring.	Toddler's behavior is goal-directed. May show different levels of inhibition and compliance according to understanding of consequences.
Self-control	24-48 months	Child's behaviors are in accordance with social expectations; developing a sense of identity. Behavior becomes more internally monitored.	Child demonstrates knowledge of social rules and conventions. Has limited flexibility in adapting to new demands. May visually check in with parent before acting.
Self-regulation	≥36 months	Child develops behavioral flexibility according to demands of the situation; develops strategies for managing different situations. Has self-awareness and can self-evaluate	Child may self-initiate clean-up. Adaptability increases, such that child can adapt to unexpected events (e.g., parent leaving for a long time), primarily because communication and language have increased.

Adapted from Kopp, C.B. (1982). Antecedents of self-regulation: A developmental perspective. *Developmental Psychology*, 18, 199–214.

Chess and Thomas^{27,28} asserted that if a child's characteristics provide a good fit (or match) with the demands of a particular setting, adaptive outcomes result. The congruence, or *goodness of fit*, between the child and his or her social and physical context determines the quality of development, influencing which occupations are reinforced and which are hindered. *Positive goodness of fit*, meaning that the social and physical environment support the child's skill development, can increase the child's developmental trajectory. Lack of goodness of fit can create disruption of psychological development and may put the child at risk for behavioral or academic problems.

To illustrate how temperament affects goodness of fit, children with arrhythmic, poorly regulated sleep/wake cycles were reported to be difficult to manage by European American families in which the parents worked and needed a consistent routine of sleeping patterns. Puerto Rican parents did not have difficulty in accommodating children with poorly regulated sleep/wake cycles because they molded their schedules around them and allowed their children to sleep when they wanted. In the Puerto Rican families, the incidence of child behavior problems was very low, particularly before school age when a school schedule was imposed.⁸⁵ These studies and many others suggest that the child's temperament and behavior affect goodness of fit between the caregiver and the child, which influences developmental outcomes.²⁸

Emotion Regulation

Emotion regulation is related to temperament and can be influenced by caregivers, the environment, and experience. It refers to the modulation of emotional reactions, including its inhibition, activation, and grading.¹²¹ Emotion regulation includes

the child's ability to control his or her emotions and use adaptive behaviors when frustrated or experiencing negative emotions, that is, "processes used to manage and change if, when and how intensely one experiences emotion and emotion-related motivational and physiological states and how emotions are expressed as behaviors."⁴⁰ Similar to other skill sets, emotion regulation increases with age and shifts from external sources of control to internal child factors. As presented in Table 3-2, a child's self-regulation of emotion emerges from socialization with primary caregivers and others and is linked to language and cognitive development. In early emotion regulation, physiologic and sensory modulation determines behavior; however, as toddlers learn self-control, between 2 and 3 years of age, the child's behaviors become more influenced by social demands. The self-control learned in the second and third years becomes more flexible and adaptable as rules are learned and remembered.⁸⁰ Children who have achieved self-regulation of emotions can use multiple strategies flexibly to cope with stressful events. For example, a child can shift attention away from a distressing event to decrease arousal or can focus attention on positive aspects of an event. A child's positive affect appears to increase emotion regulation, and children who have had frequent positive experiences appear better able to cope with negative experiences or stressful events.¹⁴⁰

Attachment as a Basis for Social-Emotional Development

One aspect of early social-emotional development, attachment to a primary caregiver, can potentially influence social relationships and intimacy throughout life. Attachment can be defined as a bond that develops between the infant and his or her

caregiver over the first year of life.^{12,14} Infants are genetically programmed to seek and maintain proximity to an attachment figure. In an early study of attachment, infants 2 to 4 months old orient to adults, grasping and reaching for them, smiling and babbling. They appear to have indiscriminate attachments and respond similarly to any caregiver. Infants increasingly orient to familiar persons after 3 months. Infants 3 to 6 months old actively seek proximity exclusively to familiar caregivers and use them as a secure basis from which to explore. Social responses are greater and more positive for familiar people, particularly primary caregivers. After 6 months, the infant prefers the primary caregiver with whom he or she has formed an attachment, and the infant develops separation anxiety, signaling that the relationship with the attachment figure has become more intense and exclusive. The primary caregiver becomes a base from which the infant explores. When the infant is mobile (1 to 2 years of age), he or she demonstrates attachment behaviors designed to maintain proximity to the attached parent. By age 3, the child has developed a greater understanding of what the parent means by stating that she will return soon. At this age, the child becomes more flexible about his or her relationship with attached caregivers.^{15,36}

Attachment to caregivers provides the child with an understanding of emotions and social relationships. Successful accomplishment of attachment results in a sense of security, and separation from the attachment figure leads to infant distress. Five patterns of attachment have been identified in infants: (1) a secure pattern that results from interactions with a caregiver who is sensitively responsive to the infant's signals, reading them accurately and responding appropriately; (2) an anxious pattern characterized by clinginess or need for constant reassurance, related to a parent who is excessively protective; (3) an insecure-avoidance pattern of minimal emotional expression related to a less responsive, slightly rejecting caregiver; (4) an insecure-ambivalent pattern related to a caregiver who appears to be overinvolved, inconsistent, or neglectful in his or her responses to the child; and (5) a disorganized pattern that

results from parents who are intrusive, withdrawn, negative, or abusive.^{15,17} A parent's (typically mother's) sensitive responses can heighten a child's positive emotions and inhibit negative emotions. Secure attachment facilitates a child's formation of a coherent and organized relationship with the parent, including an ability to predict the parent's responsiveness. These patterns suggest that the parent-child relationship has a primary role in a child's representation of his or her social world and that the attachment relationship shapes that child's understanding of self.¹⁵

Self-Identity and Self-Determination Development

Although attachment, temperament, and emotion regulation explain certain aspects of a child's social participation, other theories describe how self-identity and self-determination develop and contribute to participation. Erikson^{42,43} described the stages of psychosocial development as conflicts and explained that resolution of these conflicts directly influences the child's self-identity, motivation, and personality. Of equal influence at this time, Maslow⁹¹ developed a hierarchy of human needs to explain what motivates behavior and which needs must be met to reach self-actualization.

Self-Identity and Motivation

According to Erikson, the first stage that characterizes infants, birth to 1 year, is the development of trust.⁴³ Because the infant is dependent on caregivers in the first year, trust is based on dependability and responsiveness of caregivers. If the infant develops trust, he or she feels safe and secure; failure to develop trust results in fear and insecurity. Through the first four stages, children have opportunities to develop hope (trust), will (autonomy), purpose (initiative), and competence (industry). These qualities and virtues are important to the child becoming an occupational being. Erikson's psychosocial stages are defined in Table 3-3.

TABLE 3-3 Erikson's Psychosocial Stages, 0-12 Years

Stage/Age (Approximate)	Outcomes	Examples of Key Related Developmental Activities
Basic Trust vs. Mistrust Birth-2 years	Infant develops trust, believes the world is dependable. When parents are not sensitive or responsive, the infant becomes insecure, lacks trust, withdraws from others.	Infant is regularly fed; caregivers respond when he cries; caregivers give comfort when distressed.
Autonomy vs. Shame and Doubt 2-4 years	Child develops autonomy and will, attempts new challenges, becomes more self-sufficient. When parents are restrictive, the child can feel doubt and become reluctant to attempt new challenges.	Child feeds self, begins to dress self; becomes toilet trained; moves about the environment; caregivers support the child's performance, allow some choice.
Initiative vs. Guilt 4-5 years	Child begins to take initiative, plans activities, accomplishes tasks. When parents are dismissive, the child may feel ashamed or become overly dependent.	Child directs own play; attempts to assert control over others. Demonstrates imaginative and dramatic play.
Industry vs. Inferiority 5-12 years	Child develops a sense of pride in his accomplishments. Child strives to master new skills; when encouraged he develops a feeling of competence and self-confidence. When adults do not encourage, he does not believe in his skills and doubts that he will be successful. Child feels inferior.	Child participates in school and school-related activities. Social play and sports become important. Games, sports, and school work give the child opportunities to accomplish and demonstrate competence.

From Erikson, E.H. (1950). *Childhood and society*. New York: Norton.

Another psychologist who followed Erikson also developed a developmental hierarchy that explained how behaviors were based on a hierarchy of human needs. Maslow, sometimes considered the father of humanistic psychology in the United States,⁷⁰ outlined a hierarchy of basic human needs that is believed to follow a longitudinal sequence.^{91,92} An individual's most basic needs, those at the base of this hierarchy, are *physiologic needs*, such as food, water, rest, air, and warmth, that are necessary to basic survival. The next level is characterized by the *need for safety*, broadly defined as the need for both physical and physiologic security. The *need for love and belonging* promotes the individual's search for affection, emotional support, and group affiliation. The *need for a sense of self-esteem*, which is defined as the ability to regard the self as competent and of value to society, is evidenced as an individual grows. The *need for self-actualization*, which represents the highest level, is attained through achievement of personal goals.

Maslow proposed that each of these needs serves as a motivator to achieve a higher level of human potential. Throughout development, individuals must satisfy their most basic needs before they are motivated by or interested in other life goals. Foundational biologic and egocentric needs must be satisfied before an individual has social interests and can fully participate in social relationships. With important social relationships established, an individual becomes interested in the broader community and has a broader sense of commitment and responsibility to others within the community. If the lower level needs are not met, the individual is unable to direct his or her energies toward higher levels. For example, a child who comes to school hungry finds it difficult to concentrate on the classroom learning activities. Recognition of a child's needs and the hierarchy of development of these basic needs helps the occupational therapist understand behaviors that indicate that basic needs are not met and identify needs that should become the focus of goals and interventions.

Self-Efficacy and Self-Determination

Understanding what motivates action and learning and how children develop personal well-being has expanded since the time of Maslow. Concepts explaining what intrinsic and extrinsic factors influence a child's development of self-identity, personal well-being, and self-determination are well integrated into client-centered occupational therapy approaches. Bandura⁵ explained that children are inherently self-organizing and goal-directed; they typically have interest in new events and activities, initiate new tasks, and persevere in those tasks. When they succeed, positive self-efficacy is reinforced, and they attempt other challenges. When they do not succeed, they are at risk for developing poor self-efficacy and eventually do not attempt new or challenging activities. Self-efficacy is highly linked to learning and occupational development because it influences levels of motivation, initiative, and perseverance.⁵⁻⁷

Ryan and Deci¹²⁴ further developed the theory of self-efficacy by explaining that the key elements of self-determination are competence, autonomy, and relatedness. When children feel competent, they believe that if they persist in an activity, they will succeed. A child who has succeeded in performing is more likely to persist and to continue to succeed. A child who repeatedly fails when performing an activity may discontinue attempting it and may feel a sense of failure. Children who

perceive themselves to be autonomous are intrinsically motivated to explore, learn, perform well, persist, show interest, and act energetically. Children with high autonomy and intrinsic motivation are likely to be self-directed and to have high self-esteem and general well-being. When children are externally pressured to act, they lose initiative and learn less effectively.¹²⁵ Parents and occupational therapists who promote a child's autonomy and competence are likely to instill intrinsic motivation. Competence and autonomy appear to be linked, in that feelings of competence do not enhance intrinsic motivation unless accompanied by a sense of autonomy.¹²⁵ Autonomous, intrinsically motivated pursuits are characterized by curiosity, meaningfulness, interest, and enjoyment.

A third factor, relatedness, also influences the development of intrinsic motivation. For example, intrinsic motivation is easily observed in the exploratory behavior of infants, and it is most evident in infants who are securely attached to a parent. When children are asked to perform a task or learn a new behavior, they become more competent and successful in the presence of a caring adult or interested caregiver.¹²⁶ Secure relationships form a foundation for emotional growth, increased autonomy, and intrinsic motivation and, by extension, increased participation.

Occupational therapists assess and facilitate a child's inner motivation to engage in occupations (tasks with meaning and purpose). Children fully participate when the fit among child, task, and environment is optimal; this fit becomes the occupational therapist's goal.^{73,84} When a child has a disability, motivation to learn and attempt new activities may be lower, and the match among child, occupation, and environment may be sub-optimal. In this case, a child may not learn independently, and adult support may be needed to motivate, provide a just-right challenge, support actions, and reinforce performance. Self-determination and self-efficacy are of high importance to occupational therapists, who understand that intrinsic motivation underlies a child's interest in learning from the environment and in participating in occupations. Intrinsic motivation is discussed further in other chapters, including [Chapters 4, 12, and 25](#).

Resiliency

Children develop self-efficacy when they are raised in a supportive environment and learn that they are competent, autonomous, and supported by caregivers.¹¹¹ *Resiliency* refers to a child's internal characteristics that enable him or her to thrive and develop despite high-risk factors in the environment. The concept of resiliency emerged from studies of child development in which the context included risk factors known to have negative effects (e.g., child abuse, parental mental illness or substance abuse, socioeconomic hardship).^{142,146} A resilient child has protective factors that enable him or her to develop positive interpersonal skills and general competence despite stressful or traumatic experiences or social environments known to limit developmental potential (e.g., that of an adolescent, single parent). Both child protective factors (e.g., intelligence, prosocial behavior, and social competence) and family protective factors (e.g., material resources; love, nurturance, and sense of safety and security; quality of parent-child relationship) are important to positive child outcomes. Researchers have demonstrated that a high-quality relationship with at least one parent, characterized by high levels of warmth and openness

and low levels of conflict, is associated with positive outcomes across levels of risk and stages of development.¹⁴⁷

A child's *resiliency versus vulnerability* also seems to relate to basic physiologic and regulatory characteristics. Children with low cardiovascular reactivity and high immune competence cope better with stressful situations and are less vulnerable to illness when stressed.¹⁴⁶ In middle childhood, well-developed problem solving and communication skills are important to a child's ability to deal with stress. Resilient boys and girls tend to be reflective rather than impulsive, demonstrate an internal locus of control, and use flexible coping strategies in overcoming adversity.¹⁴⁶ In addition to intelligence and competence, emotional regulation—that is, being able to monitor, evaluate, and modify the intensity and duration of emotional reactions—is important to positive outcomes.¹⁴²

These concepts suggest that in the interpretation of the influence of environmental factors on a child's development, variables internal to the child can overcome negative contextual variables, including variables believed to have a profound influence (e.g., poor caregiving). Although the evidence suggests that children with strong resilience can overcome a high-risk environment (e.g., abusive situations, poverty), a research synthesis of risk and resilience studies found that both internal (e.g., child's intelligence, positive affect, emotional regulation) and contextual (e.g., supportive family relationships) protective factors are needed for positive outcomes (e.g., school success, positive relationships).¹⁴¹ Taken together, the theories that explain how children grow and develop into competent adults and full participants in the community suggest that a child's development of occupations must always be understood as an interaction between the child's biologic being and his or her cultural, social, and physical contexts.

Development of Occupations

Occupations can be defined as the “patterns of action that emerge through transaction between the child and environment and are the things the child wants to do or is expected to do” (p. 22).⁷³ Although most children accomplish certain occupations and their corresponding tasks in a known sequence, the way these tasks are accomplished is unique for each child. A child learns new occupations based on the facility that the child brings to the activity. Motor and praxis, sensory-perceptual, emotion regulation, cognitive, and communication and social skills contribute to occupational performance.² These skill areas are interdependent; that is, they work together in such a way that the strengths of one system (e.g., visual) can support limitations in others (e.g., kinesthetic). Which systems are recruited for a task varies according to the novelty of the activity and the degree to which the task has become automatic.

Eating a meal illustrates the interdependence of the above-described developmental areas. Research has shown that self-feeding using a spoon involves visual-perceptual, kinesthetic, visual-motor, and cognitive systems.^{32,55,71} Eating also relates to emotion regulation and social-emotional development.¹²⁷ As previously described, grasp of the spoon initially is guided by vision, and the child uses trial-and-error to hold the spoon so that he or she can scoop the food. With practice and maturation, grasp of the spoon is guided primarily by the kinesthetic system, and correct grasp becomes automatic; vision plays a

lesser role. When food is in the mouth, chewing skills require primarily oral motor skills and somatosensory perception of food texture and food location within the mouth. The skills involved in occupational performance vary not only according to the learning phase but also according to the child's learning preferences and styles. Eating also relates to emotion regulation that may affect whether or not the child approaches the spoon. A child may resist eating because of past negative experiences with food or mealtime, anxiety about new foods, need for highly structured routines at mealtime, and difficulty coping with the social demands inherent in a mealtime. The complexity of the occupation of eating, often viewed as a simple occupation, reveals the level of understanding and analysis required when a child experiences eating challenges.

Humphry⁷³ suggests that children learn through both direct and indirect social participation. A young child often first learns about an occupation through observing parents, siblings, and other adults or peers. The first representational pretend play is typically imitation of the mother's actions when cleaning and cooking. Children imitate their parents' gestures and speech without being explicitly taught to do so. They also learn the consequences of actions by observing how their parents respond to each other or to their siblings. They can learn that an action is wrong by observing punishment of a peer for that action. Vicarious learning appears to be particularly important to a child's assuming cultural beliefs and values. Children learn the traditions and rituals of a culture by observing their family's participation in these. Inclusive models of education are believed to be effective learning environments for children with disabilities based on the known benefit of observing and interacting with typical peer models.^{37,38} When in a child's presence, occupational therapists should always be conscious that their actions and words influence children's learning and whether these actions are directed toward the child.

Learning is generally more vigorous when the child actively participates in an occupation. Children's play with each other is an integrated learning experience in which the child acts, observes, and interacts. Play involves most or all performance areas, including affective, sensory, motor, communicative, social, and cognitive. When children play together, they learn from, model for, challenge, and reinforce each other. This flow of interactions occurs in meaningful activities that generally bring pleasure and intrinsic reinforcement and enable learning.

To learn a specific skill, the child must actively practice it. Specific scaffolding, guidance, cueing, prompting, and reinforcement by an occupational therapist can assist the child in learning to perform a skill. This direct support from a caregiver or other adult can facilitate performance at a higher level or at a more appropriate level so that the fit between the child and desired occupations and context becomes optimal. In the case of a child with disabilities, a more intensive level of direct support and scaffolding may be necessary for learning new skills. Adult guidance and support of the child during play can facilitate a successful strategy, help the child evaluate his or her performance, and encourage and reinforce continued practice. Occupational therapists can also optimize the environment to support and reinforce the child's performance. Participation in play occupations in a natural environment results in integrated learning across performance areas (e.g., including sensory, motor, cognitive, and affective learning) (Figure 3-7).

FIGURE 3-7 This child engages in meaningful play occupations based on his interest in airplanes in a natural environment (home).

The child's play and actions are always within a social, cultural, and physical context.¹¹² To understand the development of occupational performance, the occupational therapist must understand the child's play and actions as coherent occupations within specific contexts.

Ecologic Models and Contexts for Development

Children develop occupations through participation in family activities and cultural practices. As a child participates in the family's cultural practices, the child learns occupations and performance skills that enable him or her to become a full participant in the community. Rogoff et al. explain, "People develop as participants in cultural communities. Their development can be understood only in light of the cultural practices and circumstances of their communities."¹¹⁶ Variations in the child's play activities (e.g., how he builds with wooden blocks, draws a picture of himself, or sings a song) reflect the child's biologic abilities and the influence of cultural, social, and physical contexts.

The ecologic model, developed by Bronfenbrenner,¹⁸ situates child development in the center of the child's community. In this model, children are most influenced by their families and their home environment, termed the microsystem.¹⁸ The child is also an integral part of a neighborhood and community, and this broader community has indirect but important influence by providing opportunities and cultural context for the child's development. Bronfenbrenner's ecologic model defines the importance of the physical and social context on child development and explains the interactions among family, cultural, and societal influences. The broadest influence on a child's occupations is the community in which the child is raised. Communities and society in general have invested in children's occupations by providing playgrounds, preschools, child-oriented music, child-oriented restaurants, and soccer fields. A community's orientation toward children determines available opportunities to play organized sports, learn about art and music, play safely in neighborhoods, and develop friendships with diverse peers. Communities that value organized sports and outdoor activities may have soccer or baseball teams, horseback riding, and swimming specifically designed for children with disabilities (e.g., Special Olympics, Miracle League Baseball, therapeutic horseback riding). Characteristics of the community become barriers or opportunities for the child and family and their desired occupations. As advocates for children with disabilities, occupational therapists can influence the development of programs that are accessible and appropriate for children with a wide range of abilities. They can emphasize the importance of supporting the participation of all children in community activities, recognizing the different levels of support and accommodation needed.

A child's cultural, social, and physical contexts change through the course of development and tend to expand as the child matures. The environment surrounds and supports the child's action; it also forces the child to adapt and assists or accommodates that adaptation. As a child perceives the affordances of the environment, he or she learns to act on those affordances, expanding a repertoire of actions. At the same time, the child's understanding of how the world responds to his or her actions increases. Rogoff^{116,117} argued that culture affects every aspect of the child's development, which cannot be understood outside this context. The child is nested in his or her family, culture, and community, which have influenced the child's genetic makeup and continue to provide the learning environment.¹¹⁷ By recognizing this influence, occupational

therapists view each child in his or her cultural context and work as change agents within that context.

Cultural Contexts

Cultural practices are the routine activities common to a people of a culture and may reflect religion, traditions, economic survival, community organization, and regional ideology. A child's learning is highly influenced by participation in these cultural practices. Reciprocally, the child's participation in the occupations and cultural practices of his or her family and community contributes to that community.

Cultures vary in many aspects, such as the roles of women and children, values and beliefs about family and religion, family traditions, and the importance of health care and education. The continuum of interdependence versus autonomy of individuals varies in cultural groups and is a significant determinant of childhood occupations. The value an ethnic group or a community places on interdependence among its members versus individual autonomy creates differences in child-rearing practices and different experiences for developing children.¹² Most middle-class European Americans value independence as a primary goal for their children. Parents in the United States encourage individuality, self-expression, and independence in their children's actions and thoughts. Families from Asian and Hispanic backgrounds often value interdependence and reliance on family members throughout the life span. Cultures that value interdependence over independence also value cooperation over competition. For example, children of Asian and Hispanic backgrounds have been found to be more cooperative in play than children from European American backgrounds.¹¹⁶

To illustrate, parents in the United States, in part to foster early independence in children, do not co-sleep with their infants; instead infants sleep in their own room or crib. Co-sleeping may be more common among cultures in which parents value interdependence, promote high reciprocity with their children, and encourage the primacy of family relationships.¹¹⁶ For example, it is prevalent across other societies in the world, such as Asia, Africa, and South America, where infants sleep in their parents' bed or room.¹⁴⁹ Mayan infants and toddlers sleep in the same room with their parents, often in the mother's bed.⁷⁵ Asian and Middle Eastern parents tend to sleep with their infants because they believe that these sleeping arrangements are important to nurturing and bonding. In the United States, co-sleeping is four times more common in Asian and African American families than in white families.¹⁴⁹ Close physical contact at night and into the day can foster interdependence within families.⁵⁶

One consequence of infants sleeping in their own crib, separated from their parents, is that middle-class U.S. parents often engage in elaborate and time-consuming bedtime routines (e.g., reading books, lullabies). Black and Hispanic parents are less likely to establish an interactive bedtime routine with their young children.⁶⁹ Parents of these ethnic groups may not value an interactive bedtime routine. In addition, a routine to separate at bedtime may not be needed when infants sleep with the parents. These examples briefly illustrate how cultural beliefs and values influence the ways parents raise their children.

Social Contexts

Culture influences the social relationships that envelop the child, yet certain aspects of the child's social context appear to

be independent of cultural influences and are consistent across cultures. The most important relationships formed during infancy are the relationships with parents or primary caregivers.¹⁰¹ When caregivers are sensitive and responsive to the infant, healthy social-emotional development results.^{39,87} Infants' interactions with parents serve to enhance the infants' basic physiologic and regulatory systems. When parents attune to the infant's sensory modulation and arousal needs and support these needs, the infant develops secure attachment. Mothers who modulate their behaviors to match their infants' needs for stimulation and comfort also promote the infants' abilities to self-regulate. A child's interaction with a caregiver gives the child essential information about how self and other are related, which becomes important to engaging in future relationships. Attachment patterns seem to influence the child's style of interaction and engagement in later years. Sensitive responding consolidates the infant's sense of efficacy and provides a foundation of security for confident exploration of the environment.^{39,101}

Csikszentmihalyi and Rathunde³⁵ describe parenting as a dance between supporting and challenging the child. Supporting the child enables him or her to assimilate or explore the environment—to play. Parental challenge requires a child to accommodate and conform. Parenting provides a combination of these supports and challenges. All parents use some measure of support to bolster children's attempts to master skills and some degree of challenge to move children toward higher levels of mastery.^{101,116} These elements are subtly provided by parents in the ways they present tasks and select when and how they instruct or intervene. Effective guidance relies on careful observation of the child's cues. Sensitivity and responsiveness to the child's needs appear to be among the most important variables in the promotion of child development.⁸⁵

In typical situations, infants receive care from multiple care providers, including childcare providers, grandparents, and other adults. The infant may or may not attach to caregivers other than the parents or primary caregivers; however, these social relationships are important to the infant's emotional development and provide opportunities for the development of social skills. About 55% of children 3 to 5 years of age participate in nonparent childcare, including center-based and family childcare.¹⁴¹ A study for the National Institute of Child Health and Human Development revealed that positive caregiving occurred when children were in small groups; child-to-adult ratios were low; caregivers did not use an authoritarian style; and the physical environment was safe, clean, and stimulating.¹⁰⁴ Family factors predicted child outcomes even for children who spent many hours in childcare. The family environment appears to have a significantly greater effect on a child's development than the childcare environment.^{47,88}

Physical Contexts

The physical environment surrounds and supports the child's actions; it forces the child to adapt his or her actions to meet the demands and constraints of the physical surroundings. As a child perceives the affordances of the environment, the child learns to act on those affordances, expanding a repertoire of actions. At the same time, the child's understanding of how the world responds to his or her actions increases. Gibson⁵⁸ explained how a child's exploration of physical surfaces and objects allows the child to develop and practice mobility and

manipulation skills. Examples of the interactions of a child and his or her physical environments and the developmental consequences are presented next.

Children's Occupations, Performance Skills, and Contexts

This section describes a child's development of play occupations as enabled by the child's performance skills and cultural, physical, and social contexts. For three age groups—infancy, early childhood, and middle childhood—typical play occupations and activities are described. The contribution of motor, sensory, emotional, cognitive, and social abilities and contexts to the development of play occupations is described. Although children's occupations are similar within a particular age level, the contexts, individual abilities, and activities are varied and diverse, resulting in a unique occupational performance for each child. Recognition of the uniqueness of a child's development and of how these components contribute to performance within individuals is key to analysis of occupational performance.

Although the child learns occupations other than play (e.g., occupations related to activities of daily living or school functions), occupational therapists are invested in play outcomes and most often use play activities to engage the child in the therapeutic process. Play activities serve as the means to improve performance because they are self-motivating and offer goals around which the child can self-organize.¹⁰⁶ Play also serves as the end or goal of therapy services.¹¹² Children put effort and energy into play activities because they are inherently interesting and fun. (A more detailed description of play as a goal and modality of therapy is provided in [Chapter 17](#).) Descriptions of a child's development of feeding, self-care, activities of daily living, instrumental activities of daily living, and school function are presented in other chapters (see [Chapters 14, 15, 16, and 23](#)). The child's ability to communicate, although essential to the development of play and other childhood occupations, is not specifically described in this chapter because language and communication are the domain of speech-language pathologists and are well described in many other texts.

Infants: Birth to 2 Years

Play Occupations

The play occupations of infants in the first 12 months are exploratory and social—they are related to bonding with caregivers ([Boxes 3-1 and 3-2](#)). As in every stage, these occupations overlap (e.g., bonding occurs during exploratory play with the parent's hair and face, and the parent's holding supports the infant's play with objects). Much of the infant's awake and alert time is spent in exploratory play, often play that occurs in the caregiver's arms or with the caregiver nearby.

Exploratory play is also called *sensorimotor play*. Rubin¹²¹ defined *exploratory play* as an activity performed simply for the enjoyment of the physical sensation it creates. It includes repetitive movements to create actions in toys for the sensory experiences of hearing, seeing, and feeling. The infant places toys in the mouth, waves them in the air, and explores their surfaces with the hands. These actions allow for intense perceptual learning and bring delight to the infant (without any more

BOX 3-1 Development of Play Occupations: Infants—Birth to 6 Months

Play Occupations

Exploratory Play

Sensorimotor play predominates

Social play

Focused on attachment and bonding with parents

Performance Skills

Regulatory/Sensory Organization

Quiets when picked up

Shows pleasure when touched and handled

Relaxes, smiles, and vocalizes when held

Cuddles

Listens to a voice

Uses hands and mouth for sensory exploration of objects

Fine Motor/Manipulation

Follows moving person with eyes

Develops accurate reach to object

Uses variety of palmar grasping patterns

Secures object with hand and brings to mouth

Transfers objects hand to hand

Examines objects carefully with eyes

Plays with hands at midline

Gross Motor/Mobility

Lifts head (3-4 months), raises trunk when prone (4-6 months)

Kicks reciprocally when supine

Sits propping on hands

Plays (bounces) when standing with support from parents

Rolls from place to place

Cognitive

Repeats actions for pleasurable experiences

Uses hands and mouth to explore objects

Searches with eyes for sound

Bangs object on table

Integrates information from multiple sensory systems

Social

Coos, then squeals

Smiles, laughs out loud

Expresses discomfort by crying

Communicates simple emotions through facial expressions

Data from Parks, S. (2007) *HELP Strands*. Palo Alto, CA: VORT Corp; Gesell, A., & Amatruda, G. (1947). *Developmental diagnosis* (2nd ed.). New York: Harper & Row.

complex purpose). [Research Note 3-1](#) explains Gibson's ecological theories on how the infant learns through exploration of object affordances.

In the second year of life, the infant engages in *functional*, or *relational*, play; an object's function is understood, and that function determines the action ([Boxes 3-3 and 3-4](#)). Initially, children use objects on themselves (e.g., pretending to drink from a cup or to comb the hair). These self-directed actions signal the beginning of *pretend play*.¹¹⁰ The child knows cause and effect and repeatedly makes the toy telephone ring or the battery-powered doll squeal to enjoy the effect of the initial action.

By the end of the second year, play has expanded in two important ways. First, the child begins to combine actions into play sequences (e.g., he or she relates objects to each other by stacking one on the other or by lining up toys beside each other). These combined actions show a play purpose that

BOX 3-2 Development of Play Occupations: Infants—6 to 12 Months

Play Occupations

Exploratory Play

Sensorimotor play evolves into functional play

Functional Play

Begins to use toys according to their functional purpose

Social Play

Attachment to parents and caregivers

Social play with parents and others

Performance Skills

Regulatory/Sensory Organization

Enjoys being held up in the air and moving rapidly through the air

Listens to speech without being distracted

Finger-feeds self, including a variety of food textures

Cooperates with dressing

Fine Motor/Manipulation

Mouths toys

Uses accurate and direct reach for toys

Plays with toys at midline; transfers hand to hand

Bangs objects together to make sounds

Waves toys in the air

Releases toys into container

Rolls ball to adult

Grasps small objects in fingertips

Points to toys with index finger, uses index finger to explore toys

Crudely uses tool

Gross Motor/Mobility

Sits independently

Rolls from place to place

Independently gets into sitting position

Pivots in sitting position

Stands, holding on for support

Plays in standing when leaning on support

Crawls on belly initially, then crawls on all fours (10 months)

Walks with hand held (12 months)

Cognitive

Responds to own name

Recognizes words and family members' names

Responds with appropriate gestures

Listens selectively

Imitates simple gestures

Looks at picture book

Begins to generalize from past experiences

Acts with intention on toys

Takes objects out of container

Social

Shows special dependence on mother

May show stranger anxiety

Lifts arms to be picked up

Plays contentedly when parents are in room

Interacts briefly with other infants

Plays give and take

Responds playfully to mirror (laughs or makes faces)

RESEARCH NOTE 3-1

Gibson, E.J. (2000). *Perceptual learning in development: Some basic concepts*. *Ecological Psychology*, 12, 295–302.

Gibson eloquently presents her theory of perceptual learning in this research synthesis. These concepts can explain early perceptual-motor development:

- Infants learn by exploring their environment and selecting the movements that optimally fit environmental affordances.
- Through perception of objects and their surfaces, shapes, actions, and function, the infant learns which movements are most effective and efficient for exploring and activating the object.
- When the infant grasps an object in view and brings it to his mouth, he learns what is within reaching distance, how long his arm is, how large the object is, how much it weighs when transported, and how it feels in his mouth. From this action, the infant learns how far he needs to extend his arm, how much force is needed to hold the object, and how to turn the object to bring it to his mouth. The result is the infant selects the most efficient movements and action for reaching, grasping, and mouthing an object.
- The infant quickly learns that proprioceptive information from his arm in carrying an object to his mouth matches perfectly visual information from watching the object travel to his mouth. This match of visual and proprioceptive information is redundant and invariant, allowing the infant to select only one sensory system to guide his movements, and he generally selects the proximal sensory (proprioceptive) system as the most efficient.
- Economy of action and reduction of perceptual information are principles that the infant uses to develop coordinated and efficient movements.
- These principles of perceptual-motor reciprocity can be easily observed in the refining of grasping patterns and actions applied to objects in the first 2 years of life.

matches the function of the toy. Second, 2-year-old children now direct actions away from themselves. The objects used in play generally resemble real-life objects.⁸⁶ The child places the doll in a toy bed and then covers it. The child pretends to feed a stuffed animal or drives toy cars through a toy garage. At 2 years of age, play remains a very central occupation of the child, who now has an increased attention span and the ability to combine multiple actions in play. The emergence of *symbolic*, or *imaginary*, play with toys and objects offers the first opportunities for the child to practice the skills of living.¹⁰²

The child also engages in gross motor play throughout the day. As the child becomes mobile, exploration of space, surfaces, and large action toys becomes a primary occupation. Movement is enjoyed simply as movement; the child delights in swinging and running or attempting to run and moving in water or sand. Deep pressure and touch are craved and requested. As in exploratory play, the child's exploration of space involves simple, repeated actions in which the goal appears to be sensation. Often, extremes in sensation seem to be enjoyed and are frequently requested. Repetition of these

BOX 3-3 Development of Play Occupations:
Infants—12 to 18 Months**Play Occupations****Relational and Functional Play**

Engages in simple pretend play directed toward self (pretend eating, sleeping)

Links two or three schemas in simple combinations
Demonstrates imitative play from an immediate model

Gross Motor Play

Explores all spaces in the room
Rolls and crawls in play close to the ground

Social Play

Begins peer interactions
Parallel play

Performance Skills**Regulatory/Sensory Organization**

Enjoys messy activities
Reacts to extreme sensations, such as warm, cold, sweet

Fine Motor/Manipulation

Holds crayon and makes marks; scribbles
Holds two toys in hand and toys in both hands
Releases toys inside containers, even small containers
Stacks blocks and fits toys into form space (places pieces in board)

Attempts puzzles

Opens and shuts toy boxes or containers

Points to pictures with index finger

Uses two hands in play, one to hold or stabilize and one to manipulate

Gross Motor/Mobility

Sits in small chair

Plays in standing

Walks well, squats, picks up toys from the floor

Climbs into adult chair

Flings ball

Pulls toys when walking

Begins to run

Walks upstairs with one hand held

Pushes and pulls large toys or boxes on floor

Cognitive

Acts on object using variety of schemas

Imitates model

Symbolic play with real props (e.g., pretends to drink with cup)

Understands how objects work

Understands function of objects

Uses trial-and-error in problem solving

Recognizes names of various body parts

Social

Moves away from parent

Shares toys with parent

Responds to facial expressions of others

Data from Parks, S. (2007). *HELP Strands*. Palo Alto, CA: Vort; Linder, T. (2008). *Transdisciplinary play-based assessment* (rev. ed.). Baltimore: Brookes; Gesell, A., & Amatruda, G. (1947). *Developmental diagnosis* (2nd ed.). New York: Harper & Row.

BOX 3-4 Development of Play Occupations:
Toddlers—18 to 24 Months**Play Occupations****Functional Play**

Multischema combinations
Performs multiple related actions together

Gross Motor Play

Enjoys sensory input of gross motor play

Pretend or Symbolic Play

Makes inanimate objects perform actions (dolls dancing, eating, hugging)

Pretends that objects are real or that they symbolize another object

Social Play

Participates in parallel play

Imitates parents and peers in play

Participates in groups of children

Watches other children

Begins to take turns

Performance Skills**Regulatory/Sensory Organization**

Enjoys solitary play for a few minutes

Uses Play-Doh

Enjoys rough and tumble play

Fine Motor/Manipulation

Completes 4- to 5-piece puzzle

Builds towers (e.g., 4 blocks)

Holds crayon in fingertips and draws simple figures (straight stroke or circular stroke)

Strings beads

Begins to use simple tools (e.g., play hammer)

Participates in multipart tasks

Turns pages of book

Gross Motor/Mobility

Runs, squats, climbs on furniture

Climbs on jungle gym and slides

Moves on ride-on toy without pedals (kiddy car)

Kicks ball forward

Throws ball at large target

Jumps with both feet (in place)

Walks up and down stairs

Cognitive

Links multiple steps together

Has inanimate object perform action

Begins to use nonrealistic objects in pretend play

Continues to use objects according to functional purpose

Object permanence is completely developed

Social

Expresses affection

Shows wide variety of emotions: fear, anger, sympathy, joy

Can feel frustrated

Enjoys solitary play, such as coloring, building

Engages in parallel play

Laughs when someone does something silly

Data from Parks, S. (2007). *HELP Strands*. Palo Alto, CA: Vort; Linder, T. (2008). *Transdisciplinary play-based assessment* (rev. ed.). Baltimore: Brookes.

full-body kinesthetic, vestibular, and tactile experiences appears to be organizing to the CNS (Figure 3-8). In addition, this repetition is important to the child's development of balance, coordination, and motor planning. The occupational goal of movement and exploration becomes the means for development of multiple performance areas.

In the first year, the goal of an infant's *social play* is attachment, or bonding, to the parents. As described by Greenspan,⁶⁷ this is a period in which the infant falls in love with the parents and learns to trust the environment because of the care and attention provided by the parents or caregivers. These

FIGURE 3-8 Gross motor fun of a 2-year-old.

BOX 3-5 Emergence of Self-Efficacy

Infants develop an initial sense of efficacy through cause-and-effect actions (e.g., crying brings adult attention). Infants who experience success in controlling environment events become more attentive to their own behavior and more competent in learning. In addition to seeing the effects of their actions, infants develop self-efficacy when they can differentiate themselves from others. Infants learn that their actions produce effects different from others' actions, and they begin to perceive themselves as distinct selves, differentiated from others.⁶ When parents make remarks, such as "look what Audrey did, isn't she cute," or "You are such an ornery baby," the infant gains self-knowledge and begins to understand that she is a distinct individual. From this knowledge, self-efficacy emerges.

From Bandura, A. (1993). Perceived self-efficacy in cognitive development and functioning. *Educational Psychologist*, 28, 117–148.

occupations are critical foundations to later occupations that involve social relating and demonstration of emotions. At 1 year of age, infants play social games with parents and others to elicit responses. As the toddler gains competence and is supported by parental responsiveness, he or she gains a sense of personal agency and self-efficacy. See [Box 3-5](#) for an example of how Bandura⁶ explains the emergence of self-efficacy early in life. Although infants at this age engage readily with individuals other than family, they require their parents' presence as an emotional base and return to them for occasional emotional refueling before returning to play.¹³⁸

By the second year, children exhibit social play in which they imitate adults and peers. Imitation of others is a first way to interact and socially relate.⁸ Both immediate and deferred imitation of others are important to social play as children enter preschool environments and begin to relate to their peers.

Performance Skills

Sensory Functions

The newborn can interpret body sensations and respond reflexively. He enjoys and needs a consistent caregiver's physical contact and tactile stimulation. The neonate turns his head

FIGURE 3-9 In prone position, the infant shifts his weight from side to side when playing with toys; later he learns to pivot while prone to expand where he can reach and what he can visualize.

when touched on the cheek, relaxes in his mother's arms, and expresses discomfort from a wet diaper. Self-regulation of sleep/wake cycles, feeding, and display of emotions and arousal emerge in early infancy. The infant molds himself to the parent's embrace, clinging to the parent's arms and chest. The newborn's vestibular system is also quite mature as he calms from rocking and enjoys the motion of a parent walking him about the room. The neonate demonstrates orientation and attention to visual, auditory, and tactile stimuli. An important fact is that the newborn also exhibits *habituation*, or the ability to extinguish incoming sensory information (e.g., ability to sleep by blocking out sound in a noisy nursery). [Chapter 9](#) further describes sensory development of infants and young children.

Gross Motor and Mobility

The first movements of newborns appear to be reflexive; however, on closer examination, they reveal the ability to process and integrate sensory information. The neonate's movements contribute to perceptual development and organization and initiate his learning about the world. In the first month of life, the infant moves the head side to side when in a prone position and rights the head when supported in sitting. By 4 months, the prone infant lifts the head to visualize activities in the room. This ability to lift and sustain an erect-head position appears to relate to the infant's interest in watching the activities of others as well as improved trunk strength and stability. As the infant reaches 6 months, he or she demonstrates increased ability to lift the head and trunk when in a prone position to visualize the environment. When prone, the infant can also move side to side on the forearms, then on the hands ([Figure 3-9](#)). When supine, the infant actively kicks and brings the feet to the mouth. Over the next 6 months, this dynamic, postural stability prepares the infant to become mobile.

Rolling is normally the infant's first method of becoming mobile and exploring the environment. Initially, rolling is an automatic reaction of body righting; usually the infant first rolls from the stomach to the side and then from the stomach to the back. By 6 months, the infant rolls sequentially to move across the room. Heavy or large infants may initiate rolling

several months later, and infants with hypersensitivity of the vestibular system (i.e., overreactivity to rotary movement) may avoid rolling entirely.

Most infants enjoy supported sitting at a very early age. As their vision improves in the first 4 months, they become more eager to view their environment from a supported sitting position. The newborn sits with a rounded back; the head is erect only momentarily. Head control emerges quickly. By 4 months, the infant can hold the head upright with control for long periods, moving it side to side with ease. Most 6-month-old infants sit alone by propping forward on the arms, using a wide base of support with the legs flexed. However, this position is precarious, and the infant easily topples when tilted. Many 7-month-old infants sit independently. Often their hands are freed for play with toys, but they struggle to reach beyond arm's length.

By 8 to 9 months, the infant sits erect and unsupported for several minutes. At that time, or within the next couple of months, the infant may rise from a prone posture by rotating (from a side-lying position) into a sitting position. This important skill gives the infant the ability to progress by creeping to a toy and then, after arriving at the toy, to sit and play. By 12 months, the infant can rise to sitting from a supine position, rotate and pivot when sitting, and easily move in between positions of sitting and creeping (Figure 3-10).

FIGURE 3-10 A, In dynamic sitting, the infant has sufficient postural stability to reach in all directions. B, By 10 months of age, the infant easily moves into and out of sitting positions.

After experimenting with pivoting and backward crawling in a prone position, the 7-month-old infant crawls forward. The infant may first attempt belly crawling using both sides of the body together. However, reciprocal arm and leg movements quickly emerge as the most successful method of forward progression. Crawling in a hands-and-knees posture (sometimes called *creeping*) requires more strength and coordination than belly crawling. The two sides of the body move reciprocally. In addition, shoulder and pelvic stability are needed for the infant to hold the body weight over the hands and knees. Mature, reciprocal hands-and-knees crawling also requires slight trunk rotation (Figure 3-11). Through the practice of crawling in the second 6 months of life, the child develops trunk flexibility and rotation. Most 10- to 12-month-old infants crawl rapidly across the room, over various surfaces, and up and down inclines.

Infants at 5 and 6 months of age delight in standing, and they gleefully bounce up and down while supported by their parents' arms. The strong vestibular input and practice of patterns of hip and knee flexion and extension are important to the development of full upright posture after 1 year. The infant also prepares for a full upright posture by standing against furniture or the parent's lap. A 10-month-old infant practices rising and lowering in upright postures while holding onto the furniture. By pulling up on furniture to standing, the infant can reach objects previously unavailable. This new level of exploration and increase in potential play objects motivates infants to practice standing and motivates parents to place breakable objects on higher shelves (Figure 3-12). At 12 months, the infant learns to shift the body weight onto one leg and to step

FIGURE 3-11 This infant transitions into crawling, allowing him to explore new spaces. Crawling on all fours promotes the rotational patterns needed for ambulation.

to the side with the other leg. The infant soon takes small steps forward while holding onto furniture or the parent's finger.

The infant's first efforts toward unsupported forward movement through walking are short, erratic steps with a wide-based gait and arms held in high guard. All these postural and mobility skills contribute to the infant's ability to explore space and obtain desired play objects. By 18 months, the infant prefers

FIGURE 3-12 Supported stance is a favorite play position for infants 8 to 11 months old.

walking to other forms of mobility, but balance remains immature, and the infant falls frequently. The infant continues to use a wide-based gait and has difficulty with stopping and turning. However, infants remain highly motivated to practice this new skill because walking brings new avenues of exploration and a sense of autonomy, and the parent must now protect the infant from objects that previously could not be reached and from spaces that have not yet been explored.

Fine Motor and Manipulation

The newborn moves the arms in wide ranges, mostly to the side of the body. In the first 3 months, the infant contacts objects with the eyes more than with the hands. By age 3 months, the infant follows his mother's face in a smooth arc, crossing midline. By 1 to 2 months of age, an infant learns to swipe at objects placed at his or her side. This first pattern of reaching is inaccurate, but by 5 months, the accuracy of reaching toward objects increases greatly.¹¹⁹ The infant struggles to combine grasp with reach and may make several efforts to grasp an object held at a distance. As postural stability increases, the infant also learns to control arm and hand movements as a means of exploring objects and materials in the environment. By the time an infant is 6 months old, direct unilateral and bilateral reaches are observed, and the infant smoothly and accurately extends the arm toward a desired object.¹⁴³ Table 3-4 describes how the stages of motor learning are exemplified by the development of reach and grasp.

Grasp changes dramatically in the first 6 months (Figure 3-13). Initially, grasping occurs automatically (when anything is placed in the hand) and involves mass flexion of the fingers as a unit. The object is held in the palm rather than distally in the fingers or fingertips. Infants 3 to 4 months of age squeeze objects within their hands, and the thumb does not appear to be involved in this grasp. At 4 to 5 months of age, the infant exhibits a palmar grasp in which flexed fingers and an adducted

TABLE 3-4

Stages of Motor Learning for Reach and Grasp

Stage/Age	Motor Pattern
Reach	
I. Exploratory 1-3 months	Swipes at objects, reach is inaccurate; infant cannot combine reach and grasp.
II. Perceptual learning/ transitional stage 3-6 months	Reaching becomes more accurate, becomes more direct; infant reaches to midline. By 6 months, combines reach and grasp with two hands.
III. Skill achievement/adaptability and flexibility 6-9 months	Reaches with one or two hands; accurate and direct reach; can change direction of reach midstream. By 8-9 months, infant can reach in all directions. Reach is smooth and efficient. Infant easily combines reach and grasp. Infant carries object through space.
Grasp	
I. Exploratory 3-5 months	First voluntary grasp begins between 2 and 3 months. Infant squeezes object with all fingers, thumb does not participate. Release is random, without voluntary control. Grasp is inefficient and infant cannot move object in his hand.
II. Perceptual learning/ transitional stage 6-12 months	Radial palmar and radial digital grasping patterns emerge. Infant actively uses thumb to grasp objects. Infant is unable to move an object within his hands but can transfer hand to hand and explore in his mouth. Voluntary release begins at 6-7 months. Infant awkwardly prehends small objects.
III. Skill achievement/adaptability and flexibility 12 months-2 years	By 12 months, infant demonstrate a pincer grasp; this grasp is precise by 18 months. By 18 months, demonstrates precision release. By 2 years, grasp is dynamic, allowing tool use; the child can use an object while holding it (toothbrush, spoon). Blended grasping patterns develop—the child can move an object while maintaining his grasp of the object.

FIGURE 3-13 A and B, Grasping patterns evolve from palmar grasp without active thumb use (A) to radial digital grasp (B). C, At 4 months, the infant holds the object tight against the palm, with all fingers flexing as a unit. D, At 8 months, the infant holds objects in the radial digits.

thumb press the object against the palm (Figure 3-13, C). At 6 months, the infant uses a radial palmar grasping pattern in which the first two fingers hold the object against the thumb. This grasp enables the infant to orient the object so that it can be easily seen or brought to the mouth (Figure 3-13, D). The infant secures small objects using a raking motion of the fingers, with the forearm stabilized on the surface.

Grasp continues to change rapidly from 7 to 12 months.^{22,34} A radial digital grasp emerges in which the thumb opposes the index and middle finger pads. At approximately 9 months, wrist stability in extension increases, and the infant is better able to use the fingertips in grasping (e.g., the infant can use fingertips to grasp a small object, such as a cube or cracker). By holding objects distally in the fingers, the infant can move the object while it is in the hand; movement of objects within the hands allows the infant to explore them and use objects for functional purposes. A pincer grasp, with which the infant holds small objects between the thumb and finger pads, develops by 10 to 11 months. A 12-month-old infant uses various grasping patterns, often holding an object in the radial fingers and thumb.

The infant may also grasp a raisin or piece of cereal with a mature pincer grasp (i.e., the thumb opposes the index finger).

In the second year of life, grasping patterns continue to be refined. The child holds objects distally in the fingers, where holding is more dynamic. By the end of the second year, a tripod grasp on utensils and other tools may be observed. Other grasping patterns may also be used, depending on the size, shape, and weight of the object held. For example, tools are held in the hand using first a palmar grasp and then a digital grasp. Blended grasping patterns develop toward the end of the second year, allowing the child to hold a tool securely in the ulnar digits while the radial digits guide its use.

Voluntary release of objects develops around 7 to 8 months of age. The first release is awkward and is characterized by full extension of all fingers. The infant becomes interested in dropping objects and practices release by flinging them from the highchair. By 10 months of age, objects are purposefully released into a container, one of the first ways the infant relates separate objects. As the infant combines objects in play, release becomes important for stacking and accurate placement. For

example, the play of 1-year-old children includes placing objects in containers, dumping them out, and beginning the activity again.

By 15 to 18 months of age, the infant demonstrates release of a raisin into a small bottle and the ability to stack two cubes. Stacking blocks is part of relational play because the infant now has the needed control of the arm in space, precision grasp without support, controlled release, spatial relations, and depth perception. The infant can also place large, simple puzzle pieces and pegs in the proper areas. At the same time, the infant acquires the ability to discriminate simple forms and shapes. The infant's learning of perceptual skills is supported by improved manipulative abilities, and increased perceptual discrimination promotes the infant's practice of manipulation.¹⁰⁷ Perception of force increases, enabling the infant to hold an object with the just-right amount of pressure (e.g., so cookies are not crushed before eaten).

The complementary use of both hands to play with objects develops between 12 months and 2 years. During this time, one hand is used to hold the object, while the other hand manipulates or moves the object. It is not until the third year that children consistently demonstrate use of two hands in simultaneous, coordinated actions (e.g., using both hands to string beads or button a shirt).⁴⁴

Cognitive

In the first 6 months, the infant learns about the body and the effects of its actions. Interests are focused on the actions with objects and the sensory input these actions provide. The infant's learning occurs through the primary senses: looking, tasting, touching, smelling, hearing, and moving. The infant enjoys repeating actions for their own sake, and play is focused on the action that can be performed with an object (e.g., mouthing, banging, shaking), rather than the object itself.⁸⁶ By 8 to 9 months of age, the infant has an attention span of 2 to 3 minutes and combines objects when playing (e.g., placing a favorite toy in a container). At this age, children begin to understand object permanence; that is, they know that an object continues to exist even though it is hidden and cannot be seen.³⁰ They can also find a hidden sound and actively try to locate new sounds.

By 12 months of age, the infant's understanding of the functional purpose of objects increases. Play behaviors are increasingly determined by the purpose of the toy, and toys are used according to their function. The infant also demonstrates more goal-directed behaviors, performing a particular action with the intent of obtaining a specific result or goal. Tools become important at this time because the infant uses play tools (e.g., hammers, spoons, shovels) to gain further understanding of how objects work. At the same time, the infant begins to understand how objects work (e.g., how to activate a switch or open a door).

In the second year, the child can put together a sequence of several actions, such as placing small "people" in a toy bus and pushing it across the floor. The sequencing of actions indicates increasing memory and attention span. Some of the first sequential behaviors illustrate the child's imitation of parent or sibling actions; increased ability to imitate and increased play sequences appear to develop concurrently (Figure 3-14).

Social

The infant's emotional transition from the protective, warm womb to the moment of birth is a dramatic change. The primary purpose of the newborn's system is to maintain body

FIGURE 3-14 This 1½-year-old boy engages in social play, imitating an adult, sequencing action, taking turns, and demonstrating understanding of object permanence on self.

functions (i.e., cardiovascular, respiratory, and gastrointestinal systems). However, as the infant matures, the focus shifts to increasing competence in interaction with the environment. The sense of basic trust or mistrust becomes a main theme in the infant's affective development and is highly dependent on the relationship with the primary caregivers. According to Erikson,⁴² the first demonstration of an infant's social trust is observed in the ease with which he or she feeds and sleeps (see Table 3-3).

The basic trust relationship has varying degrees of involvement. Parent-infant bonding is not endowed but is developed from experiences shared between parent and child over time. These feelings are seen in the progression of physical contact between parent and infant. The infant shows a differentiated response to the parent's voice, usually quieting and calming. Although infants are capable of crying from birth, they begin to express other emotions by 2 months, such as smiling and laughing.

By 5 to 6 months, the infant becomes very interested in a mirror, indicating a beginning recognition of self. By 4 to 5 months, he or she vocalizes in tones that indicate pleasure and displeasure. In the second year of life, the parents (or caregivers) remain the most important people in the child's life. The 2-year-old infant likes to be in constant sight of the parents and expresses emotions by hugging and kissing them.

TABLE 3-5 Development of Emotion Regulation and Related Social Behaviors

Age	Emotion Regulation	Social Interaction Skills
0-12 months	Self-soothes Learns to modulate reactivity Regulates attention Relies on caregiver for support during stressful situations	Discriminates others' expressions Shows expressive responsiveness to stimuli Demonstrates different facial expressions
12-30 months	Shows increasing self-awareness Shows emerging consciousness of own emotional responses Can be irritable because of constraints and limits imposed when desiring to explore	Expresses self-consciousness, shows shame, pride, coyness Understands more language and more emotions Expresses affective state

Adapted from Saarni, C. (1999). *The development of emotional competence* (pp. 18–19). New York: Guilford Press; Kopp, C. (1982). Antecedents of self-regulation: A developmental perspective. *Developmental Psychology*, 18, 199–214.

Although toddlers practice their autonomy around parents, they have no intention of giving up reliance on them and may become upset or frightened when the parents leave. Children at age 2 are interested in other children, but they tend to watch them rather than verbally or physically interacting with them. In a room of open spaces, 2-year-olds are likely to play next to each other. Their side-by-side play often involves imitation, with few verbal acknowledgments of each other. As discussed in the section on [emotion regulation](#), [Table 3-5](#) describes how the development of emotion regulation influences social interaction during infancy.

Contexts of Infancy

Cultural Contexts

The family's cultural beliefs and values influence caregiving practices and determine many of the child's earliest experiences. Breastfeeding practices influence the infant's development. Breastfeeding and bottle-feeding practices vary across different cultures and ethnic groups. In the United States, breastfeeding rates in the first 6 months for all ethnic groups is 73%; however, among women of Hispanic background, it is 80%, and among black mothers, it is 54%. Hispanic mothers tend to seek breastfeeding advice from their families; in contrast, white mothers tend to rely on advice from their health care providers.²⁴ In the United Kingdom, black and Asian mothers have the highest breastfeeding rates compared with white mothers.⁷⁷ Culture (as well as education) interacts with race and ethnicity in determining breastfeeding rates. Factors that contribute to a woman's decision to breastfeed include social and cultural norms, social support, guidance and support from health care providers, work environment, and the media,^{24,88} illustrating Bronfenbrenner's ecological model of social influences. The mother's decision to breastfeed can affect the child's nutrition, health, eating habits, and growth.

Race and ethnicity also influence how attentive parents are, how often they hold the infant,⁵⁰ how quickly a crying infant is consoled,¹³⁹ and many other aspects of infant caregiving.¹³ For example, Chinese parents are often very attentive, carrying and holding their infants throughout the day, even during naps. When infants are not held, they are kept nearby and picked up immediately if they cry.²⁶

Physical Contexts

Although many infants have a supplemental play area in a childcare center, the home provides the infant's first play

environment. The crib is often a play environment, providing a place for comforting toys (e.g., music boxes, colorful mobiles). Other early play spaces include a playpen, infant seat, and swing. The infant also spends time playing on the floor's carpeted surface or on a blanket. Because the infant is not yet mobile, safety is not as much of a concern as it will be in the next 2 years of life. Early play also occurs in the parent's or caregiver's arms. Exploratory play and attachment occupations are pursued on the parent's lap, and the infant is fascinated by the parent's face and clothing. At the same time, the infant feels safe and comforted by the parent's presence.

In the second 6 months, the infant requires less support to play, and a major role of the parent becomes one of protector from harm. As the infant becomes more mobile, spaces are closed, and objects now within reach are removed. Exploration of all accessible spaces becomes an infant's primary goal.

In the second year of life, the child's environment may expand to the yard, to neighbors' homes and yards, and to previously unexplored spaces in the home. Most children have opportunities for play in their home's yard or in the fenced-in areas of their childcare centers. Although the child's increasing interest in visiting outdoor spaces provides important opportunities for sensory exploration, it also creates certain safety concerns. Parents invest in gates and other methods of restricting the child's mobility to safe areas.

Early Childhood: Ages 2 to 5 Years

Play Occupations

The three types of play that predominate in early childhood are (1) *pretend*, or *symbolic play*; (2) *constructive play*; and (3) *rough-and-tumble*, or *physical play* ([Boxes 3-6](#) and [3-7](#)). Similar changes are observed in each type of play. First, the child's play becomes more elaborate—the child now combines multiple steps and multiple schemas. Short play sequences become long scripts involving several characters or actors in a story.^{79,86} Second, play becomes more social. The preschool-age child orients play toward peers, involving one or two peers in the story and taking turns playing various roles. When preschool-age children play with peers, the interaction appears to be as important as the activity's goal. As the child approaches 5 years of age, all play becomes increasingly social, generally involving a small group of peers.^{79,132}

Beginning at 2 years of age and continuing through the early childhood years, the child's play is symbolic and imaginative.

BOX 3-6 Development of Play Occupations: Preschoolers—24 to 36 Months

Play Occupations

Symbolic Play

Links multiple schema combinations into meaningful sequences of pretend play
Uses objects for multiple pretend ideas
Uses toys to represent animals or people
Plays out drama with stuffed animals or imaginary friends
Plays house, assigning roles to others, taking on specific roles

Constructive Play

Participates in drawing and puzzles
Imitates adults using toys

Gross Motor Play

Likes jumping, rough-and-tumble play
Makes messes

Social Play

Associative, parallel play predominates

Performance Skills

Regulatory/Sensory Organization

Handles fragile items carefully
Enjoys interesting tactile surfaces
Plays with water and sand
May experience difficulty with transitions

Fine Motor/Manipulation

Snips with scissors
Traces form, such as a cross
Colors in large forms
Draws circles accurately
Builds towers and lines up objects
Holds crayon with dexterity
Completes puzzles of 4-5 pieces
Plays with toys with moving parts

Gross Motor/Mobility

Rides tricycle
Catches large ball against chest
Jumps from step or small height
Begins to hop on one foot

Cognitive

Combines actions into entire play scenario (e.g., feeding doll, then dressing in nightwear, then putting to bed)
Shows interest in wearing costumes; creates entire scripts of imaginative play
Matches pictures
Sorts shapes and colors
Plays house

Social

Cooperative play, takes turns at times
Shows interest in peers, enjoys having companions
Begins cooperative play and play in small groups
Shy with strangers, especially adults
Engages in dialog of few words
Can be possessive of loved ones

Data from Parks, S. (2007). *HELP Strands*. Palo Alto, CA: Vort; Linder, T. (2008). *Transdisciplinary play-based assessment* (rev. ed.). Baltimore: Brookes.

The child pretends that dolls, figurines, and stuffed animals are real. The child may also imitate the actions of parents, teachers, and peers. At ages 3 and 4, pretend play becomes more abstract, and objects, such as a block, can be used to represent something else. Pretend play now involves many steps that relate to each other. Children develop scripts as a basis for their play (e.g., one

BOX 3-7 Development of Play Occupations: Preschoolers—3 to 4 Years

Play Occupations

Complex Imaginary Play

Creates scripts for play in which pretend objects have actions that reflect roles in real or imaginary life
May use complex scripts for pretend sequences; portrays multiple characters with feelings

Constructive Play

Creates art product with adult assistance
Works puzzles and blocks

Rough-and-Tumble Play

Enjoys physical play, swinging, sliding board at playground, jumping, running

Social Play

Participates in circle time, games, drawing, and art time at preschool
Engages in singing and dancing in groups
Associative play: plays with other children, sharing and talking about play goal

Performance Skills

Fine Motor/Manipulation

Uses precision (tripod) grasp on pencil or crayon
Colors within lines
Copies simple shapes; begins to copy letters
Uses scissors to cut; cuts simple shapes
Constructs three-dimensional design (e.g., 3-block bridge)
Manipulates objects within the hand

Gross Motor/Mobility

Jumps, climbs, runs
Begins to skip and hop
Rides tricycle
Stands briefly on one foot
Alternates feet walking upstairs
Jumps from step with 2 feet

Cognitive

Uses imaginary objects in play
Makes dolls and action figures carry out roles and interact with other toys
Categorizes and sorts objects
Shows a sense of humor

Social

Attempts challenging activities
Prefers play with other children; group play replaces parallel play
Follows turn-taking in discourse and is aware of social aspects of conversation
Shows interest in being a friend
Prefers same-sex playmates

Data from Knox, S. (2008). Development and current use of the Knox Preschool Play Scale. In L. D. Parham & L. Fazio (Eds.), *Play in occupational therapy for children* (2nd ed., pp. 55–70). St. Louis: Mosby; Folio, M. R., & Fewell, R. R. (2000). *Peabody Developmental Motor Scales* (rev. ed.). Austin, TX: Pro-Ed.

child is the father and one is the mother). They base these scripts on real-life events and play their roles with enthusiasm and imagination, creating their own stories and enjoying the power of their imaginary roles (Figure 3-15). Their dramatic play is quite complex at this time. However, when they are in small groups, their interaction with their peers seems to be more important than the play goal, and they can easily turn to new activities suggested by one member of the group.

FIGURE 3-15 Pretend play of this 4-year-old focuses on his interests.

By 5 years of age, this imaginary play is predominantly social, as small groups of two and three join in cooperative play. A 5-year-old child engages in pretend play about one third of the time.¹²² However, this pretend play is based on imitation of real life and dressing up to play certain roles (e.g., firefighter, police officer, ballerina). Although children of this

BOX 3-8 Development of Play Occupations: Preschoolers—4 to 5 Years

Play Occupations

Games with Rules

- Begins group games with simple rules
- Engages in organized play with prescribed roles
- Participates in organized gross motor games such as kickball or "duck, duck, goose"

Constructive Play

- Takes pride in products
- Shows interest in the goal of the activity
- Constructs complex structures

Social Play/Dramatic Play

- Participates in role play with other children
- Participates in "dress up"
- Tells stories
- Continues with pretend play that involves scripts with imaginary characters

Performance Skills

Fine Motor/Manipulative

- Draws using a dynamic tripod grasp
- Copies simple shapes
- Completes puzzles of up to 10 pieces
- Uses scissors to cut out squares and other simple shapes
- Colors within the lines
- Uses two hands together well, one stabilizing paper or object and the other manipulating object
- Draws stick figure or may begin to draw trunk and arms
- Copies own name
- Strings small beads

Gross Motor/Mobility

- Jumps down from high step; jumps forward
- Throws ball
- Hops for long sequences (4-6 steps)
- Climbs on playground equipment, swinging from arms or legs
- Throws ball and hits target
- Skips for a long distance
- Walks up and down stairs reciprocally

Cognitive

- Understands rules to a game
- Remembers rules with a few reminders
- Makes up stories that involve role playing with other children
- Participates in goal-oriented, cooperative play with two or three other children
- Participates in planning a play activity
- Begins abstract problem solving

Social

- Enjoys clowning
- Sings whole songs
- Role plays based on parents' roles

Data from Linder, T. (2008). *Transdisciplinary play-based assessment* (rev. ed.). Baltimore: Brookes.

age demonstrate some understanding of adult roles, they erroneously assume that roles are one-dimensional (e.g., a firefighter has one role, that of putting out fires). Through pretending, children develop creativity, problem solving, and an understanding of another person's point of view (Boxes 3-8 and 3-9).¹²⁹ Case Study 3-1 presents an example of applying Vygotsky's theories to a preschooler's learning the skills that support pretend play.

BOX 3-9 Development of Play Occupation: Kindergartners—5 to 6 Years**Play Occupations****Games with Rules**

Board games
Computer games
Competitive and cooperative games

Dramatic Play

Elaborate imaginary play
Role plays stories and themes related to seasons or occupations
Emphasis is on reality
Reconstructs real world in play

Sports

Participates in ball play

Social Play

Participates in group activities
Organized play in groups
Goal of play (winning) may compete with social interaction at times

Performance Skills**Fine Motor/Manipulation**

Cuts with scissors
Prints name from copy
Copies triangle; traces diamond
Completes puzzles of up to 20 pieces

Traces letters, begins to copy letters

Manipulates tiny objects in fingertips without dropping
Uses two hands together in complementary movements

Gross Motor/Mobility

Hops well for long distances
Skips with good balance
Catches ball with two hands
Kicks with accuracy
Stands on one foot for 8-10 seconds

Cognitive

Reasons through simple problems
Bases play more on real life than on imaginary world

Participates in organized games

Uses complex scripts in play

Demonstrates deferred imitation

Sorts objects in different ways

Copies elaborate block structures

Social

Participates in groups of two to four that play in organized, complex games

Has friends (same sex)

Enjoys singing and dancing; reflects meaning of words and music

Demonstrates understanding of others' feelings

**CASE STUDY 3-1****Example of Vygotsky: Scaffolding and the Zone of Proximal Development**

Sarah is a 4-year-old girl with autism spectrum disorder. She demonstrates age-appropriate development in motor skills; however, she has difficulty with motor planning and sequencing a series of movements. Her communication, play, and activities of daily living skills appear to be at a 2-year-old level. She also has difficulty with perceptual skills and often confuses concepts such as up-down, right-left, and spatial awareness. Teresa, an occupational therapist, selected a dress-up activity to promote Sarah's self-care, self-identity, and pretend play development. Teresa, who has collaborated with the speech-language pathologist, also tries to elicit simple questions and use of action verbs in this play scenario.

Teresa sets up the activity by inviting Sarah to come explore the large bin of dress-up clothes in the preschool classroom. As Teresa holds up a fireman's jacket and a doctor's coat, she asks Sarah to identify the top and bottom and to state what part of the body it fits. When Teresa asks Sarah what she wants to be ("Would you like to be a princess, a nurse, a superhero?"), Sarah's pretend skills are not sufficiently developed to choose. Teresa suggests that she be a princess, wearing a gown, princess shoes, and a crown. Teresa asks, "How will you get on your gown?" Sarah is hesitant, so Teresa points to the top and bottom, shows the zipper, and indicates that she can step into the gown. Sarah hesitates, and Teresa holds her hand to encourage her to step into the gown. She verbally cues her to slide her arms through the sleeves and models the action with an imaginary dress. Physical assistance is unnecessary as Sarah dons the gown with this cueing.

Throughout the activity, Teresa helps Sarah learn and integrate body awareness, saying, "Where are your toes? Let me see your hands and fingers." When Sarah has her gown, shoes, and crown on, Teresa suggests that she dance in front of a mirror to see how the gown flows and to imagine being a princess. They parade through the preschool classroom so that the other children can see her gown. When it is time to go outside and Sarah must take off the gown, Teresa decides to allow Sarah to sequence the undressing activity without verbal or physical cueing. She kneels by Sarah, prepared to help or give guidance, but knowing that undressing is easier, she hopes that Sarah can accomplish it on her own. Although Teresa begins the zipper, Sarah removes her princess clothing independently. Teresa reminds her of top and bottom, right and left during the undressing to reinforce those concepts.

Although this is a simple play scenario, common in preschool classrooms, Teresa has applied principles of Vygotsky's theories. She selected an activity within Sarah's proximal zone of development that she could achieve with a minimal amount of support. Teresa was prepared at each step to provide assistance (e.g., physical assistance in donning), but she first observed what support was needed to give the just-right amount of support. She promoted Sarah's development of pretend play, self-care, and self-identity by selecting an appropriate activity, providing just-right cues and guidance, and reinforcing perceptual concepts.

FIGURE 3-16 Children enjoy reading and writing activities at school. Molly is proud of her first book!

Play that involves building and construction also teaches the child a variety of skills during early childhood. At first, these skills are demonstrated in the completion of puzzles and toys with fit-together pieces (Figure 3-16). However, with mastery of simple pegs and puzzles, the child becomes more creative in construction. For example, a 4-year-old child can develop a plan to build a structure with blocks and then carry out the steps to complete the project. With instructions and a model, a 5-year-old child can make a simple art project or create a three-dimensional design. A 5-year-old child can also put together a 10-piece puzzle. The final product has become more important, and the child is motivated to complete it and show others the final result. The planning and designing involved in building and construction play help the child acquire an understanding of spatial perception and object relationships. This activity also appears to be foundational to academic performance in school.

Children 2 to 5 years of age are extremely active and almost always readily engage in rough-and-tumble play. They continue to delight in movement experiences that provide strong sensory input. Activities such as running, hopping, skipping, and tumbling are performed as play without any particular goal. Although rough-and-tumble play generally involves other children, it is generally noncompetitive and rarely organized. Children enjoy this activity for the simple, simultaneous pleasure of movement as they play together.²³

In associative physical play, children are generally more interested in being with other children than in the goal of the activity. However, some children enjoy primarily social play,

whereas others enjoy solitary play. These differences do not relate to ability as much as they relate to preferences and temperament.¹³⁸

Performance Skills

Gross Motor and Mobility

Young children are amazingly competent individuals, and their repertoire of motor function leaps forward during the preschool years (see Performance Skills in Boxes 3-6, 3-7, 3-8, and 3-9). By age 2 years, the child walks with an increased length of stride and an efficient, well-coordinated, and well-balanced gait. Although children begin to run by 2 years, they do not exhibit true running (characterized by trunk rotation and arm swing) until 3 to 4 years of age. The 4-year-old child demonstrates a walking pattern similar to that of an adult. By 5 to 6 years of age, the mature running pattern has developed, and children test their speed by challenging each other to races.

As mobility develops, children gain access to spaces previously unavailable to them. By 2 years of age, a child walks up stairs without holding onto a parent's hand, and at 2½ years, the child can walk down stairs without support. A child 3½ years old walks up and down stairs by alternating the feet and without needing to hold onto a rail.

Running and stair climbing become possible, in part, because the child's balance and strength increase. Emerging balance can be observed as the 2-year-old child briefly stands on one foot to kick a ball. By 5 years of age, the child can balance on one foot for several seconds and walk on a curb without falling.⁴⁹ Between 3 and 5 years, the child may successfully attempt to use skates or roller blades.

Jumping is first observed in 2-year-old children. This skill requires strength, coordination, and balance. By 3 years of age, the child can jump easily from a step. Hopping requires greater strength and balance than jumping and is first observed at 3½ years. Skipping is the more difficult gross motor pattern because it requires sequencing of a rhythmic pattern that includes a step and a hop. A coordinated skipping pattern is not observed until 5 years of age.⁷⁸

A 2-year-old child can begin to pedal a tricycle and move small riding toys. By 3 years of age, the child can pedal a tricycle but may run into objects. A 4-year-old child can steer and maneuver a tricycle around obstacles.

By 2½ years, most children can catch a 10-inch ball. This pattern of maturity enables the 4-year-old child to catch a much smaller ball, such as a tennis ball, successfully.⁴⁹ The first pattern of throwing involves a pushing motion, with the elbow providing the force for the throw. The 4-year-old child demonstrates more forward weight shift with throwing, increasing the force of the ball and the distance thrown. Kicking emerges in the 2- to 3-year-old child, with accurate kicking to a target exhibited by 6 years of age. Ball skills become increasingly important as the child begins participating in organized sports during the primary grades.

Fine Motor and Manipulation

Early childhood is a time of rapid improvement in fine motor and manipulation performance. By 4 years of age, children learn to move small objects efficiently within one hand (i.e., in-hand manipulation). A 4-year-old child can hold several small objects in the palm of the hand while moving individual pieces with the radial fingers.¹⁰⁷ In-hand manipulation indicates that isolated finger movement is well controlled and that the

thumb easily moves into opposition for pad-to-pad prehension. These skills also indicate that the child can modulate force and that he or she has an accurate perception of the gentle force needed to handle small objects with the fingertips.¹⁰⁷

With efficient in-hand manipulation, the preschool child also learns the functional use of drawing and cutting tools. Most 3-year-old children hold a pencil with a static tripod grasp (i.e., with the pencil resting between the thumb and first two fingers) and use forearm and wrist movement to draw; however, by 5 years, a child demonstrates a mature, dynamic tripod. In this grasp pattern, the pencil is held in the tips of the radial fingers and is moved using finger movement. By controlling the pencil using individual finger movements, the child can make letters and small forms.

Drawing skills progress from drawing circles to lines that intersect and cross in a diagonal (e.g., an X). The 5-year-old child can draw a person with multiple and recognizable parts. Drawing is often a strong interest at this age and contributes to the child's imaginative play.¹⁴⁸ He or she can also draw detailed figures created in the imagination (i.e., monsters, fairies, and other fanciful creatures) (Table 3-6).

The development of scissors skills follows the development of controlled pencil use. The first cutting skill, observed at 3 years, is snipping with alternating full-finger extension and flexion. Between 4 and 6 years, bilateral hand coordination, dexterity, and eye-hand coordination improve, enabling the

child to cut out simple shapes. Mature use of scissors is not achieved until 5 to 6 years because it requires isolated finger movements, simultaneous hand control, and well-developed eye-hand coordination for cutting accuracy.^{49,103}

Other fine motor skills acquired during the preschool years are important to the child's constructive and dramatic play. Activities such as putting puzzles together, building towers, stringing small beads, using keys, and cutting out complex designs usually require dexterity, bilateral coordination, and motor planning.

Cognitive

Preschool-age children create symbolic representations of real-life objects and events during play. In addition, they begin to plan pretend scenarios in advance, organizing who and what are needed to complete the activity. Play becomes an elaborate sequence of events that is remembered, acted out, and later described for others. For example, the child may act out the role of an adult, imitating action remembered from an earlier experience. This form of role play demonstrates the child's understanding of how roles relate to actions and how actions relate to each other (e.g., the child may role play a grocery store clerk, displaying items for sale, taking money from the customer, and placing the money in a toy cash register).

Abstract thinking begins in the preschool years as the child pretends that an object is something else. For example, the

TABLE 3-6 Dynamical Systems Theory Perspective on Development of Drawing Skills (4-6 Years)

Stages of Drawing Development	
Age	Developmental Skills
2-3 years	Makes scribbling marks on paper that are without symbolic meaning (exploratory phase). Repetitious marks.
3-4 years	Interprets drawing after it has been produced. Shapes emerge from scribbling.
4-5 years	Draws an image, draws with intent a picture that represents an object, person, or event. Has shapes and distinct elements, may be disordered, incorrect sizing, but has some semblance to intent.

Dynamical Systems Influencing Drawing Skill, 3-5 Years

Performance	Intrinsic Factors (Individual)	Extrinsic Factors (Environment)
Dynamic grasp of pencil or marker	Haptic perception of pencil in hand. Moves object in hand while holding (efficient intrinsic muscle use). Demonstrates dynamic tripod grasp.	Experience holding different drawing utensils, e.g., crayons, markers. Experience drawing on different surfaces. Experience in manipulating small objects, e.g., puzzles, blocks, small figurines.
Eye-hand coordination	Visual acuity. Visual perception. Motor coordination. Coordination of arm, hand, and finger action.	Experience in eye-hand coordination, e.g., stringing beads, stacking, puzzles. Available colors, contrasts, lighting, sizing of drawing utensils.
Draws shapes	Motor planning skills. Visual motor coordination.	Experience moving through the environment, handling objects with different shapes. Available colors, contrast, shapes in 2 and 3 dimensions. Cues from adults or others. Feedback from adults.
Draw figures and forms	Motor planning skills. Spatial relation skills.	Cues that guide drawing, e.g., models, examples. Adult reinforcement. Available color, lighting, surfaces, utensils.
Drawing represents an action, person, object, or event	Cognitive skills of attributing symbolic meaning, demonstrating representational thinking.	Play opportunities. Adult guidance. Peer models. Experience with books, pictures, stories, art.

From Ziviani, J., & Wallen, M. (2006). The development of graphomotor skills. In A. Henderson & C. Pehoski (Eds.), *Hand function in the child* (2nd ed., pp. 217–238). St. Louis: Mosby.

child may pretend a block is a doll bed; later the same block may become a telephone receiver or a train car.

In construction play (e.g., constructing train sets or building castles with Lego blocks), the child discriminates object size and shape. Building in three dimensions also requires spatial understanding and problem-solving skills. When building from a set of blocks, the child usually must first categorize and organize the blocks. Next, the child must solve the problem of how to fit them together to replicate a model or create the imagined structure.

In a similar way, the emergence of drawing skills reflects cognitive abilities, motor planning, and perceptual skills. The 3-year-old child makes crude attempts to represent people and objects in drawings. By 4 years of age, a child can draw a recognizable person, demonstrating the ability to select salient features and represent them on a two-dimensional surface. The 4-year-old child not only identifies the parts of a person but also relates them correctly, although the size of the parts is rarely proportional to real life. At 5 years, the child's drawing is more refined, more realistic, and better proportioned. By this age, pictures begin to tell stories and reflect the child's emotions (see Table 3-6).^{86,148}

Social

In early childhood, interaction and play with peers take on increasing importance. Children become social beings and identify themselves as individuals (i.e., separate from parents). Autonomy dominates psychosocial development from 2 to 4 years as the toddler shows his or her independence by moving away from the parent. The child is adamant about making personal decisions. The development of trust in the environment and improvements in language bring forth control over self, strengthening the child's autonomous nature.

The discovery of the body and how to control it promotes independence in self-care. Success in acting independently instills a sense of confidence and self-control. The child also begins to perceive that now all of his independent actions meet the approval of adults. See previous section on self-identity development.

Children need to achieve a balance between initiative to act independently and the responsibility they feel for their own actions. Children 4 to 5 years old explore beyond the environment, discovering new activities. They seek new experiences for the pleasure of learning about the environment and for the opportunities they offer for exploration. If the child's learning experiences are successful and effective and his or her actions meet parental approval, a sense of initiative is developed. Through these activities, the child learns to question, reason, and find solutions to problems.

Adult-child relationships and early home experiences also influence later peer relations. According to research, children whose attachments to their mothers are rated as secure tend to be more responsive to other children in childcare settings. They are also more curious and competent.⁸⁰ Peer play becomes an important avenue for the child's development of social and cognitive abilities. With their peers, they practice social roles, engage in dramatic play, and enjoy rough-and-tumble play.¹⁰⁹

The development of autonomy provides a foundation for the child's imagination. The young child explores the world not only through the use of his or her senses but also by thinking and reasoning. Although play can be reality based, it usually

includes fantasy, wishes, and role play. Words, rhymes, and songs also complement this type of play.¹⁰⁸

Contexts

Cultural and Social Contexts

The social roles of young children are influenced by cultures, ethnicity, and community. In the United States, the importance of interaction with peers is stressed at young ages. Most American children begin to interact with their peers (same age group) at about 3 years of age. Same-age peers become increasingly important through elementary school and dominate the social life of a teenager. In the United States and much of the world, children are grouped exclusively by age. These age groupings may provide more opportunities for play, but they also diminish opportunities for older children to teach and nurture younger children. Younger children have fewer opportunities to imitate older children.

Children in other parts of the world play and socialize with people of different ages. Cultural influences on social play behaviors are time and space to play, access to objects and materials, adult behavior and attitudes, and the availability of play partners.⁴⁵ For example, in Hispanic communities, children spend almost all of their time with siblings and other young relatives of a wide range of ages and primarily play with family members, including extended family. They socially participate in mixed-age groups, playing "on the edge" and watching intently until they can join in the play. Toddlers play with children of various ages, and they often play with older siblings. This "enduring social network" remains in place over time to care for, teach, and discipline children to adulthood.¹¹⁶ When children spend their days with people of various ages, they have many opportunities to imitate and learn from older children and adults. Interaction with children of varying ages provides older children the opportunity to practice teaching and nurturance with young children and provides young children the opportunity to imitate older children.¹⁴⁸

At very young ages, Mayan children play within their parents' work activities.¹¹ For example, children engage in play activities while helping their mothers wash clothes. The children's play in the Mayan culture is tolerated during daily work activities but is not specifically encouraged.¹¹ Bazyk and colleagues¹¹ found that children's work was playful, blurring the European American distinction between work and play. When children play in work activities, they are learning skills that will serve them well in adulthood. In contrast, the age-based groupings used in U.S. childcare centers and preschools provide children with opportunities to play with same-age peers but reduce their opportunities to play within adult work activities.

Families in the United States specifically design and encourage their children's play and at times become playmates with children. Although play is emphasized as the primary occupation for young children, children demonstrate interest in helping parents accomplish their work. Parents may encourage young children (e.g., 5 to 6 years old) to participate in household tasks, such as picking up their own toys. When children begin school, parents usually expect them to participate more in household tasks such as cleaning and meal preparation (see Chapter 16).⁸³

Physical Contexts

By the age of 5, a child's outdoor environment has expanded beyond the areas around the home and childcare center. A

variety of outdoor environments offer space for rough-and-tumble play, and expanded social and physical environments give the child new opportunities for learning (and generalizing) the skills he or she has achieved. Although adult supervision remains essential, the entire neighborhood may become the child's playground.

The availability of new indoor environments is also to be expected. Preschool classrooms usually have centers for different types of activities (e.g., creating art, listening to stories, playing games). In addition, community groups often sponsor a variety of indoor activities (e.g., preschool gymnastics, organized play programs) in which the child can participate.

Expanded environments offer children the opportunity to adapt play skills learned at home to the constraints of new spaces. For example, the child who climbs and slides down the stairs at home learns to climb a 6-foot ladder and slide down the slide in the neighborhood park. Parks and playgrounds also provide the child with new surfaces that challenge balance and equipment that offers intense vestibular experiences.

Cultural and socioeconomic differences can influence a child's physical environment. Inner-city parents frequently confine their children to the immediate household and forbid them to go outside after school, particularly to play. These protective strategies limit children's exposure to dangerous neighborhood influences, but they also restrict the physical context available for play.^{20,51,144,145}

Most preschool-age children also enjoy spending time in quiet spaces. Quiet spaces can be organizing and calming after a day in a childcare center (Figure 3-17). Based on sensory preferences, arousal levels, and activity levels, other children may seek stimulating environments that are full of activity, or they may create their own high activity in an otherwise quiet space.

When placed in new environments, children often respond by instinctively exploring the new spaces (e.g., hallways, cupboards, corners, furniture). Exploring the features of an environment can help orient children to the spaces that surround them, promote perceptual learning, and provide an understanding of the play possibilities in that environment.

FIGURE 3-17 Children enjoy pretend play and creating fun games that may challenge balance, strength, postural stability, and coordination.

Middle Childhood: Ages 6 to 10 Years

Play Occupations

Although 6-year-old children continue to enjoy imaginative play, they begin increasingly to structure and organize their play. Box 3-10 describes Piaget's classification of games that correspond to stages of cognitive development. By the time a child is 7 or 8 years old, structured games and organized play predominate (Box 3-11). *Games with rules* are the primary mode for physical and social play. Groups of children organize themselves, assign roles, and explain (or create) rules to guide the game they plan to play. The goal of the game now competes with the reward of interacting with peers, and children become fascinated with the rules that govern the games they play.

At 7 or 8 years of age, children do not understand that rules apply equally to everyone involved in the game, and they are often unable to place the rules of the game above the personal need to win.⁴⁸ However, breaking the rules may incur the criticism of peers, who also acknowledge the importance of rules at this time. By 9 and 10 years of age, children are more conscientious about obeying rules. They also learn to negotiate the rules of a game and construct their own rules.

BOX 3-10 Piaget's Stages of Cognitive Development as Expressed in Children's Games

Dimitri's Favorite Games

Dimitri, who is 5 years old, loves games, and although he has spastic diplegia cerebral palsy, he fully engages in games that match different cognitive levels as defined by Piaget.

Practice (Sensorimotor Exploratory) Games

Dimitri loves to wrestle with his brother on the living room rug. In this game, Dimitri pulls his 7-year-old brother to the floor. Mostly they roll on top of each other vying for the top position. This game does not have rules or structure, and, most often, the wrestling ends without a victor, when Dimitri tires or his mother intervenes.

Symbolic Games

Dimitri also loves playing with his dinosaurs, doing battles, roaming for food, and running over hills and valleys in the sandbox. The dinosaurs can talk and often bargain with each other for dominion of the sand mountain. This game also lacks structure. Dimitri plays with his friend Samuel or alone, and the dinosaurs' play scenarios are often the same.

Games with Rules

Dimitri also plays "Go Fish" and "Candyland" with his brother. Dimitri knows most of the rules, plays cooperatively and takes turns, and knows how the game ends. At 5, he does not always figure out when his older brother breaks the rules to gain the lead in the game.

Although these classifications of play reflect different cognitive levels, children play at all three levels over an extended period of time.

These play categories also have different goals and outcomes for the child's performance across developmental domains. All three play categories can be social play, object play, or both.

BOX 3-11 Development of Play Occupations: Middle Childhood—6 to 10 Years

Play Occupations

Games with Rules

Computer games, card games that require problem solving and abstract thinking

Crafts and Hobbies

Has collections

May have hobbies

Organized Sports

Cooperative and competitive play in groups or teams of children

Winning and skills are emphasized

Social Play

Play includes talking and joking

Peer play predominates at school and home

Plays with consistent friends

Performance Skills

Fine Motor/Manipulation

Good dexterity for crafts and construction with small objects

Bilateral coordination for building complex structure

Precision and motor planning evident in drawing

Motor planning evident in completion of complex puzzles

Gross Motor/Mobility

Runs with speed and endurance

Jumps, hops, skips

Throws ball well at long distances

Catches ball with accuracy

Cognitive

Abstract reasoning

Performs mental operations without need to try physically

Demonstrates flexible problem solving

Solves complex problems

Social

Cooperative, less egocentric

Tries to please others

Has best friend

Is part of cliques

Is less impulsive, is able to regulate behavior

Has competitive relationships

Children who are 8 or 9 years old become interested in sports, and parents are generally supportive of sports activities. Although a form of play, organized sports can assume a serious nature (i.e., intrinsic motivation and the internal sense of control are overridden by the external demands of practice and serious competition with peers). In addition to organized sports, physical play is a favorite interest, including climbing, rollerblading, skipping rope, and skateboarding (Figure 3-18).

Interest in creating craft and art projects continues into middle childhood. During this time, the child shows an increased ability to organize, solve problems, and create from abstract materials. However, the completion of craft and art projects continues to require the support of adults to organize materials and identify steps. The final product, which is relatively unimportant to younger children, is now valued. Computer play and video games are popular and may dominate play in middle childhood into adolescence (see Chapter 4).¹²⁸

In middle childhood, children play in cooperative groups and value interaction with their peers. Increasingly, social

FIGURE 3-18 Favorite play activities for all children include swimming, ball play, and outdoor sports.

contact is virtual, through e-mail, texting, and social media websites. When friends come together, almost all activity is play and fun. Simply talking and joking become playful and entertaining. Children spend more than 40% of their waking hours with peers.³¹ In these peer groups, children learn to cooperate but also to compete.⁴⁸ They are now interested in *achievement* through play; they recognize and accept an outside standard for success or failure and criteria for winning or losing. With competition in play comes risk taking and strategic thinking. Children who compete in sports and other activities exhibit courage to perform against an outside standard.¹¹³

Performance Skills

Gross Motor and Mobility

During the elementary school years, gross motor development reflects the refinement of previously acquired skills with increases in speed, precision of movement, and strength. To achieve this refinement, children spend hours in repetition of favorite physical activities, including sports, to attain mastery. Children ride bicycles, scale fences, swim, skate, and jump rope (Figure 3-19). Although motor capabilities are highly varied for this age group, balance and coordination improve throughout the middle childhood years, providing children with the agility to dance and play sports with proficiency. Research indicates that children who struggle with physical skills have lower self-esteem and are very socially marginalized.⁹⁰ Not only does self-esteem improve as children master physical skills, but also peer acceptance improves.

Fine Motor and Manipulation

By middle childhood, children become increasingly efficient in tool use (e.g., scissors, tweezers) and demonstrate precise drawing skills. Children handle and manipulate materials (fold, sort, adhere, cut) with competency. The drawing skills of 8- and 9-year-old children demonstrate appropriate proportions and accuracy, and handwriting skills improve in speed and accuracy as children learn manuscript and then cursive writing.⁶⁵ These improvements provide evidence of increased dexterity and coordination. Construction skills, manipulation, and abilities to use tools continue to generalize across performance areas, with increases in speed, strength, and precision.

FIGURE 3-19 Children enjoy playing and swimming at the beach.

Cognitive

In middle childhood, concepts and relationships in the physical world are understood and applied. The child relates past events to future plans and comprehends how situations change over time. Thinking has become more flexible and abstract. The child has become a reasoning individual who can solve problems by understanding variables and weighing pertinent factors before making decisions. The child now has a clear understanding of the difference between fantasy and reality, and he or she chooses to move from one to the other.

At younger ages, children could apply only one solution, and they often were stuck when the solution of choice did not work. However, by 8 and 9 years of age, children recognize that different solutions can be tried, and they arrive at answers through abstract reasoning rather than through concrete trial-and-error. At this age, children can also pay attention to more than one physical characteristic at a time and can systematically put elements together.

In play, children order objects by size or shape, demonstrating the ability to discriminate perceptual aspects of objects and to order them accurately. They also understand the relationship of the whole to the parts, and they imagine pieces as parts of a whole. With this understanding, they become more competent in organizing tasks and organizing time. Children 9 to 10 years of age can give instructions to others and tell stories in detail.

By middle childhood, children learn to combine tasks and routines into complex games and competitive sports. Because numerous rules are needed to play sports, such as baseball or hockey, the child understands the need to combine the rules into a complete game. To participate in the activity successfully, the child also understands when rules apply and when rules can be negotiated. Most children also know rules can be implemented with flexibility and can be negotiated with adults.¹⁰⁹ The child's progression from games with some structure and flexible rules to highly competitive games demonstrates progression in moral development.

Social

Children 6 to 10 years old form close friendships and “belong” to one or more peer groups that greatly influence their

FIGURE 3-20 Brothers and cousins enjoy outdoor activities at their family farm, including tractor rides.

decisions, how they spend their time, and what they value. Florey and Greene explain, “In the beginning of middle childhood, friendships are characterized by sharing of interests. Toward the end of this period, children tend to organize around common values, commitment, loyalty, and mutual support” (p. 282).⁴⁸

Children in middle childhood focus on meeting challenges in themselves as well as challenges presented by others. Children appreciate the recognition that comes with successful completion of assignments or projects. Comparison with peers is increasingly important during this time. If a child's schoolwork is compared with the work of a more successful student, a negative evaluation can reduce his or her sense of mastery and may produce feelings of inferiority.

School-age children seek independence of identity. They are not as egocentric as young children and demonstrate a more objective view of themselves. Children at this age have a definite subculture, or clique, that includes only certain friends (Figure 3-20). At this age, children are quick to criticize others who do not conform to the group esthetic. Rejection by the child's peers may result from a lack of conformity in dress or physical appearance. Children who have difficulty communicating or who do not know how to initiate relationships are less likely to have close friendships. Children who are socially able and positive are more accepted and have more close friendships. At this age, children develop a peer culture and derive self-worth from their group of peers.⁴⁸

During middle childhood, children become disinterested in adults, including their parents. The values of peers become significantly more important than those of adults. Data indicate that children 7 to 10 years old are highly compliant with and easily shift in the direction of their peers.⁴⁸

Contexts

Cultural Contexts

Expectations for children to work vary across cultures. These expectations determine the timing and type of occupations children develop and the balance between work and play. Examples for countries other than the United States and countries of Europe illustrate these differences. In a study of 50

communities, children at 5 to 7 years of age were given responsibility for caring for younger children, for tending animals, and for carrying out household chores.¹¹⁸ Larsen and Verma⁸² reported that in nonindustrial populations, work during middle childhood exceeds 5 hours per day. In the United States, chores are rarely given to children younger than 8 or 9 years old. Many American families do not expect children to take responsibility for chores until the age of 10 or 11. In contrast, Polynesian children develop household skills by 3 or 4 years, at which time they gather wood, sweep, or run errands to the store. In West Africa, children have duties and run errands when they are 3 years old. In Kenya, 8-year-old girls perform most of the housework.¹¹⁶

Mayan children are continuously at their parents' side during work days. At early ages, they participate in work tasks, such as running errands and helping with cleanup. Bazyk et al.¹¹ found that although Mayan children began work activities at a very early age, they embedded play in these chores. Children in Central Africa acquire work experience from toddler age, and by age 12 they can trap animals, kill game, make medicines, and garden.¹¹⁶ In Nigeria, young children are taught to be helpful, responsible, and respectful. Before age 5, Nigerian girls are taught to perform household chores such as washing, sweeping, cooking, and caring for their younger siblings, and by middle childhood, the girls take full responsibility for these work roles. The number of errands a child was required to run and cognitive performance were significantly related, indicating that having children participate in work tasks at an early age may enhance cognitive competence.¹⁰⁵

In the United States, most children and youth have very few opportunities to work with adults. By one estimate, children contribute about 15% of all labor in households.⁶³ Rogoff et al.¹¹⁶ believe that American children are missing valuable opportunities for learning and gaining self-satisfaction. Compared with practices in societies outside the United States, the lack of work opportunities for American children limits their practice of skills important to their future and may delay their entry into adult work roles. Through experiences in school and guided participation in household work, children may develop work skills and learn social rules and cultural values.⁸³ Children who participate in household chores have higher self-esteem, are more responsible, and can cope more easily with frustrations. One of the best predictors of success as an adult is participation in household tasks during childhood.¹²⁰

Physical Contexts

In middle childhood, the child's play environment is now large and complex; more activities take place in the neighborhood and at school. The school's playground supports both social and physical play of small groups (or pairs) of children. Play occurs on ball fields and in community centers, amusement parks, and sports arenas. Organized activities are often sponsored by churches or by groups such as the Young Men's Christian Association (YMCA). By middle childhood, children have the mobility skills to maneuver through all environments (e.g., rough terrain, busy city streets). The society of school-age children dominates neighborhood streets and backyards, with bicycle races and spontaneous street hockey games. These children explore the woods and go on adventures in nearby parks to find areas unexplored by others. Although supervision by

adults is still needed at times, intermittent supervision usually suffices.

Children spend many of their waking hours in school. Schools offer complex environments (e.g., playgrounds, computer rooms, libraries, classrooms, lunchrooms) with many social and learning opportunities.

Summary

The development of occupational performance is influenced by many systems and variables in the individual child and in the environment. The various patterns observed in children provide insight into how and why a child follows a certain developmental trajectory. Sensory, motor, cognitive, and social skills support the child's performance in play occupations. At the same time, a child's activities are highly influenced by his or her cultural, social, and physical contexts. As an essential occupation of childhood, play provides a means of understanding and appreciating children's performance and a means for enhancing functional performance when development is delayed. The ability to play is also an important outcome of occupational therapy, one that reflects the being of childhood.

Summary Points

- Cognitive development reflects the interaction of genetic endowment and experience. Piaget and Vygotsky theorized that children learn through interaction with the environment and are particularly influenced by their social environment.
- Occupational therapists understand that children acquire new skills within their zone of proximal development through adult scaffolding of the just-right challenge to the child's learning.
- In dynamical systems theory, children acquire new skills through the interaction of intrinsic and extrinsic factors that are flexibly assembled to meet goals that are meaningful to the child.
- Children actively explore their environment. Manipulation skills emerge from perceptual exploration of objects and surfaces. Tactile, proprioceptive, and haptic perception develops from active manipulation of objects.
- Attachment, temperament, and emotion regulation contribute to social-emotional development. Children who develop emotion regulation can cope with stressful events by flexibly using multiple strategies.
- Children develop self-determination by attaining a sense of autonomy, competence, and relatedness. When a child can act independently and competently with the support of others, the child develops intrinsic motivation and self-determination.
- Children develop occupations through participation in family activities and cultural practices. Cultural context influences the child's self-identity, motivations, values, and interests and determines the range of activities and occupations in which the child can participate.
- Occupational therapists working with children must be knowledgeable about the child's development of play and its related performance skills.

CHAPTER

4

Adolescent Development: Transitioning from Child to Adult

Kerryellen Vroman

KEY TERMS

Adolescents	Peer relationships
Physical development	Body image
Psychosocial development	Identity

GUIDING QUESTIONS

1. What are the typical physical, psychological, and social developmental processes of adolescence?
2. What are the milestones of healthy adolescent development?
3. How do occupations promote and support development of adolescents?
4. What is the interrelationship between mental health, a sense of well-being, and adolescent psychosocial development?
5. How do adolescents' developmental issues influence and guide the occupational therapist's choice of therapeutic activities and interventions?
6. How can parents and occupational therapists promote self-determination and healthy autonomy for all adolescents?
7. What are the challenges of adolescents with disabilities, and how do these challenges influence their development?
8. What are community opportunities for adolescents, including adolescents with physical disabilities, chronic illness, and behavioral and emotional disorders, to engage in social participation to promote healthy development?
9. What are the roles and responsibilities of occupational therapists in facilitating social participation and community engagement in age-related activities by adolescents with disabilities?

This chapter focuses on cognitive, physical, and psychosocial development of adolescents and explains how the developmental process of adolescence influences participation in occupations and occupational performance. In particular, the chapter explores the effect of disabilities and chronic health conditions on adolescents' experiences and participation in age-related occupations that promote healthy development. The information in this chapter comes with the caveat that occupational therapists need to see each adolescent as an individual and apply

knowledge of typical development judiciously, cognizant that variability in development is normal. An adolescent's strengths, goals, needs, priorities, context (e.g., sociopolitical, economic, cultural), and current developmental status are integral in a comprehensive client-centered evaluation and occupation-based intervention plan.

Adolescence

Of all the stages of life adolescence is the most difficult to describe. Any generalization about teenagers immediately calls forth an opposite one. Teenagers are maddeningly self-centered, yet capable of impressive acts of altruism. Their attention wanders like a butterfly, yet they can spend hours concentrating on seemingly pointless involvements. They are lazy and rude, yet when you least expect it they can be loving and helpful.²³

Adolescents live mostly in the moment. They have moments of joy and pleasure, overwhelming loneliness and isolation, laughter and fun, unbearable emotional pain, anger, frustration, and embarrassment, which are equal to moments of supreme confidence and perceived immortality. They want the security of family but push back on the boundaries set by parents, demanding to be seen as grown up at the same time expecting and wanting unquestioned support. They desire and experience the closeness of peer friendships; they experience the pleasure and anxiety of exploring intimacy; and they have intense and seemingly eternal passion for clothes, music, sports, or other interests, which for a week, a month, or a year are all-absorbing. More than anything, they wish to belong, to fit in, to be seen the same as others, while at the same time wishing to be seen as unique. These are the experiences of all American teenagers. In *Case Study 4-1*, Caroline, whose teenage sister is intellectually developmentally disabled, speaks to the universality of being a teenager. The universality of the experiences and desires of adolescents is also the foundational principle of the I Am Norm campaign (<http://iamnorm.com>).

Adolescent Development

Adolescence is generally viewed as the developmental stage occurring between the ages of 12 and 18 years. Early adolescence encompasses the middle school years between ages 10 and 13, middle adolescence is the high school years between ages 14 and 17, and late adolescence is 17 through 21 years, which are typically the first years of work or college.^{4,99}

**CASE STUDY 4-1 My Sister Is a Teenager**

In the 6th edition of Occupational Therapy for Children, Caroline Glass, a college student at Wake Forest University, wrote the following excerpt about her sister Corinne, an adolescent who is moderately developmentally disabled.

My younger sister, Corinne, was born with Noonan's syndrome, a genetic disorder. Corinne is lucky to have few of the characteristic physical problems of her disorder; however, her speech and cognitive abilities are delayed. As a 17-year-old girl, Corinne is meeting many of the same decisions and difficulties that "typical" teenagers face (Figure 4-1).

Corinne goes to a public school and takes a mixture of classes. Some are integrated with regular students, and others are only with other teenagers with disabilities. High school is a trial for everyone, and my sister is no exception. Seeing people's reactions to Corinne's differences is always interesting, and many times disappointing. She is subject to teasing, bullying, and, perhaps worst of all, pity. Many people do not regularly interact with people who are mentally retarded and do not understand that Corinne wants no special treatment; she simply wants to be like everyone else.

Just like everyone else, Corinne has to tackle the teenage years. As she gets older, she desires more independence, just as I did at her age. When Corinne's disability presents her with situations in which she is forced to accept help, she becomes frustrated and angry. Her mood swings are like those of any other adolescent, easy to trigger and quick to pass. Her adolescence is complicated by the fact that logical explanations do not always satisfy her. Corinne has an incomplete understanding of time and events, which can make it difficult to relate to her way of thinking.

When faced with such daunting challenges, it is easy for Corinne to forget her strengths. Our family tries to remind Corinne of her abilities every day, and we find that in frustrating situations, it is often helpful to distract her with what she can do, instead of focusing on what she cannot do. Corinne has an incredibly detailed memory and has the ability to locate missing keys or beat anyone in a matching card game. However, her greatest strength is her unwavering ability to

love. The kids at school wave to Corinne while passing in the hallway and she responds with unrivaled enthusiasm. In fact, everywhere we go, people recognize her. That's because Corinne is never afraid to say hello to new people, give them a hug, or call them her friend. Even when she is made fun of or excluded, she never judges. As Corinne's older sister, I thought it would be my job to teach her. However, I have come to realize that Corinne has much more to teach me.

Today, Caroline and her sister as young adults have both left home. For this 7th edition, Caroline updates Corinne's story and shares with us her path into early adulthood.

2014 Update

In recent months, Corinne has experienced many changes, mostly positive, to her daily routine. At 21 years old, she exited the public school system in Virginia. She graduated from high school at age 18, but stayed in the public school system in an extended special education class, called Reaching Educational and Career Hopes (REACH). The REACH program worked on vocational and social participation skills and community involvement. It was not an academic class, but a program designed to help students from special education programs find and integrate into postschool opportunities.

The REACH program turned out to be an ideal way for Corinne to transition into adult life. After aging out of the program at 21, she received a Medicaid Intellectual Disability (ID) waiver from the Commonwealth of Virginia. Thousands of people are assessed as eligible to receive an ID waiver, yet only a few are granted each year. Corinne was fortunate to be awarded one of them, and with an ID waiver she was eligible to join a day support program and live in a residential placement. Attending the program 5 days a week, Corinne engages in a variety of educational services while having the opportunity to interact socially with the others and make friends. The length of the day and the structure of the schedule are similar to her experiences in high school and REACH, and Corinne has responded enthusiastically to participating in the program.

A more difficult transition has been our family's decision to move Corinne into a supported living arrangement. Corinne moved into a residential placement with a full-time care provider 6 months after being enrolled in the day support program. She lives with one other boy with special needs. Her care provider is someone our family has known for years and whom Corinne knew as a substitute teacher in middle school as well as a part-time care provider. Her familiarity with Corinne's personality and needs and her long-term participation in the special needs community were major factors in my parents' decision to move Corinne into her home. We liked the fact that Corinne would receive highly individualized care, which is more difficult to achieve in larger group homes. It was important for my parents that Corinne would have the flexibility to come to her family home and to participate in family holidays and activities as she and they wanted.

We chose to wait until Corinne had acclimated to the day support program before changing her living situation because

CASE STUDY 4-1 My Sister Is a Teenager—cont'd

too many new things at once can be overwhelming—both for her and for us. In the weeks leading up to the move, we spoke to her at length about what this change would mean. Ultimately, referring to her new home as her “apartment” is what helped Corinne to understand this step—she compared her “apartment” with my apartment in Baltimore, where I currently live, and our brother’s apartment in Washington, D.C. Seeing her life following our typical transitions, such as moving away from home and getting an apartment, helped her to understand that some of her things would stay at our parents’ house, for when she returns home to visit, and some things would be moved permanently to her apartment. However, there were still some difficult moments; a new home means new rules and routines. Like any new living

arrangement, Corinne has had moments of frustration with her care provider and her roommate. In addition, she has faced many new challenges and the need to develop other life skills, such as packing to come home (my mother previously had always packed for her) and remembering which items are at which house. Mostly, these small trials are beneficial because they push Corinne to become more independent and expose her to new things. The challenges have not only been Corinne’s; at times it has been difficult for my family members and me to have Corinne in the care of another person. Knowing decisions and plans can change and that we will continue to think critically and work with Corinne about which of her choices are the best for her well-being makes it easier to embrace change and move forward.

BOX 4-1 Facts About American Teenagers

- There are 64 million teenagers in the United States between the ages of 10 and 24 years (United States Census Bureau, 2010).
- Adolescents between 10 and 24 years old are more racially and ethnically diverse than the general population: 52.2% are white, 16.5% are Hispanic, 13.6% are black non-Hispanic, 3.9% are Asian/Pacific Islander, and 0.9% are American Indian/Alaskan Native.
- Two thirds of teenagers live in suburban areas, with the highest percentage in the South (35.6%) followed by the Midwest (23.5%), West (22.7%), and East (18.1%).
- Two thirds of teenagers between the ages of 12 and 17 years live with both parents. Black adolescents are the least likely to live in a two-parent home (2006 data).
- Of young people, 24% live in immigrant families (2008 data).
- Approximately 94.6% of teenagers 16 to 17 years old are enrolled in school (2006 data). More girls than boys are enrolled in school. The high school dropout rate is highest among Hispanics (22.5%), blacks (10.8%), and whites (6%) (2005 data). One third of high school students also work.
- Of children and adolescents younger than age 17, 17% live below the federal poverty line. Black and Hispanic adolescents are more likely to experience poverty.
- Although there has been a decline in mortality rates over the last 20 years, male teens continue to have a higher mortality rate than female teens. Significant racial and ethnic disparities exist, with American Indian/Alaskan Native and African Americans experiencing the highest death rate among teens.
- More than 5 million children and adolescents (8%) between the ages of 5 and 20 years have a disability.

During this period of life, a child prepares for adulthood. This intense period of physical and physiologic (biologic) maturation and psychosocial development influences an adolescent’s ability to think, relate, and act as a competent adult. A period of learning, experimentation, and experiences, adolescence influences an individual’s choice of long-term occupation, social participation, and his or her physical and psychological well-being. Box 4-1 lists facts about teenagers in the United States.

In observing the developmental process of adolescence, occupational therapists observe adolescents’ physical growth and his or her physiologic, emotional, and psychological changes. They are cognizant that it is important to evaluate how adolescents perform common age-related tasks. This evaluation includes developing an occupational profile of the teen, including his or her occupational choices, interests, personal causation (i.e., how competent he or she feels in performing in age-related skills), and how he or she participates in social contexts. Also relevant is how the adolescent seeks out new and novel experiences, self-regulates impulsive behavior, and expresses emerging values. These age-related tasks and experiences are crucial to the process of adolescents gaining physical

and financial independence and redefining their psychological and emotional relationships with their parents. As they develop, adolescents establish norms and lifestyles congruent with the values and culture of their peers and their families. They accept and explore the physical and sexual development of their bodies. They work to establish their gender, personal, moral, and occupational identity. Successfully navigated, adolescence culminates in an overall state of well-being and a positive transition to adulthood and adult roles. Failure to integrate and engage in the roles and tasks of adolescence can result in ongoing physical and psychosocial difficulties that potentially affect an adolescent’s future occupational performance and roles.⁵⁴

A working knowledge of adolescent development and awareness of occupations that facilitate age-appropriate development are fundamental to effective occupational therapy with adolescents. Effective occupational therapy interventions begin with an evaluation of physical, cognitive, and psychosocial factors associated with adolescents’ development and the quality of their occupational performance. This process includes standardized criterion-referenced (based on performance expected

of an adolescent) or norm-referenced (based on actual performance of other adolescents) assessments that evaluate client factors and performance. Ideally, the evaluation process is occupation-based. Only interventions based on thorough evaluation are likely to be age-appropriate, promote healthy development, and foster performance skills. This chapter provides an overview of adolescent development intended to guide occupational therapy evaluations and interventions with adolescents.

Physical Development and Maturation

Adolescence is characterized by the biologic and physiologic changes of puberty, dramatic increases in height and weight, and changes in body proportion. The age for the onset of puberty is variable, and a child may begin to notice these changes from ages 8 to 14 years. The stimulus for this physical growth and physiologic maturation of reproductive systems is a complex interaction of hormones. It involves the hypothalamus and the pituitary gland that releases hormones that control growth and stimulate the release of sex-related hormones from the thyroid, adrenal glands, and the ovaries and testes (collectively referred to as the gonads).¹¹⁰

The growth- and sex-related hormones initiate a period of rapid physical growth, which varies in intensity, onset, and duration. In this growth phase, people gain approximately 50% of their adult weight and 20% of their adult height. This process, which generally lasts about 4 years, can start at 9 years of age and may continue in some adolescents to age 17. In the United States, the average peak of growth occurs around age 11 for girls and age 13 for boys.

Growth of the skeletal system is not even; head, hands, and feet reach their adult size earliest. Bones become longer and wider. Calcification, which replaces the cartilaginous bone composition of childhood, makes bones denser and stronger. Muscles also become stronger and larger. This process of skeletal growth and muscle development culminates in increased overall strength and endurance for physical activities. Increases in strength are greatest about 12 months after adolescents' height and weight have reached their peak and are associated with an overall improvement in motor performance, including better coordination and endurance. Increases in muscle mass and heart and lung function are typically greater in boys than in girls. This growth is the basis of the difference in strength and gross motor performance between males and females.²⁰ Motor performance peaks for males in late adolescence around 17 to 18 years of age.¹⁷ Girls typically show an increase in motor performance, including enhancements in speed, accuracy, and endurance, around age 14. However, the changes in motor performance in girls are highly variable and are influenced by a complex interaction of physical and social factors, such as their musculoskeletal development, onset of menses, personal interests, motivation, and participation in physical activities.¹⁷

An adolescent finds security and social confidence in fitting within the "norm" for physical development, and perceived physical competency in activities such as sports builds self-esteem, particularly for adolescent boys. Self-confidence in early maturing teens benefits from enhanced physical performance and enhanced social status. However, expectations of coaches, parents, and peers to excel at sports can add unwelcome pressure and anxiety. These adolescents are more concerned with

being liked and are likely to adhere to rules and routines. Adolescents who achieve the "desired standard" for physical appearance or level of physical performance (e.g., high school sports teams with high visibility such as football, cheerleading, or basketball) receive validation and approval from their peers and from adults. During adolescence, early-maturing boys are reportedly more popular, described as better adjusted, more successful in heterosexual relationships, and more likely to be leaders at school. Conversely, late maturing boys are reported to feel self-conscious about their lack of physical development.⁴⁵

Physical Activities and Growth: Teenagers with Disabilities

Physical activity is important for the health of all teens, including individuals with physical, emotional, or cognitive disabilities. Participation in physical activities maintains functional mobility, enhances well-being and overall health, and provides opportunities for social interaction with peers. However, compared with teens without disabilities, adolescents with disabilities are less likely to engage in regular physical activity.⁴⁷ For example, adolescents with cerebral palsy report walking less than they did as children.²

Scholars have frequently reported that physical functioning (e.g., mobility) deteriorates in adolescents with congenital physical disabilities because of secondary musculoskeletal impairments associated with adolescent growth.^{2,110} These secondary impairments include an inability of muscles to lengthen in proportion to bone growth, deterioration of joint mobility because of contractures, fatigue, overuse syndromes, obesity, and early joint degeneration. However, evidence does not support that such deterioration in performance is inevitable.⁹² Studies have shown maintenance or improvement in teens with disabilities who engage in physical fitness or therapy programs.^{3,92} Activity and exercise programs have resulted in adolescents' improving and maintaining gross motor function and walking speed. The achieved independence promotes self-efficacy.⁶⁴ For example, Darrah et al.²⁴ reported that teens with cerebral palsy who participated in a community-based fitness program showed significant gains in strength and reported improved psychosocial skills at school.

Occupational therapists take an active role in assisting teens to identify opportunities for physical activity within supportive environments (e.g., teams and physical fitness programs that accommodate and welcome adolescents with disabilities). Occupational therapists work with the teen's education team to facilitate inclusion in junior high and high school sports and fitness programs as specified as goals in a teen's individual education program. Physical activities can also include programs outside of school, such as summer camps and community activities. All such activities strengthen occupational performance skills and promote physical and emotional health.

Physical growth in adolescents with disabilities can lead to performance difficulties that require occupational therapy interventions. For example, changes in height and weight often require reassessment at the level of client factors (e.g., positioning, balance, strength, and coordination) that affect clients' occupational performance and activities of daily living (ADLs). Clients may need new or modified assistive devices or mobility aids (e.g., a wheelchair); they may also need new adaptive strategies, strengthening, and endurance training to ensure full participation in their occupations. With new environmental and

activity demands,¹ such as transitioning between classrooms in high school, some teens elect to conserve their energy and use a wheelchair instead of crutches or replace a manual chair with a powered chair.

Teens with progressive disorders (e.g., spinal muscular atrophy, Friedrich's ataxia, and muscular dystrophy) may require ongoing therapy as their functional abilities deteriorate. For example, boys with Duchenne's muscular dystrophy, the most common type of muscular dystrophy, use wheelchairs by early adolescence for functional mobility because of their progressive muscle weakness. Their ability to use their hands and fingers for eating, writing, and keyboarding becomes weaker throughout adolescence. Respiratory and trunk muscles become progressively weaker, and scoliosis and other skeletal deformities, including joint contractures at the ankles, knees, elbows, and hips, are common. With these adolescents, occupational therapists have an active role in facilitating adaptation to the progressive loss of motor function. Often they implement compensatory strategies such as wheelchair seating to maintain skeletal alignment, splinting to prevent deformities, and assistive technology (e.g., voice recognition software for computers) to maintain occupational performance.

Primary caregivers must also adjust to the physical growth and physiologic maturation of the adolescent. Adolescence can be challenging, especially for parents and caregivers of adolescents with moderate to severe physical disabilities or intellectual disability because of the continued and, at times, increased levels of care required. For example, transferring small children into and out of vehicles, lifting them into the shower, and dressing them are relatively easy. As the adolescent grows and gains weight, these caregiving tasks become more difficult. Significant household modifications may be needed to accommodate to the changes, and additional adapted equipment, such as the use of a commode chair or hoists for transfers, may be required for basic ADLs.

In other situations, such as when an adolescent is developmentally disabled, the family's challenge is to encourage more autonomy and independence in self-care to prepare for a transition to semi-independent settings such as a group home. This situation can require that parents reduce supervision and the adolescent develop independence in new self-care routines, such as shaving or managing menses.

Although the occupational therapist effectively addresses practical needs with adolescents and parents, it is equally important that the therapist be aware of the emotional adjustment for parents. With each new developmental stage that has a universally recognized marker of progress (e.g., going to junior high school, first date, learning to drive), parents may revisit their grief as they adapt to the realization that their child may not have the opportunity to enjoy many of these activities. Adolescence can heighten parents' awareness of the barriers and limitations that exist for their children.⁵² An effective, empathetic occupational therapist is sensitive to the meaning of adolescence for teens and their families and acknowledges the experience and concerns that this period brings.

Puberty

Puberty is the term used to define the maturation of the reproductive system. The onset of puberty has typically been viewed

as the marker that indicates the adolescent developmental stage; however, studies show that puberty may and does occur in preadolescence.⁴³ During puberty, primary and secondary sex characteristics develop in conjunction with significant physical growth. This period involves both biologic and psychosocial development. A complex interaction/feedback loop involving the pituitary gland, hypothalamus, and gonads (ovaries in females and testes in males) controls biologic development. In healthy adolescents, full sexual development may vary 3 years from the average age. The average age at onset of puberty for American girls is 8 to 13 years, with occurrence of the first period (menarche) between 12 and 13 years of age.^{8,83} For boys, puberty generally begins later than it does in girls, on average between 11 and 12 years of age.

Changes in the sex organs involved in reproduction (e.g., menarche in girls and the growth of penis and testicles in boys) are the hallmark of puberty. In girls, race, socioeconomic status, heredity, and nutrition influence the time of menarche. Ovulation usually occurs 12 to 18 months after the onset of menarche.¹⁰⁰ Breasts, areolar size, and adult pubic hair patterns develop over a 3- to 4-year period. This is also a period of peak growth in height, and a girl usually reaches her full height 2 years after she begins menstruating.

Puberty has additional challenges for adolescents with developmental and physical disabilities. Minimal information about puberty in this population is available to guide these adolescents, their caregivers, or health professionals.⁹⁸ Some research suggests that in girls with moderate to severe cerebral palsy, sexual maturation begins earlier or ends much later than it does on average in the general population.¹²⁸ A retrospective study involving women with autism spectrum conditions reported menarche either 8 months earlier than is typical (i.e., around the age of 13 years) or later.⁶⁶

In boys, development of primary sex characteristics, such as an increase in the size of the testicles and the penis (length and circumference), coincides with overall physical growth. Changes include growth of the larynx, causing a deepening of the voice, and the ability to obtain an erection and ejaculate. First ejaculations (spermarche) occur on average between the ages of 12 and 13 years, but the seminal fluid does not contain mature sperm until later (around age 15). In this process, referred to as adrenarche, the adrenal glands are largely responsible for the secondary sex characteristics such as the growth of axillary and pubic hair, axillary perspiration, and body odor. Also, many adolescents, especially boys (70% to 90%), develop acne because of the effect of testosterone.^{41,88}

For adolescents with disabilities, puberty can present additional practical and psychosocial issues. For example, misperceptions exist about the capacity of an adolescent with a disability to be in a sexual relationship, experience sexual desire, and reproduce successfully.⁴⁴ Many adolescents with disabilities report that others ignore or avoid their emerging sexuality. Consequently, they receive minimal education about contraception or sexually transmitted diseases or how their disability may affect their sexuality or reproductive capacity.^{44,62} Sexual development and the individuation process can be difficult for parents, especially when the child requires extensive caregiving.⁶² Adults with disabilities describe the ambivalence and difficulties that their parents had in acknowledging them as sexual beings.^{48,114} Mary Stainton poignantly describes the demands associated with managing her menses, the emotional

strain this task posed for her mother, and the decisions that denied her womanhood. In the following excerpt, she describes her mother's response to her menses: "Frustration ripped through her as she cleaned between my legs and pulled up the Kotex pad. She felt she constantly needed to be with me when I went to the bathroom. I felt guilty for making a mess: for bleeding at all."¹¹⁴ Her menarche was not celebrated as a coming of age as a woman; instead, she writes, "Around the time I was 12 or 13, we started talking about options. She [her mother] took me to doctors. I was put on the pill, then, given shots to stop or at least curtail my menstrual flow. A normal body process was now a huge problem, we had to control."¹¹⁴

A meta-analysis of 36,284 adolescents in the seventh through twelfth grades with visible (e.g., physical) and nonvisible (e.g., deafness) disabilities found no differences between adolescents with or without disabilities with respect to the proportion who have had intercourse, age at first sexual experience, pregnancy, contraceptive use, or sexual orientation.¹¹⁹ However, a significant number of girls with invisible conditions reported a history of sexual abuse. A similar finding was reported in a study of children and adolescents with mobility impairments in which more girls with visible conditions reported a history of a sexually transmitted disease.⁵⁷ The conclusion drawn in these studies is that adolescents with chronic conditions and disabilities are at least as sexually involved as other teens. However, these teens are significantly more likely to be sexually abused.

Occupational therapists working with adolescents with disabilities and chronic conditions need to be receptive to teen-initiated discussions and open to dialog with adolescents and their parents on topics ranging from physical development, sexual expression, and contraception. They also need to be aware of signs of sexual abuse.

Psychosocial Development of Puberty and Physical Maturation

Adolescents regard the physical changes in their bodies and their emerging sexuality with a combination of anxiety and pride. These changes can cause confusion, excessive anxiety, or emotional turmoil. With changes in physical stature and the development of secondary sex characteristics, physical appearance becomes increasingly important. Sexuality and the development of healthy relationships are critical to positive personal adjustment.⁴⁹ How an adolescent views his or her own physical and sexual development influences self-esteem.¹⁰⁷ Adolescence involves integrating these significant physical and physiologic changes into a healthy self-concept that includes a positive body image (Table 4-1).

Body image, a dynamic perception of one's body, affects a person's emotions, thoughts, and behaviors and influences both public and intimate relationships.⁹⁷ Adolescents need support to learn about their bodies and to understand that their feelings and thoughts about their bodies are universal among their peers. Such support significantly reduces the anxiety associated with physical and sexual development. Support from family and friends and the availability of information positively influence adolescents' adjustment to their bodies' physical and physiologic changes.

Self-esteem, self-worth, and the perceived evaluations of others influence perceptions of and attitudes toward one's

TABLE 4-1 Normal Development of Body Image

Stage of Adolescence	Healthy Behaviors and Concerns
Early adolescents	Are preoccupied with self Are self-evaluative about their attractiveness Make comparisons between their own body and appearance and that of other teens Have an interest and anxiety about their sexual development
Middle adolescents	Have achieved pubertal changes Are developing an acceptance of their bodies Are less preoccupied with their physical changes and shift their interest to their appearance, grooming, and "trying to be attractive" Are more apt at this age to develop eating disorders and other body image-related disorders (e.g., anorexia nervosa or body dysmorphic disorder)

Modified from Radizik, M., Sherer, S., & Neinstein, L. (2002). Psychosocial development in normal adolescents. In L. S. Neinstein (Ed.), *Adolescent health: A practical guide* (4th ed.). Philadelphia: Lippincott Williams & Wilkins.

body.²² Teenage girls pepper their conversations with remarks about their appearance (e.g., "Do you think my thighs are too big?" or "I'm too fat."). Negative body image is associated with both low self-esteem and mental health problems, including anxiety, depression, and eating disorders, all disorders with a peak onset in adolescence. It is estimated that 50% to 80% of girls, especially in early adolescence, are dissatisfied with two or more aspects of their appearance.⁴² Studies show that body dissatisfaction is universal. Girls of all ethnicities express a desire to be thin.⁷⁴ Peer attitudes and perceptions in relation to body image concerns are a factor among girls' weight-related behavior. Peer weight-related attitudes and behaviors in early adolescence have been shown to be predictive of individual girls' level of body image concern, dieting, extensive weight loss behaviors, and binge eating.⁵⁶

Boys also compare their internalized perceptions of masculinity with the image they see of themselves in the mirror. This ideal body image is defined by characteristics such as height, muscle mass, broadness of the upper body, and strength.¹³⁵ Boys dissatisfied with their bodies generally want to gain weight and develop muscle mass in their upper body (i.e., shoulders, arms, and chest),³⁷ and such desires can lead to excessive weight training and use of steroids. However, concerns about being overweight are also becoming prevalent among boys.³⁶ Research shows that by 18 years of age, boys and girls are more satisfied with their bodies than they were in early adolescence and mid adolescence.³⁴

Socially constructed views of femininity and masculinity affect how a teenager develops a body image. One powerful

social influence is the media (e.g., advertisements, magazines, music videos, video games, movies, and the fashion industry). The media markets a physical appearance that represents little of the diverse population of teens in the United States. They portray an “ideal” that bears little resemblance to the “average” teen. It is not surprising that many adolescents are critical of their bodies.¹⁶ When girls compare themselves with the media’s images of slim, large-breasted, small-waisted women with perfect skin or when boys try to measure up to the lean, strong, attractive, acne-free men, they inevitably feel inadequate compared with these illusions of perfection. The media’s portrayal often includes proximity of equally “perfect” members of the opposite sex, and possessions such as cars and consumer goods equating attractiveness with success.²²

Because the process of healthy body image development involves comparison with peers and the media’s “ideal” image, one might expect that developing a healthy body image would be even more challenging for adolescents with visible disabilities or conditions (e.g., spina bifida, cerebral palsy, Tourette’s syndrome, or congenital limb abnormalities). However, the research in this area is contradictory. Stevens et al.¹¹⁵ reported no significant differences between adolescents with and without disabilities in self-esteem or satisfaction with physical appearance, and Meeropol⁸⁰ found that most adolescents with spina bifida and cerebral palsy surveyed felt they are attractive to other people. However, other studies report that adolescents with physical disabilities view themselves as different from their peers and unattractive to others.⁵⁰

Body image can also be difficult for a teen who develops a disorder or illness (e.g., cancer, diabetes, epilepsy) in adolescence; their previously healthy bodies “fail” them. Research indicates that teens experiencing long-term effects (e.g., impaired organ function, scars, skeletal deformities) from serious illness have a negative body image and impaired emotional functioning.¹⁴

As with physical growth and development, sexual maturation has social implications. Adolescents who outwardly appear sexually mature and seem older than their actual age can encounter demands and expectations (including sexual) that they are not psychologically equipped to navigate. In contrast to boys, early-maturing girls often demonstrate lower self-esteem and poor self-concept associated with body image, and they engage in more risky behaviors (e.g., unprotected sex).¹²⁶ They also experience more psychological difficulties (e.g., eating disorders and depression) than more slowly developing girls do. They are more likely to have lower grades, engage in substance abuse (alcohol, drugs), and have behavioral issues. Late maturation in boys is associated with inappropriate dependence and insecurity, disruptive behaviors, and substance abuse.⁴¹ Some late-maturing boys find validation in academic pursuits and nonphysical competitive activities, especially boys from middle and upper socioeconomic status families that value such achievements.⁴⁵

Adolescents use appearance to express their individuality or make a statement of belonging (e.g., fashionable clothes similar to those of friends, gang colors and insignia). Since the 1990s, body piercing and tattoos have emerged as forms of self-expression among adolescents. Whatever the “body project” (e.g., clothes, jewelry, hairstyles, make-up, tattoos), these activities related to appearance are within the adolescent’s control and are consistent with practices within Western countries.¹²

Experimentation with appearance is healthy for most adolescents and is integral to developing self-identity. It promotes a level of satisfaction and connectedness with peers. However, adolescents with psychological difficulties may abuse their bodies by engaging in activities such as cutting, excessive piercings and tattoos, or extreme weight loss; others adopt clothing and make-up that marginalizes them. All such actions further alienate vulnerable teens from mainstream society. Piercing and tattooing of minors is regulated in many states, and the struggle for autonomy can be an act of rebellion or a public display of “I own my body; I can do to it what I choose.”¹²

Adolescents who have a disability may depend on others for their self-care, may not have their own discretionary money from part-time work, and may lack independence in mobility. Their opportunities to participate in activities of self-expression, experimentation, and expressing personal control are limited. For example, adolescents with disabilities are not always encouraged or offered opportunities to experiment with appearance (clothes, hairstyles) or interests that differ from those sanctioned by family and caregivers. Sometimes, it is more comfortable for parents and others to prolong the childhood of teens with disabilities. Because making choices about appearance and experimentation are part of the adolescent experience that contributes to self-identity, self-esteem, and healthy body image, occupational therapists have a role in working with both teens and parents as they navigate these adolescent changes.

Cognitive Development

Cognition is the term used to define the mental processes of construction, acquisition, and use of knowledge as well as perception, memory, and use of symbolism and language.⁹¹ Advances in magnetic resonance imaging have enhanced understanding of the neurobiologic processes that enable these higher level cognitive functions and the changes that occur in the brain during adolescence. For example, the prefrontal lobe matures later than other regions, and its development is reflected in increased abilities in abstract reasoning as well as processing speed and response inhibition.¹³³

The quality of an adolescent’s thinking changes during adolescence. Piaget⁹⁶ referred to this cognitive development as logical thinking (formal operations), which involves functions such as symbolic thought and hypothetical-deductive reasoning.^{60,135} Adolescents’ ability to think becomes more creative, complex, and efficient in both speed and adeptness. Thinking is more thorough, organized, and systematic than it was in late childhood, and problem solving and reasoning become increasingly sophisticated. In developing the capacity to think abstractly, adolescents rely less on concrete examples. For example, hypothetical-deductive reasoning does not require actual situations. Instead, a person identifies and explores many imagined possible outcomes to determine the most likely outcome to a particular situation or problem as well as the relationship between present actions and future consequences. Hypothetical-deductive reasoning is essential for problem solving and for the process of arguing. Preadolescents have difficulty considering possibilities as generalizations of actual real events, whereas adolescents appreciate that the actual world is one of many possibilities.⁹¹

The development of cognitive abilities enables adolescents to achieve independence in thought and action.¹⁹ They develop a perspective of time and become interested in the future. Cognitive development is also central to the development of personal, social, moral, and political values that denote membership in adult society. The development of moral and social reasoning is seen in the adolescent's newly acquired ability to deal with concepts such as justice, truth, identity, and a sense of self.⁹¹

Because of this cognitive development, teens come to understand the consequences of their actions and the values influencing their decision making. They also become future oriented. They increasingly evaluate their behaviors and decisions in relation to the future they desire. The impulsive behaviors of a middle school or early high school student are replaced by decisions and actions that anticipate the consequences. This emerging self-regulation means that the adolescent gains the ability to control emotions and to moderate behavior appropriately relative to both situation and social cues.

Adolescents with cognitive impairments have difficulties comprehending the consequences of their actions and moderating their behavior accordingly. Because of the lack of hypothetical-deductive reasoning, problem solving in relation to future, or responsiveness to subtleness of social cues, self-evaluation that typically informs judgment is lacking. Instead, their impulsive decisions and actions are more consistent with a cognitive level arrested at the preformal stage, and their occupational performance skills are limited. Adolescents with autism spectrum disorders, teens with developmental disabilities whose abilities are classified in the moderate to higher functioning levels of intellectual disability, and teens who have had a traumatic brain injury at this stage may find that the academic demands of high school markedly exceed their abilities. Their peers' increasing psychosocial maturity and independence accentuate the long-term implications of their cognitive and social disabilities. At this phase of their education, they often transition into prevocational programs and programs that better align with their skills and facilitate an optimal level of independence in adulthood.

Psychosocial Development

It is useful to view adolescent psychosocial development in three phases (Table 4-2). The middle years of adolescence are the most intense period of psychosocial development. In this phase, peers displace parents as the significant influence in the adolescent's life. Conformity with peer groups is desirable, and the opinions of friends and peers matter.

Late adolescence is about consolidation; adolescents ideally are developing into responsible young adults who can make decisions, have a stable and consistent value system, and can successfully take on adult roles, such as an employee or a contributing member of the community. A stable, positive sense of self and self-knowledge of ability enable late adolescents and young adults to establish healthy relationships.

Difficulties navigating psychosocial development can have adverse health and social outcomes, such as psychological problems (e.g., eating disorders, depression, substance abuse) and psychopathology with behavioral problems (e.g., oppositional defiance disorder, criminal activity). Psychological problems do

not result in difficulties in adult life, although disorders can increase the vulnerability for further psychological and life challenges. However, some adolescent disorders, such as conduct disorder, are associated with adverse outcomes (e.g., dropping out of school, lower employment rates, substance abuse).^{21,79}

Search for Identity: Identity Formation

Research suggests identity is a key variable in adolescent development.⁸¹ Self-identity has two components. One is an individualistic component: Who am I? A healthy individualistic sense of identity is an internalized, stable self-concept from which a person interacts effectively with the physical and social world around them.⁷⁶ The other component of identity is contextual: Where and how do I fit in my world?⁶⁹ The contextual component is the position from which a person understands his or her values, beliefs, interests, and commitments to a job or career and social roles, such as daughter or friend.⁷⁶ The contextual dimension of self-identity is more visible to others and is shaped by external influences (i.e., peers, family, and society) (Box 4-2).

Identity formation is regarded as the optimal outcome of the "psychosocial crisis" and a crucial psychosocial task during adolescence. The hallmark of identity formation is developing problem-solving strategies, a sense of responsibility for one's actions, a capacity to self-regulate emotions and behaviors, and commitment to a set of values and beliefs congruent with the social norms and values of one's community. Exploration and experimentation is believed to lead to a positive sense of identity (i.e., an investment in a set of values, beliefs, interests, and an occupation).³⁶ In this complex process, adolescents identify

BOX 4-2 Being Disabled Is Not an Identity

Social acceptance is highly valued and important to identity. Adolescents with disabilities or chronic health disorders have additional challenges. Teens are acutely self-aware and want to be "like everyone else," that is, like other teens in their social groups. Teens with disabilities or health conditions must also constructively integrate their disabilities or health problems into a healthy self-concept that does not make their disabilities or health problems their identities. Adults (e.g., teachers, occupational therapists) and friends in their lives who refer to them as "disabled teens" or by any other label (e.g., autistic, disruptive) reinforce and shape an adolescent identity based on the disability rather than on the adolescent's unique qualities (e.g., personality characteristics, interests, values, and abilities).

The occupational therapist has a role in:

- Modeling appropriate use of first-person language. For example, rather than saying, "Steve, who has arthrogryposis ..., " it would be preferable to identify Steve by qualities or characteristics other than his disability (e.g., "Steve with red hair ...").
- Avoiding the use of emotive language that marginalizes and assumes that disability is always a negative experience (e.g., "Lisa, who suffers from cerebral palsy. ").
- Assisting teens to identify abilities, interests, and positive qualities that will be the primary characteristics of their identity.

TABLE 4-2 Typical Characteristics of Psychosocial Development

Stage of Adolescence	Typical Psychosocial Development Characteristics
Early adolescents	Are engrossed with self (e.g., interested in personal appearance) Separate from parents emotionally (e.g., reduced participation in family activities) Display less overt affection to parents Comply less with parents' rules or limits as well as challenge other authority figures (e.g., teachers, coaches) Question adults' opinions (e.g., are critical of and challenge their parents' opinions, advice, and expectations); begin to see parents as having faults Have changeable moods and behavior Have mostly same-sex friendships with strong feelings toward these peers Demonstrate abstract thinking Fantasize idealistically about careers; think about possible future self and roles Need privacy (e.g., they have their own bedrooms with doors closed, write in diaries, and have private telephone conversations) Become interested in experiences related to personal sexual development and exploration of sexual feelings (e.g., masturbation) Self-consciously display modesty (blushing, awkwardness about self and body) Display an ability to self-regulate emotional expression and can limit behavior but do not think beyond immediate want or need and are susceptible to peer pressure May experiment with drugs (cigarettes, alcohol, and marijuana)
Middle adolescents	Continue to move toward psychological and social independence from parents Increase their involvement in peer group culture, displayed by adopting peer value system, codes of behavior, style of dress, and appearance, all of which demonstrate in an overt way individualism and separation from family Are involved in formal and informal peer group activities, such as sports teams, clubs, gangs Accept body development, engage in sexual expression, and experiment with sex (e.g., dating, sexual activity with partner) Explore and reflect their feelings and feelings of other people Become more realistic in career/vocational aspirations Show increased creative and intellectual abilities and interest in intellectual activities and capacity to do work (e.g., mentally and emotionally) Use risk-taking behaviors to minimize or alleviate feelings of omnipotence (sense of being powerful) and immortality (e.g., reckless driving, unprotected sex, high alcohol consumption, drug use) Experiment with drugs (cigarettes, alcohol, marijuana, and other illicit drugs)
Late adolescents	Become more stable as the sense of self becomes stable in opinions, values, and beliefs Strengthen relationships with parents (e.g., seek out and value parental advice and assistance) Increase their independence in decision making and the ability to express ideas and opinions Have increased interest in their future and consider the consequences of current actions and decisions on the future, leading to delayed gratification, setting personal limits, monitoring their own behavior, and reaching compromises Resolve their earlier angst regarding puberty, physical appearance, and attractiveness Feel diminished peer influence and increased confidence in personal values and sense of self Show a preference for one-to-one relationships and start to select an intimate partner Become realistic in vocational choice or employment, establishing worker role and financial independence Develop a value system (e.g., moral, belief system, religious affiliation, and sexual values) that becomes increasingly stable

Data from Radzick, M., Sherer, S., & Neinstein, L. (2002). Psychosocial development in normal adolescents. In L. S. Neinstein (Ed.), *Adolescent health care: A practical guide* (4th ed.). Philadelphia: Lippincott Williams & Wilkins; and American Academy of Child and Adolescent Psychiatry. <<http://www.aacap.org/publications>> Accessed September 7, 2004.

their spiritual and religious beliefs; intellectual, social, and political interests; and a vocational or career path. It also involves exploration of friendships and intimate relationships, gender orientation (i.e., awareness and acceptance of one's male or female identity and sexual orientation), culture, ethnicity, and perceptions of one's personality traits (e.g., introverted, extroverted, open, conscientious).

To achieve a sense of identity, adolescents daydream and fantasize about their real and imagined selves. These images energize and motivate. Adolescents actively attempt to make sense of their world and find meaning in what happens to them

and their life experiences by exploring different roles, expressing a variety of opinions and preferences, making choices, and seeking to interpret their experiences. They engage in various activities and try different lifestyles before settling on a viewpoint, set of values, or life goals. Adolescents are reflective and introspective. They spend time thinking about themselves, making social comparisons between self and peers, and evaluating how others view them. They set goals, take action, learn to resolve conflicts and problems,⁶⁹ and, through this process, identify what makes them individual and how to interact effectively with the world with a stable sense of self.

Adolescents' behaviors, thoughts, and emotions can seem contradictory, especially between ages 13 and 15. For example, a teen might have body piercings, break parental rules, and attend school erratically but at the same time responsibly hold a job and dress appropriately for the work setting. Similarly, adolescents may choose healthy behaviors such as vegetarianism or sports participation but also experiment with alcohol, drugs, or tobacco. Adolescents can be fickle and contrary; they may be interested in different religions and political systems, arguing passionately with their parents on political views or outwardly dismissing parental values. One day they express disinterest in relationships with the opposite sex, but the next day is spent exclusively with a girlfriend or boyfriend.

Erikson^{35,36} was the first to propose that acquiring a sense of identity is a critical task of adolescence characterized by one of two states, *identity resolution* or *identity confusion*. This theory of how identity develops through recognition of one's abilities, interests, strengths, and weaknesses by the self and others continues to be the basis of how identity formation is viewed in research and clinical practice. Significantly expanding on Erikson's developmental theory of adolescents, Marcia⁷⁶ in his *identity status model* argues that identity development is understood by examining the extent to which an adolescent explores and commits to an identity in a variety of life domains, such as occupation, religion, friendships, gender roles, and intimate relationships. *Exploration* and *commitment* are two key components of this process that lead to identity formation. Exploration is when adolescents actively consider and investigate a variety of alternatives in many domains of their lives. By exploring and evaluating options and making choices, they identify their preferred choices and commit to them. The commitment to their choices becomes a stable investment in values, beliefs, goals, politics, and interests that define their sense of self and their way of seeing the world. Marcia⁷⁶ describes four states of identity formation: *identity diffusion*, *moratorium*, *identity foreclosure*, and *identity achievement*. Other developmental theorists have criticized Marcia, claiming his description of identity as "states" implies the existence of a final ideal state of identity formation, rather than the reality one observes among adolescents, which is a complex ongoing process of negotiation, adaptation, and decision making that extends into and throughout adulthood.

The identity states model continues to be used and can be helpful when working with adolescents to understand behaviors. *Identity diffusion*, most frequently associated with early adolescence, is a state characterized by an ill-defined sense of identity. In this state, adolescents have little or no interest in exploring their options. They have not made any commitments to choices, interests, or values and have little interest in the question, "Who am I?"⁹ However, adolescents who continue to experience identity diffusion into their middle and late teen years can have difficulty meeting the psychosocial demands of adolescence. They may demonstrate an "I don't care" attitude of impulsivity, disorganized thinking, and immature moral reasoning resulting in poor choices in many domains of their lives.²⁰ Identity diffusion is associated with lower self-esteem; a negative attitude; and dissatisfaction with life, parents' lifestyle, and school.^{20,59} In this state, adolescents seldom anticipate and think about their future and have difficulties meeting day-to-day demands of life, such as completing schoolwork or participating in sports or extracurricular activities. Consequences of

prolonged identity diffusion can be unhappiness and loneliness, and finding employment can be a problem later because of a lack of exploration of interests and awareness of personal strengths.⁸

Moratorium is a state in early and middle adolescence that involves actively exploring and developing a sense of identity. In a state of identity diffusion, adolescents avoid or ignore exploring and experimenting, whereas the opposite mindset characterizes moratorium. Developing one's identity is a project that is pursued vigorously. Teens in moratorium (searchers) openly investigate alternatives. They strive for autonomy and a sense of individuality. Prolonged moratorium that extends into late adolescence or early adulthood is problematic. Indecision about life goals, course of study, or future career can cause anxiety, self-consciousness, impulsiveness, and depression.²⁰

Identity foreclosure is associated with achieving a sense of identity prematurely without having engaged adequately in self-exploration and experimentation. An adolescent making premature decisions about career, relationships, and interests characterizes foreclosure by committing to an identity early in adolescence.⁶⁸ Adolescents demonstrating identity foreclosure commonly accept their parents' values and beliefs and follow family expectations regarding career choices without considering other possibilities, personal interests, or possible options. Such adolescents are conventional in their moral reasoning, less autonomous than their peers, less flexible in their thinking regarding opinions about what is "right," and more comfortable with a structured environment.⁶⁸ Research has found foreclosure is associated with approval-seeking behaviors, avoidance of new experiences, and a high respect for authority. These teens are less self-reflective, less intimate in personal relationships, and less open to experiences than peers, but foreclosure on identity makes these adolescents less anxious than many of their peers (see [Box 4-2](#)).²⁰

Identity achievement, also referred to as identity formation and described earlier, occurs in the latter years of adolescence. Gains in identity achievement are often seen in college years because students have opportunities to explore career choices, ideas, and different lifestyles and cultures and commit to interests, values, gender orientation, political views, careers or jobs, and moral stances after exploring the possibilities. Identity achievement represents coherence between a person's identity and his or her self-expression and behaviors and is associated with autonomy and independence, especially in decision making.^{68,107}

More recent thinking on identity development is moving away from viewing it as a progressive process from identity diffusion leading to identity achievement. Meta-analysis of longitudinal identity research strongly supports a pattern of continuity as well as identity progression as a lifelong process that extends into adulthood.^{68,81} Developmental researchers propose that breadth and depth of exploration contribute differently to identity achievement. Breadth in exploration has been found to be negatively associated with making commitments to choices in an active manner, whereas depth of exploration is positively associated with actively maintaining a commitment to existing choices.⁸¹ Although this concept is similar to Marcia's model, the dual-cycle model of identity formation assumes adolescents have more stability of identity than previously thought. It is proposed that we view adolescents as starting with a set of commitments, not yet strongly established, that

are related to their existing ideological and personal identities. The process is one of gradually working toward making commitments to the values, interests, and occupations that will be the basis of one's identity.⁸¹

Self-Identity and Well-Being

Adolescents' quest for self-identity is the material of films, TV shows, and literature, and the "angst" of adolescence is found in lyrics of popular music targeted at this age group and is reflected in Facebook and YouTube postings and blogs. However, research suggests that the reality is less dramatic, and most adolescents navigate this psychosocial developmental stage with minimal distress.⁶⁰ Adolescents who have a stable sense of identity are able to adapt and respond to personal and social demands without undue anxiety. Studies show that adolescents who are committed to a sense of identity (identity achiever) report higher levels of well-being.⁸¹ A relatively stable sense of self is associated with self-esteem and efficacy in one's abilities. Adolescents who have a commitment to their values, occupations, and interests are less self-absorbed, less self-conscious, and less susceptible to pressure from peers. They can be open and creative in their thinking and have a capacity for intimacy. They are able to self-regulate emotions, and they demonstrate mature (postconventional) moral reasoning.

Adolescents who are unable to develop a stable and distinct sense of self may have difficulties, such as a lack of confidence and lower self-esteem. They are more likely to experience depression or anxiety and report a poor sense of well-being than their peers who demonstrate strong commitments.⁸¹ Adolescents who continue to search and fail to make a commitment are not adapting or developing lifelong skills required for the future. As adults, they may have problems with work, establishing and maintaining intimate relationships, and meeting the responsibilities of life, such as parenting or being a contributing member of their community. Identity formation enables adolescents and young adults to integrate contradictory aspects of the self into a global self-concept, which enables them to meet different situational (contextual) demands.

The study of identity development continues to expand interdisciplinary perspectives, including the effect of external barriers and culture on adolescents' exploration and commitment to identity.¹³¹ Occupational therapists observe identity exploration in the activities adolescents choose, the roles they take on, and the desires they express about their futures. Occupational therapists promote psychosocial development, including identity formation, by emotionally supporting adolescents, working with them to develop abilities in their chosen activities and roles, and offering opportunities for self-directed exploration through participation in age-related activities. Occupational therapy sessions develop and explore work and leisure activities, promote the acquisition of social and life skills, promote participation and self-determinism, and address barriers to community access. Occupational therapy sessions can create an environment that supports identity achievement.

Sexual Orientation: Gender Identity

Sexual orientation refers to an individual's pattern of physical and emotional arousal toward other persons of either the

opposite or the same sex.³⁹ Awareness of sexual orientation generally occurs during adolescence, a time of sexual exploration, dating, and romance. Most adolescents identify their sexual orientation as heterosexual, although about 15% of teens in mid-adolescence experience an emotional or sexual attraction to their own gender. Approximately 5% of teens identify their sexual orientation as gay or lesbian,¹⁰² although they often delay openly identifying their sexual orientation until late adolescence or early adulthood. Reasons for this delay include a lack of support among their peers and experiences of verbal and physical harassment in high school.^{39,59} Openness and a willingness to discuss emerging sexuality with all adolescents is important for all occupational therapists working with them. Occupational therapists need to use gender-neutral language (e.g., partner rather than boyfriend or girlfriend; protection rather than birth control), inquire if they suspect violence in intimate relationships, and provide nonjudgmental support to adolescents as they develop their sexuality and sexual orientation.³⁹

Self-Concept and Self-Esteem

As adolescents define their identity, their self-concept (the feelings and perception of one's identity consisting of stable values, beliefs, and abilities) becomes differentiated.¹⁰⁰ Self-concept is multifaceted. It includes self-acceptance, which is associated with many areas of the adolescent's life (e.g., sports and athletic competence, parent and peer relationships, academic competence, social acceptance, and physical appearance). In adolescence, self-concept develops from a self-absorbed description based on social roles and personality characteristics in early adolescence to an integrated self-concept that reflects development in cognition, moral reasoning, and social awareness.

A significant aspect of self-concept is self-esteem, the global self-evaluation of values and positive and negative qualities (i.e., how a person feels about oneself). In early adolescence, self-esteem tends to decline, partly because of an increased self-awareness and a tendency to compare oneself with the ideal and realize a discrepancy between one's actual self and desired ideal self.¹⁰⁰ However, self-esteem usually improves throughout adolescence. Table 4-3 provides an outline of the behavioral characteristics of positive and negative self-esteem throughout adolescence. Persistent low self-esteem is associated with serious psychological difficulties (e.g., depression; anxiety disorders such as social phobia, bulimia, and self-abuse). Self-abuse may take the form of cutting or harming oneself, excessive use of alcohol and drugs, or engaging in risky behaviors such as unprotected sex. Behaviors such as frequent negative self-critical statements, fears of anticipated failure, and difficulty coping with perceived failure also indicate poor self-esteem. Teens with poor self-esteem are hypersensitive to negative comments from peers and adults alike and to a lack of responsiveness or overreaction from others, and they can be defensive to constructive criticism. In a desire to belong or "fit in" by seeking social approval, they are more susceptible to peer-group influence.

Factors contributing to self-esteem of adolescents with disabilities are similar to factors that affect teens without disabilities, especially the value-laden self-assessment of one's own attributes and limitations.⁵ A stereotypic view of adolescents with disabilities infers that self-esteem is low. However, a

TABLE 4-3 Behavioral Indicators of Self-Esteem

Self-Esteem	Behavioral Indicators
Teen with positive self-esteem	- Expresses opinions - Mixes with other teens (e.g., interacts socially with groups of teens) - Initiates friendly interactions with others - Makes eye contact easily when speaking - Faces others when speaking to them - Observes comfortable, socially determined space between self and others - Speaks fluently in first language without pauses or visible discomfort - Participates in group activities - Assumes leadership role among peers - Works collaboratively with others - Gives directions or instructions to others - Volunteers for tasks and activities
Teen with negative self-esteem	- Avoids eye contact - Appears overly confident (e.g., brags about achievements or skills to mask a lack of self-efficacy in performance skills) - Expresses self-criticism, makes self-deprecating comments, makes fun of self as a form of humor - Speaks loudly or dogmatically to avoid others responding - Is submissive and overly agreeable to others' requests or demands, even if he or she does not wish to do them - Gives opinions or views reluctantly, especially if it will draw attention to himself or herself - Monitors behaviors (e.g., hypervigilant of surroundings and other people) - Makes excuses for performance, seldom evaluates personal performance as satisfactory or good - Engages in putting others down, name calling, gossiping, and, at worst, bullying - Reports a lack of emotional support from parents and friends

Modified from Santrock, J. W. (2003, 2012). *Adolescence*. New York: McGraw-Hill.

meta-analysis of studies examining self-esteem in teens with minor physical disabilities reported that they had lower self-esteem about physical competencies compared with their peers without disabilities, but the effect on their general, social, and physical appearance self-esteem was only moderate.⁸² This analysis did find a relationship between the severity of physical disability and level of general self-esteem. Miyahara and Register⁸³ found that this low self-esteem was related to misunderstanding by peers and adults and poor performance that reflected lack of effort rather than disability. A study of self-esteem and self-consciousness among adolescents with spina bifida found that their perception of being treated by parents in an age-appropriate manner and parents' tolerance of social participation contributed positively to self-esteem, whereas school problems and the perceptions of disability by others contributed negatively.¹²⁷ Similarly, positive peer attitudes and inclusion contribute to an adolescent's self-esteem and sense of worth. Occupational therapists need to recognize potential obstacles to positive self-esteem and incorporate strategies and experiences that validate and facilitate self-recognition of one's strengths and abilities as part of the therapeutic process.

Adolescence and Mental Health

Mental health is defined as the "successful performance of mental functions, resulting in productive activities, fulfilling relationships with others, and the ability to change and cope with adversity."¹¹⁷ Adolescents who have good mental health generally have better physical health than peers who have poor mental health; they demonstrate positive social behaviors and are less likely to participate in risky behaviors (Box 4-3).⁶⁷

However, there is an increased vulnerability to mental health disorders in adolescence and early adulthood. Most diagnosable mental health disorders, associated with altered thinking, mood, or changes in behavior causing distress or impaired cognitive functioning, begin in adolescence, many before the age of 14. Adolescents who have mental health disorders (e.g., depression, substance abuse) are likely to have difficulties learning and developing social and life skills and are more likely than peers to engage in risky health behaviors. Engaging in risky behaviors can further heighten the vulnerability to mental health problems or are a precursor.

"The Mental Health of Adolescents: A National Profile" report estimates that 1 in 5 adolescents experiences symptoms of emotional distress and that 1 in 10 is emotionally impaired.⁶⁷ The most common disorders are depression, anxiety disorders, substance use/abuse, and attention-deficit disorder (with and without hyperactivity). The Youth Risk Behavior Surveillance System study reported that 35.9% of female and 21.5% of male high school students answered "yes" to the question "Have you ever felt so sad or hopeless every day for two weeks in a row that you couldn't do some of your usual activities?"³¹ This depression in young people (15 to 20 years of age) is often comorbid with other mental health disorders, such as addictions, anxiety disorders, and conduct disorder. Suicide, the third leading cause of death in adolescents, is significantly associated with depression. In 2011, 15.8% of high school students (ninth to twelfth grades) reported seriously considering suicide in the previous 12 months, 7.8% attempted suicide, and 2.4% required medical treatment.³¹ Although suicide attempts were more frequent among female students, especially in the ninth grade, the number of deaths among boys 10 to 14 years old

BOX 4-3 Critical Health Behaviors of American Adolescents**Alcohol Use**

Alcohol is the most widely used substance by adolescents (more than tobacco or illicit drugs).

- Typical initial drug use for boys is alcohol.
- The proportions of eighth, tenth, and twelfth graders who reported drinking an alcoholic beverage in the 30-day period before being surveyed were 10%, 26%, and 39%, respectively.
- Binge drinking has continued to decline from its peak level in the 1990s.
- Alcohol is a factor in approximately 41% of all deaths from motor vehicle accidents.

Drug Use

The annual prevalence of adolescents using any illicit drug including marijuana has continued to increase. In 2013, it increased by 1.3 percentage points (eighth, tenth, and twelfth grades combined). Marijuana use remains relatively stable. *Psychotherapeutic* (prescription) drugs are increasingly a more significant problem than in the previous decade. This trend is due in part to the fact that adolescents perceive them as safer than street drugs, and the availability of street drugs has declined.

- Among twelfth graders, 15% reported misusing prescription drugs in the previous year.
- Marijuana and alcohol use are positively correlated at the individual level.
- Rural teens have equal access to drugs as urban teens.

Tobacco Use

- Every day, approximately 4000 adolescents 12 to 17 years old try their first cigarette. Typically, initial drug use for girls is cigarettes. Lifetime prevalence for cigarette use is declining owing to fewer students initiating smoking. The 2013 prevalence was 15% of eighth graders, 26% of tenth graders, and 38% of twelfth graders.
- About one fourth of ninth through twelfth graders (18.5% of girls and 28.1% of boys) reported they smoked a cigarette or cigar or used other forms of tobacco on at least one day during the past 30 days.
- Boys are more likely than girls to have engaged in tobacco use (cigarettes, chewing tobacco, cigars, little cigars, and snuff).

Injury and Violence (Including Suicide)

- Injury and violence are the leading cause of death among youth aged 10 to 24 years: motor vehicle crashes (26% of all deaths), all other unintentional injuries (17%), homicide (16%), and suicide (13%).
- Nationwide 5.4% of students (ninth to twelfth grade inclusive) report carrying a gun; more boys than girls reported they brought their guns onto school property.
- Almost one third (32.8%) of students report being in a physical fight in the past 12 months.

Nutrition

- Healthy eating is associated with reduced risk for many diseases, including the three leading causes of death: heart disease, cancer, and stroke. In 2011, 62.3% of high school students reported eating vegetables and 64% reported eating fruit or drinking fruit juices one or more times per day during the past 7 days. Consumption was slightly higher for boys.
- Among adolescents, 19% drank a bottle, can, or glass of soda one or more times per day during the 7 days before the Youth Risk Behavior Surveillance System survey.

Physical Activity

- Nationwide, 13% of adolescents are obese, and 15% are overweight.
- The 2012 Youth Risk Behavior Surveillance System survey found 32.4% of ninth to twelfth graders had participated in a physical education class 1 or more days per week when in school.
- More than half (58.4%) participated in at least one sports team during the past 12 months.
- Approximately half of American adolescents (12 to 21 years old) are vigorously active on a regular basis. Inactivity is more common among girls (14%) than boys (7%) and among black girls (21%) than white girls (12%).

Sexual Behaviors

- Approximately 50% of high school students are sexually active; by graduation, two thirds will have had sexual intercourse.
 - Less than 2% of adolescents have had sex by age 12 years.
 - Almost 33% have had sex by age 15 years.
 - Nearly 50% have had sex by age 17 years. The average teen has his or her first sexual experience at age 17.
- The first experience was reported to be with a steady partner by 70% of girls and 56% of boys.
- Most teens used contraception the first time they had sex and continue to use conception.⁷⁸ However, European teens have higher use and use more effective methods than U.S. teens.¹⁰⁶
- Approximately half of the 19 million new sexually transmitted infections in the United States affect adolescents 15 to 24 years old. In 2007, 39% of sexually active high school students did not use a condom during last sexual intercourse.
- The teenage pregnancy rate is decreasing, most markedly between 2010 and 2011, when teen pregnancies decreased by 8%. The live birth rate was 31.3 per 1000 girls 15 to 19 years old.⁸⁶

was 2.5% higher than deaths among girls and among boys 15 to 19 years old was 3.5% higher.³¹ Programs designed to reduce suicide among adolescents offer essential resources for health care practitioners and educators working with adolescents.

Other mental health disorders include eating disorders (e.g., anorexia nervosa and bulimia), learning disorders, and behavioral disorders (e.g., conduct disorder and oppositional defiance disorder). Schizophrenia and bipolar disorder are serious but less common disorders. The onset of schizophrenia (excluding paranoid schizophrenia) in males is typically in late adolescence. Both schizophrenia and bipolar disorder have significant implications for teens because they disrupt participation in typical developmental activities, and these lost opportunities can contribute to lifelong disability.

Occupational therapists can assist with early identification of children and adolescents with mental health disorders because initially (e.g., in early adolescence) these individuals may receive therapy services for related difficulties such as learning and behavioral problems. Occupational therapists also are among the professionals involved in interdisciplinary teams providing early detection and intervention for teens with mental health disorders such as schizophrenia and bipolar disorder.

Areas of Occupation: Performance Skills and Patterns

In the American Occupational Therapy Association (AOTA) Practice Framework, activities that humans engage in are categorized into domains. These are ADLs, instrumental ADLs (IADLs), rest and sleep, education, work, play, leisure, and social participation.¹ Participation in all of these areas develops self-efficacy (confidence in one's abilities to achieve desired outcomes), peer acceptance, and promotion of social status and self-esteem. Adolescents are likely to adopt the values that are associated with the work, play, leisure, and social activities in which they participate.³² In this section, adolescent development and participation in four domains (work, IADLs, leisure and play, and social participation) are described.

Work: Paid Employment and Volunteer Activities

Work is a general term associated with a job (work undertaken as a means of earning money) or a career (an organized life path that often involves a formal occupation or vocation). Studies of working patterns in teenagers in the United States report that approximately 70% of adolescents older than age 16 work while also attending school.⁶ The age at which teens may work is 14 years; however, the hours they may work are regulated. Beyond the age of 16, teens attending school cannot work more than 4 hours on a day that they attend school and are restricted on the evening hours they may work. Although working can be beneficial for adolescents, excessive working (i.e., >20 hours a week) for high school students can be detrimental. It is associated with emotional distress, early onset of sexual activity, and substance abuse.¹¹⁸ Work takes time away from schoolwork, recreational activities, social activities, and participation in sports, and it may expose teens to work-related injuries.¹⁰³ Despite these adverse consequences, approximately 18% of high school students work 20 hours or more per week.⁹⁰

Work includes unpaid work such as volunteerism. The 2000 edition of "America's Children: Key National Indicators of Well-being" reported that 55% of high school students participated in volunteer activities. Educators and organizations such as sports teams and church groups encourage participation in community service. Similar to adults, the reasons teens cited for participating in volunteer activities included a desire to help others, social interaction, and recognition of contributions.¹⁰⁹ An adolescent's personal future goals also influence his or her participation in volunteer activities. Students with higher grade point averages and higher academic self-esteem who have plans for higher education volunteer in their communities.⁵⁸

Work (both paid and unpaid) significantly contributes to healthy adolescent development. In work settings, adolescents interact with adults on a more equal level, have opportunities to assume responsibilities and learn social behaviors, shape values, and develop knowledge of their possible preferences for an adult career/work.⁶⁵ Participating in paid employment and volunteerism also develops life and social skills beyond the work environment, such as managing money, organizing time, developing routines, developing skills in collaboration, and negotiating relationships with other people. It also provides opportunities to learn from and communicate with more diverse social and racial groups than in their family and school contexts.¹⁰³ The disposable income earned from paid employment gives some adolescents discretionary spending money and a sense of economic independence, whereas others need to work to support themselves financially or contribute to their families. Whatever the circumstances, work helps adolescents assume adultlike responsibilities.

Occupational therapy programs for adolescents focus on strategies that develop work skills and behaviors that assist in their transition from school to work. These skills and behaviors constitute the performance dimension of work required for adult employment. In addition to these skills and behaviors, another significant aspect of engaging in work is the development of an occupational identity.

Occupational identity combines interests, values, and abilities into a realistic choice of a job or career path. It begins in early adolescence with the development of abstract thinking and a capacity for future-oriented thinking. Adolescents start to fantasize about their future work occupations. Initially, these daydreams are idealistic aspirations about a possible adult self. By mid-adolescence, such fantasies become more realistic, and by late adolescence, aspirations have a realism based on interests, values, and a match between performance abilities and actual job demands. Pursuing postsecondary education (college or university) delays the transition to full-time work, and settling on an occupational identity may be deferred. Professional academic programs of study that begin with undergraduate degrees (e.g., nursing, occupational therapy, and engineering) proactively facilitate and shape occupational identity generally earlier than postsecondary degrees in other sciences or liberal arts.

Full-time employment is a tangible marker of the transition from adolescent to adult. The worker role with accompanying financial independence replaces the student role. The successful transition to the worker role involves a choice of occupation that integrates personal identity and interests with individual occupational performance skills and job requirements. Occupational therapy programs start to explore occupational identity

early in adolescence and combine this process with skill development, ensuring future work options.

Work Opportunities and Outcomes for Adolescents with Disabilities

Opportunities for paid employment have increased for teens with physical, cognitive, and learning disabilities, but they still significantly lag behind their peers without disabilities, and early work experiences remain elusive for adolescents with severe disabilities.^{15,51} Occupational therapists work to foster skills and strategies that assist adolescents to transition from school to work (see [Chapter 25](#)). Successful work experiences for teens with disabilities are contingent on strong social networks, formal and informal support within the work setting, support of supervisors, and a workplace culture that positively supports inclusion and diversity in hiring practices.¹³

Positive work experience and exploration are critical for adolescents with high incidence disabilities (i.e., learning disabilities, emotional disorders, and speech and language impairments). They are among the students who have significant difficulties transitioning from high school. Although children with high incidence disabilities often receive occupational therapy services, they no longer receive such services at the high school level. Because adolescents with high incidence disabilities have higher dropout rates from high school and lower postsecondary education enrollment than their peers, additional supports and services are needed during these transition years.^{105,123} Factors that contribute to their pattern of lower achievement include lower self-esteem, poor awareness of the expectations and requirements of the workplace, delays in career maturity, and reduced capacity and judgment for making and attaining realistic career goals.¹⁰¹ Intervention can mitigate self-imposed lower occupational aspirations that limit their postsecondary work and education choices.

Instrumental Activities of Daily Living

IADLs support daily life within the home and the community, and although the tasks can appear mundane, competency in the performance skills associated with everyday living is essential. Developing independence and interdependence in IADLs establishes the foundation of physical and financial independence.

Adolescents take on more responsibility for IADLs; for example, the chores and simple routines of childhood increase from cleaning one's room to tasks that contribute to the household (e.g., mowing lawns, doing laundry, cleaning the car, cooking). As autonomy increases, teens gain experience with most IADLs. They learn to drive or use public transport so they can move about the community without adult supervision. Although continuing to receive parental oversight, they take on their own health management, such as taking medications, learning about health risks, and making decisions about health behaviors (e.g., smoking, having protected sex, nutrition, and personal hygiene routines). They learn money management associated with IADLs, such as shopping, planning how and when to spend money, saving for the future, and managing a credit card and bank account.

By middle adolescence, teens may also take on responsibilities of caring for children by babysitting and assisting with coaching or lifeguarding. With these tasks, they develop a

knowledge and awareness of safety and emergency procedures. These roles and associated responsibilities further extend their repertoires of skills. Positive role models such as adult family members and other significant adults facilitate the gradual development of multiple and complex IADLs.

Adolescents initiate communication and use a wide variety of communication technologies to interact with peers. Of adolescents between the ages of 12 and 17, 87% interact through online social networks.⁷² Consequently, they have almost 24-hour connection with peers through text messaging, cell phones, instant messaging, and increased contact with adults such as teachers and coaches via e-mail; this is particularly true of girls, and their contact increases with age. These social networks are equally available to teens with and without disabilities. Adolescents' use of the Internet has intensified and broadened: they log on more often and do more things when they are online. They shop online, play games, and research information for school assignments. Girls dominate most content created online by teens; 35% of girls blog, whereas only 20% of boys blog; 54% of girls post photos compared with 40% of boys; but more boys post video content.⁷³ In a Canadian study, adolescents' reported use of technologies could be seen as a continuum from highly interactive to fixed information sources that fell within one of four domains. These were personal communication (telephone, cell phone, and pager), social communication (e-mail, instant messaging, chat, and bulletin boards), interactive environments (websites, search engines, and computers), and unidirectional sources (television, radio, and print).¹¹² Consequently, teens have access to a vast amount of information and connect with people beyond their known social networks and geographic locations.

The enjoyment of social network sites and the use of social applications, such as Facebook or Twitter, are tempered with risks. Teens are making moral decisions about the information accessed and the people with whom they interact, often outside of parental or adult oversight. Discerning use of technology integrates cognitive skills, values and interests, and knowledge of the need to protect personal identity and privacy, all at an age when risk taking is more likely, the anticipation of consequences is underdeveloped, and problem-solving skills are inconsistent. The Internet and communication technologies, which provide a complex virtual, social, and physical world for children and adolescents, are increasingly becoming an area of research in child and adolescent development.⁴⁶ In the future, this research will expand the understanding of how these technologies influence and facilitate cognitive, psychological, and social development.

Achieving Competencies in Instrumental Activities of Daily Living with a Disability

Adolescents with disabilities and their families face an array of challenges in the area of IADLs. They deal with the paradox of achieving emotional and psychological independence and developing identity as a self-determining individual (which in society is represented overtly by work and autonomy in IADLs), while remaining physically dependent on their parents or caregivers. These teens may always require the assistance or oversight of other people for many IADLs. Although teens with developmental delays eventually learn skills to optimize their autonomy, most have semidependent relationships with their care providers, who make executive life decisions with them.

However, it is a different scenario for cognitively able teens with physical disabilities. To enter adult life, these teens must learn to apply their executive cognitive skills and emotional self-regulation to IADLs. They need opportunities to develop decision-making and problem-solving skills applicable to IADLs, such as health management, money management, and community access (maybe driving an adapted vehicle), all decisions previously undertaken by parents. They need these experiences because eventually as adults they will instruct and oversee attendant caregivers. It is the responsibility of the adults in their lives (occupational therapists, family members, and other caregivers) to augment this learning. As caregivers gradually transfer such responsibilities to the teen, they simultaneously change their roles in relation to their child.

Parents as primary caregivers have different demands and new emotional strains as their child enters adolescence. Similar to parents of teens without disabilities, they are seeking the balance of “letting go,” while still being supportive. Yet they and their adolescent also manage additional life challenges that are psychologically and socially demanding. This transition is difficult for parents, and retrospective studies report that adults with disabilities say that, as adolescents, their parents tended to be overprotective.⁸⁵

Although adolescents with physical and developmental disabilities may struggle to become autonomous self-determining individuals, at-risk, emotionally troubled teens often find themselves prematurely independent. Although they continue to need the support and nurturing of a stable family, these teens, because of personal and socioeconomic circumstances, have a pseudoindependence that they are not developmentally ready to manage. They may lack adequate cognitive development and performance skills to meet their IADL and ADL needs. Sometimes, they are even caregivers of their own children. Adolescents in such circumstances often deal with issues such as violence, poverty, homelessness, school failure, and discrimination, while struggling through normal developmental processes.¹³³

Leisure and Play

“We must be careful not to discourage our twelve-year-olds by making them waste the best years of their lives preparing for examinations.”

—Freeman John Dyson, *Infinite in All Directions*

Leisure and play activities are the discretionary, spontaneous, and organized activities that provide enjoyment, entertainment, or diversion in social environments that may be different from school and work settings.^{93,129} These activities account for more than 50% of American adolescents’ waking hours.⁷⁰ In an occupational therapy study, teens reported that leisure provided enjoyment, freedom of choice, and “time-out.”⁹⁴ The use of this free time may seem like “time-out,” but it can have a significant role in development. In this free time, teens explore and engage in new behaviors and roles, are exposed to different interests, establish likes and dislikes, and socialize with an array of social groups, developing skills, patterns of behavior, and self-identity.

Unstructured use of time, particularly passive activities (e.g., watching television and playing computer games), have few positive benefits. The main criticism of passive activities is that

they contribute to boredom, which is associated with a greater risk of dropping out of school, drug use, and antisocial or delinquent activities.¹²⁵ Alternatively, constructive use of non-school hours in nonacademic extracurricular and leisure activities such as sports is linked with positive adolescent health and well-being and development of physical, intellectual, and social skills.³³ These extracurricular school programs (e.g., sports teams, school band or orchestra, drama club) and community-based activities such as scouts, music, or dance classes typically include goal-directed activities as well as a sense of belonging to a peer group (Figure 4-2).

An additional benefit of these activities is relationships with nonfamilial adults. Positive interactions with coaches, adult leaders, and teachers facilitate problem solving, provide social support (sometimes compensating for a lack of parental validation and support), increase self-esteem, and promote skill acquisition and competency.³³ Participation in these extracurricular activities is also associated with higher academic performance and occupational achievement such as the likelihood of attending college.¹⁰ Male students with lower academic achievement or from lower socioeconomic backgrounds who play sports are more likely to finish high school, be involved in the community, and have better interpersonal skills. They also have lower rates of alcohol and drug use or antisocial behaviors.^{33,48,77}

An area of concern is the decline of physical extracurricular and leisure activities, which is linked to an increased risk for poor health among adolescents, including obesity and chronic health conditions such as diabetes.⁶¹ The national public health initiatives to promote adolescents’ participation in physical extracurricular and leisure activities, which have not been successful, have significant implications. Adolescent physical leisure activity patterns predict adult physical activity levels.¹²² Males are more likely to continue to participate in and have a positive attitude toward physical activities than females, perhaps because of the relationship between masculinity and vigorous sports, competition, and sports achievement.¹²² The stereotypes of bodily contact, face-to-face opposition, and endurance associated with male sports and esthetics or gracefulness associated with female sports may explain why some girls drop out of sports and physical activities⁵⁰ and why girls are more likely to participate in dance and gymnastics, which do not compromise their femininity. Although stereotypes and other influences such as parents and teachers affect participation in physical activity, the strongest influence is peer participation.¹²²

Participation in popular adolescent activities that are transferable beyond the context of occupational therapy develops performance skills and facilitates social behaviors that enhance self-efficacy and autonomy. The outcome of developing leisure skills in occupational therapy can be successful participation in peer activities and increased social inclusion. Having the skills to engage successfully in leisure activities contributes to healthy and perceived quality of life by providing a social network and enjoyment and promoting constructive use of time. Developing competence in leisure skills can have additional value, especially for adolescents who may not gain employment.

Social Participation

Social activities, friendships, and the behaviors associated with these activities and roles that characterize and define individuals within society are salient to adolescents’ development of social

FIGURE 4-2 Examples of goal-directed activities. **A**, Baseball. **B**, Snowboarding. **C**, Basketball.

participation. Social roles and relationships are explored and developed by engaging in a variety of social activities, especially peer group activities.⁹⁴ In middle and high school, teens strive to “fit in” and make friends. Peer-focused social interactions and relationships formed in school through leisure activities provide social status and develop adolescents’ social identity.⁵² This emerging identity may differ from the teen’s identity in his or her family. The changes represent moving from family members as the primary source of emotional and social support to a reliance on friends, peers, and nonfamily adults.^{7,53}

Peer Relationships

Having friends significantly contributes to social and emotional adjustment in adolescents.^{132,134} A Norwegian longitudinal study found the frequency of meeting friends and subjective well-being were the strongest predictors of psychosocial functioning in early adulthood.²⁸ Peer relationships offer social integration and a sense of belonging or acceptance. Initially, these relationships develop around cliques that are small, cohesive groups of teens that have a flexible membership, meet personal needs, and have common activities. Participation in peer cliques provides a normative reference for comparison with peers and

influences adolescents’ developing social attitudes and behaviors as well as their academic adjustment.⁷ Making the shift from middle school to high school can be easier with membership in supportive and peer-recognized cliques. Initially, in early and middle adolescence, membership in cliques develops spontaneously around common interests, school activities, or even neighborhood affiliations. In junior high, cliques are usually same sex; by middle to late adolescence, these groups expand to include the opposite sex. In late adolescence, cliques weaken, and they are replaced by loose associations between groups that consist of couples.⁵³ Lack of participation in peer groups or exclusion from cliques comes with a cost (e.g., a sense of rejection, a lack of opportunity to participate in peer activities, social isolation, a lack of social status). Adolescents who do not find their niche in cliques are more likely to be depressed and lonely and have other psychological problems.¹⁹ Exclusion from cliques and the resulting lack of choices are suggested as the reason some adolescents join less constructive peer groups such as gangs or groups who engage in illegal or antisocial activities.

Most adolescents also have lasting stable friendships that differ from the relationships within cliques. Initially, they are same-sex friendships that develop around sharing activities and

a closeness of mutual understanding. They can be emotionally intense, involve openness and shared confidences, and depend less on social acceptance; however, these same-sex friendships also imply a heightened vulnerability.¹⁹ Girls' friendships are interdependent and reflect a preference of intimacy, whereas boys' friendships are congenial relationships established around shared interests such as sports, music, or computer games. These friendships evolve with social and cognitive development. In middle adolescence, the basis of friendships is shared

loyalty and an exchange of ideas; in late adolescence, friendships progress to incorporate autonomy and interdependence, and as intimate relationships develop in late adolescence, the salience of these friendships lessens.

Navigating Social Participation with a Disability

Because teens strive for conformity and identification with their peers, making and maintaining friendships can be particularly difficult for teens with disabilities (Case Study 4-2). The data

CASE STUDY 4-2 Friendship: Sam's Experience

"Intimacy, companionship, closeness and low levels of conflict" typify a friendship.¹²⁰ However, when you grow up with an intellectual or developmental disability, friendship, as just described, becomes harder to come by as you transition into adolescence. Studies show that adolescents with intellectual or developmental disabilities experience friendship differently compared with their typically developing counterparts. These differences include warmth and closeness and positive reciprocity.¹²⁰ They spend less time outside of school, or school-based activities, with their friends and are less likely to have a consistent group of close friends.

I have seen firsthand the change in friendships as a child with an intellectual or developmental disability grows into adolescence and then adulthood. My younger sister, Sam, has Down syndrome (Figure 4-3). She has always been very friendly and eager to meet new people. She is the definition of a people person. So why is it that, over time, her friendships with peers disintegrated as she aged? In elementary school, Sam was surrounded by friends and often was invited to play dates or had friends over our house. She was having typical

friendships, for her age, with her peers. At this age, parents are still involved in peer-related activities (e.g., coordinating play dates and supervising extracurricular activities), which may have contributed to her ability to participate in activities with her friends.

As Sam grew into a preteen and entered middle school, a change in her friendships was evident. She began getting fewer calls from friends and spending less time with friends outside of school. Where she might have had 10 or more friends in elementary school, she now had, maybe, 4 or 5 friends who were regularly in touch with her. Although she may not have noticed the significance of the change, she did begin to spend more time on her own or with our immediate family. She frequently asked to call friends and ask them to come over, but more often than not that friend was busy.

In high school, the decrease in time with friends was more marked than in middle school. She frequently talked about friends from school but rarely had anyone over or went to any friend's houses. She began getting involved in extracurricular activities, such as being the freshman field hockey manager. Even though she was participating in after-school activities alongside her peers, she was still very isolated outside of these activities. As high school came to an end, she maintained maybe one or two friendships and still keeps in touch with these people today.

Now 21 years old, Sam has developed friendships with peers who also have developmental or intellectual disabilities. These friendships have developed through programs such as Friends in Action, Camp Pals, and Best Buddies UNH, and she has been able to form and maintain relationships in a supportive environment. I have come to believe, through observation and conversation with my sister, that her sense of self-identity, her social skills, and social behaviors have developed further since high school because of the opportunities, experiences, and relationships brought about by programs designed to provide social opportunities in an environment that supports positive social interactions and social behaviors while participating in functional activities.

on the social life of adolescents with disabilities provide contradictory information. A national Canadian study found that adolescents with physical disabilities reported good self-esteem; strong family relationships; and positive attitudes toward school, teachers, and many close friends.¹¹⁵ However, other studies found that because teens with disabilities lack the “qualities” that bestow social status among adolescents (e.g., excellence in sports or physical attractiveness), they often are not included socially in peer groups.¹¹⁶ Teens with disabilities reported more loneliness, participation in fewer social activities, fewer intimate relationships, and more social isolation than their peers without disabilities reported.^{29,116} Even teens with disabilities with good social relationships in school had less contact with friends outside the school setting than their peers without disabilities.^{40,115} Factors that affect social acceptance of teens with physical disabilities include role marginalization (lacking a clear role and the inability to undertake the tasks of typical adolescent roles), lower social achievement, and limited contact with peers.⁸⁴ Adolescents without disabilities consider their peers with physical disabilities as less socially attractive and report that they are less likely to interact with them in social settings.⁴⁰ An asset for teens with disabilities is academic achievement because high academic achievement is shown to promote better social acceptance.⁸⁴ See Chapter 12 for a comprehensive examination of social participation.

Understanding the interaction between adolescents and their environments helps the occupational therapist facilitate social participation on multiple levels. The World Health Organization’s International Classification of Functioning, Disability, and Health (ICF) model provides a way to interpret this interaction of individual and environment. The ICF has replaced the concepts of disability and handicap with the constructs capacity and performance. Performance is defined as what an adolescent does (performs) in the environmental context in which he or she actually lives, and capacity refers to an adolescent’s ability to execute a task or action, usually in a standardized evaluation setting such as a clinic.⁸⁷ Capacity and motivation to engage in an activity produce performance (Fig. 4-4). Teens with disabilities may experience a gap between their

capacity and performance because of social and physical environmental barriers that limit their access and opportunities to engage with peers. In other situations, they may lack performance skills for inclusion in age-related social activities. For example, in early and middle adolescence, play and leisure activities frequently involve physical skills, which can exclude adolescents with physical disabilities.⁵ Later in adolescence, peers have a driver’s license, independently move about the community, and have earned discretionary income to spend on activities. In comparison, teens with disabilities may have limited participation because of lack of transportation, accessibility challenges, limited opportunities to work, negative peer attitudes, and parental concerns.⁶² Regardless of the personal challenges in mobility, communication, and cognitive skills, it is the assumptions and discrimination of others that most often widen the gap between capacity for friendship and actual ability to form friendships.¹¹⁹

When adolescents with disabilities are with teens without disabilities, they deal with their differences in a variety of ways. Some attempt to mask or make fun of their disabilities, attempting to make their peers without disabilities feel more comfortable. Self-image and self-esteem of teens with disabilities can create barriers to social acceptance and integration. If they internalize the negative societal attitudes, they will limit their social participation and lower their expectations. However, some teens find alternative ways for inclusion that capitalize on their strengths rather than weaknesses and on their ability rather than disability. Doubt and McColl³⁰ describe one student’s approach to forging friendships with his peer group:

I approached the [hockey team] about being a statistician because I really wanted to get involved in the team. This is probably the closest [to the team] without playing ... that I could [get] ... plus I’m doing work for them too, so I am useful and that’s a good way to get involved ... and it really gives me a chance to be one of the guys, finally; a secondary guy but one of the guys nonetheless.

Evolution of Adolescent-Parent Relationships

Adolescents are apt to claim, “Parents don’t understand.” As increased social participation with peers and close friendships provide intimacy and reflect adolescents’ social and emotional adjustment and self-knowledge, the child-parent relationship shifts. Through an almost constant stream of communication among adolescents (being together, e-mailing, and texting), they share their concerns and fears with friends rather than with parents. This reframing of the parent-child relationship and peer friendships facilitates self-identity. It is an important transition because close friendships are associated with better self-esteem and social skills and less anxiety and depression.²⁰

Although peer relationships are significant, the stability and security provided by relationships with parents or significant adults are equally important. Contrary to popular belief, major conflict between parents and adolescents is not a normal part of adolescence, and if conflicts exist, they are mostly during early adolescence.⁷¹ When adolescents’ relationships with parents are stable, periods of physical and emotional distancing

FIGURE 4-4 Matt plays the drums for the high school assembly.

from parents and of questioning parents' values and beliefs eventually evolve into positive adolescent-parent relationships.

Environments of Adolescence

The environment is a significant determinant of an adolescent's choice of activities and success.⁴⁸ The social (e.g., friends, team members, family, and social groups), cultural (e.g., race, religion), and socioeconomic and physical (e.g., home, school, and community) environments in which the adolescent lives influence his or her development. Environments can encourage positive behaviors and provide opportunities or conversely fail to provide the adolescent the support and resources needed for healthy development. One example is the influence of membership in social groups. Social groups have cultures, belief systems, and norms that shape values and participation⁶³ and can offer both social status and privileges. Psychosocial development involves the ability to recognize the expectations of social groups and an ability to develop behaviors and values that are congruent with the norm. In disadvantaged communities, excelling in school sports activities may be linked with the identity of "good student," resulting in opportunities and status among peers and within a community. In higher socioeconomic status communities, where academic achievement is highly valued, other types of extracurricular activities, such as music, science clubs, theater, and volunteerism, are also associated with the "good student" and are positively reinforced.⁴⁸

Environments that are unsafe, lack resources, or are unhealthy can be a barrier to growth and development. Membership in less desirable social groups (e.g., recent immigrants, less popular high school groups, low socioeconomic status) can marginalize teens and make them more susceptible to adverse outcomes and negative influences (e.g., behaviors such as drug use, criminal activity, dropping out of school, or being a victim of bullying). These teens lack opportunities such as access to high-quality education, adequate health care, and the expectation of personal safety. Disenfranchised youth are more likely to seek a sense of belonging in groups such as gangs.

The occupational therapist's understanding of the nuances of an adolescent's social environment and cultural context is vital to the development of an intervention plan.¹¹¹ The culturally competent occupational therapist is cognizant of the norms and expectations of ethnic and sociocultural contexts and how these shape adolescents' perceptions of themselves and the development of constructive self-esteem.¹¹³ These factors influence adolescents' choices of activities, interests, the expectations of their families, and the values they develop. Likewise, the adolescent's social peer context shapes "adaptive social and emotional development."⁷⁷

Context can have adverse consequences on an adolescent's development. Lower socioeconomic status and family disorganization increase the likelihood that a child or adolescent will exhibit deviant and high-risk behaviors leading to adverse outcomes.⁷⁷ These environments can limit access of adolescents (often minority adolescents) to information and to resources and limit their opportunities to develop self-esteem, personal mastery, and complex cognitive development.⁷⁷ Experiences in school, occupational therapy, and extracurricular activities can have a compensatory role in meeting a teen's needs and

BOX 4-4

Environmental and Contextual Factors of Healthy Adolescent Development

Support

- Family support that includes positive parent-adolescent communication
- Parental involvement in school activities (e.g., schoolwork, sports activities)
- Constructive relationships with adults (e.g., friends, coaches, teachers)
 - Adolescents who report they have good communication and relationships with an adult are less likely to engage in risky behaviors
- Caring, inclusive neighborhood and school environments

Empowerment

- Community that values youth
- Useful and valued roles in community
- Involvement in community service activities that value their contribution and opinions
- Safe home and community environment

Boundaries and Expectations of Adolescents

- Family boundaries that include realistic and fair rules and consequences
- School and neighborhood boundaries that include rules, consequences, and community monitoring of behavior
- Positive and varied adult role models
- Positive peer influences
- High and positive expectations: family, friends, and school personnel expect adolescent to do well

Modified from Search Institute (2014). *40 Developmental assets for adolescents: External assets*. <<http://www.search-institute.org/content/40-developmental-assets-adolescents-ages-12-18>> Accessed February 2014.

ameliorating the effect of an inadequate social and home environment.

The multidimensional influence of context is considered in all intervention programs. Family contexts that value and facilitate the development of peer partnerships, participation in extracurricular activities, and mentoring by caring adults promote healthy adolescents. Conversely, school or community contexts that pose barriers to participation, limit positive opportunities, or encourage involvement in unhealthy groups need to be discouraged. For example, in a client-centered approach, the occupational therapist provides choices, opportunities for decision making, and autonomy, all of which provide a sense of personal control and efficacy. Similarly, a therapeutic milieu offers the adolescent opportunities for self-directed exploration and experimentation within a safe, supportive environment. Box 4-4 lists some of the characteristics of contexts that support and foster adolescent self-development and acquisition of skills.

Occupational Therapy to Facilitate Adolescent Development

Improving the quality of life of adolescents with disabilities is a major goal of the national health promotion and prevention initiative Healthy People 2020. The 23% to 35% of adolescents

in the United States who have chronic health conditions, disabilities, or special health care needs have the same developmental needs as other adolescents, but because of their special needs or dependence on parents and other caregivers, they have fewer opportunities to explore and develop a sense of their own abilities.⁸⁹ Their successful transition from adolescence to adulthood requires that they have the same experiences as teens without disabilities (Case Study 4-3). They need to have opportunities to resolve the psychosocial issues of adjusting to the physical changes of puberty and to develop psychological, if

not physical, independence from parents or caregivers. They need opportunities to build social and intimate relationships with peers to establish a sense of identity and skills that will equip them to navigate adult life. These developmental tasks are prerequisites for choosing a job, completing school, finding meaningful work, and developing adult relationships.²⁶

Adolescents with disabilities have fewer opportunities to engage in typical adolescent experiences; to make their own choices; to engage in social relationships; or to explore the world of ideas, values, and cultures different from those of their

CASE STUDY 4-3 Bullying: Nick's Story

"I am a 14-year-old student in eighth grade. I don't like going to school because I have problems with the kids there. Sometimes my classmates yell at me, and sometimes they hit me. One time when I was in the locker room a kid punched me and tore my sweatshirt. Another time, I was punched in the face and thrown into a locker. In gym class, people throw balls at me and hit me with lacrosse sticks. In my class, a girl yells at me and calls me names. She gets other students to join her. Since I've been diagnosed with Tourette's and Asperger's, students call me Tourette's Man and Twitchy. I don't like to go to school because kids don't treat me very nice. I don't feel like I have very many friends. When I'm at school, I feel like I'm alone, and I feel sad. I wish school was better and I had more friends."

School can become an unhappy place, a daily experience of harassment, alienation, and victimization. Adolescents with Asperger's syndrome are among students who are vulnerable to discrimination. Both teachers and other students can be intolerant toward students with interpersonal and learning challenges, especially when learning and classroom work involve collaboration.¹⁰⁴ Adolescents with disabilities are vulnerable and at heightened risk of victimization compared with their peers without disabilities.^{121,124} They report rejection by other students, bullying, or being ignored and treated negatively when working in groups.¹²⁴ Nick's story highlights bullying and the experiences of adolescents who are susceptible to bullying.¹⁸ The passage he wrote for this case study resonates with the frustration, disappointment, hurt, and isolation that he and other teens experience at the hands of peers.

The level of verbal abuse is consistent across educational levels, whereas physical bullying increases in elementary school, peaks in middle school, and declines in high school.⁵⁵ Students subjected to bullying are at risk of mental health problems (e.g., depression). They report being lonely, show deterioration in performance (grades), and avoid school or drop out.²⁷ Bullying increases the likelihood that victims will commit acts of violence.²⁵

Cyberbullying is increasing with serious consequences for adolescents. A 2010 study in which cyberbullying was defined as when a "person repeatedly harasses, mistreats, or makes fun of another person online or while using cell phones or other electronic devices" reported that approximately 20% of a sample of 4441 adolescents reported they had experienced cyberbullying in their lifetimes. Online was the most commonly cited form of cyberbullying experienced.⁹⁵ This

frequently anonymous form of bullying is cruel and devastating and has long-term effects because the exposure is wider than the immediate social network. A University of New Hampshire study for the National Center for Missing and Exploited Children reported that online bullying increased by 50% between 2000 and 2005.¹³⁰

Bullying is often underreported, minimized, or unacknowledged in schools. Student surveys have shown that teachers seldom discuss bullying in class or intervene effectively. When adults do intervene, students often see the interventions as ineffective or as worsening the situation.⁵⁵ In combating bullying, it is important to empower all students, especially students with disabilities, through a mastery-focused school climate. The U.S. Department of Education issued an official statement regarding disability harassment in school. In the same year, the National Center on Secondary Education and Transition provided advice and strategies on school interventions and educational programs to address and deter bullying (<http://www.ncset.org>). Specifically targeting the prevention of disability harassment, the U.S. Department of Education makes the following recommendations¹²⁵:

- Create a campus environment that is aware of and sensitive to disability concerns and harassment.
- Weave discussion and awareness of bullying into the curriculum or extracurricular programs.
- Encourage parents, students, employees, and community members to discuss disability harassment and report it when they become aware of its occurrence.
- Publicize antiharassment statements and procedures for addressing discrimination complaints.
- Provide appropriate training for staff and students regarding harassment.
- Counsel both victims and perpetrators of harassment.
- Implement monitoring programs to follow up on resolved issues of disability harassment.
- Assess and modify existing disability harassment policies and procedures to ensure effectiveness.

Acknowledgment

Thanks to Nick for writing about his experiences. His frankness about being bullied offers us insight into the experience of being bullied. Thanks also to Nick's mother for her perspective as a parent. This fall, Nick started at a high school that has a zero tolerance policy for bullying that includes consequences for bullies. Nick's grades have improved, and he says school is okay.

family.¹¹ As outlined earlier in this chapter, exploration and experimentation provide teens with experiences of success and failure, both of which are required if they are to develop a sense of the boundaries of their competence.¹³⁴ Adolescents with disabilities face many additional challenges, including their own and others' negative perceptions and lower expectations of them.⁷⁵ They also face barriers such as lack of resources, problems related to mobility and environmental access, discrimination, and the stigma of disability.³⁰

Flexibility, a sense of humor, a capacity to see strengths and potential before identifying problems, and the ability to set clear and consistent boundaries are ideal attributes in occupational therapists working with teens. It is essential that the occupational therapist integrate typical adolescent developmental needs into the occupational therapy evaluation process and interventions. However, the occupational therapist needs to keep in mind that most teens, including teens with mental health, developmental, or physical disabilities, successfully

navigate adolescence.¹⁰⁸ This knowledge means that the occupational therapist can convey an encouraging attitude grounded in a realistic, yet positive, outcome for most adolescents.

Occupational therapists provide evaluation and interventions that help adolescents address their difficulties and disabilities, acquiring skills and fully participating in the social and academic opportunities provided in school and the community. Occupational therapy services within the public school system are available to many adolescents up to the age of 21 years under the Individuals with Disabilities Education Act. The transition from high school to work or secondary education is a significant time for students to receive occupational therapy reassessment and interdisciplinary programs that develop life and prevocational skills. Occupational therapists work collaboratively with students, families, and teachers to identify each student's strengths so that the student can develop the basic life skills and emotional resources needed to move forward into adulthood. [Case Study 4-4](#) presents an example of occupational

CASE STUDY 4-4 Understanding That Development Is the Foundation of Effective Occupational Therapy Practice

Jeremiah, a 15-year-old boy with Down syndrome, is living at home with his parents. His two older siblings have left home to work and attend college. Psychological test scores classify Jeremiah as mildly mentally retarded under the guidelines of the DSM IV-TR. Before high school, Jeremiah had participated in mainstream school activities, with some accommodations within the classroom. He has good social skills and enjoys being with others. However, as the cognitive abilities required to achieve academically in high school have increased, the gap between his functioning and that of his peers has widened. He now spends most of his day in an alternative class that has a vocational emphasis. Jeremiah's recent individual educational program (IEP) prioritized goals to facilitate his transition from high school to the community. His goals are to live in a group home and have a job.

The Individuals with Disabilities Education Act (IDEA) of 1997 recognized the need to facilitate the transition from high school for students with disabilities with an amendment that required an individualized transition plan (ITP). The IDEA requires that the IEP team carefully consider post-school goals when the student is about to enter high school at age 14 because the highest dropout rate occurs in the first 2 years of high school. Beginning at age 16 (or younger, if appropriate), a statement of transition services needed must be included in a student's IEP. Jeremiah's goals might be that he would achieve semi-independence and a personal sense of autonomy, understand and accept his physical changes, form and maintain friendships, and achieve independence in his community mobility to transition from an educational setting to a community and a work environment. Occupational therapy for adolescents such as Jeremiah requires that a occupational therapist understand the extent to which an adolescent's biologic development (e.g., cognition and motor skills) will support development of social competencies and daily living skills associated with adolescence. Based on the findings of his functional evaluation and specific assessments of client

factors, realistic goal setting and intervention planning can be determined. An occupational therapist selects evidence-based interventions to help students such as Jeremiah acquire the life and social skills they need to live and work in the community with support or oversight.

For example, when working with adolescents with cognitive disabilities, the occupational therapist needs to understand the developmental functional level of their cognitive abilities. This information can identify the types of difficulties the adolescent may have in processing information and how these limitations in understanding and using information will influence the ability to do and acquire everyday skills. This is crucial information in optimizing learning and determining accommodations that need to be implemented to support functioning. In Jeremiah's case, recognizing that his cognitive assessment scores indicate that he processes information at a preformal (i.e., concrete) operational level, the occupational therapist might use a cognitive disability approach to formulate an intervention plan. Jeremiah has a stable condition that influences how he learns, how much information he can handle at one time, how well he remembers and recalls information, and the complexity of instructions he can follow. The occupational therapist may use a direct, skill-teaching approach to ensure that Jeremiah acquires activities of daily living, instrumental activities of daily living, work, and social participation performance skills. An example would be a visual list to provide the sequence of activities to ensure safety in the kitchen or to improve accessibility. The information about his cognitive abilities and developmental level also helps determine the level of interdependence he will require in his group home; it also helps others understand how to adapt his environment to support his optimal level of independent functioning and, most important, his well-being and life satisfaction. The skilled occupational therapist develops expectations specific to the adolescent that include the "just-right" challenge to meet his goals and to promote his successes.

therapy that supports adolescents with cognitive deficits; sensory impairments; and physical, communicational, or behavioral disabilities in their school-to-work transition.^{29,116}

Summary

Adolescence is a distinct developmental stage characterized by growth and maturation, the refinement of skills, self-determinism, relative individuation, and development of a sense of identity that culminates in a positive self-concept as a healthy adult. Many of these qualities and skills are achieved through critical tasks in all areas of development. An adolescent's development of critical thinking and reasoning skills is integral to acquiring personal values and beliefs, a sense of accountability, and a burgeoning understanding of one's responsibilities and actions that extends beyond the egocentric concerns for self.

Summary Points

- Adolescent cognitive competencies support enhanced communication and interpersonal skills, including a capacity for meaningful relationships with peers and adults and, ultimately, intimate adult relationships.
- The social development of adolescents results in an understanding of their rights and responsibilities as members of society.
- In addition to significant cognitive and social development, adolescents experience and adjust to the physical changes and maturation of puberty.

- Adolescents need to develop a healthy body image that incorporates acceptance of these physical changes. The exploration of physical skills and participation in sports, leisure activities, and work enhances and builds knowledge of one's skills, interests, and performance competency that contribute to identity and occupational choice. An important goal is that healthy lifestyle patterns (e.g., physical fitness and nutrition) become life habits.
- The desired outcomes of adolescence are a sense of personal identity, autonomy, independent decision making, and adequate life skills for adulthood.
- Occupational therapists who work with adolescents use clinical reasoning to integrate discipline-specific expertise, knowledge of adolescent development and associated disorders, and occupation-based practice to facilitate healthy development. They forge therapeutic relationships with each teen, his or her family, and the interdisciplinary team members to facilitate a successful transition to adulthood.

To conclude this chapter, an occupational therapist who is a mother of a daughter with significant developmental and physical disabilities shares some advice:

The best thing I can tell occupational therapy practitioners and students is that every parent and every child/adolescent, like our daughter Brie, has his or her own values and unique story. Occupational therapy practitioners can facilitate relationships and friendships, promote full participation in regular classes, and assist in developing a future. As a parent and occupational therapist, I hope each occupational therapist, through his or her actions, is recognized and remembered by the adolescents they work with as "someone who really made a difference in their lives."—Ann Donoghue Dillon, MEd, OTRL.

CHAPTER

5

Working with Families

Lynn Jaffe • Sharon Cosper

KEY TERMS

Families facing multiple challenges
Family adaptation and resilience
Family as a dynamic system
Family diversity

Family occupations: routines and rituals
Family-centered services
Functions of a family
Parent-professional partnership

GUIDING QUESTIONS

1. How does family systems theory describe the occupations and functions of families?
2. What is the family life cycle, and how do we identify times of potential stress for families of children with special needs?
3. How does having a child with special needs influence family function and the co-occupations of family members?
4. How do we learn about a family's culture and background, and why is knowledge of diversity important?
5. What are the roles of the occupational therapist when collaborating with families?
6. How does an occupational therapist establish and maintain partnership with a family?
7. How can families be empowered to facilitate their children's development?
8. What are the best strategies for supporting the strengths of families facing multiple challenges?

This chapter introduces a range of issues related to families, particularly families of children who have special developmental or health care needs. It considers how family members fulfill the functions of a family by collectively engaging in daily or weekly activities and by sharing special events. The chapter explores factors that contribute to the variety of families with whom occupational therapists may work in providing occupational therapy for children. After presenting this background on the occupations of families and family diversity, the chapter then discusses how the special needs of children bring opportunities and challenges to families. This discussion includes the ways in which having a child with disabilities can influence how family members organize their time, engage in activities, and

interact with one another. Principles and strategies that follow a family-centered philosophy and research evidence are emphasized throughout the chapter.

Reasons to Study Families

"Why do I need to read a chapter on families? I was raised in a family, I know all about families. . . ."

Families are complex systems. Having a child with a disability or chronic health condition, which can happen in families anywhere on the socioeconomic spectrum, of any educational, ethnic, or genetic background, can add an appreciable degree of stress into this complex system. Families with low socioeconomic status, poor education, or minority status are more likely to have negative outcomes.⁴¹ Occupational therapists encounter and must be prepared to work with every type of family. Children cannot be treated as isolated individuals; they are members of families, the social units that shape behavior and life experiences. Evidence has shown that child outcomes may be shaped by how well occupational therapists communicate with families and how well the partnership between them has been established.^{28,57,82} Learning about family systems is important preparation for working in any practice setting.

The development of children's occupations cannot be understood without insight into what shapes their daily activities. All major health-related disciplines, including but not limited to psychology, sociology, and nursing practice, use the ecologic view of children and the family—that each is interconnected with the other and the environments that they experience. Although children's activities vary from one culture to the next, universally their families play the major role in guiding how children spend their time, influencing what they do, and helping them understand why the things they do are important.^{70,125,149} The more completely occupational therapists understand these guiding factors, the better prepared they will be to support families in shaping their child's development.

Another reason to study families explicitly is to circumvent the inclination to reference one's own family experiences as a template for the way families operate. Walsh pointed out that when people speak of "the family," they suggest a socially constructed image of a "normal" family, giving the impression that an ideal family exists, in which optimal development occurs.¹⁵⁴ In reality, many different types of families are successfully raising children. In this chapter, two or more people who share an enduring emotional bond and a commitment to

pool resources and carry out typical family functions can be seen as a family.^{87,149,155} This chapter focuses on families raising children. One or more parents, grandparents, and stepparents, as well as adoptive or foster parents, can successfully bring up children. We refer to the caregiving adult as the “parent” of the child, and focus specifically on the “parent” only when it is germane to the discussion of family diversity (Box 5-1).

A third reason to study families is that the involvement of family members is central to the best practice of occupational therapy. In addition to organizing and enabling daily activities, the family provides the child’s most enduring set of relationships throughout childhood, into early adulthood, and possibly beyond. During the course of his or her lifetime, a person with a disability may receive services from people working through health services, educational programs, and social agencies. These relationships exist because professionals bring the expertise required by the special needs of the young person. As the type of services needed changes, professionals enter and leave the young person’s life. The family represents a source of continuity across this changing pattern of professional involvement. The family forms a unique emotional attachment to their child, and their continued involvement gives them special insight into the child’s needs, abilities, and occupational interests. In light of the family’s expertise, occupational therapists strive to collaborate with family members, follow their lead, and support their efforts in promoting the well-being and development of the child with special developmental or health care needs.^{16,28,132} Case Study 5-1 on pp. 152–156, which describes the actual experiences of parents raising three children with special needs, provides additional insight into the essential nature of family relationships.

BOX 5-1 Therapists’ Professional Responsibility in Light of Family Diversity

Family diversity is a social construct defined in the eyes of the beholder; families that appear atypical may have been defined as “just an average family” in another era or culture. It is not sufficient to strive to treat all families the same because each family has different needs and expectations for how professionals can support them.¹⁵²

The therapist should strive to do the following:

- See each family in light of what makes it unique and also how similar it is to all other families raising children.
- Recognize differences among families by reflecting on one’s own cultural model and associated beliefs and critically analyze how knowledge about families is constructed.^{1,125}
- Gain an understanding of families with different backgrounds by reading the literature or finding other people who can share an insider’s perspective because they have been parts of similar families.
- Initiate conversations that solicit a parent’s explanation about family membership, family’s cultural model, and activities valued for and by the child.
- Talk with parents about how they do things together during their daily and weekly routines and the meanings that they give these shared activities as a place to start.
- Design interventions that fit into daily routines and are compatible with family traditions.

Finally, including families in the process of providing services for children is not just best practice—it is the law. In recognizing the power of families, federal legislation requires service providers and educators to seek the input and permission of a parent or guardian in regard to any assessment, intervention plan, or placement decision. The importance of the family in the early part of the child’s life (from birth to 3 years old) is reflected by the emphasis on family-centered services in Part C of the Individuals with Disabilities Education Improvement Act 2004 (IDEA; <http://idea.ed.gov>).⁷² It requires providers to meet with parents and develop a family-directed, Individualized Family Service Plan (IFSP) regarding the resources that the family needs to promote the child’s optimal development. Later, in the school system, parents are involved in developing the Individualized Educational Program (IEP), which guides special education and related services (see Chapters 22 and 23).

The Family: A Group of Occupational Beings

Family members, individually or together, engage in a variety of activities that are part of home management, caregiving, employed work, education, play, and leisure domains that help them feel connected to each other. A father fulfills one of his family roles by picking up groceries on his way home from work, or a child studies for a test because his or her parents expect good grades. Family occupations occur when daily activities or special events are shared among family members, such as a parent helping a son study for a test, the whole family going to a movie, or brothers shooting baskets. By engaging in occupations together, families with children fulfill the functions of the family unit expected of them by members of their community.

Societies first anticipate that families provide children with a cultural foundation for their development as occupational beings. Family members share and transmit a *cultural model*, a habitual framework for thinking about events, for determining which activities should be done and when, and for deciding on how to interact.⁴⁵ By providing a cultural foundation, families ensure that children learn how to approach, perform, and experience activities in a manner consistent with those in their cultural group (Box 5-2). Culture is passed from generation to

BOX 5-2 Outcomes of Family Occupations

Family occupations contribute to the following outcomes for children:

1. Establish a cultural foundation for learning occupations that enable children to participate in a variety of contexts
2. Help shape children’s basic sense of identity and emotional well-being
3. Help children learn to master routines and habits that support physical health and well-being
4. Foster readiness to learn and participate in educational programs
5. Foster readiness to assume a place in the community and society

generation through rituals that include celebrations, traditions, and patterned interactions that give life meaning and construct family identity.¹²⁹

Occupations have meaning because they convey a sense of self, connect us to other people, and link us to place.⁵⁹ Routine family occupations give order to life and structure the achievement of goals.¹³ Routine family occupations and special events also form the basis for repeated interpersonal experiences that give family members a sense of support, identity, and emotional well-being.¹³⁴ The importance of family occupations is reflected by the fact that families create special activities for the specific purpose of spending time together.^{128,147}

Families are expected to help their children develop fundamental routines and lifestyle habits that contribute to their physical health and well-being. In the context of receiving care and sharing in family activities, children acquire skills that lead to their independence in activities of daily living (ADLs) and learn habits that will influence their health across their life span. For example, in the context of sharing in family dinners and leisure activities after dinner, children establish habits that can reduce or increase future problems with obesity.

Families also prepare children for formal or informal educational activities and experiences that prepare young people to become productive adults.¹²⁵ Parents, in the context of their daily routines and through their encouragement, provide children with participation experiences that influence how they approach learning.⁷¹ Families of children with disabilities must meet all these expectations.

Guided by their cultural models, special circumstances, and community opportunities for activities, families use their resources in different ways (Box 5-3). For example, one family may choose to pay (using financial resources) to have the yard work done so that time (another asset) on Saturday afternoons can be used for having a picnic together. Another family invests interpersonal energies (an emotional resource) to get everyone to help with the yard work on Saturday afternoon so that money will be available to pay for music lessons. Financial, human, and emotional resources, as well as time, are not limitless, and, in healthy families, members negotiate a give and take of their assets. Mothers of children with developmental

coordination disorder (DCD) or attention-deficit/hyperactivity disorder (ADHD) may set aside extra time to help with their children's activities and rely on hired help or assistance from other family members to get household tasks done.^{47,109} Typically, families with children have a hierarchical organization in which one or more family members (e.g., a parent) take(s) major responsibility for determining how the resources are distributed, enabling the family to engage in activities that fulfill family functions. Availability of resources varies for many reasons, within families and within their communities. Challenges for families and occupational therapists occur when families or the communities they live in have severely limited resources.^{24,133}

System Perspective of Family Occupations

A family functions as a dynamic system in which its members, comprising subsystems, engage in occupations together to fulfill the functions of a family. As with any system, the activity of one person can influence the activities of other members. These *interdependent influences* define the dynamic relationship among the different parts, similar to the movement of a piece of a hanging mobile that causes movement of all the other parts. For example, a sixth grader may ask to stay after school with his friend, which means that he is not available to watch his sister that afternoon while his mother shops. Consequently, the mother brings her daughter to the grocery store. Shopping with the preschool daughter takes the mother longer than shopping alone. As a result, they do not get home as quickly, and dinner is started late. The interdependent nature of family members' activities is illustrated by the fact that the boy's choice of what he wanted to do in the afternoon altered the activities of his mother and sister and indirectly affected the family's mealtime routine that evening. Recognizing that a family functions as a whole, an occupational therapist who suggests an after-school horseback riding class for a child with cerebral palsy needs to appreciate that the recommendation must be weighed in light of the family resources and the implications of that activity for the entire family system. As a complex social system, family members have to coordinate what and when they do things to share in family routines and rituals (Box 5-4). They accomplish this within subsystems through their communications and family rules.¹⁴⁶

BOX 5-3 Family Resources

Family resources: Properties family members use to engage in a balanced pattern of needed and desired activities in a way that enables them to fulfill the family functions

Financial: Remuneration from productive activities that enable the family to acquire material things such as a place to live, food, and clothing

This may also determine which types of community activities are available for family members.

Human: The knowledge and skills family members bring to activities

For example, a teenager who learns to use the Internet at school brings this skill home and can help his or her parent learn how to pay bills online.

Time: Minutes, hours, days to engage in activities that enable families to fulfill their functional roles

Emotional energy: Experiencing close interpersonal relationships during shared activities

BOX 5-4 Key Concepts of a Family System Model

1. A family system is composed of individuals who are interdependent and have reciprocal influences on each other's occupations.
2. Within the family, subsystems are defined, with their own patterns of interaction and shared occupations.
3. A family must be understood as a whole, and it is more than the sum of the abilities of each member.
4. The family system works to sustain predictable patterns in family occupations and be part of a larger community.
5. Change and evolution are inherent in a family.
6. A family, as an open system, is influenced by its environment.

FIGURE 5-1 Matthew and his family enjoy a ball game. (Courtesy Jill and Mark McQuaid, Dublin, Ohio.)

With all the activities a family does, and the different members who can carry out these tasks, it would become confusing and drain family resources if everyone had to negotiate daily who was going to do what, when, and in which way. An effective family system organizes itself into *predictable patterns* of daily and weekly activities and familiar ways with special events. Guided by their cultural models, and often organized through unspoken family rules, families settle into *daily routines* for various household activities.^{29,48,134} These daily routines include interactive rituals that take on symbolic meaning and seem to be so habitual that people do not think of doing them any other way, and they resist changing them.^{47,129,147} Bedtime routines for a child, for example, can have a set sequence of taking a bath, brushing teeth, and the parent reading a book. If routines are interrupted, even by a welcomed event, such as a grandparent coming to visit, family members invest extra family resources to reconfigure their daily routines under the changed circumstances. For example, time is spent making up a bed on the sofa rather than giving the daughter a bath, and emotional energy is expended to help the daughter fall asleep in the living room so that the grandparent can sleep in her bedroom. Families may experience the disruption of their daily routines as unsettling and taxing, and it is not uncommon to hear family members sigh in relief when they can return to predictable patterns—that is, when “things get back to normal.”

In addition to routines for daily or weekly activities (Figure 5-1), families also establish predictable patterns for what they do during rituals, such as special events. *Family traditions*, such as cooking special food for birthday celebrations or sharing leisure activities on Sunday afternoons, help family members develop a sense of group cohesion and emotional well-being (Figure 5-2). Families may decide to maintain their traditions rather than address an individual member’s needs because these customary activities fulfill family functions. For example, a family that traditionally vacations with grandparents for several weeks in the summer may value how special activities together reinforce their sense of being a family. Conflict with the occupational therapist could arise if the therapist assumes that the family will shorten their traditional vacation to attend some therapy sessions during the summer. When the occupational

FIGURE 5-2 Matthew’s brothers and friends play ball. (Courtesy Jill and Mark McQuaid, Dublin, Ohio.)

FIGURE 5-3 Noah and family celebrating Father’s Day.

therapist offers a range of options and asks the family to set priorities, family members can consider all of their routines and traditions and determine how they want occupational therapy services to fit into their lives.

Celebrations are predictable patterns of doing activities, such as religious rituals, that are shared with members of the community. Therefore, what is done during family celebrations may be similar to what other families that share a similar background do for the same celebration. This link to others gives family members a sense of meaning associated with their special events that connects them to a community of families (Figure 5-3). Occupational therapists may be asked for assistance so that children can participate in celebrations. For example, a parent may want positioning suggestions so that her daughter with cerebral palsy will be comfortable during Christmas Eve services. The family of a boy with sensory processing problems may need ideas for coping that they can use while attending a Fourth of July fireworks display with the neighbors. By enabling these children’s occupational engagement, the entire family

participates in community celebrations and confirms their identity as a family, like every other family raising children. Needless to say, culturally aware occupational therapists are always respectful of families that choose to not engage in the celebrations thought to be typical in the larger society.

Among the researchers who have investigated family routines and practices, Fiese and colleagues^{29,30,134} have examined the meaning of routines and related ritual interactions of families' daily activities and religious celebrations. Their studies show that families who reported finding more meaning and commitment to their routines and special activities experienced better health of family members and stronger interpersonal relationships. Occupational therapists who suggest home carryover of interventions must be sure that the activities will fit within the family's values and their existing routines; otherwise, the intervention may not be incorporated.^{15,130,131}

Family Subsystems

Parents

Regardless of the type of family structure (e.g., birth, adoptive, partner, blended, foster), caregiving adults sharing parental duties need to coordinate their efforts. These adults form the *parent subsystem* of the family, which can be a positive force and can contribute to the child's ability to face developmental challenges. However, when stressed, it may be a negative influence on the child's development.⁵ Parents may deal with child-care in a variety of forms, which may all be adaptive if they enable the system to operate and meet family functions.⁷⁹ Some studies note that the type and severity of a child's disability may necessitate additional time for caregiving co-occupations, such as in the mother-child subsystem.³³ Although some have found these time demands to be similar to those of typical children, the meaningfulness and enjoyment of the time and occupations may be different for parents of children with disabilities.⁴⁷

All parents may experience increased levels of stress, especially when first taking on this role. Stresses may become even greater for parents of children with disabilities, although this is still equivocal.^{12,17,34,35,139} Disabilities that seem to create more stress and caregiving effort for the family include autism, severe and multiple disabilities, behavior disorders, and medical problems that require frequent hospitalization and in-home medical care.^{27,59,124} Although researchers had previously reported that mothers experience greater stress, currently, with the increase in the number of two-earner families and of fathers as primary caretakers, the stress level of both parents has been found to be more similar than earlier studies had suggested.^{33,79,134,143,150} (Figure 5-4). Often, the caregiving parent has the potential to be more isolated, yet is also the person who interacts with others about the child and may experience more support in that regard. The primary caregiving parent has the added burden of sharing information with his or her partner, which may also increase the level of stress. Professionals need to be sure to include both parents, as well as other caregivers, in their communications about a child to ensure that information is transmitted accurately and unburden the caregiving parent of the responsibility of transmitting all the information.

Children affect the relationship between husband and wife, in positive and negative ways. Although there is evidence that a child with disabilities can increase the stress on a marital

FIGURE 5-4 Noah doing a ropes course at the zoo with Dad's help.

relationship,⁹ there is also evidence that marriages are strengthened when raising a child with a disability.¹²⁴ Differences in marital satisfaction between families of children with disabilities and those of typically developing children tend to be minimal.²⁴ Stress in dealing with the child may bring parents together for problem solving, and they may rely on each other for emotional support and coping. A strong relationship between husband and wife seems to buffer parenting stress. Teaching parents intervention techniques to use with behaviorally challenging children has also been shown to reduce stress levels.¹⁴

Siblings

Siblings are an important source of support to each other throughout life. Having a brother or sister with special needs may change the experiences of other children growing up in that family (Figure 5-5). In general, the relationships between children with disabilities and their siblings can be as strong and positive as those of typical siblings.⁹⁷ The research findings, however, are varied across types of disabilities, sibling place in the family (older or younger), and sibling genders. Conflict among siblings may be more prevalent when a child has a disability such as hyperactivity or behavioral problems. Conflict tends to be less prevalent when a child has Down syndrome or an intellectual disability.^{65,83} Williams and colleagues¹⁵⁷ investigated factors that might influence behavioral problems or the self-esteem of children who had a sibling with a chronic illness (e.g., cancer, diabetes, cystic fibrosis) or developmental disability (e.g., autism, cerebral palsy). They found that the mental health of siblings of children with disabilities appeared more related to co-occurring risk factors, such as low socioeconomic status (SES) or single-parent household, than to the sibling relationship. These factors and the siblings' understanding of the disease or disability were related to whether the typically developing sibling had behavioral problems. When the siblings felt supported, their behavior, moods, and self-esteem were more positive than when they felt unsupported.¹¹²

Often, the roles of siblings are asymmetric, with the typically developing child dominating the child with the disability. Siblings without disability generally engage the child with a disability in play activities in which they can participate, such as rough and tumble play rather than symbolic play. Siblings may

FIGURE 5-5 A, Two brothers enjoy playing together on the playground. B, Sisters play a sorting game together.

be asked to take on caregiving roles, and assuming caregiving roles can have positive and negative effects.¹⁴⁰ Siblings learn to relate and interact in the context of a family. Positive and solid marital systems seem to promote more positive sibling relationships, and marital stress has a deleterious effect on sibling relationships.¹²⁴

Because occupational therapists promote engagement in a full range of activities as a way of helping a child participate in family life, the inclusion of siblings is an important step in occupation-centered practice. Siblings are likely to be the best playmates and can often elicit maximum effort from their brother or sister. In addition, sibling involvement gives the therapeutic activity additional meaning (play), and siblings can act as models for teaching new skills. Peer support groups for the typically developing siblings can also be occupation-centered. Occupational therapists can develop a recreational program for brothers and sisters of children with whom they work so that the siblings can meet one another and realize that their family is not the only one that faces challenging behaviors. These groups generally participate in structured activities and have open-ended discussions about what it means to have siblings with disabilities. One formalized support group for siblings is Sibshops, a recreational program that addresses needs and concerns through group activities.¹⁰⁸ Sibshops' primary goals for brothers and sisters of children with special needs are to meet their peers, discuss common joys and concerns, learn

how others handle common experiences, and learn more about their siblings with special needs.

Extended Family

In the extended family, the experience of having a child with special needs depends on the meaning family members bring to their relationship with the child. Family members, such as grandparents, uncles, and aunts of the child, are especially important to fathers and mothers for emotional and practical assistance (Figure 5-6). When extended family members are not supportive, parents may experience frustration and hurt over their lack of contact.³⁸ For some grandparents, grandchildren represent a link to the future and an opportunity for vicarious achievement. Researchers have found that when children have disabilities, grandparents express positive and negative feelings and go through a series of adjustments similar to those of the parents.⁹⁹ Many of the negative feelings, such as anger and confusion, appear to decrease with time, although some may never completely disappear. Positive feelings, such as acceptance and a sense of usefulness, increase over time. A grandparent's educational level and sense of closeness to the child are positively associated with greater involvement with the child. Factors such as the grandparent's age and health and the distance the grandparent lives from the child do not appear to influence involvement. Grandparents learn information about their grandchild's condition primarily through the child's parents. However, some seek information from other sources, such as support groups for grandparents of children with special needs. Margetts et al.⁹⁹ found that grandparents of children with autism spectrum disorder felt strongly about the caring and support that they provided for their children and grandchildren. For professionals to be truly family-centered, they need to ask whether the parents want to include the grandparents in the initial assessment of the child.⁹⁹

Family Life Cycle

Family systems undergo metamorphosis and adapt as family members change. Some transitions with developing children can be anticipated and seem to be tied to age more than ability. For example, *normative events* in children that require adjustments in families include the birth of a child, starting kindergarten, transitions between schools, leaving high school, and living outside the home. Other changes in the family are not anticipated. *Non-normative events* may include a grandparent coming to live with the family or a parent accepting a job in another city. Families that are cohesive and adaptable adjust interactive routines, reorganize daily activities, and return to a sense of "normal" family life. If interactive routines and role designation are set too rigidly, the family may not be able to operate effectively through periods of transition. This is especially true if the family experiences unanticipated, threatening events, such as a job loss or medical crisis. All families use coping strategies to accommodate periods of transition.

Occupational therapists must understand that all families are unique. Although life cycle models consist of predictable events, the individuality of each family must be acknowledged. The characteristics and issues at each life stage are highly variable, and each family moves through the stages at different

FIGURE 5-6 A, Noah with Uncle. B, Noah celebrating a birthday with Grandpa.

rates. Some family members may experience and resolve their feelings when they first learn about their child's diagnosis, or they may take months to "come to grips" with the information.¹²⁰ In addition, the family may experience additional cycles of sadness and acceptance, within and between life stages. Issues that the family seemed to resolve when the child was an infant may occur again when the child reaches school age and

an educational diagnosis is made or a learning problem is identified. Other life stage-related events, such as the child's ability to develop friendships when first entering grade school, may become an issue again when the child enters high school. (*Case Study 5-1* on pp. 152–156, provides examples of the issues that arise in each of the life stages.) Finally, different members of the family may be at different stages at the same time. Therefore, characteristics of the family members and child's phase of development must be considered. For example, in a skipped-generation family, grandparents frequently have to deal with changes associated with old age at the same time they are parenting their grandchildren. A young couple may have more energy and resources to cope with the birth of a child with special needs than an older couple with four other children participating in school activities.

Early Childhood

Identifying a child as being at risk for health or developmental problems is usually a complicated process. Unless the child is born with medical problems, congenital problems in a body structure, or features that suggest a syndrome, a child may be not diagnosed for months, and sometimes years. Families that describe their experiences in raising a child with a disability frequently recall their journey by looking back to a period when "something was not right."⁴² Families of children with pervasive developmental delays recall a sense that they had to search for a diagnosis with repeated testing and visits to several clinics or evaluation centers. Even parents of a child with an unusual physical complaint, such as joint pain that occurs only at night, might have to persevere in finding the cause when professionals suggest that the child is only seeking attention. After receiving a diagnosis and ending a period of uncertainty, families hope for a period of stability, but, as one educated father commented, "No amount of professional or personal preparation trains you for the reality of chronic illness" (p. 243).⁶⁷ Parents' first questions often include accessing quality childcare, medication management, insurance issues, and available support systems.⁶⁹

Parents whose first child has special needs do not have the same experiences to draw on as those of families with older children. Parents of young children may ask questions such as, "Do you think he can go into a regular classroom?" and "Do you think she will be able to live on her own some day?" Thoughtful responses to these questions recognize the parents' need for optimism and hope. However, the responses must be honest and realistic. Even occupational therapists with years of experience and extensive knowledge about disability and development cannot make definitive statements about the future. Long-range predictions about when the child will achieve a certain milestone or level of independence are always speculative. However, parents feel frustrated when they are told that the future cannot be predicted. Lawlor and Mattingly⁹¹ found that families want to be exposed to anticipatory planning. Parents want to understand that they have reason to expect that their child, despite disabilities, will have a place in society and an opportunity to engage in socially valued occupations during adulthood. Occupational therapists can help parents understand the range of possibilities by telling them about the continuum of services for older children and young adults in the community. Talking with parents of older children with a similar condition or hearing the occupational therapist's story

of a child with the same issues provides some insight into the future.^{44,156} Even without knowing the child's developmental course, parents start to develop an understanding that services are in place, and they begin to create new stories about their child's future. Given information about the system, their rights, and the resources available to them in their communities, parents can solve problems and access needed services independently.

The caregiving routines of parents whose young child has a disability are not particularly different from those of all parents of young children. At this time in the child's life, the parent's work consists of managing the child's play environment and introducing new, developmentally appropriate objects and materials. The parent ensures the child's safety and may adjust or arrange the play environment so that an infant can access objects of interest. Feeding, diapering, bathing, and daily care are also natural parenting activities at this time. Only when infants and young children have serious medical conditions or behavioral problems are daily occupations significantly altered. When children are medically unstable, but still at home, a family may have home-based nursing for extended periods (i.e., months to several years). Murphy¹¹⁰ has described the stress created by the constant presence of nurses and professional care providers in the home. Role ambiguity often results when parents think that they must take on unpaid nursing work and nurses take on a parenting role. Parents also report stress from a lack of privacy and the continual feeling that they are "on duty." Parents of medically fragile children must make tremendous accommodations, which must elicit high levels of sensitivity and responsiveness from professionals.¹⁰⁰ When parents have a medically unstable infant and 24-hour, in-home nursing care, services such as respite become a priority. When a child has life-threatening food allergies, the parent may need support sharing that information with personnel at the childcare center or preschool. Occupational therapists can be an essential support for families' interactions with the community (Research Note 5-1).

School Age

When a child enters school, all families are excited about the new opportunities for learning and the child's new demonstration of independence. However, school entry can be challenging for families of children with disabilities. Families who experienced early intervention services may be disappointed to find fewer family services and less family support offered by the school. Typically, parents are not encouraged to attend classes or school-based therapy sessions. Many parents view the transition to school as an opportunity to be less involved and a sign of their child's maturation, but some are distressed by the separation. To ease the transition from home to school, the parents of children with special needs should learn about the school's programs, schedules, rules, and policies (Figure 5-7).

For children with mild learning disabilities, entry into school may be the first time that the gap between a child's performance and teachers' expectations for performance is identified. Therefore, this may also be the first time that parents receive information that their child has special needs. When this is the case, parents can experience surprise, disbelief, or relief. School age is a time when children with disabilities may first discover that they have differences. How they make the adjustment to

Khetani, M. A., Orsmond, G., Cohn, E., Law, M. C., & Coster, W. (2012). *Correlates of community participation among families transitioning from part C early intervention services*. OTJR: Occupation, Participation and Health, 32 (3), 61–72.

Abstract

Objective. This study examined factors that contributed to level (full or restricted) of community participation in order to guide practice.

Method. This was a secondary analysis of data from the National Early Intervention Longitudinal Study (NEILS) on data through computerized telephone interviews. This study used a subsample of 2003 families across 20 states. Classification and regression tree (CART) analysis was used to examine correlates of full and limited community participation.

Results. 1450 families were classified into the limited community participation group and 553 families into the full participation group. Families in the full participation group tended to have younger children, live in two-parent households with higher income, have more formal education, and have paid jobs.

Conclusion. Difficulty in managing the child's behavior is a significant barrier to community participation and is associated with the degree of social support.

Implications for Practice

Occupational therapists should ask caregivers about family's levels of participation in community events and whether that is satisfactory. They should also ask about their strategies to manage their child's behavior and their level of social supports.

FIGURE 5-7 Child has an aide at school who supports his participation in both academic and nonacademic activities.

this information depends on the knowledge and sensitivity of the adults and children around them.

To the school-age child, making and keeping friends becomes critically important. Some parents report concern if their child appears lonely, isolated, and friendless. Children with behavioral problems frequently have no friends, leaving the parents with the additional responsibility of creating and supervising play opportunities with other children. Having peer friendships is associated with more positive school behaviors.¹¹¹ Teachers and occupational therapists can use different strategies to promote friendships in inclusive environments. Typically developing peers can take turns being a child's "special buddy," and they can offer assistance with projects or tutoring. In situations in which social stigma is an issue, peer relations can be promoted by explaining the disability to the other children and by designing classroom activities that promote cooperation and positive interaction.

Adolescence

Adolescence is a challenging and potentially stressful time for all families because the development of self-identity, sexuality, and expectations of emotional and economic autonomy herald the transition to adulthood. These issues may pose additional challenges in the lives of children with disabilities as they maneuver through adolescence. Parents need to prepare the young person to handle his or her growing social, financial, and sexual needs, as well as how to avoid substance abuse. (See the study of high-risk behaviors in adolescents with physical disabilities by Jones & Lollar.⁷⁵) In certain cases, parents face decisions about their child's use of birth control and protection from sexually transmitted diseases.⁵¹ With adolescence, new concerns about a son's or daughter's vulnerability increase as that child ventures further into the community and beyond. These decisions vary significantly depending on the nature of the disability—cognitive, physical, social, visible—and can be mediated by financial opportunities or constraints.

Although the child usually is well accepted by family members, the social stigma incurred from peers and others may increase during adolescence. The cute child with unusual behaviors may become a not so cute adolescent, with socially unacceptable behaviors. As one mother said, "The community accepts our children much more easily when they are small and cute. Babyish mannerisms are no longer acceptable. . . . [Our son] has had real problems with his social relationships. He simply does not know how to initiate a friendship. He has difficulty maintaining a sensible conversation with his peers. He doesn't handle teasing well, so he is teased unmercifully" (p. 90).⁴

Adolescence is the time when most parents must learn to let their children make their way in the world (Figure 5-8). For parents of children with disabilities, this time may require additional emotional support and financial resources. In addition, some parents experience difficulty caring for their child's growing physical needs. As the child reaches adulthood, parents who are reaching middle age may feel their strength and energy declining. As with all facets of the life cycle, this is a time for a sensitive, collaborative approach between families and service providers so that the right supports and resources are offered to each family. (See Chapters 4 and 12, on adolescent socialization, for more on this topic.)

Family Resources and the Child with Special Needs

Having a child with special needs does not eliminate any of the functions of a family. Families continue to provide a cultural and psychosocial foundation and guide their children's experiences in activities that will lead to optimal health and participation in the larger community. Understanding how families make choices in light of finite resources and their vision of a child's future puts some of the decisions families make about daily activities and what they want to work on in a different light. Sometimes, especially when a problem is recently diagnosed or when medical treatment is needed, family resources (e.g., time, money, emotional energy) may be directed primarily to the needs of the child.¹⁰⁶ For example, a mother who has a full-time job to help pay medical and therapy bills and spends 4 hours a day feeding her medically fragile child has limited time and emotional energy to devote to helping another child with homework or sharing in recreational activities. Over time, this allocation of resources may become more balanced or could have negative implications for family members.

Financial Resources

Having a child with special needs has implications for family economics. Parents with children who have disabilities have many hidden and ongoing expenses. When children are hospitalized, many expenses (e.g., days out of work, childcare for siblings, transportation, meals, motel rooms) are incurred, in addition to costs not covered by insurance.¹¹⁷ Mothers on welfare have reported that they face multiple barriers. Although they wanted to become self-sufficient, they found that employment seemed like a distant dream as they struggled with transportation and finding childcare, particularly for older children.^{94,153}

Many insurance plans have caps on the number of therapy visits allowed per year. Therefore, some parents must cut back on services or pay for sessions by finding a way to save somewhere else. Children who require extensive medical treatment can bring economic devastation to a family, especially when insurance coverage is inadequate.¹¹⁷ Financial problems create added stress, and occupational therapists need to be aware of how costs associated with their own services and recommendations may affect the family and child whom they are serving. There might be times when a decision to cancel an appointment is made for financial reasons.⁷⁴

Another challenge to financial resources occurs when a parent decides to remain unemployed so that he or she has time to provide extra caregiving. A number of studies have documented that a parent may need to work fewer hours, or not work at all, to care for the child.^{49,121} With one spouse unable to take on paid employment, these households are at higher risk for problems associated with low income. Financial strain is increased in single-parent homes. Case-Smith⁴¹ has found that mothers of children with medical conditions left employment because of the frequency of their children's illnesses. These children needed specialized medical care (e.g., nursing care) that prohibited them from attending community childcare centers. The need to stay home with a child who has multiple medical needs and frequent illnesses, coupled with lack

FIGURE 5-8 Participation through the family life span. **A**, Infant twins (Sadie and Madie) change the family dynamics as parents balance their new roles. **B**, School aged-children take on new roles (students) and associated responsibilities. **C**, Dad pulls his tired children through a theme park. **D**, Years later, young adult Keith helps his dad by taking his turn pulling through a theme park.

of community childcare for such a child, can become a particularly difficult situation for parents to manage. Part of the essence of family-centered care is addressing these needs in a family.⁷³

Human Resources

The human resources important to a family raising children are education, practical knowledge, and problem-solving ability. Sometimes, the challenges of raising a child with disabilities are related to the sense of competence that the parent experiences.³⁰ An understanding of the basis of the child's problems and of possible adaptations is a powerful resource when helping families establish effective patterns of daily activities. A comprehensive parent-professional partnership should include ongoing sharing of information with parents. Initially, most parents want information about their children's conditions and about accessing services.⁴¹ After that, they need information about potential complications and how to care for their child's physical and psychological needs on a daily basis.⁶⁹ The timing of

parents' ability to use this knowledge and engage in home programs varies appreciably from the time of initial diagnosis of disability through adjustment to their situation. Qualitative studies have suggested that meeting the need for information is challenging because it is difficult to judge a family's priority needs and their readiness to assimilate information about managing their child's condition.^{69,120} Occupational therapists need to keep their therapeutic listening and observation skills sharp and be flexible in their information sharing.

Families who are coping with stress have reported that "the ability to build on personal experience and expertise" (p. 261)⁵⁴ is an essential coping strategy. Parents can develop this knowledge through parent groups in which families can share strategies with other families who have had similar types of issues.^{42,156} Occupational therapists, by listening to parents and individualizing the information, as well as connecting family members to other resources, help build the parents' personal resources. The CanChild Centre for Childhood Disability Research has developed a formal, individualized information package for parents, The KIT: Keeping It Together, which has been shown to

increase parents' "perceptions of their ability and self-confidence in getting, giving and using information to assist their child with a disability" (p. 498).¹³⁸ Occupational therapists must remember that many parents are the experts on their own children and often have extensive information or stories to share about what works for them.¹³

Time Resources

Daily and weekly activities require time investment, and every family at some point experiences stress because there are too many things to be done and not enough time. Children with disabilities often depend on caregivers longer than typically developing children, and the extra daily care or supervision needed can extend for many years.^{33,42,98,127} Much of the research on caregiving time has focused on mothers, although the distribution of caregiving between parents has changed in recent years, with a shift of some caregiving tasks to fathers.

Helitzer and colleagues⁶¹ have found that mothers of children with disabilities reported that they used "structure, routine, and organized time management as a way to maintain a sense of control" (p. 28). However, their busy structured lives often were disrupted by crises, such as trips to the hospital or urgent care department, and, as a result, the mothers felt that they were "living on the edge" and that every disruption in their routine was experienced as a crisis. In a qualitative study of parents of children with chronic medical conditions and disabilities, parents reported that they had 24-hour responsibilities in administering medical procedures and performing caregiving tasks.²⁷ They described the challenges of "always being there" to care for their child's extraordinary medical needs and engage their very dependent child in developmentally appropriate activities. Children with feeding concerns also present a major challenge to managing time and tasks.¹⁵⁸

Service providers need to consider the family's time and emotional resources when recommending home programs. Providers seeking to implement family-centered practice often expect parents to take on responsibility for implementing therapy.^{93,96} These home assignments can become a source of guilt and marital difficulty as the family struggles to meet the demands of the provider or else be labeled as noncompliant. Less experienced occupational therapists, in their enthusiasm to help, often neglect to consider the family's time commitments when offering suggestions. Careful listening and asking about the degree of comfort that each caregiver has with aspects of intervention go a long way in building and maintaining good rapport and meeting the needs of the family. Exploring the possibilities of caregiving activities being shared between the parents, and possibly other family members, can make them more manageable and reduce the everyone's stress levels (Research Note 5-2).

Emotional Energy Resources

Families of children with disabilities may experience special forms of stress, social isolation, and less psychological well-being than families with typically developing children.^{10,36,102} The idea that parents of children with disabilities experience recurrent grief is pervasive in the literature, but has been disputed.^{43,149} Fox and colleagues⁴² conducted a qualitative investigation to understand how children with developmental delays

RESEARCH NOTE 5-2

Fingerhut, P. E. (2013). Life Participation for Parents: A tool for family-centered occupational therapy. American Journal of Occupational Therapy, 67, 37-44.

Abstract

Objective. This study describes the continued development of the Life Participation for Parents (LPP), an assessment to facilitate family-centered pediatric practice.

Method. A cohort of 162 parents of children with special needs receiving intervention at 15 pediatric private practice clinics completed LPP questionnaires. Instrument reliability and validity were examined.

Results. Good internal consistency and test-retest reliability were established. A construct validity was examined through an assessment of internal structure and comparison of the instrument to related variables. A principal components analysis resulted in a two-factor model accounting for 44% of the variance. As hypothesized, the LPP correlated only moderately with the Parenting Stress Index—Short Form. A child's diagnosis, age, and time in therapy did not predict parental responses.

Conclusion. The LPP is a reliable and valid instrument for measuring satisfaction with parental participation in life occupations.

Implications for Practice

The LPP can guide intervention by providing information on the caregiver's participation in life occupations.

and behavioral problems influenced the family's lifestyle. The parents they studied reported that dealing with the child's 24-hour, 7-day-a-week needs required emotional energy and often engendered frustration. Parents reported that individuals who offered "a shoulder to lean on" and professional assistance, encouragement, and information were particularly helpful.

There is evidence that parents of children with disabilities may experience anxiety and depression.^{60,127} Mothers appear more vulnerable than fathers. Hastings,⁶⁰ investigating levels of stress, depression, and anxiety in a cohort of 18 couples with children with autism, found that mothers and fathers felt similar levels of stress; however, mothers were more anxious. It was suggested that mothers may feel more responsibility for the child and may take on a larger part of the extra care that a child with disabilities requires. Sawyer and colleagues¹²⁷ found that mothers who experienced increased time pressure to complete all their tasks had higher rates of mental health problems. When parents must administer medical support, beyond the typical parent-child activities of nurturance, caregiving, and play, they often find themselves exhausted and sleep-deprived, and appear to experience increased stress and anxiety.⁶² In addition, they often do not have the time and resources to access energizing and relaxing activities, such as socializing or recreation.^{10,127}

Stress level in families with children with chronic diseases or conditions has been found to have a strong relationship with family income and family function, with lower income associated with higher stress, especially as the children become adolescents.¹⁰ Parents with limited resources, whether financial, educational, emotional, or a combination, are at higher risk of

experiencing parental stress, which may lead to abusing or neglecting children with disabilities.^{63,135}

Sources of Diversity in Families

Families with children who need occupational therapy services come from many different backgrounds and have a variety of forms. Occupational therapists working with these children have the rewarding opportunity to learn from these families, but must find a balance between focusing on the similarities and appreciating the differences among families. Because individuals are inclined to view the world through their own cultural model and use personal experiences as a point of reference, it takes professional commitment to become skilled at working with a variety of families.

Family researchers and service providers have focused on understanding how a family's culture and traditions affect child-rearing practices and how these might be adaptive, strengthening a family and bringing about positive developmental outcomes.⁸⁴ Families have patterns of different characteristics (e.g., family structure, family income, having a family member with a disability) and the ecology in which families' function varies (e.g., religious opportunity, crime rate in the neighborhood, period in history). Therefore, generalizations of research findings about diverse family groups may not be accurate, and sensitivity to the unique differences of each family is always needed.³² The three sources of family diversity discussed next are the family's ethnic background, family structure, and socioeconomic status. A fourth section considers differences in parenting styles and practices.

Ethnic Background

Ethnicity is a term used to describe a common nationality or language shared by certain groups of families. It tends to be a broad concept, and heterogeneity among families within groups described as Hispanic, African American, Anglo American, or Asian is often anticipated. However, people may identify themselves as belonging to more than one ethnic group, making it harder to use this concept to guide how the occupational therapist works with families. Coll and Pachter³¹ have offered two reasons for retaining ethnicity as an important variable when working with families raising children. First, families that are not part of the dominant ethnic group may experience a discontinuity between their cultural models and the majority culture, which shapes the social institutions. Thus, a cultural and language gap may exist among health systems, educational programs, and the families of minority ethnic groups.² In addition, as the proportion of ethnic groups grows in the United States, the sons and daughters of these groups will make up a larger proportion of the overall population of children in this country. Occupational therapists who serve children with special needs can anticipate working with an ever-growing, ethnically diverse group of families. The influence of ethnic background on how a family fulfills its functions and raises its children is a complex topic that is merely introduced here. Resources on the Evolve website provide further information.

Ethnic groups share cultural practices that can determine who has the authority to allocate family resources and a value

system that sets priorities for family routines and special events. Families in an ethnic group may have similar daily activities, ways of interacting, and ways of thinking about events and may find similar meaning in their routines, traditions, and celebrations. Differences among ethnic groups are expressed in gender role expectations, child-rearing practices, and expectations at certain ages, as well as in definitions of health and views of disability. Cultural practices are not static traits but change when members of the group adapt to new situations.⁵⁸

The recent influx of immigrants expands the diversity within ethnic groups that therapists encounter. Within a community, one family may have members who have been in a country for generations, and the family next door may have recently relocated to the country. Migration affects the family and how it functions at multiple levels.⁴⁰ Relocation to another country frequently includes a series of separations and reunions of children and family members, sometimes for 2 years or longer.¹⁴¹ In some families, the tradition of having a child live with a grandparent or other relative may buffer the initial separation and help reduce the stress. When both parents emigrate ahead of their children, it is not unusual for the children subsequently brought into the country to have to adjust to living not only with their parents again, but also possibly with younger siblings born in the new country. Occupational therapists working with immigrant families need to be sensitive to the possibility of family friction, depression, and sense of uncertainty among family members.

For each immigrant family, the process of *acculturation* varies; this is the process of selectively blending their traditions of how things are done, which activities are important, and interactive styles with the cultural practices of the majority group.⁴⁰ Parenting practices might insulate children from exposure to the language, ways, and values of the majority culture until the children go to school. For example, some cultures may equate enrolling children in childcare programs with child abandonment. Those families may bring a grandparent with them as part of the immigration process to be the caregiver, so that both parents can find paid employment. These children may have had few experiences beyond their home environment before entering school. In school, surrounded by new peers, the children's acculturation process is accelerated, creating conflict among family members.⁹⁸ Unfortunately, feeling disconnected from home or discriminated against at school leads some youth, including youth with disabilities, to drop out of school as a way to ease the tension.⁵⁸

Although every family wants its children to be successful members of the community, the family's vision of what this entails varies among different ethnic groups and influences the time use and expectations of children. Carlson and Harwood²⁶ observed Anglo American and Puerto Rican mothers in their daily routines and found that Puerto Rican mothers controlled their infants' behaviors more than the Anglo American mothers, who tolerated more off-task behaviors. Puerto Rican parents seemed to be guided by the anticipation that their children will join a Puerto Rican community that values respectful cooperation. The Anglo American willingness to follow the child's lead is compatible with valuing individual autonomy. Without insight into ethnic differences, an occupational therapist, observing a parent-child interaction, may mistakenly interpret a Puerto Rican mother's physical control and effort to divert a child's attention to the needs of others as intrusive and

insensitive to the toddler's sense of self-efficacy. Occupational therapists avoid this type of error by understanding what a parent hopes to achieve before formulating an opinion about the appropriateness of a family's interactive routines.

Family Structure

Family features, such as the presence of children in the household, marital status, sexual orientation, and age or generation, are factors described as the *family structure*.¹ It is important to remember in working with families that acceptance of diversity within the family structure and family subsystems is necessary to be effective.

Family structure, in combination with its cultural model, influences how the family organizes itself to fulfill essential roles, such as caregiving of dependent family members or allocation of family resources. The idea that there is a best family structure in which children are raised is a myth.⁸ For example, single-parent families have been portrayed as dysfunctional and as leaving children more vulnerable to having problems,³ yet single parents, especially single fathers, have also been found to raise competent, well-adjusted children.²³ The Fragile Families and Child Wellbeing Study is an attempt to discard myths and replace them with evidence that will guide intervention and policy making to support low-resource families.¹⁰⁵ Some of their findings have demonstrated that “unwed parents are committed to each other and to their children at the time of birth.... Most unmarried mothers are healthy and bear healthy children” (p. 3).

Larson⁸⁸ sampled the activities and emotions of employed mothers in two-parent or single-parent homes of adolescents and found that the stereotype of the single-parent home was not necessarily the rule. Single mothers in his study had less stressed, more flexible routines after a day at work and friendlier relationships with their teenagers than their counterparts in two-parent homes. Mothers with a husband reported more hassles trying to make and serve dinner by a designated dinner time and experienced housework as more unpleasant. Larson⁸⁸ speculated that the negotiation of responsibilities and trying to live up to expectations of being a “wife” in a two-parent home contributed to these differences. Clearly, every family structure has advantages and risk factors.¹¹

Many single-parent families are formed through divorce. This can cause disruption that alters household routines, traditions, and celebrations. Sometimes, the stress between marital partners leads to impaired occupational functioning of the children, and the divorce may come as a relief. Factors that contribute to positive developmental outcomes for children after couples break up include the parents' psychological well-being, economic resources, whether the family is part of a larger kinship network, and how parents navigate the separation and dissolution process. Greene, Anderson, Hetherington, Forgatch, and DeGarmo⁵⁵ reported contradictory findings regarding how well children adjust after their parents' divorce. Initially, parenting practices were erratic, and the parent-child relationship, especially between custodial mothers and young sons, could be stormy. Yet, 2 years after a divorce, many of the problems had diminished; therefore, some of the consequences of divorce depend on where in the adjustment process researchers conduct their study. The occupational therapist can be supportive by acknowledging that these parents face

considerable challenges in raising children alone and by aiding the parent in identifying resources, such as friends, extended family, religious groups, and other single parents.

Gay, lesbian, and bisexual families reflect one variation of family structure that therapists encounter; parents who are not heterosexual comprise 1% to 12% of families.¹³⁶ Children may be the products of a parent's previous heterosexual relationship or may be born or adopted into families headed by adults who are gay, lesbian, or bisexual.^{87,118} Studies comparing the psychological adjustment and school performance of children being raised by lesbian or gay parents with those of children with heterosexual parents have generally found no differences.¹¹⁸

When birth parents are unable or unavailable to care for children, *kinship care* is a way to preserve family ties that might be lost if children are placed in foster homes.⁴⁶ Households in which grandparents are raising their grandchildren are examples of those providing kinship care and are a growing source of differences between families. These families, primarily headed by middle-aged or older women, and disproportionately by women of color, are often formed after adverse events, such as child neglect or abandonment, maternal substance abuse, or incarceration or death of the parents.^{46,86,123} Much of the research on grandparents raising their grandchildren has explored the issue of caregiver stress. Evidence from qualitative and quantitative studies has suggested that grandparents caring for their grandchildren (or great-grandchildren) find it rewarding and challenging.⁴⁶ Grandparents reported satisfaction in being able to “be there” for the child or children, and that they had to learn new parenting skills in response to the new generation. However, some also experienced parenting stress, which was exacerbated when they lacked social and/or financial resources or were in poor health.

During their childhood, many children experience changes in the family structure. Unwed mothers may marry, or parents in a family may divorce, and later one or both may remarry. A child may transition from a two- to three-generation family when an aging grandparent moves into the home. Therapists should talk with family members in an inclusive manner that does not suggest an assumed family structure. Asking a parent or child, “Can you tell me about your family?” does not suggest any expectations and helps family members openly express their definition of who is in their family.

Socioeconomic Status

The influence of the family's SES on children's occupations and development is complex.⁶⁶ SES reflects a composite of different factors, including the social prestige of family members, educational attainment of the parents, and family income. These factors influence each other, and have various implications for how a family fulfills its functions, by influencing the degree of access that families have to activities and experiences for their children. Parents who pursue higher or continued education may be more likely to incorporate new ideas about a healthy lifestyle and child development into their parenting practices. Factors that influence employment, such as a below-average education, inability to speak English, or disability of a family member, leave families more vulnerable as job opportunities come or go. When employment is found, the job may not pay enough to meet the family's needs, leaving the family with no resources if unexpected events occur.

Low income or limited education is associated with differences in the quality of parents' interactions with their children.^{66,125} In these circumstances, parents may not be as responsive, addressing the child less often, providing fewer learning opportunities, and not engaging in an interactive teaching process. Factors associated with having children with disabilities, including the increased cost of raising such children and decreased ability of their mothers to be employed, increase the likelihood that families will live in poverty.¹¹⁶ Suggestions for working with families with low SES are described later in this chapter.

Therapists need sensitivity and skill to work with families across the SES continuum. Having a higher SES clearly affords additional opportunities, time, and expectations of parents to advocate for those experiences that they desire for their children. The concept of "helicopter parents," who hover over every aspect of their child's life, also applies to parents of children with special needs. Therapists must draw on their many skills in assisting these parents to find balance between what can be done through direct service, what they can do themselves, and how to allow a child space in which to be a typical child and do for him- or herself.

Parenting Style and Practices

The individual interactive style and parenting practices of an adult raising a child are additional factors that must be considered to understand the diversity of families. Steinberg and Silk¹³⁷ have distinguished between *parenting style*, the emotional climate between parent and child, and *parenting practices*, goal-directed activities that parents do in raising their children. For example, two parents may believe that if they want their child to do well in school, it is their responsibility to spend time with the child reviewing the homework (a parenting practice). However, the interpersonal interactions while they engage in this shared activity (parenting style) can be distinctly different. One parent may discuss the work and help the child find solutions to problems, whereas the other parent may feel that she or he only has the emotional energy to point out errors. There is no test or license for parenting in this country. In the past, extended family members provided mentorship and modeling for parenting practices. In today's nuclear families, stresses run higher, and skills may be lacking.

A well-adapted child develops as a result of complex interactions between parenting style and practice. Regardless of ethnic background, socioeconomic status, or parenting practices, a parenting style that is warm, responsive, and positive, and that provides structure and learning opportunities, is associated with children who rank higher on many measures of social and cognitive development.^{6,137}

The collaborative nature of the relationship between parents and occupational therapist may not be smooth if each holds different ideas about parenting style or parenting practices. This tension increases if the parents worry about the occupational therapist's disapproval.^{39,93} The professional cannot assume to have more knowledge than the parent about what the child needs to be able to do or about the interactive style that best accompanies shared activities.⁷⁶ Occupational therapists can be supportive and empower parents by working with them so that family resources, such as time and emotional energy, are available when shared activities occur.

An Ecologic Perspective

As with any other open system, the social and physical features surrounding the family influence it. An ecologic and transactional perspective of development and parenting encourages occupational therapists to consider family resources and the adult's psychological background, personal history, and personality, which are in constant interaction with characteristics of the child being parented.^{25,85,126} In addition, some occupations of families take place beyond the home. Many of the resources for family activities that enable families to function effectively are available in the neighborhood and larger community. Proximity to places of worship, stores, high-quality childcare, and friends is part of the family's ecology and influences how family members spend their time. It is important to take an ecologic perspective and investigate whether families can access a range of community activities that will enable them to fulfill their functions. At a slightly more removed level, family functions are supported when social institutions make services available (e.g., a health department that runs an immunization clinic, volunteer group that helps parents choose the best childcare centers, businesses that raise money for a school system). Occupational therapists who strive to enable children's occupations use a collaborative empowerment model in which families draw on their knowledge of their children's abilities and receive support from other families and professionals to make changes at the community level.¹⁴⁸ By joining with families in advocating for children's rights, occupational therapists contribute to a synergistic force that increases the family's access to resources outside their homes and helps them function as a family.

Supporting Participation in Family Life

Development of Independence in Self-Care and Health Maintenance Routines

Occupational therapists who understand the nature of family occupations can help parents manage and adapt daily living tasks with their children. The occupational therapist assists the parent in establishing goals about daily routines and tasks that the parent values, and then observes how they are being done. The occupational therapist may engage the parent in a discussion of alternative strategies or may model techniques that help the child perform daily living activities with greater skill and independence. With knowledge of the biomechanics of lifting and moving, the occupational therapist considers whether the task is performed in a way that conserves energy and avoids injury. This consideration is especially important when a physical impairment significantly limits mobility. Strategies to help a 5-year-old bathe, dress, and use the toilet may no longer be safe for the parent's back when the child becomes an adolescent. An occupational therapist's knowledge of adaptive solutions to self-care, such as Velcro fasteners or, if standing balance is too challenging, dressing while sitting, can be quite helpful to parents, especially first-time parents.¹⁰⁹ Any extra time that the therapist asks the parent to spend teaching new steps in self-care should be in response to a parent's identified need. In addition, the effort should be justified by evidence that the

FIGURE 5-9 A, Recreational opportunities in the community provide an important family occupation. (Courtesy Jill and Mark McQuaid, Dublin, Ohio.) B, Wee Can Ski provides equipment for children with diverse abilities. C, Keith has a tennis lesson while Dad watches proudly.

altered routine has a good chance of bringing about an immediate change. Alternative suggestions should be made quickly when an adapted technique does not work. The goal of occupational therapy recommendations should be to benefit the entire family by increasing the child's independence at minimal cost in time and energy to the parents.¹⁴⁶

Becoming independent in self-care occupations frequently requires repeated practice until performance becomes a habit. Occupational therapists can help parents reinforce a child's efforts at independence. Continuity in frequently repeated self-care occupations, such as using the toilet and eating with utensils, is increased when the occupational therapist initiates communication with teacher, parents, and others. A notebook that the child carries between school and home may serve this purpose.

Participation in Recreational and Leisure Activities

The family's ability to engage family members in recreational and leisure activities is the result of a multidimensional process

that includes the community family and child with a disability^{80,81} (Figure 5-9). One factor that can directly influence participation is the availability of an inclusive program, wherein peers and activity leaders support the child's ability to participate. Other factors, such as the extent to which the parents perceive acceptance from friends and neighbors and how parents view being active, indirectly shape whether families choose to participate in recreational activities in the community. Parents of children with developmental delays and behavioral problems sometimes limit taking their child into the community in response to negative reactions of other people.^{21,43} Parents of children with a developmental coordination disorder may need to consider individual rather than team sports as options for their children¹⁰⁹ (Figure 5-10). Resources, such as money to purchase equipment and time to transport children, influence the extent to which a family can participate in recreational activities. Families that can afford vacations will find that many theme parks have become more accommodating to their needs.

Occupational therapists can communicate that they respect the value of recreation and leisure by including it in assessment and intervention plans. Occupational therapists can suggest

FIGURE 5-10 Most skiing facilities have equipment for children unable to stand independently.

adapted equipment that the child can use to make recreational activities possible. With the passage of the Americans with Disabilities Act in 1990, more recreational opportunities became available to those with disabilities. Information about community recreational activities is often available in local newsletters or on websites. Occupational therapists can note which activities are accessible and appropriate for children with disabilities (Figure 5-11). They can also suggest strategies for making the family's outings more successful, such as providing headphones for a child with auditory sensitivity. Practitioners can also help parents accomplish caregiving tasks efficiently to make more time available for recreation. Scheduling therapy and education programs at times that allow families to engage in recreational activities can also support family function.

Socialization and Participation in Social Activities

Socialization not only is needed for health but is an important mechanism for preparing family members to enter their cultural group and participate in community activities. Most families of children with disabilities, particularly children with problem behaviors, report that far too few opportunities exist for participation in the community. Families perceive that they are the only socialization agents for their children because community social activities simply do not accommodate their children.⁸⁹ In addition, children with disabilities may interact more frequently with adults than with peers, particularly if they have classroom aides. Constant interaction with adults to the exclusion of peers may exacerbate feelings of social incompetence in interactions with peers. Educational and intervention programs should focus more attention on helping friendships develop and flourish.

A child's disability may also create barriers to the parents' opportunities to socialize. Families of children with special needs often feel that they have less time to spend participating in social activities.^{33,89} Because childcare is typically difficult to arrange and must be set up in advance, taking advantage of spontaneous social opportunities is rarely possible.⁷ Children

FIGURE 5-11 Activity centers with soft mats, bolsters, balls, and tunnels for tumbling offer safe and accessible environments for children with physical disabilities.

who act out or demonstrate disruptive behaviors may be particularly difficult to manage in social situations.

Parents often find it helpful to develop friendships with other parents experiencing similar circumstances. A number of studies have found that increased social supports are associated with healthier family functioning and lower levels of stress.^{20,150} Helitzer and colleagues⁶¹ implemented a program for mothers of children with disabilities to address their concerns and difficulties in daily routines and coping. The mothers were encouraged to provide emotional support to one another and assist each other in resolving specific dilemmas in daily routines. They perceived that they had changed their self-image and coping strategies through participation in the group sessions. They placed great value on having "a supportive opportunity to discuss their feelings and thoughts in a setting that was

nonjudgmental and comfortable” (p. 408).¹⁵⁰ Similar programs offer parents social supports and strategies to help in coping, as well as practical ideas that make everyday life easier, help them adapt to stress, and give them a more positive attitude toward their children.¹⁵⁶ These social supports appear to be of equal or greater importance to families than professional services.²⁴

Fostering Readiness for Community Living

Families of children with disabilities express concerns about the future for their children, particularly once they leave school. They worry that their children will not have the life skills needed to live independently.⁹⁸ As children become adolescents and then young adults, parents need information on possible living arrangements in the community. Often, young adults are capable of leaving home but need support persons and arrangements for short- or long-term supervision and monitoring. These young adults may not have many options, and the options may be overly restrictive (to secure funding) or may not provide sufficient supervision. Parents of young adults with disabilities emphasize the need for information on housing, particularly innovative, supported, living arrangements. For these young adults to succeed in living in the community with support, families need assistance in finding roommates, other support persons, funding, and arrangements for supervision and monitoring.

Young adults with disabilities face many challenges in finding and maintaining employment; however, new models that support work performance and assisted community living have demonstrated success.^{10,98,122} (See [Case Study 5-1](#) for an example.) Families and professionals need to work together to advocate for changes in the community to create opportunities for young adults to become employed and productive members of society (see [Chapters 12](#) and [25](#)).

Family Adaptation, Resilience, and Accommodation

Despite the inclination of families to organize their activities into predictable patterns in the form of their routines, traditions, and celebrations, these are dynamic systems, and change is inherent in being a family. Pressures that can alter family activities include daily hassles, such as multiple demands on a parent’s time or unpredictable transportation, as well as positive life transitions, such as the birth of a baby or an older son’s leaving home to take a job, which alter household routines. Other events requiring that families adapt their routines and traditions may be unexpected, such as job loss, illness, or an event that affects the community (e.g., a natural disaster). When families experience new demands and stresses, they continue to function by creating meaning about the stressful event and by working as a system to adapt and continue their daily activities.

The process of *adaptation* starts when a family recognizes the state of affairs—an interruption in their activities or a loss of emotional well-being.^{53,119} Families use a variety of strategies to make sense of what is happening.¹⁵⁴ They may tell stories about a similar situation or another generation that experienced a comparable event or redefine what seems like a catastrophic

event by making a comparison with another family. Finding positive meaning in an adverse event is a way of changing how it is experienced. Regardless of the strategy used, by co-constructing their own definitions of events, families diminish the feeling of being out of control and, based on how they define the state of affairs, can allocate resources to manage the situation.

Families demonstrate resilience when they draw on resources to reconstruct their routines or create new ones that enable them to continue to fulfill family functions. McCubbin and colleagues¹⁰¹ have identified factors that contributed to families’ resilience and ability to manage when children were diagnosed with cancer. Based on their interviews of 42 parents, they found *resiliency factors* that made it easier for the family to construct new routines to deal with the situation. These families drew on their own resources, such as religious beliefs and emotional support of each other, and then reset their definition of how they would live or operate as a family. The parents rearranged their routines so that one parent could be with the child receiving inpatient medical treatment while the other stayed at home with the siblings. Parents reported that they also drew on resources in their community. For example, when neither parent had time to cook, members from their church brought in meals so that the family could share meals together. In a longitudinal study of families with a child with developmental delays, Bernheimer and Weisner¹⁵ refer to these changes that maintain daily routines as *accommodations*. They identified 10 accommodation domains (e.g., services, marital roles, social support) that varied in frequency of need over time. When the children were 3 years old, the highest frequency areas of accommodation were childcare tasks, sources of information, and support. They noted that family daily routines were strongly influenced by cultural and family values and goals.

The family members’ ability to communicate with each other is important to co-construction of meaning and adaptation of daily routines. Families engage in affective and instrumental communication. In *affective communication*, family members express their care for and support of each other. In *instrumental communication*, members give each other role assignments, establish schedules, make decisions, and resolve conflicts. Clear, effective communication is important for establishing meaning for an event or problem and for planning resolution of the crisis. As Patterson¹¹⁹ noted, “A family’s belief in their inherent ability to discover solutions and new resources to manage challenges may be the cornerstone of building protective mechanisms and thereby being resilient” (p. 243).

A child with exceptional health or developmental needs creates new demands on a family system. Families with sufficient resources and flexibility respond by adapting their daily routines and special events so that they can fulfill their family functions. Occupational therapists who recognize the power of daily routines and family traditions are sensitive to the disruption of a family’s pattern of activities and can assist parents in reestablishing or creating meaningful family routines. For example, the occupational therapist may suggest strategies that enable a child with a gastrostomy tube to participate in the family mealtime, such as explaining to the parents what foods the child can safely “taste” at the dinner table.

The fact that most families adjust successfully to children’s disabilities should not lead occupational therapists to ignore the initial and ongoing challenges that families face. Times of

coping and adaptation vary according to whether a family must adjust to an acute traumatic event leading to a disability or the family gains a gradual, unfolding understanding of the child's developmental differences. After the diagnostic period, when the child's problems are identified, the family goes about the process of living. During this period, the demands for adaptation and coping vary. The following sections describe how occupational therapists can offer support, intervention services, and education to families.

Partnering with Families

Parent-professional partnership grows from an appreciation that by working together, both the occupational therapist and parent can share important expertise and knowledge that will make a difference in the child's life. The sustained involvement and special insights that families bring were discussed earlier; this section goes into more specificity regarding the different ways occupational therapists work with families.

Family-centered services refers to a combination of beliefs and practices that define particular ways of working with families that are consumer-driven and competency-enhancing. These beliefs and practices are necessary if occupational therapists are to be successful in team development and implementation.^{68,145} Definitions range from acting as service coordinators to addressing the needs of the family for financial and social resources as part of an intervention program to empowering family members as part of a team to make decisions about their child's program.⁹⁶ Three complementary models for family-centered services are family support, direct services, and family collaborative education.

Family support is designed to bolster a network of social support to enhance the family's natural strengths and family functions. DeGrace³⁶ has recommended being aware of how a disability affects family occupations in addition to addressing the child's issues. Social support, such as being able to talk with other parents, decreases the family members' feelings of isolation and stress.^{31,102,156} Promoting a family's well-being through emotional support and practical suggestions allows families to engage in responsive interactions with their children. The occupational therapist's role in providing family support is to help the family secure needed resources and capitalize on its existing competencies and strengths.^{52,56}

Direct services are provided when the occupational therapist engages a child in an activity with the goal of promoting the child's skill acquisition and minimizing the consequences of a disability. This is the traditional and, for the occupational therapist and most institutional facilities, the more reimbursable form of interaction. Family members should be present and participating in the therapeutic activity, but the occupational therapist's attention is on promoting the child's engagement in the activity. Unless handled with skill and sensitivity to the family, this type of service may fall outside family-centered practice.

Family collaborative education has a number of purposes and should be individualized to the families' interests, learning styles, and knowledge levels. In parent-mediated therapy, the caregiver is taught how to engage the child in an activity designed to achieve a parent-identified goal or outcome.⁸ Interventionists then guide parents in using strategies that can be

implemented within the natural flow of everyday activities.⁷⁷ Strong evidence indicates that the more parents know about development, the more responsive and supportive they are in interacting with their child and the better prepared they are to foster optimal development.^{138,151}

When considering the father specifically, if he is the family's primary decision maker, it is critical that he receive complete information about the decisions that need to be made. Also, it has been reported that when teaching fathers an intervention that they then explain to their spouses, a resulting decrease in maternal stress levels was found.¹⁴ Benefits to collaborative education are found beyond the scope of parental involvement and broaden to include grandparents and siblings.^{99,144}

Sharing information with families is likely to be most effective when the child demonstrates interest in doing the activities that the team has targeted. At that point, the occupational therapist becomes a "coach" who facilitates an exchange of ideas that helps the parent discover ways of helping the child learn the activity.⁵⁷ This dialogue includes periods of observation and reflection. Coaches bring pragmatic understanding of the intervention strategy and serve as a resource.^{52,77} Unlike in direct therapy, the family is the focus of the therapist's attention, and the parent or family member is the one interacting with the child ([Research Note 5-3](#)). Sharing with a family in

RESEARCH NOTE 5-3

Graham, F., Rodger, S., & Ziviani, J. (2013). Effectiveness of occupational performance coaching in improving children's and mothers' performance and mothers' self-competence. *American Journal of Occupational Therapy*, 67, 10–18.

Abstract

Objective. This study examined the effectiveness of occupational performance coaching in improving children's and mothers' occupational performance and mothers' parenting self-competence.

Method. A one-group time-series design was used to evaluate changes in children's ($n = 29$) and mothers' ($n = 8$) occupational performance at four time points: (1) pre-wait list; (2) preintervention; (3) postintervention; and (4) follow-up.

Results. Significant improvements in occupational performance occurred postintervention for children and mothers that were maintained 6 weeks after intervention. Mothers' self-competence in parenting also improved.

Conclusion. These findings provide preliminary evidence supporting the effectiveness of occupational performance coaching in improving children's and mothers' occupational performance and mothers' parenting self-competence. Improvements were sustained and appeared to generalize to other areas of performance.

Implications for Practice

Family-centered care involves addressing the needs of the parents and child to foster the accomplishment of goals. Coaching caregivers may have more effect on children than direct service alone. Coaching in one area of performance may lead to generalized improvements in other areas.

this way requires a range of skills, including an understanding of development, well-grounded expertise in how to implement an intervention that has proved effective, and ability to communicate in an egalitarian way, which the family can choose to follow or not.^{77,93} The therapist wants to empower the family, not engender dependence on a professional's expertise.^{8,37,96}

Family education that focuses only on helping the parent minimize the child's disability and optimize developmental gains is too narrow. Furthermore, teaching must be a two-way process that will strengthen the family by recognizing the expertise of its members. Involving parents who are knowledgeable about community organizations and activities designed for children with special needs as educators in collaborative teams promotes their expertise. Parents can contribute information, resources, and strategies for caregiving for a child with special needs well beyond the professional's knowledge.¹⁶

Establishing a Partnership

The first interactions of the therapist with a family open the door to the establishment of a partnership. In a family-centered approach, the therapist demonstrates a family orientation that establishes trust and builds rapport through the use of open communication, mutual respect, shared decision making, and parental empowerment.¹⁶ The therapist's initial interview reflects an interest not only in the child's behaviors but also in the family's concerns with managing those behaviors. These first interactions demonstrate that an equal partnership is desired, and encourage a give and take of information. At the same time, parents begin to understand that professionals are there to help them and can provide information and resources to support the child's development.^{8,56,145}

Trust building is not easily defined; it is associated with nonverbal language, words, and mutual respect. Thinking the best of families is important to the development of this partnership. This may not always be easy, particularly when the family's lifestyle contradicts that of the professional. Being positive and maintaining a nonjudgmental position with a family can be challenging, but it is essential to establishing and building a trusting relationship. Parent participants in focus groups have defined respect as simple courtesies from professionals, such as being on time to meetings.¹⁸ The professionals who were interviewed linked respect to being nonjudgmental and accepting of families. When professionals are disrespectful to families, parents may become reluctant to access services or may lose their sense of empowerment. Demonstrating respect for families becomes particularly important when they are of different racial, ethnic, cultural, and SES. Families from different cultures often have different perspectives on child rearing, health care, and disabilities. [Table 5-1](#) lists cultural characteristics, examples, and possible consequences for intervention programs.

Qualitative studies have revealed snapshots of actual family experiences with service providers. Blue-Banning and colleagues¹⁸ found that families emphasized that partnerships were built on equality and reciprocity. A sense of equality was created when professionals acknowledged the validity of the parents' points of view, and partnerships flourished when there were opportunities for each member to contribute. In contrast, Lea⁹² found that teenage mothers perceived a lack of partnering on

the part of the early intervention service providers and thought that their concerns were ignored. Professionals must reflect on their practices and determine whether they are truly valuing the families they are working with, and whether their expectations for intervention are aligned with the family's values and goals.⁹⁶

Providing Helpful Information

Child-related information that may be of benefit to parents includes information about the child's development, disability, health, and assessment results.⁹⁰ To provide up-to-date information, occupational therapists must continually engage in reading and other professional development activities. Naturally, families want the most accurate and complete information, which places a responsibility on professionals to obtain current information and continually update their skills. The families in one qualitative study "admired providers who were willing to learn and keep up to date with the technology of their field. . . . [A] competent professional is someone who is not afraid to admit when he or she does not know something, but is willing to find out" (p. 178).¹⁸

Although parents express that they want information about their child and diagnosis, it must be given in a supportive manner. Describe what the child has accomplished using a criterion-referenced instrument, such as the Pediatric Evaluation of Disability Inventory, to help parents remain positive and encouraged. Use an occupation-centered approach by asking which self-care activities the child is attempting or which play skills are emerging. Articulate a therapeutic goal linked to an emerging skill that the parents have identified to reduce the use of professional jargon and help parents understand how the intervention plan relates to their child. Typically, parents hope to receive recommendations for activities that help the child play, toys that match the child's abilities, and strategies that lead to independence in self-care. They also look to the occupational therapist for help in managing motor impairments or differences in sensory processing that limit occupational performance.

Providing Flexible, Accessible, and Responsive Services

Because each family is different and has individualized needs, services must be flexible and adaptable. The occupational therapist should continually adapt the intervention activities as the family's interests and priorities change. Families value the commitment of professionals to their work and believe that it is important for professionals to view them as "more than a case."^{18,57,103} Parents expressed appreciation when professionals exhibited "above and beyond" commitment by meeting with them outside the workday, remembering their child's birthday, or bringing them materials to use. See [Box 5-5](#) for suggestions from parents.

Although occupational therapists are often flexible and responsive to the child's immediate needs and parent's concerns, the range of possible services is sometimes limited by the structure of the system. When a parent desires additional services, a change in location (e.g., home-based versus center-based care), or services to be provided at a different time, the occupational therapist may or may not be able to accommodate

TABLE 5-1 Cultural Considerations in Intervention Services

Cultural Considerations	Examples	May Determine:
Meaning of the disability	Disability in a family may be viewed as shameful and disgraceful or as a positive contribution to the family.	Level of acceptance of the disability and the need for services
Attitudes about professionals	Professionals may be viewed as persons of authority or as equals.	Level of family members' participation; may be only minimal if the partnership is based only on respect or fear
Attitudes about children	Children may be highly valued.	Willingness of the family to make many sacrifices on behalf of the child
Attitudes about seeking and receiving help	Problems in the family may be viewed as strictly a family affair or may be shared easily with others.	Level of denial; may work against acknowledging and talking about the problem
Family roles	Roles may be gender-specific and traditional or flexible. Age and gender hierarchies of authority may exist.	Family preference; may exist for the family member who takes the leadership role in the family-professional partnership
Family interactions	Boundaries between family subsystems may be strong and inflexible or relaxed and fluid.	Level of problem sharing or solving in families; family members may keep to themselves, deal with problems in isolation, or problem-solve as a unit
Time orientation	Family may be present or future-oriented.	Family's willingness to consider future goals and future planning
Role of the extended family	Extended family members may be close or distant, physically and emotionally.	Who is involved in the family-professional partnership
Support networks	Family may rely solely on nuclear family members, on extended family members, or on unrelated persons (e.g., godparents).	Who can be called on in time of need
Attitude toward achievement	Family may have a relaxed attitude or high expectations for achievement.	Goals and expectations of the family for the member with the disability
Religion	Religion and the religious community may be strong or neutral factors in some aspects of family life.	Family's values, beliefs, and traditions as sources of comfort
Language	Family may be non-English-speaking, bilingual, or English-speaking.	Need for translators
Number of generations removed from country of origin	Family may have just emigrated or may be several generations removed from the country of origin.	Strength and importance of cultural ties
Reasons for leaving country of origin	Family may be immigrants from countries at war.	Family's readiness for involvement with external world

BOX 5-5 Suggestions for Therapists from Parents on Providing Flexible and Responsive Services

1. Listen with empathy to understand family concerns and needs.
2. Verbally acknowledge family priorities.
3. Make adaptations to services based on parent input.
4. Explain the constraints of the system when the parents' requests cannot be met.
5. Suggest alternative resources to parents when their requests cannot be met within the system.
6. Discuss parents' suggestions and requests with administrators to increase the possibilities that policies and agency structure can change to benefit families.

From Turnbull, A. P., & Turnbull, H. R. (1990). *Families, professions and exceptionality: A special partnership* (pp. 156–157). Columbus, OH: Merrill.

the request because of his or her schedule. Often, the agency or school system enforces policies regarding the occupational therapist's caseloads and scope of services. Practitioners are caught in the middle—between the system's structure and individualized family needs. A ready solution does not always exist for the occupational therapist who is constrained by time limitations, demands of a large caseload, or institutional policies.

Much of the time, the occupational therapist recognizes that he or she cannot change the structure of the system and must work as efficiently as possible within it. At the same time, the occupational therapist should inform the family of the program's rules and policies so that family members are aware of the constraints of the system. The occupational therapist can also take the initiative to work toward changing the system to allow more flexibility in meeting family needs. It is

necessary for occupational therapists to have a voice in policy issues.

Respecting Family Roles in Decision Making

Parents who share in decision making regarding intervention for their child are more satisfied with services.^{50,107} Although professionals readily tend to acknowledge the role of parents as decision makers, they do not always give parents choices or explain options in ways that enable parents to make good decisions. Too often, plans that should be family-centered are written in professional jargon and do not always address family concerns.³⁹ Parents are involved in decision making about their child in the following ways:

1. Parents can defer to the therapist in decision making. Deferring to the therapist may reflect confidence in the therapist's judgment and may be an easy way for parents to make a decision about an issue that they do not completely understand.
2. Parents have veto power. It is important that parents know that they have the power to veto any decision made or goal chosen by the team. Awareness of the legitimacy of this role gives parents assurance that they have an important voice on the team and can make changes, should they desire them.
3. Parents share in decision making. As described earlier, when parent-professional partnerships have been established, the parents fully participate in team discussions that lead to decisions about the intervention plan. Service options and alternatives are made clear, and parents have the information needed to make final decisions. Requests of parents are honored (within the limitations of the program).

Families cannot always be given a wide range of choices about who will provide services and when and where these services will be provided. However, their role in decision making should still be emphasized; otherwise, family-centered practice is not being implemented.^{15,39,93,96} Families who are empowered to make decisions early in the intervention process will be better prepared for that role throughout the course of the child's development. In most cases, assessment of choices and good decision-making are skills that parents promote in their children as they approach adulthood.

Communication Strategies

Effective communication is built on trust and respect; it requires honesty and sensitivity to what the parent needs to know at the moment. Therapists have tremendous amounts of information to impart to parents. Effective helping is most likely to occur when the information given is requested or sought by the parent.

Occupational therapists communicate with parents using a variety of methods—formal and informal, written, verbal, and nonverbal. Table 5-2 describes communication strategies consistent with the principles described earlier. These strategies are based primarily on feedback from parents regarding what they have found to be effective help from occupational therapists.^{57,64}

Home Programs: Blending Therapy into Routines

Throughout this text, recommendations are given for ways to integrate therapeutic strategies into the daily occupations of children, with the clear recognition that learning occurs best in the child's natural environment. Skills demonstrated in therapy translate into meaningful functional change only when the child can generalize the skill to other settings and demonstrate the skill in his or her daily routine. Occupational therapists often recommend home activities for parents to implement with their child, so that he or she can apply new skills at home. However, before making recommendations, the occupational therapist should ask the parents about daily routines and the typical flow of family activities during the week. Home programs are most effective when the child responds well to the procedures and the demands on the parent are reasonable.^{113,130,143} Understanding which routines and traditions hold special meaning for the family will help occupational therapists focus.⁹⁵ The result of this close examination of the typical week enables the occupational therapist and parents to embed goals and activities in interactive routines, in which the therapeutic process does not diminish the value and pleasure.

Working with Families Facing Multiple Challenges

Challenges to a family's ability to fulfill its functions (e.g., living in poverty, acute onset of a disability in the parent) increase the vulnerability of children with special needs and add unique challenges to family functions. Parents with their own chronic illnesses may require extra physical or emotional support.¹¹⁵ By identifying protective factors that bolster the child's resilience, the occupational therapist can approach issues from a positive perspective to support strengths, capitalize on family assets, and work to make maximum use of community resources.

The occupational therapist grounded in family systems' perspective and committed to empowering families works effectively with a whole-family system, regardless of the type of disability of one or more family members. Understanding and valuing how the family system orchestrates members' occupations to fulfill family function allows the occupational therapist to take a holistic view of the family's needs and priorities. Although parents advocate a positive view, it is important to recognize when an unusual parental behavior reflects family dysfunction (e.g., child abuse, child neglect). When family dysfunction is pervasive, most occupational therapists need input from colleagues with expertise in counseling and family systems. Services for the child with special needs continue, but the occupational therapist considers ecologic and family systems factors in collaborating with the team to set priorities and provide services.

Families in Chronic Poverty

Chronic poverty has a pervasive effect on family and child experiences. Poverty has any number of causes. Most families receiving public assistance are children and mothers with poor educational backgrounds, an inconsistent work history, and

TABLE 5-2 Communication Methods between Parents and Professionals

Type of Communication Method	Purpose	Role of Professional
Formal team meeting with the family to develop an IFSP or IEP	To increase the parents' participation and comfort level	Provide parents with specific information about the purpose, structure, and logistics of the meeting. Information about parental rights must be explained to parents before and during the meeting. Decipher legal terms so that parents have practical knowledge regarding IDEA safeguards. Before meeting, parents should be informed of the questions that the team members may ask (e.g., "What are your visions for your child?") so that they can formulate thoughtful responses. Parents should receive assessment results before the meeting so they have an opportunity to think about the assessment and be prepared to discuss their goals for the child in the team meeting. A telephone call before the meeting also gives the therapist an opportunity to ask about the parents' concerns and prepare options for meeting those concerns in the child's educational program or intervention plan. Encourage parents to ask questions, express opinions, or take notes. Use jargon-free language, avoiding technical terms. Plans should be specific and should include dates, tasks, and the names of those who are responsible for the plans.
Informal meetings during or after the child's therapy		The therapist needs to be organized and prepared for parent encounters. Casual or general responses are not adequate. The therapist should give specific examples of recent performance or state when reevaluation will occur and how those results will be reported. Listen to and acknowledge the parent's concerns. Indicate preference to respond after reviewing daily notes and charts on the child. The therapist can later make a telephone call to the parent with the child's chart in hand to avoid giving the parent erroneous or misleading information.
Written and electronic communication	If parents are not physically present, regular communication with family members relies on written strategies or phone calls.	<i>Notebooks</i> shared between therapists and parents are a highly valued way to have a regular reliable method for expressing concerns. Team members may describe a new skill that the child demonstrated that day, an action by the child that delighted the class, an upcoming school event, materials requested from the parent, snack information, or the current strategy for working on self-feeding. The parents can share their perceptions of the child's feelings, new accomplishments at home, new concerns, or reminders of appointments that will keep a child out of school. Home-based therapists may initiate a notebook for the parent to record significant child behaviors and for the therapist to make weekly suggestions for activities. In the neonatal intensive care unit, notebooks are sometimes kept at the infant's bedside to provide a method for parents and therapists to communicate with the nursing staff on successful strategies for feeding and handling the infant. <i>Handouts</i> should be individualized and applicable to the family's daily routine. Handouts copied from books and manuals are appropriate if they are individualized. Many parents prefer pictures and diagrams. Other parents have remarked that triplicate forms that could be shared among the therapist, parent, and preschool were very useful.⁵⁷ Parents' perceptions of their ability, confidence, and satisfaction significantly improved after using the Keeping It Together information organizer (see earlier).¹³⁸ Photographs are also helpful to serve as a reminder to parents and staff on ways to improve postural alignment.
E-mail and other methods of communication		E-mail has become an easy, end-of-the-day method for noting any particular daily occurrences that would be of interest to the parents. A blog or even a wiki may be a viable method for regular communication with technology-proficient partners. Regular progress reports are important to parents and are required in most school systems. A simple report covering a few areas of performance may be more meaningful to the parents than a lengthy, complicated report. A child's quotes and reports of specific performance send the message that the child is receiving individualized attention. Camcorders with software for sharing have become less expensive and the videos could be uploaded to the Internet or recorded to videocassettes or DVDs. Videos can convey information about handling, feeding, and positioning methods. Keep in mind that parents must invest time in watching the tape; short clips of direct relevance to current goals are most efficient. Written materials (and videotapes and DVDs) are helpful because parents were "not always ready to hear, understand, or accept some information, but . . . it could be available for later use" (p. 91).¹⁴²

low-wage jobs. The process of “qualifying” for services can be frustrating, depersonalizing, and degrading. Once a family qualifies for help, resources are not always enough to make ends meet. Sometimes, the family needs to forgo health care because of the pressure of other bills to pay.⁷⁴ Single parents are particularly vulnerable¹⁰⁵; without family members to help, these mothers lack control over the events in their lives. Unexpected events, such as a car breaking down or special meetings at school about a child, can cause the parent to miss hours at a job and increase financial strain. Poverty represents a multi-dimensional issue, and occupational therapists cannot make assumptions about why a family lives in poverty.

Recognizing that poverty creates a unique cultural worldview enables occupational therapists to consider what it means to provide family-centered services.^{74,92} For example, time may be perceived in the here and now, making it harder to schedule or keep appointments. Families with low SES may have difficulty following through with their plans. Therefore, planning for the future has little meaning, and participating in the setting of annual goals at IFSP or IEP meetings may not be considered important.

It is necessary to look beyond simple associations between poverty and parenting because some parents do better than others, despite a low SES.¹⁴⁷ Some parents living in poverty adapt and raise children successfully. Single parents who have strict disciplinary standards may seem harsh; however, their parenting practices may be grounded in an anticipation that their children will grow into a world in which obedience to those in authority is important for keeping a job. Other parents who restrict their children’s community activities may be effective in monitoring who they are with, minimizing the negative influences of poor neighborhoods. When a therapist is sensitive to and deeply understands a family, she or he can make recommendations that help the child with special needs while supporting the family in its precarious position.

Parents with Special Needs

Parents themselves may have special needs that require an emphasis on supportive services. Parents who face physical or sensory challenges may need help in solving problems, such as monitoring the activity of an active child or being alerted to the cry of an infant. Occupational therapists, from their extensive knowledge of activity analysis, can assist the parent in the modification of tasks. For example, adapting the location of routines, such as diaper changing and infant bathing, can enable parents with physical limitations to participate in caregiving and simple routines that build affection between the parent and child. Occupational therapists can explore the use of adaptive equipment, such as motion detectors or sound-activated alarm systems, to compensate for the parents’ sensory deficits and ensure responsiveness to their child’s cues. Most parents who have had long-term experiences with a physical limitation independently develop creative solutions for providing care for their children, and they only occasionally seek an occupational therapist’s assistance for determining how to perform specific caregiving tasks.

Parents who struggle with drug addiction or mental health conditions may worry whether they are up to caregiving responsibilities.¹⁰⁴ They often require counseling, mental health

services, and opportunities to participate in support groups.¹¹⁴ When parents have special needs that strongly influence their caregiving abilities, their needs often become the first emphasis of intervention. Professionals helping parents with intellectual or mental health impairments may need to address self-esteem and confidence issues, as well as build problem-solving skills. Everyday care for children requires constant problem solving. Therapists can help empower parents to make their own decisions, thereby increasing their sense of self-control. Often, professionals give advice or recommendations without encouraging the parents to solve the problem independently or try their own actions first. When others direct parents, they become more dependent. However, when parents successfully solve a problem, they become empowered to act independently in daily decision making. Problem solving can be taught and modeled.

Parents with intellectual disabilities, mental health issues, or drug addiction are at risk for having children with developmental disabilities. Professionals have questioned the competency of parents with intellectual delays, and courts have removed their children in disproportionate numbers.¹⁹ However, with support systems in place, these parents can be surprisingly successful. Parents at risk because of intellectual or mental health impairments appear to be most successful in caring for young children when they are married, have few children, have adequate financial support, and have multiple sources of support, attributes similar to those needed by most parents.^{78,89,102}

When occupational therapists work with parents with intellectual or mental health impairments, it becomes essential to know the parents’ learning styles and abilities. Often, instructions need to be repeated and reinforced. Occupational therapists must use good judgment about which techniques are taught to these parents, with an emphasis on safe and simple methods. The occupational therapist should also recognize the need for additional support to help parents with intellectual delays access those needed services. Regular visits in the home by aides, nurses, or teaching assistants can meet the level of support needed. If the occupational therapist communicates his or her goals and strategies to the visiting aide, therapy activities are more likely to be implemented by the parents and other professionals working with the family.

Working with parents with intellectual or mental health impairments can be frustrating when appointments are missed or requests are not followed. Therefore, an understanding of the parents’ needs is essential. The development of simple repetitive routines and systems that the parents can learn and follow enables them to become competent caregivers. With support, they can offer a child a positive and loving environment that fosters health and development.

Professionals use a variety of strategies when providing services to families with multiple challenges. When families have continual stress and problems, it is important for therapists to begin to build trust slowly, share observations and concerns, and accept parents’ choices.²² Professionals can attempt to establish rapport by using concrete, simple terms, by providing graphic and oral information, and by providing ideas that would immediately help the child. Focusing on the child’s strengths and developing trust and responsiveness are also important when parents are coping with their own challenges.

CASE STUDY 5-1 A Parent's Perspective

Beth Ball

When I was first asked to contribute to this chapter, I reflected on the myriad experiences and feelings that have emerged as a result of having children with disabilities. This seemed too vast a topic to be captured in a few typed pages. The following is a brief glimpse into my thoughts and feelings about life with my three children. There is much more than facts or history about our lives. There is, of course, emotion—deep and undeniable—and there is poetry. There is the first shed tear of realization that my child will have a life that is more difficult than most. There is the happy smile of childhood shared with supportive therapists and teachers. There is the frustrated panic of adolescence when social situations are hard and troublesome and the phone does not ring on Saturday night.

Initial Response

Learning about the disabilities of each of my children came at different times in their lives. The impact varied because of the timing of the news and disability of each child. Benjamin was born on a warm June day in 1971. On the delivery table, the nurse turned the mirror away, and I didn't understand why I couldn't see the baby. Everything seemed to happen in slow motion. The physician held him up and announced that he was a boy, but there was a small problem. His right arm tapered from the elbow to a thumblike digit for a right hand, and his left arm ended in a modified claw hand, having a center cleft halfway into his palm and syndactyly webbing between the other fingers.

The nurse placed him on my tummy, and he peed a fountain all over the sterile drapes. She said, "That works," which was comforting, but scary, because I considered that other anomalies could exist. It was not until that night in the privacy of my room that I felt the bifid femur of his right leg; the block at his knee that refused to let it extend; the very thin lower leg, which turned out to be missing the tibia; and the clubfoot. I discovered these problems one at a time. The sick feeling in my stomach was guilt. There must have been something that I had done wrong that had caused this. Even though I had followed all the doctor's instructions, I must have missed something. What would everyone think? I thought or rather felt that I must not be good enough to have a child.

Mick, my husband, and I were lucky to have a wonderful pediatrician whose first advice was exactly what we needed to hear. He told us not to withdraw from our family and friends (alluding to the feelings of shame and guilt that we had not overtly expressed). He told us to allow them to give us support—they would only want to help. The unspoken message that they would not judge us was very important to us.

And so we started on our journey of new experiences with orthopedic surgeons, prosthetists, genetic counselors, neurologists, urologists, internists, and pediatricians. Later came more professionals, occupational therapists, physical therapists, ENT specialists, vision therapists, special education teachers, and psychologists. We searched for answers to "Why?" We searched for options to deal with the issues of

discrepancies in leg length and hand function. We searched for resolution to our own feelings. But we were fortunate because, as husband and wife, we never blamed each other.

Mick and I started the journey together, and we have always turned to each other for support. Sometimes it was an "us against the world" attitude and a fierce, protective response that got us through the hard times. When joyous times came, they did so with the realization that it had taken all our efforts to get there. The reason that we have been able to deal with the problems and come out on top is that we have a commitment to each other and a deep faith in God. This statement is much too simplistic for the deep feelings of need, grace, and oneness that we have. This oneness has allowed us to go forward to meet challenges as they have come.

Another reason we have been able to go forward is that we see each of our children as a gift. They are grace without gracefulness. They are charm without all the social skills. They are fun with a sometimes struggling sense of humor. They are individuals who have enriched our lives and given us humility, wonder, and awe at their commitment to living, loving, and succeeding.

Accessing Services and Resources

Gaining services and resources for our children has not come without pain, questioning, depression, and anger. It has been a struggle that has required persistence and patience. We faced the first barrier when we attempted to find the money to cover the costs of prosthetics for our son. When we were told that it would be better to amputate Benjy's leg above the knee than to try to keep it and work through the lack of joints and musculature, we were also told about the costs of prosthetics. One of the first things our orthopedic surgeon told us was that we needed to find a source of funding beyond our insurance, because prosthetics would cost more than a small house by the time Benjy was 16. I will not go into all the details, but parents have to be persistent if they do not know where to turn to find funds. The doctors have a few ideas, but they are not the best source of information in this area. Agencies and hospitals may have more information, but getting connected to the right person to gain the information is not an easy task. Even now with SSI and waivers and additional funding available, funding for disabilities comes with reams of paperwork, confusion about agency services and a maze of providers, each with a different set of rules and information.

In the search for money to cover the costs of prosthetics, we approached a well-known agency that worked with individuals who had physical disabilities. This agency had fundraising campaigns that were earmarked for this purpose. After being told that providing prosthetics was not among its services, and because this was the third or fourth rejection that we had encountered, Mick broke down and joined me in some tears. We were then informed by the agency director that we had better pull ourselves together. This was *our* child and *our* responsibility, and we had better "face it." Shame turned to anger as we left. I felt judged, and included in the

CASE STUDY 5-1 A Parent's Perspective—cont'd

anger was the fear that we would not be able to provide for Benjy. How could this man judge us? Why didn't this administrator of an agency that provides services to children with disabilities and parents have more empathy for our situation? If he didn't help, then to whom could we turn?

This experience made us even more leery of asking for assistance. Luckily, the Shriners accepted our application, and they provided most of the funds for Benjy's prosthetics until he turned 18. I do not want to think of what might have happened if we had not had their help. Dealing with financial issues created a new level of trauma that was added to our earlier pain. Because the Shriners helped with the finances for the prosthetics, we could focus our energy on education plans and homework and hope.

One of the things we discovered from this process was the necessary and valuable aspect of networking. It was through work, friends, and family that we made contact with the Shriners. It was through people at school that we were put in touch with the local Special Education Regional Resource Center and became a part of the Parent Advisory Council. It was through many of the parents that we met in these places that we learned about the Ohio Coalition for the Education of Children with Disabilities. It has always been invaluable to us to be able to share with other parents who have similar feelings, frustrations, and breakthroughs. If it had not been for these people and these agencies, we would not have received the valuable personal, educational, and emotional support that we needed. Parents are invaluable sources of information.

Whose Distress, Whose Struggle?

When my children were small, the feelings about their disabilities could be set aside for the new dream of having the brightest, cutest, most wonderful child with special needs. I dreamed of the well-spoken poster child. These dreams might have also been called denial and led others to believe that I was unaware of the true impact of my children's problems. In truth, that may have been, but I chose to live with faith and hope.

Most feelings do not come from the big picture of the disability. They come from all the little incidents. For example, when Benjy was 12 or 13 months old, I took him out of a nice, warm tub of sudsy water and stood his chubby, slippery little nude body next to the tub so that he could hold on while I towed him dry. He stood straight and tall on his left leg, but as I watched, he tried to bear weight on his useless, dangling right leg. He bent his left leg so that his right toes touched the floor, and then he leaned to see why he could not reach the floor with his right foot. It was a moment of revelation for me. Until that moment, I think that all the focus had been on me: my inadequacy, my problem, my pain. This was a breathless revelation; it was too deep even for tears. We had been struggling with the decision of whether or not to move forward with the amputation of the malformed leg so he could be fitted with a functional prosthetic leg. We had chosen to avoid the decision; to buy time; hoping that a better solution—something less painful for us—would appear. Yet this was Benjy's life, *his* surgeries, *his* pain, and *his* inability to run swiftly through life. Seeing him search for the leg

intended to support him changed my perspective. My role was and is to help and support him. Of course, every now and then, I have my own private pity party. However, it is not my pain that is the issue; it is each child's. Somehow, there is a deeper pain in watching someone I love struggle than the pain I feel when struggling myself.

In our minds, Jessica, our second child, had no disabilities through her first 5 years of life. My dream was of a baby ballerina with grace and coordination. She did have four eye surgeries by age 5 (because of crossed eyes, muscle imbalance, and rotary nystagmus). She attended a church-related preschool. At parent conference times, when the teacher would indicate problems or ask pointed questions about behaviors at home, I would justify Jessica's performance by telling myself, or Mick, that every surgery sets a child back about 3 months. She would "catch up."

When Jessica was old enough to go to kindergarten, we were called into a special conference in which we were carefully told that she was not ready to do so. I did not hear anything else that conference that day. The impact of that statement and the carefully worded explanation was like an icy shower. It was almost as if I had awakened from a dream with a clear vision of how disabled and delayed my daughter really was. I felt guilty and ashamed. I am an occupational therapist, and I know developmental milestones. I had let my doctor and others calm my fears about delays in walking, ataxia, and fine motor challenges because I did not want to believe that this second child of mine could have more than visual impairments. I was in denial for 5 years, helped by well-meaning people who did not want to hurt me.

The night after Jessica's conference, I received an answer to my prayer of "Where do I go from here?" I attended a presentation by Ken Moses, a psychologist and counselor who writes and speaks about parenting children with disabilities. I then experienced a new step on my journey. He spoke about the grief cycle and how we are grieving not for a lost child but for a lost dream. His discussion supported what I had been feeling and experiencing. The most important factor to me was the permission he gave me to feel the way I did. He emphasized how important denial is in helping us to deal with life-affecting decisions. He pointed out that denial buys us the time to gather our resources so that we can deal head on with problems.

Ken Moses also spoke about the importance of recognizing that anger gives us the energy to take action. Many times, my children's disabilities required so many appointments, surgeries, exercises, prescriptions, Individualized Education Program (IEP) meetings, and other details that I was left with only enough energy to put one foot in front of the other. I ignored, or put on hold, things or decisions that I should have taken care of immediately. Often, it was anger that got me energized and sparked my determination to get things done. I learned that anger can actually help as long as it is not turned inward or unleashed on others. I came away from this talk with a sense of relief. To have these feelings was normal, and I was not a bad person, mom, or therapist.

Some professionals and parents believe that the word *denial* should not be used to describe parents' reactions to their children's disabilities. Instead they assert that parents'

Continued

CASE STUDY 5-1 A Parent's Perspective—cont'd

reactions are *hope*. *Denial* has been a word that has allowed professionals to make judgments about parental actions. They have used the word *denial* when parents are not following through on something recommended or are having difficulty accepting decisions about education or diagnoses. Having been on both sides of the table, I understand the issues. I have what I think is a realistic view that the word *denial* is not going to go away. Also, the anticipation and hope for each of my children's futures cannot be erased by a word called *denial*. My hopes are real and if I choose to live with them, I don't mind if someone calls them *denial*. I embrace my whole journey and all aspects of my children. I can wallow with the best of them, dig in my heels, and go in the direction that I believe is right—no matter whether someone thinks I am denying reality. I believe that parents “in denial” need to hold onto their hope and/or don't yet have the resources they need to deal with their child's disability. So, dear OTs, give them some!

I have also recently come to believe that parent's reactions come from fear as well as hope. I have been afraid that I would not do the “right” things for my children. I wanted so much to allow them to be and do their best. I wanted for them to have the “right” experiences. I wanted them to experience the “right” education. I wanted them to be in the “right” situations. I wanted them to see the “right” doctors.

Mick says that he believes, regardless of the words, parents' behaviors and attitudes are justified: “If the judgment word is denial, parents are just buying time to accumulate resources. If the word is hope, they are focusing on being buoyed up out of some of the harsh realities. Empowerment of parents in impossible situations is a noble mission. As parents, we want to be powerful advocates and capable guardians. To do that, we need to be emotionally healthy and grounded in reality. We arrive at that point by working through the emotions associated with our disillusionment, our fear, our anger, to ultimately be at peace *each* time we encounter another in the endless series of emotion-filled transitions of life.”

Where Do We Go From Here?

Decisions are forced on parents. There are medical decisions, therapy decisions, educational decisions, second opinion decisions, and decisions made in the middle of the night and in the emergency room. Decision making starts immediately with a diagnosis or with the search for a diagnosis. Which doctor should we use? Which hospital? What about insurance? How much intervention do we need? How much do we want? What will *they* think if we say no to this thing that they think is important for our family? Is it important?

When Jessica was in elementary school, we would wait for the bus together. Each morning while sitting on our staircase landing, Jessica and I spent 20 minutes practicing eye exercises. Some days it was easy; other days Jessica would complain, resist, and attempt to divert my attention from the task. One day, when she was 7 or 8 years old, we were doing her exercises and discussing her braces, her eye surgery, and her occupational therapy session scheduled for that afternoon. She wanted to know for the thousandth time why we had to do these things. I explained that we were trying to fix things so she would have an easier time of it. She suddenly looked up at me and asked, “Is there anything about me that you don't

have to fix?” I quickly named all of her gifts and attributes that I treasured. Later, as Jessica's bus turned the corner, I was left sitting on the steps with emptiness and guilt. I also had a new insight into the impact on her confidence from countless therapy sessions, surgeries, and home programs.

This incident also made me face another aspect of parenting. There is an unavoidable fact that there are some aspects of disabilities that cannot be fixed. I became an occupational therapist so that I could help people and make things better for them. I truly believed (and believe) that I could help eliminate some problems, that I could help heal hurts, and that I could provide training so that people could be more independent. Once I saw Jessica's problems, I was off and running. I wanted to make up for lost time. Fear drove me to leave no stone unturned if I thought that it would help Jessica get better. As a result of Jessica's question I began to understand that all needs do not require “fixing.” I stopped doing many of the recommended home programs. I found out that I needed to be “Mom” and others could be therapists. When professionals criticize parents for not following through on recommendations, I tell them that each family has its own story and now may be the time for re-grouping and just being the mom instead of the scheduler, therapist, taxi driver, MD, or counselor.

School

Other than their child's medical issues, qualifying for special education is one of the greatest traumas parents of a special needs child will encounter. It was obvious that Benjy had an orthopedic handicap. However, to qualify for special education, we had to go through an intake process. Benjy had to be tested, and we waited with bated breath to see if he would receive educational services. He did qualify, and Benjy attended kindergarten through third grade in a school that had an orthopedic handicap program. He was in a self-contained classroom for disabled children until third grade.

When attention turned to education instead of surgeries and therapies, we found that physical disabilities are more apparent than learning disabilities. Soon our priorities switched to cognition and classroom skill building. During that time, Benjy was retained in first grade because the teachers had decided that he should be assessed for a learning disability. This evaluation provided another chance for the ever-present grief cycle to jump up and bite us. Acceptance of the physical part of the disability was almost in place. However, this new evaluation crushed my new dream of having the brightest, most socially adept physically disabled child. Even though he was adorable and happy, I went through an equally bitter (if not more so) period of guilt. Once again, I also feared for his success.

When Jessica was tested, *we* requested the testing because the preschool had prepared us for the possibility that she would have trouble learning. The school said that it was too early to find a discrepancy, but we pursued it, and one was found. She qualified for the learning disabled program. For each of the next 5 years, Jessica's resource room moved from one school to another. This meant that each year, she had to adjust to a *new* building, *new* teachers, and *new* classmates. When Jessica was in fourth grade, we were told to take her to counseling because she was withdrawn and had no friends

CASE STUDY 5-1 A Parent's Perspective—cont'd

on the playground. Guess what contributed to this. I can still see her sitting on the edge of the playground playing with her imaginary “little people” in the dirt. When Jessica was in sixth grade, we moved to another district because it had neighborhood schools with special education resources in each building. There, too, the resource room for her particular grade level had been moved from the neighborhood school. She couldn’t win. She still struggles with feelings of not belonging.

When Benjy was in the third grade, Mick and I decided that he would benefit from being in the regular classroom for most of his instruction. We were a little ahead of the curve regarding inclusion, and our request received quite a response! In 1980, Benjy was a pioneer. That year was difficult for us because we decided to change priorities to allow the learning disabled program to meet his needs instead of the orthopedic handicapped program. One of the most intimidating places in the world is a room full of educators, including heads of programs, psychologists, teachers, occupational therapists, and physical therapists, and the only people who believe that you are doing the right thing for your child seem to be you and your spouse. Allowing the school’s LD program to meet our son’s needs turned out to be the right decision, but I still get uneasy when it is time for an IEP meeting (even an IEP meeting in which I am the occupational therapist). We worked very hard to get services to follow the student rather than placing the student into an existing special education program. This is becoming more the norm.

Mick and I always helped our children with their homework and school projects. I rationalized that their success with their schoolwork would help them achieve in life. Their work ethic for school was high. Unfortunately, because we provided continual support in completing their homework, they never had the opportunity to fail. It is now very clear to me that children have to learn responsibility for themselves and that failure is a vital part of the learning process. Otherwise they can become too dependent. I wanted to cushion my children’s self-esteem by ensuring that they were successful in school. However, with the complex pattern of learning and growth, there is no clear path for children who have more challenges than most. Children with disabilities do need more help with schoolwork, but how much is too much? Lessons learned later are just as valuable, but they are more challenging because there is more at stake. There is a fine line also between teaching our children to ask for help and not feel guilty that they need it but not to assume that they *deserve* more help than others.

When we find ourselves making judgments about families, a red flag needs to go up. As was pointed out earlier in this chapter, each family has a different structure and different values. Decision making in each family is complicated and sacred. I know many people thought we were crazy when we decided to have a third child. Some were even brave enough to tell us so to our faces. Service providers held their breath, and educators looked for another Ball child in their classrooms. Having another child was a decision about which Mick and I prayed. This time in our lives was like a pause in a heartbeat, filled with hope and fear but also with the knowledge that we were in it together.

Alexander was born on a cold day in February of 1981. He had no physical problems, but he was just as colicky as the other two children. He walked at 9 months and never stopped after that. He was *very busy*. In preschool meetings, I was the one to point out discrepancies in Alexander’s progress. The teacher complimented me on being accepting, and I carefully informed her that I had been through this twice before and had not been as accepting then. I told her that that was okay, too. My children did not lose everything because it took time for me to face their delays. They were doing just fine, and parents need to be allowed to feel the way they do. However, that does not mean that professionals should not be honest with them!

Receiving sympathetic and respectful honesty from professionals is the only way to know I have all the facts before I make a decision. Honesty is a gift that you, as a therapist, give parents. It does not mean that parents will hear you, follow your suggestions, or even believe that you are right. But your honest appraisal of the situation gives parents a piece of the picture and the truth that they need to help their child succeed. It helps if you take the time to listen to the parents’ dreams or if you help them put words to those dreams.

Alexander turned out to be gifted, charming, and learning disabled, with attention-deficit disorder and dyslexia. Auditory and visual processing problems and sensory defensiveness completed the picture. His disabilities were identified between kindergarten and first grade, again at our insistence. Alexander continues to reverse letters as he reads and writes. He often reads the end of words first. At age 9, he wrote out, in bold letters on a T-shirt, a commitment to avoid drugs: “Lust say on!” Classic notes left for me on the kitchen counter often told me that his “homework is bone” or the “bog ben out.”

Alexander’s disability diagnosis was also difficult for me and my husband. The feelings of loss and sadness that accompanied identification again resurfaced. Again I had to be persistent to get the correct services. I also had to watch him struggle through years of extra tutoring, vision therapy, and occupational therapy just to begin to decode words. Alexander has borne the burden of being the articulate, social child in the family. He has struggled with feelings of guilt that his disabilities are not as great as those of his siblings. He received counseling to help him deal with these feelings as well as feelings of his own inadequacy.

However, part of Alexander’s disability was a gift for me. He always needed books read to him for school. When he could not get a particular recorded book or he needed to complete one in a hurry, I spent time reading with him. We have shared insights on comparisons of religions, how Native Americans smoke peace pipes, and how to save yourself if you become lost in the middle of a forest. It has been cherished time that would not have occurred if he had the ability to read on his own.

Gifts and Dreams

Recently I heard that old saying, “I’m playing the hand I’ve been dealt.” I think that applies to all of us. It seems to me that *everyone* has many sources of distress in their lives. We, as the parents of children with disabilities, often focus on the delays and the fears. We should be allowed to feel the feelings

CASE STUDY 5-1 A Parent's Perspective—cont'd

that are associated with this situation. However, I think you'll find that we are proud of our children's small accomplishments: learning to put on a prosthesis independently, learning to turn a somersault, or hitting the right key on the keyboard to match the computer screen. We are happy and want to spend time with these individuals with unique perspectives on life.

There are some things our children will never be able to do, activities they choose not to attempt. These things would be next to impossible for them, but I never told them they couldn't do them. Parents are always in the position of encouraging the impossible. However, the reality is that it is the child who will ultimately determine what he or she can or cannot do. We have made and will make many mistakes parenting our children with disabilities, but we refuse to let their disabilities limit the possibilities.

I remember crying over *The Velveteen Rabbit* when I read it to the kids. It seemed that the problems of my children kept them from being "real" too. I knew that all the love I was showering on them could not change their physical makeup; however, I also knew that the love I was showering on them might help them cope with their "realness." Benjy has told me that he will run in heaven, and I believe that. I also know that all three of them run in their hearts every day here, and that others seeing them are challenged to be more.

As part of my job, I was asked to evaluate a student who had hands similar to Benjy's "claw" hand. He had a hearing impairment, and the special education team met to determine how best to serve him in the school setting. When we sat down in the meeting, one of my colleagues made a comment about his hands. She said she couldn't understand why his parents didn't have his hands "fixed"—they looked so strange. I sucked in a breath and my heart pounded. I could not respond. I felt immobilized in my chair, without a voice. How did my colleague have the right to judge that the boy's hands needed fixing? My pounding heart was accompanied by the resounding thought, "He has a right to those hands, his hands. He has a right to be different." In part I had these feelings because I had evaluated his hand skills and knew that despite how different his hands appeared, he was able to use them skillfully. Only after the meeting was I able to express what I thought and felt. I realized that this person had made the comment because she thought that "fixing" his hands would take away the staring and teasing that always accompany looking different.

To express my feelings, I wrote my colleague a letter. In it I explained that my husband and I had made the decision to increase function in Benjy's left hand when he was 7 months old, wishing it would look more like everyone else's. It was hard to admit that I had those feelings. I told her that Benjy's right arm, which we affectionately call "Super Pinky," will never look like everyone else's. I told her about the scars on his hand and the scars on his wrist from the site where the graft skin was taken. I talked about Benjy's surgery allowing for a little stronger grasp but not full extension or flexion. I told her that the young man about whom she had

commented had an adapted grasp for scissors and functional cutting skills.

My letter also explained that this is a bigger issue than hands; it is about attitudes. I see our roles as professionals who work with children who are different as teaching not only the children but also everyone else. The message about our kids needs to be that *different is not worse, just different*. I know that people have the capacity to be open to difference. If we lived in a perfect world, all differences would be okay, and we would not feel that we have to fix them. However, we live in the ever-present face lift, nose fix, and "Extreme Makeover" society. People are judged on their appearance. Part of our role as professionals is to learn to accept differences, particularly in appearance, and not to try to fix everything. Our job is to help others understand that different is not wrong. This is a very simplistic view of a complex problem.

When I told Benjy about the incident, he said, "That person is not cold. She just doesn't know all the facts. If God wanted everyone to look like everyone else, He wouldn't have made handicapped people. There have been times when I wanted to look like everyone else. True people are the ones who remember you for more than your physical side, and that's what really matters. True people are able to look at you and not think you are different, but that you are unique."

Benjy is living independently and working as a cashier at a grocery. He has a new diagnosis of spinal muscle atrophy. He is gradually losing function in his remaining leg and has been using a wheelchair for a couple of years. Jessica is on disability, living independently. Her diagnoses increased to include celiac disease, chronic anxiety, and also an unknown neurologic degenerative disease causing footdrop, scissor gait and falling. She has published two poetry books. Alexander is married to a wonderful young lady, and has a beautiful daughter and son. His word-decoding skills have improved. He says this is a result of helping his children learn to read. As parents of children with disabilities, we continue to be very involved in our children's lives beyond the usual time. My prayers and dreams for them remain the same as when they were small: that they will be happy, that they will be as independent as they can be, and that they will always have someone who loves them. As the kids have grown into adults, we have had to practice involvement and support—without control. We also continue to deal with emotions, because the disabilities our children have are for life.

In all stages and at all ages, families of people with disabilities value support and resources. If you take the time to hear a parent's dream, you may hear the sound of laughter and tears. You may hear the strong heartbeat of anger or the resistance to a life that is less than it could be. As a therapist, you are a gift to the parents whose lives you touch. You have a solution to some of their frustrations. You can help uncover the hope. You have the opportunity to be as honest as you can be and provide them with the information they need to make decisions. You have the answer to some parent's question.

Thank you.

Summary

Working with families is one of the most challenging and rewarding aspects of pediatric occupational therapy. The family's participation in intervention is of critical importance in determining how much the child can benefit. Therapy goals and activities that reflect the family's priorities often result in meaningful outcomes. The following summarizes the main points of this chapter.

Summary Points

- Family systems theory describes families as unique subsystems (parent, child, extended family) whose interactive patterns affect the behaviors and physical and mental health of each member as the family works to enable children to become participating members of society.
- The family life cycle defines life stages and the ecologic influences at each stage. Raising a child with special needs influences the co-occupations of family members by influencing time use, stress levels, satisfaction with life, and the meaning found in daily occupations.
- Families' cultures and backgrounds influence their unique perceptions of the world and what they want their children to do. For intervention to be effective, occupational therapists must listen carefully and respond to what is important to each family.
- When collaborating with families, occupational therapists focus on family priorities, partner in decision making, may coach caregivers to apply specific strategies, and support caregivers in becoming advocates for their child.
- Occupational therapists establish and maintain partnership with families through respectful interaction, honest and consistent communication, and supportive attitudes.
- Families can be empowered to facilitate their children's development through effective information sharing, full inclusion in team decision making, and provision of adequate support.
- Strategies for supporting the strengths of families facing multiple challenges are similar to those for supporting all families—using clear communication, adapting tasks and routines if modification will ensure a better result, and attending to the specific needs of those caregivers so that they feel competent to fulfill their roles.

CHAPTER

6

Use of Standardized Tests in Pediatric Practice

Pamela K. Richardson

KEY TERMS

Standardized test	Measures of central tendency
Performance-based test	Measures of variability
Self-report test	Standard score
Reliability	Correlation coefficient
Norm-referenced test	Validity
Criterion-referenced test	Ethics in testing
Normative sample	

GUIDING QUESTIONS

1. What are the characteristics of commonly used standardized pediatric tests?
2. What are the differences between norm- and criterion-referenced tests and the purpose of each?
3. How do performance- and observation-based tests differ?
4. What descriptive statistics are used in standardized pediatric tests?
5. What do standard scores used in standardized pediatric tests mean?
6. How do reliability and validity relate to a test's integrity?
7. How do occupational therapists demonstrate competency in and ethical use of standardized tests?

What are standardized tests, and why are they important to occupational therapists? A test that has been standardized has uniform procedures for administration and scoring.⁶³ This means that examiners must use the same instructions, materials, and procedures each time they administer the test, and they must score the test using criteria specified in the test manual. A number of standardized tests are in common use. Most schoolchildren have taken standardized achievement tests that assess how well they have learned the required grade-level material. College students are familiar with the Scholastic Aptitude Test (SAT), the results of which can affect decisions on admission at many colleges and universities. Intelligence tests, interest tests, and aptitude tests are other examples of standardized tests frequently used with the general public.

Pediatric occupational therapists use standardized tests to help determine the eligibility of children for therapy services, monitor their progress in therapy, and make decisions on the type of intervention that would be most appropriate and

effective for them. Standardized tests provide measurements of a child's performance in specific areas, and this performance is described as a standard score. The standard score can be used and understood by other occupational therapists and child development professionals familiar with standardized testing procedures.

Using anthropometric measurements and psychophysical testing to measure intelligence, Galton and Cattell developed the initial concept of standardized assessments of human performance late in the nineteenth century. The first widespread use of human performance testing was initiated in 1904, when the minister of public education in Paris formed a commission to create tests that would help to identify "mentally defective children," with the goal of providing them with an appropriate education. Binet and Simon developed the first intelligence test for this purpose. Terman and Merrill incorporated many of Binet and Simon's ideas into the construction of the Stanford-Binet Intelligence Scale,⁶⁰ which remains widely used today.⁵⁷ Although intelligence was the first human attribute to be tested in a standardized manner, tests have been developed over the past several decades that assess children's developmental status, cognition, gross and fine motor skills, language and communication skills, school readiness, school achievement, visual-motor skills, visual-perceptual skills, social skills, and other behavioral domains. Although the number and types of tests have changed radically since the time of Simon and Binet, the basic reason for using standardized tests remains the same: to identify children who may need specialized intervention or environmental adaptations because their performance in a given area is outside the norm, or average, for their particular age.

The use of standardized tests requires a high level of responsibility on the part of the tester. The occupational therapist who uses a standardized test must be knowledgeable about scoring and interpreting the test, must know for whom the test is and is not appropriate, and must understand how to report and discuss a child's scores on the test. The tester must also be aware of the limitations of standardized tests in providing information about a child's performance or participation. This, in turn, requires a working knowledge of standardized testing concepts and procedures, familiarity with the factors that can affect performance on standardized tests, and awareness of the ethics and responsibilities of testers when using standardized tests.

This chapter introduces pediatric standardized testing used by occupational therapists. The purposes and characteristics of standardized tests are discussed, technical information about standardized tests is presented, practical tips to help the student

become a competent user of standardized assessments are given, and ethical considerations are explained. The chapter concludes with a summary of the advantages and disadvantages of standardized tests and a case study that incorporates the concepts presented in the chapter into a “real-life” testing scenario. Throughout the chapter, several standardized assessments commonly used by pediatric occupational therapists are highlighted to illustrate the concepts of test administration, scoring, and interpretation.

Influences on Standardized Testing in Pediatric Occupational Therapy

When standardized tests became widely used in pediatric practice in the 1970s and 1980s, the tests available for occupational therapists focused primarily on the developmental domains of gross motor skills, fine motor skills, and visual-motor/visual-perceptual skills. These early tests were developed by educators and psychologists. The first pediatric standardized test developed by an occupational therapist was the Southern California Sensory Integration Test (SCSIT), published by A. Jean Ayres in 1972. The SCSIT assessed sensory integration and praxis, domains that were of specific interest to occupational therapists, and was instrumental in defining the measurement standards in these areas.

In the ensuing years, the number of standardized tests created by and for pediatric occupational therapists has increased dramatically, and the number of behavioral and performance domains assessed has expanded. This evolution in standardized testing in occupational therapy has been influenced by developments both inside and outside the profession. Some key developments are briefly summarized next.

The Individuals with Disabilities Education Act (IDEA) Part B defined the role of occupational therapy as a related service in school-based settings for children age 3–21 years. In this setting, standardized tests provide information that is used to determine children’s eligibility for services, measure progress, and develop individualized education programs (IEPs).

The IDEA Part C created federal support for family-centered services for children age 0–3 and their families. Occupational therapy is a supportive service that participates in multidisciplinary evaluations to determine eligibility for services, assessment of family needs, resources, and priorities to support development of an individualized family service plan (IFSP) and periodic review of progress. Standardized tests of children’s developmental status, caregiver-child interactions, and the home environment are an important part of this process.

The development of occupational therapy frameworks that consider environmental characteristics and the performance of activities within daily contexts expanded evaluation to include information about how individuals engage with their environment and how environments may support or inhibit participation in daily life. This new focus required the development of evaluation procedures that assessed characteristics of the environment and the quality of children’s interactions within the environment. Strategic frameworks that define this person-environment interaction include the model of human occupation,³⁸ the ecology of human performance,¹⁹ and the person-environment-occupation model.⁴²

The development of client-centered models of practice that advocated involvement of the client and family in the evaluation and intervention planning process required the development of evaluation methods that collected information from clients about their needs, priorities, and satisfaction with their performance. The Canadian Occupational Performance Measure (COPM) is frequently used for this purpose.⁴¹ In pediatric practice this information is generally collected from parents/caregivers and teachers. Increasingly, however, the importance of obtaining information directly from children is being acknowledged, and evaluation methods to obtain this information have been developed.^{37,39,43}

Recognition of the limitations of collecting evaluation data focused on sensorimotor skills and the need to address multiple aspects of children’s occupational performance created a call for a “top down” evaluation process¹³ whereby initial focus of the evaluation shifted to the quality and quantity of children’s engagement in daily occupations. Assessments such as the School Function Assessment (SFA)¹⁴ and the Pediatric Evaluation of Disability Inventory (PEDI)³² incorporate this approach to assessment.

The International Classification of Functioning, Disability, and Health (ICF) identified three levels of focus for interventions: body structure or function (impairment), whole body movements or activities (activity limitations), and involvement in life situations (participation restrictions).⁶⁶ The ICF for Children and Youth (ICF-CY) added characteristics associated with growth and development in children and youth, facilitating the inclusion of the school and other learning environments in intervention programs. Incorporation of participation restrictions as an area of intervention created a new focus on the effect of impairments or activity limitations on children’s abilities to participate in all aspects of daily life. As a result, methods to assess children’s participation have been developed. Participation measures are incorporated into some standardized pediatric assessments such as the SFA¹⁴ and the Miller Function & Participation Scales (M-FUN).⁴⁵ Assessments that focus on children’s participation include the Children’s Assessment of Participation and Enjoyment (CAPE), the Preferences for Activities of Children (PAC),³⁹ the Child and Adolescent Scale of Participation (CASP),⁹ and the Pediatric Evaluation of Disability Inventory Computer Adaptive Test (PEDI-CAT).³²

The preceding discussion illustrates how evolution of the occupational therapy profession has contributed to the ongoing development of standardized testing practices. One of the most significant changes in standardized testing over the past 30 years involves the inclusion of multiple information sources in the standardized testing process. Pediatric occupational therapists no longer draw conclusions about a child’s abilities and needs based only on the child’s performance on test items administered in a highly structured setting. Self-report and parent-report assessments allow therapists to obtain information about children’s performance and participation in a variety of daily contexts based on information provided by adults who are familiar with the child and in some cases from the children themselves. These multiple sources of information provide a well-rounded picture of how personal and environmental factors interact to influence children’s ability to engage productively in age-appropriate occupations. Table 6-1 lists some of the most commonly used pediatric standardized assessments.

TABLE 6-1 Summary of Selected Pediatric Standardized Tests

Test	Age Range	Domains Tested	Sources of Information	Standard Scores Used	Duration of Test
Bayley Scales of Infant & Toddler Development Motor Scale (3rd ed.) (BSID-III)	1-42 mo	Fine Motor Subtest: Prehension, perceptual-motor integration, motor planning, motor speed Gross Motor Subtest: Static positioning, locomotion and coordination, balance, motor planning	Performance-based	Scaled scores Composite scores Percentile ranks Confidence intervals Growth scores Developmental age equivalent Z-scores T-scores Scaled scores Age-equivalent scores Developmental motor quotient scores	15-20 min
Peabody Developmental Motor Scales (2nd ed.) (PDMS-2)	1-84 mo	Fine Motor Scale: Grasping, hand use, eye-hand coordination, manual dexterity Gross Motor Scale: Reflexes, balance, locomotor, nonlocomotor, receipt and propulsion	Performance-based	Z-scores T-scores Scaled scores Age-equivalent scores Developmental motor quotient scores	45-60 min for total test, 20-30 min for each scale
Miller Function & Participation Scale (M-FUN)	2 yr 6 mo-7 yr 11 mo	Fine Motor, Visual Motor, and Gross Motor subtests each assess aspects of four neurologic foundations: hand function, postural abilities, executive function and participation, nonmotor visual perception Test Observations: Examiner rating of child's behavior during testing session Home Observations: Caregiver rating of child's participation in activities of daily living (ADLs) and leisure activities at home Classroom Observations: Teacher or examiner rating of participation in classroom activities	Performance-based Context-based: examiner, caregiver, and teacher ratings	Scaled scores Confidence intervals Percentile scores Age equivalents Progress scores Criterion-referenced participation scores	40-60 min for performance activities 5-10 min for participation checklists
Bruininks-Oseretsky Test of Motor Proficiency (2nd ed.) (BOT-2)	4 yr 0 mo-21 yr 11 mo	Fine Manual Control: Motor skills for drawing and writing Manual Coordination: Motor skills for reaching, grasping, and manipulating objects; emphasis on speed, dexterity, and coordination Body Coordination: Motor skills involved in balance and coordination of upper and lower extremities Strength and Agility: Large muscle strength, motor speed, motor skills for maintaining body position for walking and running	Performance-based	Scale scores Composite standard scores Percentile ranks Total motor composite Age-equivalent scores Descriptive categories Confidence intervals	40-60 min for complete form; individual subtests can also be administered
Pediatric Evaluation of Disability Inventory Computer Adaptive Test (PEDI-CAT)	6 mo-7 yr	Social Function, Self-Care, and Mobility scales: Each scale is scored according to functional skills, amount of caregiver assistance, and modifications for walking and running	Self-report: caregiver and/or therapist/professional ratings; can be completed by one or more respondents	Normative standard score Scaled score	40-60 min when scoring by caregiver report
School Function Assessment (SFA)	Grades K-6	Participation in nonacademic school tasks Task Supports: Five assistance and five adaptation scales Activity Performance: Physical tasks and cognitive-behavioral tasks	Self-report: teachers and other school staff ratings. Can be completed by one or more respondents	Criterion scores for each scale Cutoff scores for each scale for grades K-3 and grades 4-6	Total time 1.5-2 hr; 5-10 min per scale

Continued

TABLE 6-1 Summary of Selected Pediatric Standardized Tests—cont'd

Test	Age Range	Domains Tested	Sources of Information	Standard Scores Used	Duration of Test
Sensory Profile (SP)	3-10 yr	Sensory Processing: Auditory, visual, vestibular, touch, multisensory, and oral sensory processing Modulation: Sensory Processing Related to Endurance/Tone, Modulation Related to Body Position and Movement, Modulation of Movement Affecting Activity Level, Modulation of Sensory Input Affecting Emotional Responses Behavioral and Emotional Responses: Emotional/Social Responses, Behavioral Outcomes of Sensory Processing, Thresholds for Response	Self-Report: completed by caregiver	Cut score and classification system based on normative information: typical performance, probable difference, definite difference	20-30 min
Adolescent/Adult Sensory Profile (AASP)	11 yr and up	Sensory processing categories—Taste/Smell, Movement (vestibular/proprioceptive), Visual, Touch, Activity Level, and Auditory—are evaluated for each quadrant: Low Registration, Sensation Seeking, Sensory Sensitivity, and Sensation Avoiding, on a neurologic threshold continuum and behavioral response/self-regulation continuum	Context-based self-report	Cut score and classification system based on normative information: Quadrant grid Quadrant summary Quadrant profile	10-15 min
Sensory Processing Measure (SPM)	5-12 yr (Grades K-6)	Social participation Vision Hearing Touch Body awareness Balance and motion Planning and ideas Total sensory systems	Self-Report: completed by caregiver (Home Form), teacher (Main Classroom Form), teacher and other school staff (School Environments Form)	Standard scores, T-score, percentile score (Home and Main Classroom Forms) Cutoff scores (School Environments Form)	15-20 min for Home and Main Classroom Forms 5 min for each of six rating sheets for School Environments Form
Assessment of Motor and Process Skills (AMPS)	3 yr and up	Motor and process skills in performance of basic and instrumental activities of daily living (IADLs)	Performance-based	ADL ability measure Logit scores for motor and process scales	30-40 min
School Assessment of Motor and Process Skills (School AMPS)	3-11 yr	Occupational performance in school motor and process skills in five classroom tasks: pen/pencil writing, drawing and coloring, cutting and pasting, computer writing, manipulatives	Performance-based	Logit scores for motor and process scales	30-40 min
Goal-Oriented Assessment of Life Skills (GOAL)	7-17 yr	Functional motor skills needed for activities of daily living	Seven gross and fine motor activities composed of 54 steps—small units of easily observed behavior based on childhood occupations: Gross Motor and Fine Motor Standard Scores and Progress Scores	Performance-based	45-60 min

TABLE 6-2 Developmental Domains Assessed in Four Screening Tools

Screening Tool	Age Range	Domains Assessed
Ages and Stages Questionnaire (3rd ed.)	1-66 mo	Communication, gross motor, fine motor, problem-solving, personal-social
Denver Developmental Screening Test (Revised)	1 mo-6 yr	Personal-social, fine motor adaptive, language, gross motor
Developmental Indicators for Assessment of Learning (3rd ed.)	2.5-6 yr	Motor, language, concepts
FirstSTEP: Screening Test for Evaluating Preschoolers	2 yr 9 mo-6 yr 2 mo	Cognition, communication, physical, social, and emotional, adaptive functioning

Purposes of Standardized Tests

Standardized tests are used for several reasons. For example, a standardized test can be used as a screening tool to assess large numbers of children quickly and briefly and identify those who may have delays and are in need of more in-depth testing. Examples of screening tests frequently used by occupational therapists include the revised Denver Developmental Screening Test (Denver-II),²⁵ Ages and Stages Questionnaire–2nd (ASQ), and the FirstSTEP (Screening Test for Evaluating Preschoolers).⁴⁴

Screening tests typically assess several developmental domains, and each domain is represented by a small number of items (Table 6-2). Screening tests generally take 20 to 30 minutes and can be administered by professionals or by paraprofessionals such as classroom aides, nurse's aides, or teaching assistants. Therapists who work in settings that primarily serve typically developing children (e.g., a public school system or Head Start program) may become involved in developmental screening activities. In addition, occupational therapists frequently use assessment tools to evaluate children with specific developmental problems. Therefore it is important for all therapists to be aware of the strengths and weaknesses of specific tests used in their settings. Although the screening tools mentioned are not discussed in greater depth, the concepts of developing, administering, scoring, and interpreting standardized tests (discussed later in this chapter) should also be considered when using screening tools.

Occupational therapists most frequently use standardized tests as in-depth assessments of various areas of occupation and performance skills. Standardized tests are used for five main purposes:

1. To assist in the determination of a medical or educational diagnosis
2. To document a child's developmental, functional, and participation status
3. To aid the planning of an intervention program
4. To measure outcomes of programs
5. To measure variables in research studies

Determination of Medical or Educational Diagnoses

A primary purpose of standardized tests is to assist in the determination of a diagnosis through use of normative scores that compare the child's performance with that of an age-matched sample of children. Standardized tests are frequently used to

determine if a child has developmental delays or functional deficits significant enough to qualify the child for remedial services such as occupational therapy. Many funding agencies and insurance providers use the results of standardized testing as one criterion in deciding whether a child will receive occupational therapy intervention. In school-based practice, standard scores are helpful for identifying specific student problems that may indicate that the involvement of an occupational therapist is appropriate. Funding approval for special services generally depends on documentation of a predetermined degree of delay or deficit in one or more developmental or academic domains, and standardized test results are an important component of this documentation. The results of standardized testing performed by occupational therapists, when used in conjunction with testing done by other professionals, can help physicians or psychologists arrive at a medical or educational diagnosis.

Documentation of Developmental, Functional, and Participation Status

Another purpose of standardized testing is to document a child's status. This can include developmental levels, functional skills, and the child's level of participation in home, school, and community activities. Many funding and service agencies require periodic reassessment to provide a record of a child's progress and to determine if the child continues to qualify for services. Standardized testing is often a preferred way of documenting progress because the results of the most current assessment can be compared with those of earlier ones. Periodic formal reassessment can also provide valuable information to the therapist working with the child. Careful scrutiny of a child's test results can help identify areas of greatest and least progress. This can assist the therapist in prioritizing intervention goals. Many parents are also interested in seeing the results of their child's periodic assessments. Standardized tests used in periodic assessments must be chosen carefully so that areas of occupation or performance skills addressed in the intervention plan are also the focus of the standardized testing.

A discussion about the child's progress in areas that may not be measured by standardized testing should accompany the discussion of test performance. Structured or unstructured observations of the child's play, academic, social, and/or self-care performance; interviews with the caretaker or teacher about the child's home or school routine; the developmental, educational, and medical histories; and a review of

pertinent medical or educational records are equally important components of the assessment process.

Planning Intervention Programs

A third purpose of standardized testing is program planning. Standardized tests provide information about a child's level of function, and they help therapists determine the appropriate starting point for therapy intervention. Most commonly, criterion-referenced standardized tests are used as the basis for developing goals and objectives for individual children and measuring progress and change over time. Criterion-referenced tests are used extensively in educational settings and include tools such as the Hawaii Early Learning Profile (HELP)⁵⁰; the Assessment, Evaluation, and Programming System for Infants and Children¹⁰; and the SFA.¹⁴ Criterion-referenced tests are described in more detail in the following section.

Measuring Program Outcomes

Occupational therapists are increasingly being required to document efficacy of their interventions, not only individually but at the program level. When a number of children participate in a similar intervention program and standardized instruments are used to evaluate change of status, the data can be combined and analyzed to provide outcome data about the program.⁴⁸ These data can be used for program development and modification and to support allocation of necessary resources to continue the program.

Measurement Instruments for Research Studies

Because of the psychometric properties of standardized tests, standard scores obtained from these tests can be statistically manipulated and analyzed. This allows test scores to be used for both descriptive and experimental research. Standardized tests can be used to obtain descriptive data about particular populations or groups. Experimental studies compare scores obtained before and after interventions or compare the outcome scores for two different interventions. Data obtained through descriptive and experimental studies enhance our knowledge about client groups and provide evidence regarding the efficacy of occupational therapy interventions.

Characteristics

As stated, standardized tests have uniform procedures for administration and scoring. These standard procedures permit the results of a child's tests to be compared either with the child's performance on a previous administration of the test or with the test norms developed by administration of the test to a large number of children.

Standardized tests characteristically include a test manual that describes the purpose of the test (i.e., what the test is intended to measure). The manual should also describe the intended population for the test. For pediatric assessments, this generally refers to the age range of children for whom the test was intended, but it may also refer to specific diagnoses or types of functional impairments. Test manuals also contain technical

information about the test, such as a description of the test development and standardization process, characteristics of the normative sample, and studies done during the test development process to establish reliability and validity data. Finally, test manuals contain detailed information about the administration, scoring, and interpretation of the test scores.

Another characteristic of standardized tests is that they are composed of a fixed number of items. Items may not be added or subtracted without affecting the standard procedure for test administration. Most tests have specific rules about the number of items that should be administered to ensure a standardized test administration. These rules may differ significantly from test to test. For instance, the Bruininks-Oseretsky Test of Motor Proficiency (2nd ed.) (BOT-2) specifies that within each subtest the entire item set be administered regardless of the child's age.^{11,67} In contrast, the Bayley Scales of Infant and Toddler Development (3rd ed.) (BSID-III) has 17 start points for the test.⁷ Examiners are instructed to begin testing at the start point corresponding to the child's chronologic age (or corrected age, if the child was born prematurely) and move to easier or more difficult items, depending on the child's performance. **Box 6-1** explains how to compute ages corrected for prematurity.

A third characteristic of standardized tests is fixed protocol for administration. The term *fixed protocol for administration* refers to the way each item is administered and the number of items administered. Generally, the protocol for administration specifies the verbal instruction or demonstration to be provided, the number of times the instructions can be repeated, and the number of attempts the child is allowed on the item. For some tests, instructions for each item are printed in the manual, and the tester is expected to read the instructions verbatim to the child without deviating from the text. However, other tests allow for more freedom of instruction, especially when the test involves a physical activity (**Figure 6-1**).

Standardized tests also have a fixed guideline for scoring. Scoring guidelines usually accompany the administration guidelines and specify what the child's performance must look like to receive a passing score on the item. Depending on the nature of the item, passing performance may be described using text, a picture, or a diagram. The administration and scoring guidelines for a test item from the BOT-2 are shown in **Figure 6-2**. In this example, the instructions to be given to the child are printed in bold type. Also included are the criteria for a passing score on the item, examples of incorrect responses, the number of trials, and the time allowed for completion of the item. This example (see **Figure 6-2**) describes how to present the item and what constitutes a passing score and includes a diagram of what a passing performance looks like.

Types of Standardized Tests

The two main types of standardized tests are norm-referenced tests and criterion-referenced tests. Many pediatric occupational therapists use both types in their practices. Each type has a specific purpose, and it is important for testers to be aware of the purpose of the test they are using.

A norm-referenced test is developed by giving the test in question to a large number of children, usually several hundred or more. This group is called the normative sample, and norms,

BOX 6-1 Calculating the Chronologic Age and Corrected Age

Many standardized tests require that the examiner calculate the child's exact age on the date of testing. The method for calculating both the chronologic and the corrected age is presented in the following.

Calculating the Chronologic Age

First, the date of testing and the child's birth date are recorded in the following order:

	Year	Month	Day
Date of testing	99	6	15
Birth date	95	3	10
Chronologic age	4	3	5

Beginning on the right (the Day category), the day, month, and year of the child's birth date are subtracted from the date of testing. In the above example, the child's chronologic age is 4 years, 3 months, 5 days at the time of testing.

The convention in calculating age is that if the number of days in the chronologic age is 15 or less, the month is rounded down. Therefore in the above example, the child's age would be stated as 4 years, 3 months, or 4-3. If the number of days in the chronologic age is between 16 and 30, the month is rounded up. If the above child's chronologic age had been 4 years, 3 months, 16 days, the chronologic age would be expressed as 4 years, 4 months, or 4-4.

Sometimes, "borrowing" is necessary to subtract the birth date from the date of testing correctly:

	Year	Month	Day
Date of testing	99	6	15
Birth date	95	10	22
Chronologic age	3	7	23

Begin with the Day category. Twenty-two cannot be subtracted from 15 without borrowing from the Month category. One month must be borrowed and placed in the Day category. One month equals 30 days; 30 is added to the 15 days in the Date of testing, giving a total of 45. Twenty-two is subtracted from 45, leaving 23 days. Moving to the Month category, 1 month has been borrowed by the Day category, leaving 5 months. Because 10 cannot be subtracted from 5, 1 year must be borrowed from the Year category. One year equals 12

months; therefore 12 will be added to the 5 in the Month category for Date of testing, totaling 17. Ten is subtracted from 17, leaving 7 months. Moving to the Year category, 1 year has been borrowed by the Month category, leaving 98. Ninety-five can be subtracted from 98, leaving 3 years. Therefore this child's chronologic age is 3 years, 7 months, 23 days. Using the rounding convention as discussed, the month is rounded up, giving a chronologic age of 3 years, 8 months.

Calculating the Corrected Age

Corrected age is used for children who were born prematurely to "correct" for the number of weeks they were born before the due date. Generally, the age is corrected until the child turns 2 years of age, although this convention can vary. Given 40 weeks' gestation as full term, the amount of correction is the difference between the actual gestational age at birth and the 40 weeks' full-term gestational age. Therefore a child born at 30 weeks' gestation is 10 weeks premature. Many practitioners consider 36 or 37 weeks or above to be full-term gestation; therefore children with a gestational age of 36 weeks or above do not receive a corrected age. Because there is some variation in how and when corrected age is used, it is wise for the therapist to learn the procedures of his or her facility and to adhere to them when calculating corrected age.

If the expected due date and birth date are both known, subtracting the birth date from the due date yields an exact measurement of prematurity.

	Year	Month	Day
Due date	98	9	20
Birth date	98	6	12
	—	3	8

This child is 3 months, 8 days premature. To calculate corrected age, subtract the prematurity value from the chronologic age:

	Year	Month	Day
Chronologic age	1	1	25
Prematurity	—	3	8
	—	10	17

The child's corrected age is 10 months, 17 days, or, when rounded, 11 months.

or average scores, are derived from this sample. When a norm-referenced test is administered, the performance of the child being tested is compared with that of the normative sample. The purpose of norm-referenced testing, then, is to determine how a child performs in relation to the average performance of the normative sample.

Test developers generally attempt to include children from a variety of geographic locations, ethnic and racial backgrounds, and socioeconomic levels so that the normative sample is representative of the population of the United States, based on the most recent U.S. census data. Generally, the normative sample is composed of children who have no developmental

delays or conditions, although many tests include data from subsamples of clinical populations as a means of determining whether the test discriminates between children whose development is proceeding normally and those who have known developmental delays.

Norm-referenced tests address one or more areas of behavior. If the test evaluates more than one area, each area typically has one or more subtests. For instance the BOT-2 assesses performance in four motor-area composites: fine manual control, manual coordination, body coordination, and strength and agility. Items are chosen to represent a broad range of skills within these composite areas. Additionally, items are chosen to

FIGURE 6-1 A therapist prepares to test a child on the broad jump item from the Bruininks-Oseretsky Test of Motor Proficiency 2.

incorporate materials and activities that are reasonably familiar and typical for children of the age group being tested. A child's performance on an individual test item is not as important as the overall subtest or area score. However, it is important for the therapist to observe the quality and characteristics of a child's performance on each item, as these qualitative observations provide important information to complement the obtained standard scores.

Norm-referenced tests have standardized protocols for administration and scoring. The tester must adhere to these protocols so that each test administration is as similar as possible to that of the normative sample. This is necessary to compare any child's performance fairly with that of the normative sample.

Sometimes the examiner must deviate from the standard protocol because of special needs of the child being tested. For instance, a child with visual impairments may need manual guidance to cut with scissors, or a child with cerebral palsy may need assistance stabilizing the shoulder and upper arm to reach and grasp a crayon. If changes are made in the standardized procedures, the examiner must indicate this in the summary of assessment, and standard scores cannot be used to describe that child's performance in comparison with the normative sample.

Norm-referenced tests have specific psychometric properties. They have been analyzed by statisticians to obtain score distributions, mean or average scores, and standard scores. This is done to achieve the primary objective of norm-referenced tests: comparability of scores with the normative sample. A test under development initially has a much larger number of items than the final version of the test. Through pilot testing, items are chosen or rejected based partly on how well they statistically discriminate between children of different ages and/or abilities. Items are not chosen primarily for their relevance to functional skills. Consequently, some norm-referenced tests are not intended to link test performance with specific objectives or goals for intervention. Other norm-referenced tests, such as the Sensory Profile, are designed to specifically evaluate the effect of sensory processes on functional performance in daily life and, when combined with other evaluation and observation data, to allow therapists to develop intervention goals. A portion of the Sensory Profile questionnaire is presented in [Figure 6-3](#).

A criterion-referenced test, by contrast, is designed to provide information on how children perform on specific tasks. The term *criterion-referenced* refers to the fact that a child's performance is compared with a particular criterion, or level of performance of a particular skill. The goal of a criterion-referenced test is to determine which skills a child can and cannot accomplish, thereby providing a focus for intervention. In general the content of a criterion-referenced test is detailed and in some cases may relate to specific behavioral or functional objectives. The intent of a criterion-referenced test is to measure a child's performance on specific tasks rather than to compare the child's performance with that of his or her peers.

Many developmental checklists have been field tested and then published as criterion-referenced tests. The HELP is a good example of a developmental checklist designed to be used with children from birth to 3 years of age, and from 3 to 6 years of age.⁵⁹ It contains a large number of items in each of the domains of gross motor, fine motor, language, cognitive, social-emotional, and self-help skills. Each item correlates with specific intervention objectives. For instance, if a child is not able to pass Fine Motor item 4.81, Snips with Scissors, a list of intervention ideas is presented in the HELP activity guide.²⁸ The activity guide provides ideas for developmentally appropriate activities that link to the assessment items. The administration protocol for this item and the associated intervention activities are presented in [Boxes 6-2](#) and [6-3](#).

Administration and scoring procedures may or may not be standardized on a criterion-referenced test. The HELP has standard procedures for administering and scoring each item. In contrast, the SFA is a judgment-based questionnaire completed by one or more school professionals familiar with the child's performance at school.¹⁴ Criteria for rating the child's performance on each item are provided. School professionals are encouraged to collaborate in determining ratings and to use these ratings as a basis for designing an intervention plan. [Figure 6-4](#) shows a category of activity performance with the associated rating scale. Many other criterion-referenced tests take the form of checklists, in which the specific performance needed to receive credit on an item is not indicated. Many therapist-designed tests for use in a particular facility or setting are non-standardized, criterion-referenced tests.

Criterion-referenced tests are not subjected to the statistical analyses performed on norm-referenced tests. No mean score

BOX 6-2 Administration and Assessment Procedures and Processes for Hawaii Early Learning Profile: Item 4.81—Snips with Scissors (23-25 Months)

- Definition: The child cuts a paper edge randomly, one snip at a time, rather than using a continuous cutting motion.
- Example observation opportunities: Incidental—May observe while the child is preparing for a tea party with stuffed animals or dolls. Demonstrate making fringe on paper placemats and invite the child to help. Structured—Using a half piece of sturdy paper and blunt scissors, make three snips in separate places along the edge of the paper while the child is watching. Exaggerate the opening and closing motions of your hand. Offer the child the scissors and invite him or her to make a cut. Let the child explore the scissors (if interested), helping him or her position the scissors in his or her hand as needed.
- Credit: Snips paper in one place, holding the paper in one hand and scissors in the other (see also Credit Notes in this strand's preface).

BOX 6-3 Administration and Assessment Procedures and Processes for Hawaii Early Learning Profile Item 4.81—Snips with Scissors: Activity Guide Suggestions

The child cuts with the scissors, taking one snip at a time rather than doing continuous cutting.

1. Let the child use small kitchen tongs to pick up objects and to practice opening and closing motions.
2. Let the child use child-sized scissors with rounded tips.
3. Demonstrate by placing your finger and thumb through the handles.
4. Position the scissors with the finger holes one above the other. Position the child's forearm in mid-supination (i.e., thumb up). Let the child place his or her thumb through the top hole and the middle finger through the bottom hole. If the child's fingers are small, place the index and middle

fingers in the bottom hole. The child will adjust his or her fingers as experience is gained.

5. Let the child open and close the scissors. Assist as necessary by placing your hand over the child's hand.
6. Let the child snip narrow strips of paper and use it for fringe in art work.
7. The different types of scissors available for children are a scissors with reinforced rubber coating on the handle grips; a scissors with double handle grips for your hand and the child's hand; a left-handed scissors; and a scissors for a prosthetic hook. Use the different types of child's scissors appropriately as required.

From Furuno, S., O'Reilly, K. A., Hosaka, C. M., Zeisloft, B., & Allman, T. (2005). *HELP activity guide*. Palo Alto, CA: VORT.

or normal distribution is calculated; a child may pass all items or fail all items on a particular test without adversely affecting the validity of the test results. The purpose of the test is to learn exactly what a child can accomplish, not to compare the child's performance with that of the peer group. This goal is also reflected in the test development process for criterion-referenced tests. Items are generally chosen based on a process of task analysis or identification of important developmental milestones rather than for their statistical validity. Therefore the specific items on a criterion-referenced test have a direct relationship with functional skills and can be used as a starting point for generating appropriate goals and objectives for therapy intervention.

The characteristics of norm- and criterion-referenced tests are compared in Table 6-3. As is shown in the table, some tests are both norm- and criterion-referenced. This means that although the items have been analyzed for their ability to perform statistically, they also reflect functional or developmental skills that are appropriate for intervention. These tests permit the therapist to compare a child's performance with that of peers in the normative sample, and they also provide information about specific skills that may be appropriate for remediation.

The Peabody Developmental Motor Scales (2nd ed.; PDMS-2) is an example of both a norm- and criterion-referenced test. Although the PDMS-2 has been subjected to

the statistical analyses used in norm-referenced tests, many individual items in the test also represent developmental milestones that can be targeted as specific intervention goals. The SFA, although primarily a criterion-referenced test, provides a criterion score and standard error for each raw score based on a national standardization sample.

Standardized tests can also be categorized as performance-based or self-report. Self-report tests collect data on the child's performance, behavior, or participation in daily activities and natural environments from adults such as parents, caregivers, teachers, or therapists who interact regularly with the child or from the child himself or herself. The advantage of self-report tests is that the score represents typical or usual behavior, performance, or participation based on multiple observations of the child in different times and places. The disadvantage of self-report tests is that respondents may not carefully read or understand the test instructions or may answer according to what they believe the evaluator wants to hear. Clarity of questions and criteria for respondent ratings is crucial to the quality of a self-report test. Test development procedures include data collection from potential respondents so that they can provide input to ensure that the test content is meaningful and the items and procedures are easily understandable.⁴⁰ Careful instruction of respondents at the time of the evaluation can also facilitate accuracy of responses. Self-report tests have been developed for developmental screening—the Ages and Stages Questionnaire,

Behavior Regulation

1. Displays appropriate restraint regarding self-stimulation (e.g., refrains from head banging, hand flapping).	1	2	3	4
2. Accepts unexpected changes in routine.	1	2	3	4
3. Refrains from provoking others.	1	2	3	4
4. Uses nonaggressive words and actions.	1	2	3	4
5. Maintains behavioral control in large groups of students (e.g., cafeteria, assemblies).	1	2	3	4
6. Hears constructive criticism without losing temper.	1	2	3	4
7. Uses words rather than physical actions to respond when provoked or angry at others.	1	2	3	4
8. Seeks adult assistance, if necessary, when experiencing peer conflict, especially conflicts involving violence.	1	2	3	4
9. Responds to/handles teasing in a constructive way.	1	2	3	4
10. Handles frustration when experiencing difficulties with school tasks/activities.	1	2	3	4
11. Shows common sense in words and actions around bullies, gangs, or strangers.	1	2	3	4
12. Resolves ordinary peer conflicts or problems adequately on his/her own without requesting teacher assistance.	1	2	3	4

Technical Aspects

The following discussion of the technical aspects of standardized tests focuses on the statistics and test development procedures used for norm-referenced tests. Information on how standard scores are obtained and reported is included, as well as on how the reliability and validity of a test are evaluated. It is the responsibility of the test author to provide initial data on test reliability and validity. However, these test characteristics are never definitively determined, and ongoing evaluation of validity and reliability is necessary. Occupational therapists must comprehend the technical aspects of standardized tests to be able:

1. To analyze and select standardized tests appropriately, according to the child's age and functional level and the purpose of testing.
2. To interpret and report scores from standardized tests accurately.
3. To explain test results to caregivers and other professionals working with the child in a clear, understandable manner.

Presented next is information on (1) descriptive statistics, (2) standard scores, (3) correlation coefficients, (4) reliability, and (5) validity.

Descriptive Statistics

Descriptive statistics provide information about the characteristics of a particular group. Many human characteristics, such as height, weight, head size, and intelligence, are represented by a distribution called the normal curve (or bell-shaped curve) (Figure 6-5). The pattern of performance on most norm-referenced tests also follows this curve. The greatest number of people receive a score in the middle part of the distribution, with progressively smaller numbers receiving scores at either the high or the low end. Descriptive statistics also provide information about where members of a group are located on the normal curve. The two types of descriptive statistics are the measure of central tendency and the measure of variability.

The measure of central tendency indicates the middle point of the distribution for a particular group, or sample, of children. The most frequently used measure of central tendency is the mean, which is the sum of all the scores for a particular sample divided by the number of scores. It is computed mathematically using a simple formula:

$$\bar{X} = \frac{\sum X}{n}$$

where Σ means to sum, X is each individual score, and n is the number of scores in the sample. (The mean is also often called the *average score*.)

Another measure of central tendency is the median, which is simply the middle score of a distribution. Half the scores lie below the median and half above it. The median is the preferred measure of central tendency when outlying or extreme scores are present in the distribution. The following distribution of scores is an example:

2 3 13 14 17 17 18

The mean score is 12 [i.e., $(2 + 3 + 13 + 14 + 17 + 17 + 18) \div 7$]. The median, or middle score, is 14. In this case the score of 14 is a more accurate representation of the middle point of these scores than is the score of 12 because the two low scores, or outliers, in the distribution pulled down the value of the mean.

The measure of variability determines how much the performance of the group as a whole deviates from the mean. Measures of variability are used to compute the standard scores used in standardized tests. As with measures of central tendency, measures of variability are derived from the normal curve. The two measures of variability discussed are the variance and the standard deviation.

The variance is the average of the squared deviations of the scores from the mean. In other words, it is a measure of how far the score of an average individual in a sample deviates from the group mean. The variance is computed using the following formula:

$$s^2 = \frac{\sum (X - \bar{X})^2}{n}$$

where S^2 is the variance, $\sum (X - \bar{X})^2$ is the sum of each individual score minus the mean score, and n is the total number of scores in the group. The standard deviation is simply the square root of the variance. To illustrate, calculations are provided for the mean, the variance, and the standard deviation for the following set of scores from a hypothetical test:

17 19 21 25 28

To calculate the mean, the following equation is used:

$$\frac{(17 + 19 + 21 + 25 + 28)}{5} = 22$$

To calculate the variance, the mean must be subtracted from each score, and that value then must be squared:

$$17 - 22 = (-5)^2 = 25$$

$$19 - 22 = (-3)^2 = 9$$

$$21 - 22 = (-1)^2 = 1$$

$$25 - 22 = (3)^2 = 9$$

$$28 - 22 = (6)^2 = 36$$

The squared values are summed and then divided by the total number of scores:

$$\begin{aligned} 25 + 9 + 1 + 9 + 36 &= 80 \\ 80 \div 5 &= 16 \end{aligned}$$

The variance of this score distribution is 16. The standard deviation is simply the square root of the variance, or 4.

The standard deviation (SD) is an important number because it is the basis for computing many standard scores. In

a normal distribution (see Figure 6-5), 68% of the people in the distribution score within 1 SD of the mean (± 1 SD); 95% score within 2 SD of the mean (± 2 SD); and 99.7% score within 3 SD of the mean (± 3 SD). In the score distribution with a mean of 22 and a standard deviation of 4, three of the five scores were within 1 SD of the mean (22 ± 4 ; a score range of 18-26), and all five scores were within 2 SD of the mean (22 ± 8 ; a score range of 14-30). The standard deviation, then, determines the placement of scores on the normal curve. By showing the degree of variability in the sample, the standard deviation reveals how far the scores can be expected to range from the mean value.

Standard Scores

Standardized tests are scored in several different ways. Scoring methods include Z-scores, T-scores, deviation intelligence quotient (IQ) scores, developmental index scores, percentile scores, and age-equivalent scores.

The Z-score is computed by subtracting the mean for the test from the individual's score and dividing it by the standard deviation, using the following equation:

$$z = \frac{X - \bar{X}}{SD}$$

For the score distribution above (i.e., 17 19 21 25 28), the person receiving the score of 17 would have a Z-score of $(17 - 22) \div 4 = -1.25$. The person receiving the score of 28 would have a Z-score of $(28 - 22) \div 4 = 1.5$. The negative value of the first score indicates that the Z-score value is below the mean for the test, and the positive value of the second score indicates that the Z-score value is above the mean. Generally, a Z-score value of -1.5 or less is considered indicative of delay or deficit in the area measured, although this can vary, depending on the particular test.

The T-score is derived from the Z-score. In a T-score distribution, the mean is 50 and the standard deviation is 10. The T-score is computed using the following equation:

$$T = 10(Z) + 50$$

For the two Z-scores computed in the preceding, the T-score values are as follows: for the first Z-score of -1.25 , the T-score is $10(-1.25) + 50 = 37.50$. For the second Z-score of 1.5 , the T-score is $10(1.5) + 50 = 65$. Note that all T-scores have positive values, but because the mean of a T-score distribution is 50, any number less than 50 indicates a score below the mean. Because the standard deviation of the T distribution is 10, the first score of 37.50 is slightly more than 1 SD below the mean. The second score of 65 is 15 points, or 1.5 SD, above the mean.

Two other standard scores that are frequently seen in standardized tests are the deviation IQ score and the developmental index score. Deviation IQ scores have a mean of 100 and a standard deviation of either 15 or 16. These are the IQ scores obtained from such tests as the Stanford-Binet⁶¹ or the Wechsler Intelligence Scale for Children (WISC).⁶⁵ On these tests, individuals with IQ scores 2 SD below the mean (IQs of 70 and 68, respectively) are considered to have an intellectual disability. Individuals with IQ scores 2 SD above the mean (IQs of 130 and 132, respectively) are considered gifted. Developmental index scores are used in developmental tests such as the

PDMS-2 and the BSID-III. Like the deviation IQ scores, they have a mean of 100 and a standard deviation of 15 or 16. Children who receive a developmental index score of 2 SD below the mean (index score of 68 or 70) in one or more skill areas are considered to be in need of remedial services. In many cases children who receive developmental index scores lower than -1.5 SD (index score of 85) may also be recommended for occupational therapy services.

Two other types of scores (i.e., percentile scores and age-equivalent scores) are frequently used in standardized tests. These are not standard scores in the strictest sense, because they are computed directly from raw scores rather than through the statistically derived measures of central tendency and variability. However, they give an indication of a child's performance relative to that of the normative sample.

The percentile score is the percentage of people in a standardization sample whose score is at or below a particular raw score. A percentile score of 60, for instance, indicates that 60% of the people in the standardization sample received a score that was at or below the raw score corresponding to the 60th percentile. Tests that use percentile scores generally include a table in the manual by which raw scores can be converted to percentile scores. These tables usually indicate at what percentile rank performance is considered deficient. Raw scores can be converted to percentile rank (PR) scores by a simple formula:

$$PR = \frac{(\text{Number of people below score} + \text{One half of people at score}) \times 100}{\text{Total number of scores}}$$

Using the previous sample data (i.e., 17 19 21 25 28), percentile ranks for the highest and lowest scores can be computed. The raw score of 17 is the lowest score in the distribution and is the only score of 17. Therefore the equation is as follows:

$$\frac{(0 + 0.5)}{5} \times 100 = \frac{0.5}{5} \times 100 = 10$$

The highest score in the distribution is 28; therefore four people have lower scores and one person received a score of 28. The equation is as follows:

$$\frac{(4 + 0.5)}{5} \times 100 = \frac{4.5}{5} \times 100 = 90$$

In this distribution, then, the lowest score is at the 10th percentile and the highest score is at the 90th percentile.

Although PR scores can be easily calculated and understood, they have a significant disadvantage: The percentile ranks are not equal in size across the score distribution. Distances between percentile ranks are much smaller in the middle of the distribution than at the ends; consequently, improving a score from the 50th to the 55th percentile requires much less effort than improving a score from the 5th to the 10th percentile (see Figure 6-5). As a result, an improvement in performance by a child functioning at the lower end of the score range may not be reflected in the PR score the child achieves. Other standard scores are more sensitive at measuring changes in the performance of children who fall at the extreme ends of the score distribution.

The age-equivalent score is the age at which the raw score is at the 50th percentile. The age-equivalent score generally is expressed in years and months, e.g., 4-3 (i.e., 4 years 3

months). It is a score that is easily understood by parents and caregivers who may not be familiar with testing concepts or terminology. However, age-equivalent scores have significant disadvantages. Although they may provide a general idea of a child's overall developmental level, it may be misleading to say, for example, that a 4-year-old is functioning at the 2.5-year level. The age-equivalent score may be more or less an average of several developmental domains, some of which may be at the 4.5-year level and some at the 1.5-year level. Therefore the child's performance may be highly variable and may not reflect that of a typical 2.5-year-old. In addition, because the age-equivalent score represents only the score that a child of a particular age who is performing at the 50th percentile would receive, a child who is performing within normal limits for his or her age but whose score is below the 50th percentile would receive an age-equivalent score below his or her chronologic age. This can cause parents or caregivers to conclude incorrectly that the child has delays. Age equivalents, then, are a type of standard score that can contribute to an understanding of a child's performance, but they are the least psychometrically sound, can be misleading, and should be used only with caution.

Reliability

The reliability of a test describes the consistency or stability of scores obtained by one individual when tested on two different occasions with different sets of items or under other variable examining conditions.⁶³ For instance, if a child is given a test and receives a score of 50 and 2 days later is given the same test and receives a score of 75, the reliability of the test is questionable. The difference between the two scores is called the error variance of the test, which is a result of random fluctuations in performance between the two testing sessions. Some amount of random error variance is expected in any test situation because of variations in such things as mood, fatigue, or motivation. Error variance can also be caused by environmental characteristics such as light, temperature, or noise. However, it is important that error variance caused by variations in examiners or by the characteristics of the test itself be minimal. Confidence in the scores obtained requires that the test have adequate reliability over a number of administrations and have low error variance.

Most standardized tests evaluate two or three forms of reliability. The three forms of reliability most commonly used in pediatric standardized tests are (1) test-retest reliability, (2) inter-rater reliability, and (3) standard error of measurement (SEM).

Test-Retest Reliability

Test-retest reliability is a measurement of the stability of a test over time. It is obtained by giving the test to the same individual on two different occasions. In the evaluation of test-retest reliability for a pediatric test, the time span between test administrations must be short to minimize the possibility of developmental changes occurring between the two test sessions. However, the time span between tests should not be so short that the child may recall items administered during the first test session, thereby improving his or her performance on the second test session (this is called the learning, or practice, effect).

During the process of test development, test-retest reliability is evaluated on a subgroup of the normative sample. The size and composition of the subgroup should be specified in the manual. The correlation coefficient between the scores of the two test sessions is the measure of the test-retest reliability. A test that has a high test-retest reliability coefficient is more likely to yield relatively stable scores over time. That is, it is affected less by random error variance than is a test with a low test-retest reliability coefficient. When administering a test with a low test-retest reliability coefficient, the examiner has less confidence that the score obtained is a true reflection of the child's abilities. If the child were tested at a different time of day or in a different setting entirely, different results might be obtained.

A sample of 197 children was evaluated twice within 2 weeks (mean retest interval of 6 days) to assess the test-retest reliability (stability) of the BSID-III Motor Scale.⁷ Overall stability coefficients were 0.80 for the Fine Motor Scale, 0.82 for the Gross Motor Scale, and 0.83 for the Motor Composite. Test-retest stability was slightly higher for the older age groups. The performance of a young child often varies within short periods because he or she is highly influenced by variables such as mood, hunger, sleepiness, and irritability. The test-retest reliability coefficients for 50 children tested twice within 1 week with the PDMS-2 ranged from 0.73 for the Fine Motor Quotient and 0.84 for the Gross Motor Quotient for 2- to 11-month-old children to 0.94 for the Fine Motor Quotient and 0.93 for the Gross Motor Quotient for 12- to 17-month-old children.²⁴

To evaluate test-retest reliability of the Sensory Processing Measure (SPM),⁴⁹ a rating scale of sensory processing, praxis, and social participation in home and school environments for children age 5-12, caregivers and teachers of 77 typically developing children completed the rating scale two times within a 2-week interval. Correlation coefficients for the scales ranged from 0.94 to 0.98. These three examples of good to excellent test-retest reliability are typical examples of scales that measure children's sensory processing and motor performance. The rapid and variable development of young children and the practice effect are two factors that negatively influence a test's stability over time. The test-retest reliability of a test is critical to its use as a measure of the child's progress or of intervention efficacy.

Inter-rater Reliability

Inter-rater reliability refers to the ability of two independent raters to obtain the same scores when scoring the same child simultaneously. Inter-rater reliability is generally measured on a subset of the normative sample during the test development process. This is often accomplished by having one rater administer and score the test while another rater observes and scores at the same time. The correlation coefficient calculated from the two raters' scores is the inter-rater reliability coefficient of the test. It is particularly important to measure inter-rater reliability on tests for which the scoring may require some judgment on the part of the examiner.

Although the scoring criteria for many test items are specific on most tests, scoring depends to a certain extent on individual judgment, and scoring differences can arise among different examiners. A test that has a low inter-rater reliability coefficient is especially susceptible to differences in scoring by different

raters. This may mean that the administration and scoring criteria are not stated explicitly enough, requiring examiners to make judgment calls on a number of items. Alternatively, it can mean that the items on the test call for responses that are too broad or vague to permit precise scoring.

The inter-rater reliability of the M-FUN52 was evaluated by having pairs of examiners score the performance of 29 children on the M-FUN using the scoring rubrics developed for the standardization edition of the test. One examiner administered and scored while the second examiner observed and scored independently. Correlation coefficients were 0.91 for Visual Motor, 0.93 for Fine Motor, and 0.91 for Gross Motor. A second aspect of inter-rater reliability, decision agreement, was also evaluated. Decision agreement is the degree to which examiners' scores agree in the identification of a child as performing in the average range or below average range. Because standardized tests are used frequently to qualify children for services, it is important to know whether different examiners can consistently identify whether or not a child has impairments. On the M-FUN, decision agreement was 96% for Visual Motor, 97% for Fine Motor, and 93% for Gross Motor. The results of the inter-rater reliability studies on the M-FUN suggest that examiners can reliably score children's performance, and based on the obtained scores can make reliable determinations about the presence of impairment.

Inter-rater reliability for the PDMS-2 was evaluated using a slightly different method. Sixty completed test protocols were randomly selected from the normative sample and were independently scored by two examiners. The resulting correlation coefficients were 0.97 for the Gross Motor Composite and 0.98 for the Fine Motor Composite.²⁴ It should be noted that this method of determining reliability is not based on two independent observations of the child's performance but on review of completed scoring protocols. Hence, potential error related to the way examiners interpreted and applied the scoring criteria to determine scores on individual items was not addressed. This could result in spuriously high inter-rater reliability coefficients. In a test such as the DTVP-II, in which scores are based on a written record of the child's response, inter-rater reliability is excellent. When two individuals scored 88 completed DTVP-II protocols, the inter-scorer reliability was 0.98.³³

Examiners can exert some control over the inter-rater reliability of tests they use frequently. It is good practice for examiners to check inter-rater reliability with more experienced colleagues when learning a new standardized test before beginning to administer the test to children in the clinical setting. Also, periodic checking of inter-rater reliability with colleagues who are administering the same standardized tests is a good practice. Some simple methods for assessing inter-rater reliability are discussed in more detail later in the chapter.

For self-report tests, inter-rater reliability is generally not a meaningful indicator of the psychometric integrity of the test, because each individual who contributes information to the test does so based on knowledge of the child in a specific environment with unique demands. However, because different raters may be evaluating the child on similar constructs, some agreement between ratings should be expected. This is known as cross-rater concordance, and is a measure of the validity of the instrument rather than reliability. For instance, on the SPM, concordance between caregiver (home) and teacher (school) ratings ranged from a coefficient of 0.31 for balance and

motion to 0.55 for planning and ideas. These represent moderate to high correlations, but are lower than minimum inter-rater reliability standards for performance-based tests. These results are acceptable for a context-based instrument and reflect the importance of gathering data on a child's ability to engage in daily life tasks, activities, and occupations based on observations of the child over time in daily environments.

Acceptable Reliability

No universal agreement has been reached regarding the minimum acceptable coefficient for test-retest and inter-rater reliability. The context of the reliability measurement, the type of test, and the distribution of scores are some of the variables that can be taken into account when determining an acceptable reliability coefficient. One standard suggested by Urbina and used by a number of examiners is 0.80.⁶³

Not all tests have test-retest or inter-rater reliability coefficients that reach the 0.80 level. Lower coefficients indicate greater variability in scores. When examiners use a test that has a reliability coefficient below 0.80, scores must be interpreted with great caution. For example, if one subtest of a test of motor development has test-retest reliability of 0.60, the examiner who uses it to measure change over time must acknowledge that a portion of the apparent change between the first and second test administration is a result of the error variance of the test.

When individual subtests of a comprehensive test have a low reliability coefficient, it is generally not recommended that the standard scores from the subtests be reported. Often the reliability coefficient of the entire test is much higher than that of the individual subtests. One reason for this is that reliability increases with the number of items on a test. Because subtests have fewer items than the entire test, they are more sensitive to fluctuations in the performance or scoring of individual items. When this occurs, it is best to describe subtest performance qualitatively, without reporting standard scores.

Standard scores can be reported for the total, or comprehensive, test score. Examiners should consult the reliability information in the test manual before deciding how to report test scores for individual subtests and for the test as a whole. The test-retest and inter-rater reliability coefficients reported in the manual are estimates based on the context and conditions used during test development and may vary when children are tested in different contexts or when examiners have differing levels of training and experience.

Standard Error of Measurement

The standard error of measurement (SEM) is a statistic used to calculate the expected range of error for the test score of an individual. It is based on the range of scores an individual might obtain if the same test were administered a number of times simultaneously, with no practice or fatigue effects. Obviously, this is impossible; the SEM, therefore, is a theoretical construct. However, it is an indicator of the possible error variance in individual scores.

The SEM creates a normal curve for the individual's test scores, with the obtained score in the middle of the distribution. The child has a higher probability of receiving scores in the middle of the distribution than at the extreme ends. The SEM is based on the standard deviation of the test and the

test's reliability (usually the test-retest reliability). The SEM can be calculated using the following formula:

$$SEM = SD\sqrt{(1-r)}$$

where SEM is the standard error of measurement, SD is the standard deviation, and r is the reliability coefficient for the test (test-retest reliability coefficients are the ones most commonly used). Once the SEM has been calculated for a test, that value is added to and subtracted from the child's obtained score. This gives the range of expected scores for that child, a range known as the confidence interval. The SEM corresponds to the standard deviation for the normal curve: 68% of the scores in a normal distribution fall within 1 SD on either side of the mean, 95% of the scores fall within 2 SD on either side of the mean, and 99.7% of the scores fall within 3 SD on either side of the mean. Similarly, a child receives a score within 1 SEM on either side of his or her obtained score 68% of the time; a score within 2 SEM of the obtained score 95% of the time; and a score within 3 SEM of the obtained score 99.7% of the time.

Generally, test manuals report the 95% confidence interval. As can be seen by the preceding equation, when the SD of the test is high or the reliability is low, the SEM increases. A larger SEM means that the range of possible scores for an individual child is much greater (i.e., a larger confidence interval) and consequently the degree of possible error is greater. This means that the examiner is less confident that any score obtained for a child on that test represents the child's true score.

An example may help to illustrate this point. Two tests are given, both consisting of 50 items and both testing the same skill area. One test has an SD of 1.0 and a test-retest reliability coefficient of 0.90. The SEM for that test is calculated as follows:

$$SEM = \sqrt{(1-0.90)} \\ SEM = 0.32$$

The second test has an SD of 5.0 and a test-retest reliability coefficient of 0.75. The SEM for that test would be calculated as follows:

$$SEM = 5\sqrt{(1-0.75)} \\ SEM = 2.5$$

Using the SEM, a 95% confidence interval can be calculated for each test. A 95% confidence interval is 2 SEM; therefore, test 1 has a confidence interval of ± 0.64 points from the obtained score, or a total of 1.28 points. Test 2 has a confidence interval of ± 5 points, or a total of 10 points. If both tests were available for a particular client, an examiner could use test 1 with much more confidence that the obtained score is truly representative of that individual's abilities and is not caused by random error variance of the test.

Occupational therapists who use standardized tests should be aware of how much measurement error a test contains so that the potential range of performance can be estimated for each individual. Currently, the trend is to report standardized test results as confidence intervals rather than as individual scores.^{16,30} Several tests, such as the BSID-III, the M-FUN, and the BOT-2, include confidence intervals for subtest or scaled scores so that examiners can determine the potential score range for each child. According to Bayley, "Confidence intervals also serve as a reminder that measurement error is inherent

in all test scores and that the observed test score is only an estimate of true ability” (p. 104).⁷

Consideration of the SEM is especially important when the differences between two scores are evaluated (e.g., when the progress a child has made with therapy over time is evaluated).⁶³ If the confidence intervals of the two test scores overlap, it may be incorrect to conclude that any change has occurred. For instance, a child is tested in September and receives a raw score of 60. The child is tested again in June with the same test and receives a raw score of 75. Comparison of the two raw scores would seem to indicate that the child has made substantial progress. However, the scores should be considered in light of an SEM of 5.0. Using a 95% confidence interval (the 95% confidence interval is 2 SEM on either side of the obtained score), the confidence interval for the first score is 50-70, and the confidence interval of the second score is 65-85.

Based on the two test scores, it cannot be conclusively stated that the child has made progress because the confidence intervals overlap. It is conceivable that a substantial amount of the difference between the first and second scores is a result of error variance rather than actual change in the child's abilities. Therefore the SEM is a tool to aid in determining whether changes in test scores over time are statistically significant.⁴⁶ This statistically significant difference is sometimes called the minimum detectable change (MDC). Because the MDC is a statistical measure, some authors discuss the need to also calculate the minimal clinically important difference (MCID), which is an observable difference in the individual's performance or perceived quality of life.²⁷ To determine the MCID, therapists can use additional methods of obtaining data on satisfaction, perceived quality of life, or perceived improvement in conjunction with the standardized test. Assessment of clinically important difference is also consistent with recommended practice of evaluating all relevant aspects of occupational performance, including client, context, and activity.¹

Validity

Validity is the extent to which a test measures what it claims it measures.⁶³ For example, it is important for testers to know that a test of fine motor development actually measures fine motor skills and not gross motor or perceptual skills. The validity of a test must be established with reference to the particular use for which the test is being considered.⁶³ For instance, a test of fine motor development is probably highly valid as a measure of fine motor skills. It is less valid as a measure of visual motor skills and has low validity as a measure of gross motor skills.

The information on validity reported in test manuals has been obtained during the test development process. In addition, after a test becomes available commercially, clinicians and researchers continue to evaluate validity and to publish the results of their validation studies. This information about test validity can help examiners make decisions about appropriate uses of standardized tests. The four categories of validity are construct-related validity, content-related validity, criterion-related validity, and Rasch analysis.

Construct-Related Validity

Construct-related validity is the extent to which a test measures a particular theoretical construct. Some constructs frequently

measured by pediatric occupational therapists include fine motor skills, visual-perceptual skills, self-care skills, gross motor skills, and functional performance at home or school. This chapter discusses a few of the many ways to determine construct validity.

One method of establishing construct validity involves investigating how well a test discriminates among different groups of individuals. For instance, a developmental test (e.g., BSID-III, PDMS-2, BOT-2) is expected to differentiate between the performance of older and younger children. Older children should receive higher scores than younger children, providing clear evidence of developmental progression with advancing age. Because these tests are also intended to discriminate typically developing children from children with developmental delays, children in specific diagnostic categories should receive lower scores than children with no documented deficits. This type of construct validity analysis is termed the *known groups* method.⁵²

For example, during development of the Sensory Profile,¹⁷ the sensory processing patterns of children in the following clinical groups were evaluated: attention deficit hyperactivity disorder, autism/pervasive developmental disorder, fragile X disorder, sensory modulation disorder, and other disabilities. The scores for children in each of these groups differed from that of the standardization sample, with the score ranges for all factors generally lower than those for the standardization sample. Therefore the Sensory Profile is able to differentiate children with typical sensory processing from those who have sensory processing differences. In addition, score patterns for various clinical groups were identified, allowing therapists to compare client scores with those of the corresponding clinical group. Subsequent research using the Sensory Profile has identified specific differences in sensory processing scores and sensory processing profiles for children with autism spectrum disorder, fragile X disorder, and fetal alcohol syndrome.^{19,26,53,62,64}

Factor analysis can be used as another method of establishing construct-related validity. Factor analysis is a statistical procedure for determining relationships between test items. In a test of motor skills that includes gross motor items and fine motor items, factor analysis is expected to identify two factors on which items showed the strongest correlation, one composed mostly of gross motor items and one composed mostly of fine motor items. Factor analysis of the Sensory Integration and Praxis Tests (SIPT)⁴ resulted in identification of four primary factors. The constructs measured were visual-perceptual skills (related to praxis), somatosensory-praxis skills, bilateral integration and sequencing of movements, and praxis on verbal command.⁵ Factor analysis helped establish the functions that are measured by the SIPT and that can be used to interpret the results of testing individual children.

The third method of establishing construct-related validity requires repeated administration of a test before and after a period of intervention. For example, a group of children are given a test of visual-perceptual skills and subsequently receive intervention focused on improving those skills. They are then retested with the same test and the difference in scores is analyzed. A rise in test scores supports the assertion that the test measured visual-perceptual skills and provides evidence of construct-related validity.

TABLE 6-4 Correlations Between the Sensory Profile and the School Function Assessment

Sensory Profile	School Function Assessment			
	Behavioral Regulation		Positive Interaction	
	Adaptations	Assistance	Adaptations	Assistance
1 Sensory Seeking	-0.434	-0.436	-0.095	-0.328
2 Emotionally Reactive	-0.372	-0.360	-0.245	-0.282
3 Low Endurance/Tone	-0.584*	-0.721*	-0.584*	-0.716*
4 Oral Sensory Sensitivity	-0.199	-0.320	0.007	-0.300
5 Inattention/Distractibility	-0.582*	-0.584*	-0.495	-0.373
6 Poor Registration	-0.615*	-0.340	-0.348	-0.388
7 Sensory Sensitivity	-0.452	-0.478	-0.546*	-0.388
8 Sedentary	-0.551*	-0.554*	-0.545*	-0.368
9 Fine Motor/Perceptual	-0.502	-0.720†	-0.703†	-0.681†

*Correlation is significant at the 0.05 level (two-tailed).

†Correlation is significant at the 0.01 level (two-tailed).

Modified from Dunn, W. (1999). *Sensory Profile user's manual* (p. 54). San Antonio, TX: Psychological Corporation.

Content-Related Validity

Content-related validity is the extent to which the items on a test accurately sample a particular behavior domain. For instance, to test self-care skills, it is impractical to ask a child to perform every conceivable self-care activity. A sample of self-care activities must be chosen for inclusion on the test, and conclusions can be drawn about the child's abilities on the basis of the selected items. Examiners must have confidence that self-care skills are adequately represented so that accurate conclusions regarding the child's self-care skills can be made. Test manuals should show evidence that the authors have systematically analyzed the domain being tested. Content validity is established by review of the test content by experts in the field, who reach some agreement that the content is, in fact, representative of the behavioral domain to be measured.

Criterion-Related Validity

Criterion-related validity is the ability of a test to predict how an individual performs on other measurements or activities. To establish criterion-related validity, the test score is checked against a criterion, an independent measure of what the test is designed to predict. The two forms of criterion-related validity are concurrent validity and predictive validity.

Concurrent validity describes how well test scores reflect current performance. The degree of relationship between the test and the criterion is described with a correlation coefficient. Most validity correlation coefficients range from 0.40 to 0.80; a coefficient of 0.70 or above indicates that performance on one test can predict performance on a second test.

Concurrent validity is examined in the test development process to determine the relationship between a new test and existing tests that measure a similar construct. For instance, during the development of the Sensory Profile, children were scored with both the Sensory Profile and the SFA. The SFA was chosen because some aspects of children's performance at school depend on sensory processing and modulation.¹⁷ High correlations between SFA performance items and the Fine Motor/Perceptual factor on the Sensory Profile were expected, because both tests address hand use. In addition, the SFA

socialization and behavior interaction sections were expected to correlate highly with the modulation sections and factors on the Sensory Profile, because problems with regulating sensory input could result in problems with generating appropriate responses. The scores on the two tests were compared for a random sample of 16 children enrolled in special education programs. Portions of the correlational data are presented in Table 6-4. The correlations are negative because of the different scoring systems on the two tests; lower scores are desirable on the SFA but undesirable on the Sensory Profile.

As Table 6-4 shows, the two tests share areas of moderate to high correlation and areas of low correlation. Factor 9, which consists of items describing product-oriented behaviors, correlated strongly with three sections of the SFA. Factors 3, 6, and 8 on the Sensory Profile contain items that indicate low responsiveness, whereas Factor 5 contains items indicating over-responsiveness. These four factors correlated moderately with the Behavioral Regulation and Positive Interaction sections of the SFA, suggesting relationships between sensory processing and modulation, and children's social/behavioral repertoires.¹⁷ This pattern of correlation coefficients supports the research hypotheses about relationships between the constructs measured by the two tests and also supports the validity of the Sensory Profile as a measure of sensory processing and modulation.

In contrast with concurrent validity, predictive validity identifies the relationship between a test given in the present and some measure of performance in the future. Establishing predictive validity is a much lengthier process than establishing other forms of validity because often several years must elapse between the first and second testing sessions. The predictive validity of a test often is not well documented until it has been in use for several years. Barbosa, Campbell, and Berbaum studied the predictive validity of the Test of Infant Motor Performance (TIMP).⁶ These researchers examined how well the TIMP, when administered shortly after birth, predicted the infant's outcome at 12 months. Using a sample of 96 at-risk infants recruited from special care nurseries, the infants were categorized as developmentally delayed, cerebral palsy, or typical at 12 months on the basis of their scores on the Alberta

Infant Motor Scale and physician's clinical judgment. The TIMP scores at 13 weeks correctly classified all of the infants at 12 months. Two items, hand-to-mouth and fingering objects, were identified as highly accurate predictors of cerebral palsy (i.e., children with cerebral palsy did not exhibit fingering or hand-to-mouth movements).

One final point about criterion-related validity: The meaningfulness of the comparison between a test and its criterion measure depends on both the quality of the test and the quality of the criterion. Because no single measure of criterion-related validity provides conclusive evidence of the test's validity, multiple investigations should be undertaken. Important standardized assessments undergo extensive evaluation of validity after publication. The resulting information helps the test user decide when and with whom the test results are most valid.

In summary, validity is an important but sometimes elusive concept that rests on a number of judgments by authors of the tests, users of the tests, and experts in the field. It is important to remember that validity is not an absolute and that a test that is valid in one setting or with one group of children may not be valid for other uses. Test users must not assume that because a test has been developed and published for commercial distribution, it is universally useful and appropriate. An examiner must apply his or her clinical knowledge and experience, knowledge of normal and abnormal development, and understanding of an individual child's situation when deciding whether test findings are a valid measure of the child's abilities.

Rasch Models of Measurement

The Rasch models of measurement² have been used to develop item scaling for several tests in the field of occupational therapy. The SFA, the PEDI-CAT, and the Assessment of Motor and Process Skills (AMPS)^{21,22} have used Rasch methodology in the test development process. Rasch methodology has also been used to develop a school version of the AMPS (School AMPS).^{3,23}

A test instrument developed using Rasch methodology must meet several assumptions.¹⁴ The construct being measured (e.g., activities of daily living) can be represented as a continuous function with measurement covering the full range of possible performance from dependent to independent. The instrument (or individual scale of the instrument) measures one characteristic (or construct) of performance, and each item represents a sample of the characteristics measured. The scale provides estimates of item difficulty that are independent of the sample of persons tested, and an individual's ability estimate is independent of the specific items tested.

The Rasch model generates a hierarchic ranking of items on the test from easiest to most difficult, creating a linear scale of items from ordinal observations. With the items ranked along the continuum within each skill area, an individual's performance can be assessed in light of an item's difficulty rather than against a normative sample. The ranking of items creates an expected pattern of mastery of items; the model predicts that more difficult items on the continuum are mastered only after easier items have been learned. Therefore therapists who administer an assessment tool developed using Rasch methodology generally can assume that the most appropriate goals for intervention will be the items and/or skills immediately above the items successfully passed by the client.

Occupational therapy tests developed using Rasch methodology emerge from a different philosophic base than traditional standardized tests. The two main methods of data collection are naturalistic observation and parent/teacher/caregiver report. The tasks observed are the ones the child engages in daily (e.g., schoolwork, self-care, social participation, mobility) rather than items administered in a controlled testing situation. Intervention recommendations can be generated directly from the child's observed and/or reported performance and participation.

Tests developed using the Rasch model are generally not considered norm-referenced tests because individual performance is not compared against that of a normative sample. However, some of these tests provide options to calculate standard scores. For instance, PEDI-CAT scores can be converted to T-scores.³² The Rasch model provides an objective measure of performance that can be linked directly to desired occupational performance outcomes. The Rasch model has been applied to a variety of rating scales and traditional measurement instruments to assess disablement and functional status.^{31,54} It is a model that can be used alone or in conjunction with traditional test development and measurement theory to produce measurement tools that provide a clearer connection between the assessment process and intervention planning.

Becoming a Competent Test User

The amount of technical information presented here might make the prospect of learning to administer a standardized test seem daunting. However, potential examiners can take a number of specific steps to ensure that they administer and score a test reliably. These steps also help examiners interpret test results accurately so that they provide a valid representation of each child's abilities. This section discusses the process of learning to administer and interpret any standardized test, be it a screening tool or a comprehensive assessment.

Choosing the Appropriate Test

The therapist's first step is to decide which test, or tests, to learn. A number of standardized tests used by pediatric occupational therapists address a wide age span and a number of different performance skills and areas of occupation. The examiner must decide which tests are most likely to meet the assessment needs of his or her particular work setting and the children served in that setting. For instance, an occupational therapist working in an early intervention setting might use the BSID-III or the PEDI-CAT.³² A therapist working in preschools might use the M-FUN or the PDMS-2. A therapist working in a school-based setting might use the SFA, the School AMPS, or BOT-2. Instruments such as the PEDI-CAT or the AMPS can be used in a variety of settings.³⁴

A number of other standardized tests are available that assess more specialized areas of function, such as the SIPT, the Developmental Test of Visual-Motor Integration,⁸ the Sensory Profile, or the DTVP-II. Examiners should consult with other therapists working in their practice settings to determine which tests are most commonly used. In addition, they should examine the characteristics of the children referred to them for assessment to determine which tests are most appropriate.

Some children may not be able to comply with standardized testing procedures. Occupational therapists evaluating children whose behavior, cognition, motor skills, or attention limit their ability to follow standardized testing procedures often make adjustments in the standardized testing procedures or use parent-report assessments.⁵⁸

Some standardized tests provide specific instructions, guidelines, or norms to be used with children who have a variety of disabilities. For example, the PDMS-2 provides case illustrations of how the test can be adapted for children with vision impairment and cerebral palsy. The BSID-III and the Sensory Profile provide normative data for several clinical groups. Piper and Darrah, in developing the AIMS, used infants who were preterm or born with congenital anomalies, as well as those who were full term and those who did not have an unusual diagnosis.⁵¹ The PEDI-CAT, the Gross Motor Function Measure (GMFM),⁵⁵ and the SFA are examples of tests that evaluate function and participation of children with identified disabilities. The PEDI-CAT measures the level of caregiver assistance and environmental modifications required for children to perform specific functional tasks. The PEDI-CAT assesses the level of independence and the quality of performance of children whose disabilities may prevent them from executing a particular task in a typical way. The GMFM is a criterion-referenced test that measures the components of a gross motor activity accomplished by children with cerebral palsy. It provides information necessary for designing intervention programs and measuring small increments of change. The SFA evaluates the child's performance of functional tasks that support participation in the academic and social aspects of an elementary school program.

It may also be appropriate to consult other sources for information about a test. The *Seventeenth Mental Measurements Yearbook*²⁹ and *Tests in Print VII*⁴⁷ publish descriptions and critical reviews of commercially available standardized tests written by testing experts. These resources can also be accessed online through most university library systems. In addition, published studies of the validity or reliability of tests relevant to pediatric occupational therapists appear throughout the occupational therapy literature. See [Table 6-1](#) for a list of selected standardized tests arranged by information source.

Learning the Test

Once a decision has been made about which test to learn, the therapist should read the test manual carefully. In addition to administration and scoring techniques, the technical attributes of the test should be studied. Particular attention should be paid to the size and composition of the normative sample, the reliability coefficients, the validation data, and the intended population for the test. The examiner should determine the standardized administration procedures and whether they can be altered for children with special needs. He or she should also understand how the scores should be reported and interpreted if the standardized procedure is changed.

The next step in learning a test is to observe it being administered by an experienced examiner. If possible, the therapist should also discuss administration, scoring, and interpretation of the test results. One observation may suffice; however, it may be helpful to watch several administrations of the test to children of different ages and abilities. Observation is an

FIGURE 6-6 A child performs a fine motor item from the PDMS-2.

excellent way to learn how other examiners deal with the practical aspects of testing (e.g., arranging test materials, sequencing test items, handling unexpected occurrences, managing behavior). A discussion with the examiner about the interpretation of a child's performance can also be extremely helpful for acquiring an understanding of how observed behaviors are translated into conclusions and recommendations.

Once these preparatory activities have been completed, the learner should practice administering the test. Neighborhood children, friends, or relatives can be recruited to be "pilot subjects." It is a good idea to test several children whose ages are similar to those for whom the test is intended. Testing children, rather than adults, provides the realism of the mechanical, behavioral, and management issues that arise with a clinical population ([Figure 6-6](#)).

Checking Inter-rater Reliability

When possible, an experienced examiner should observe the testing and simultaneously score the items as a check of inter-rater reliability ([Research Note 6-1](#)). A simple way to assess inter-rater agreement is to use point-by-point agreement.³⁶ With this technique, one examiner administers and scores the test, while the other observes and scores ([Figure 6-7](#)). The two

RESEARCH NOTE 6-1

Eldred, K., & Darrah, J. (2010). *Using cluster analysis to interpret the variability of gross motor scores of children with typical development*. *Physical Therapy*, 90, 1510–1518.

Abstract

This descriptive study explored the utility of cluster analysis as a method to organize gross motor scoring patterns of children with typical development into clinically relevant groups using data from 66 typically developing children from two longitudinal studies. The children were assessed on the gross motor subscale of the Peabody Developmental Motor Scales at 9, 11, 13, 16, and 21 months of age and on the gross motor subscale of the Peabody Developmental Motor Scales, 2nd ed., at 4, 4.5, 5, and 5.5 years of age. Parents were interviewed when the children were 8 years of age. Cluster analysis was conducted. Four distinct and clinically relevant clusters were identified, designated as “robust scores,” “decreasing scores,” “increasing scores,” and “low scores.” The clusters illustrate that among typically developing children there are different patterns of motor development.

Implications for Practice

Aggregation of scores of children in the “low score” cluster later identified as having motor concerns suggests that children with motor problems can be identified by a consistently low scoring profile.

Children whose performance fell into the “increasing scores” cluster demonstrate that improvements in motor assessment scores can occur spontaneously without intervention.

Children whose scores decreased over time did not have a diagnosis or motor intervention by the age of 8, suggesting that decreasing scores alone are not a cause for concern.

The results reinforce the variability of skill development in typically developing children and the need to assess qualitative and functional aspects of motor performance.

The study supports the practice of developmental surveillance as a screening strategy.

examiners then compare their scores on each item. The number of items on which the examiners assigned the same score is then added.

Inter-rater agreement then is computed using this formula:

$$\text{Point-by-point agreement} = \frac{A}{A+D} \times 100$$

where A equals the number of items on which there was agreement and D equals the number of items on which there was disagreement.

The following example illustrates point-by-point agreement.

Two examiners score a test of 10 items. The child receives either a pass (+) or fail (–) for each item. The scores for each examiner are shown in Table 6-5. According to the data, the raters agreed on 7 of the 10 items. They disagreed on items 2, 7, and 9.

FIGURE 6-7 Two therapists check their inter-rater reliability by scoring the same testing session of this child. (Bottom photo © istock.com.)

TABLE 6-5

Raters' Scores for Point-by-Point Agreement

Item	Rater 1	Rater 2
1	+	+
2	+	–
3	+	+
4	–	–
5	–	–
6	+	+
7	–	+
8	–	–
9	–	+
10	+	+

Their point-by-point agreement would be calculated as follows:

$$\frac{7}{7+3} = 0.70 \times 100 = 70\% \text{ Point-by-point agreement}$$

This means that the examiners agreed on the scores for 70% of the items. To benefit from this exercise, the two examiners should discuss the items on which they disagreed and their reasons for giving the scores they did. A new examiner may not understand the scoring criteria and may be making scoring errors as a result. The experienced examiner can help clarify scoring criteria. This procedure helps bring the new examiner's administration and scoring techniques in line with the standardized procedures.

The point-by-point agreement technique can also be used for periodic reliability checks by experienced examiners, and it is particularly important if the examiners may be testing the same children at different times. No universally agreed-on standard exists for a minimum acceptable level for point-by-point agreement. However, 80% is probably a good guideline. Examiners would be well advised to aim for agreement in the range of 90% if possible. Organization of the testing environment and materials can improve reliability by creating a standard structured environment.

Selecting and Preparing the Optimal Testing Environment

The testing environment should meet the specifications stated in the test manual. Generally, the manual specifies a well-lighted room free of visual or auditory distractions. If a separate room is not available, a screen or room divider can be used to partition off a corner of the room. An example of an appropriate test setup is shown in [Figure 6-8](#).

Testing should be scheduled at a time when the child is able to perform optimally. For young children, caregivers should be consulted about the best time of day for testing so that the test session does not interfere with naps or feedings. Older

children's school or other activities should be considered in the scheduling of assessments. For instance, a child who has just come from recess or a vigorous physical education session may have decreased endurance for gross motor activities.

The test environment should be ready before the child arrives. Furniture should be appropriately sized so that children sitting at a table can rest their feet flat on the floor and can comfortably reach items on the table. If a child uses a wheelchair or other adaptive seating, he or she should be allowed to sit in the equipment during testing. Infants or young children generally are best seated on the caregiver's lap unless particular items on the test specify otherwise. The examiner should place the test kit where he or she can easily access the items but not where the child can see or reach the kit. Often a low chair placed next to the examiner's chair is a good place to put a test kit.

Each examiner should consider what adaptations are necessary to administer the test efficiently. In many cases a test manual is too large and unwieldy to have at hand during testing, and the score sheet does not provide enough information about administration and scoring criteria. Examiners have developed many ways to meet this need. A common method is preparation of a cue card on which the examiner records specific criteria for administration and scoring, including the instructions to be read to the child. This can be accomplished by making a series of note cards, putting color codes on a score sheet, or developing a score sheet with administration information.

Administering Test Items

Most important, the examiner must be so familiar with the test that his or her attention can be focused on the child's behavior and not on the mechanics of administering the test. This is a critical part of preparation, because much valuable information can be lost if the examiner is unable to observe carefully the quality of the child's responses because he or she instead must devote energy to finding test materials or looking through the test manual. In addition, young children's attention spans can be short, and the examiner must be able to take full advantage of the limited time the child is able to attend to the activities.

Familiarity with the test also allows the examiner to change the pace of activities if necessary. The child can be given a brief break to play, have a snack, or use the bathroom while the examiner interviews the caregiver or jots down notes. Most standardized tests have some flexibility about the order or arrangement of item sets, and an examiner who knows the test can use this to his or her advantage. Sometimes, because of the child's fatigue or behavior or because of time constraints, a test cannot be administered completely in one session. Most tests provide guidelines for administering the test in two sessions, and examiners should be familiar with these guidelines before starting to test.

Interpreting the Test

Before administering the test, the examiner should read the test interpretation section of the examiner's manual and discussion interpretation of the test with experienced examiners. It is essential for examiners to understand which conclusions can

FIGURE 6-8 A child completes a portion of the visual-motor subtest of the Bruininks-Oseretsky Test of Motor Proficiency 2.

and cannot be drawn about a child's performance based on the items administered and standard scores obtained. In addition to the guidelines and interpretation standards specified in the test manual, the examiner must take into account a number of other factors when interpreting an individual child's test score. The following questions should be asked when interpreting test results: How representative or typical was the child's response to the testing situation? If the child did not appear to perform optimally during testing, what influenced the child's performance? When the parent observes the testing, the examiner should ask the parent if the child's performance was typical. The parent's judgment of the child's performance during testing can be included in the report of findings.

How closely do the test scores obtained by the occupational therapist concur with standardized or non-standardized test results of other professionals or from previous testing? Are the scores congruent with observations or reports by caregivers, teachers, or other professionals? Possible reasons for discrepancies can include different performance demands or expectations in various environments, differences in characteristics and environmental supports provided to the child, differing levels of tolerance for children's behavior, or discrepant ability in different developmental or performance domains (which may be identified when several disciplines are evaluating a child).

Which strategies used during the testing were either particularly effective or ineffective in organizing, motivating, or facilitating the child's best performance? Evaluating and discussing the efficacy of management strategies can provide important information to augment test results and recommendations.

Did the tests administered provide a complete picture of the child's occupational performance and participation or is additional testing, observation, or interview required?

Evaluating the Clinical Usefulness of the Test

The final area of preparation is to evaluate the clinical usefulness of the test. The learner should discuss the test with colleagues: What are its strengths and weaknesses? What important information does it give? What information needs to be collected through other techniques? For which children does it seem to work especially well and for which is it an especially poor choice? Can it be adapted for children with special needs? Does it measure what it claims it measures? Do other tests do a better job of measuring the same behavioral domain? Is it helpful for program planning or program evaluation? An ongoing dialog is an important way to ensure that the process of standardized testing meets the needs of the children, families, therapists, and service agencies that use the tests. The steps to becoming a competent user of standardized tests are summarized in Box 6-4.

Ethical Considerations in Testing

All pediatric occupational therapists who use standardized tests in their practice must be aware of their responsibilities to the children they evaluate and to their families. Urbina has discussed several ethical issues relevant to standardized testing, including (1) examiner competency, (2) client privacy, (3) communication of test results, and (4) cultural bias.⁶³

BOX 6-4

Steps to Becoming a Competent Test User

1. Study the test manual.
2. Observe experienced examiners; discuss your observations.
3. Practice using the test.
4. Check inter-rater agreement with an experienced examiner.
5. Prepare administration and scoring cue sheets.
6. Prepare the testing environment.
7. Consult with experienced examiners about test interpretation.
8. Periodically recheck inter-rater agreement.

Examiner Competency

Examiner competency was discussed in detail in the previous section. However, it is important to re-emphasize here that examiners must achieve a minimal level of competency with a test before using it in practice. Along with knowing how to administer and score a test, a competent examiner should know for whom the test is intended and for what purpose. This also means knowing when it is not appropriate to use a particular standardized instrument. The examiner should be able to evaluate the technical merits of the test and should know how these characteristics may affect its administration and interpretation. The examiner also should be aware of the many things that can affect a child's performance on a test, such as hunger, fatigue, illness, or distractions, as well as sources of test or examiner error.

The competent examiner draws conclusions about a child's performance on a standardized test only after considering all available information about the child. Such information can include the results of non-standardized tests, informal observations, caregiver interviews, and reviews of documentation from other professionals. It is extremely important to put a child's observed performance on standardized testing in the context of all sources of information about the child; this ensures a more accurate and meaningful interpretation of standard scores.

Client Privacy

The Privacy Rule of the Health Insurance Portability and Accountability Act (HIPAA) mandates that all recipients of health care services be notified of their privacy rights; that they have access to their medical information, including provision of copies at their request; and that they be notified of any disclosure of medical information for purposes other than treatment or billing. For minor children, the parent or legal guardian must provide consent before initiation of any evaluation or intervention procedures. Agencies have different forms and processes for obtaining consent, and examiners must be aware of the procedures for their particular institution. Informed consent generally is obtained in writing and consists of an explanation of the reasons for testing, the types of tests to be used, the intended use of the tests and their consequences (i.e., program placement or qualification for remedial services), and the testing information that will be released and to whom it will be released. Parents/guardians should be given a copy of

the summary report and should be informed about who will receive the additional copies. If test scores or other information will be used for research purposes, additional consent procedures must be followed.

Verbal exchanges about the child should be limited. Although it is often necessary to discuss a case with a colleague for the purposes of information sharing and consultation, it is not acceptable to have a casual conversation about a particular child in the elevator, lunchroom, or hallway. If others overhear the conversation, a violation of confidentiality could result.

Communication of Test Results

Evaluation reports should be written in language that is understandable to a nonprofessional, with a minimum of jargon. Each report should be objective in tone, and the conclusions and recommendations should be clearly stated. When the results of tests are discussed, the characteristics of the person receiving the information should be taken into account.

Speaking with other professionals and speaking with family members require different communication techniques. When sharing assessment results with family members, the examiner should be aware of the general level of education and, in the case of bilingual families, the level of proficiency with English. Even if family members have a reasonable capability in the English language, it may be a good idea to have an interpreter available. Often the family members most skilled in English act as interpreters. However, this may not be the optimal arrangement for sessions in which test results are discussed because of the technical nature of some of the information. The ideal interpreter is one who is familiar with the agency and the kinds of testing and services it offers and who has developed techniques for helping examiners offer information in an understandable and culturally meaningful way.

When presenting information to family members, examiners must also consider the anticipated emotional response. A parent who hears that his young child has developmental delays may be emotionally devastated. Therefore the information should be communicated sensitively. Every child has strengths and attributes that can be highlighted in the discussion of his or her overall performance. The examiner should also avoid any appearance of placing blame on the parent for the child's difficulties, because many parents are quick to blame themselves for their child's problems. The examiner also gives opportunities for the caregivers to ask questions about the assessment and the findings. The tone of any discussion should be objective, yet positive, with the emphasis placed on sharing information and making joint decisions about a plan of action.

Cultural Considerations When Testing

Tests developed primarily on a white, middle-class population may not be valid when used with children from diverse cultural backgrounds. It is important for examiners to be aware of the factors that may influence how children from diverse cultures perform on standardized tests.

Children who have not had any experience with testing may not understand the unspoken rules about test taking. They may not understand the importance of doing a task within a time limit or of following the examiner's instructions. They may not be motivated to perform well on tasks because the task itself

has no intrinsic meaning to them. The materials or activities may be seen as irrelevant, or the child, having had no experience with the kinds of materials used in the tests, may not know how to interact with them. Establishing a rapport may be difficult either because of language barriers or because of a cultural mismatch between the child's social interaction patterns and those of the examiner. If the examiner is aware of these potential problems, steps can be taken to minimize possible difficulties.

For example, the caregiver or an interpreter can be present to help put the child more at ease. The caregiver can be questioned about the child's familiarity with the various test materials; this information can help the examiner determine whether the child's failure to perform individual items is the result of unfamiliarity with the materials or of inability to complete the task. The caregiver can also be shown how to administer some items, particularly those involving physical contact or proximity to the child. This may make the situation less threatening for the child. However, if these adjustments are made, standard procedure may have been violated, and it may be inappropriate to compute a standard score. Even so, the test can provide a wealth of descriptive information about the child's abilities.

Standardized tests should be used cautiously with children from diverse cultures. Occupational therapists who find themselves frequently evaluating children from cultural or ethnic groups that are underrepresented in the normative samples of most standardized tests may want to consider developing "local norms" on frequently used instruments that reflect the typical patterns of performance among children of that culture. This information can help provide a more realistic appraisal of children's strengths and needs. Several studies have evaluated the performance of children from different countries and/or different cultural groups on pediatric standardized tests developed in the United States and identified differences in test outcomes.^{11,12,15,20,35} In addition, observation of the child in a variety of contexts and communication with the family, caregivers, and others familiar with the child are essential to the assessment process.

Clearly, professional communication skills are essential when administering tests and reporting information. Awareness of family and cultural values helps put the child's performance in a contextual framework. An understanding of the professional and ethical responsibilities involved in dealing with sensitive and confidential information is also extremely important. A competent examiner brings all of these skills into play when administering, scoring, interpreting, and reporting the results of standardized tests.

Advantages and Disadvantages of Standardized Testing

Standardized tests have allowed occupational therapists and other professionals to develop a more scientific approach to assessment, and the use of tests that give statistically valid numeric scores has helped give the assessment process more credibility. However, standardized tests are not without their drawbacks. This section discusses the advantages and disadvantages of using standardized tests and presents suggestions on how to make test results more accurate and meaningful.

Advantages

Standardized tests have several characteristics that make them a unique part of the assessment inventory of pediatric occupational therapists. For example, they are tests that in general are well known and commercially available. This means that a child's scores on a particular test can be interpreted and understood by therapists in other practice settings or geographic locations.

Standard scores generated by standardized tests allow testers from a variety of professional disciplines to “speak the same language” when it comes to discussing test scores. For example, a child may be tested by an occupational therapist for fine motor skills, by a physical therapist for gross motor skills, and by a speech pathologist for language skills. All three tests express scores as T-scores. An average T-score is 50. The child receives a fine motor T-score of 30, a gross motor T-score of 25, and a language T-score of 60. It is apparent that although this child is below average in both gross and fine motor skills, language skills are an area of strength; in fact, they are above average. These scores can be compared and discussed by the assessment team, and they can be used to identify areas requiring intervention and areas in which the child has particular strengths.

Standardized tests can be used to monitor developmental progress. Because they are norm-referenced according to age, the progress of a child with developmental delays can be measured against expected developmental progress compared with the normative sample. In this way, occupational therapists can determine if children receiving therapy are accelerating their rate of development because of intervention. Similarly, children who are monitored after discharge from therapy can be assessed periodically to determine whether they are maintaining the expected rate of developmental progress or are beginning to fall behind their peers without the assistance of intervention.

Standardized tests can be used for program evaluation to determine response to intervention across a large number of clients. Standard test scores can be subjected to statistical analysis to evaluate efficacy of interventions. These data can contribute to evidence-based practice and provide information about areas of strength and weakness in the intervention program that can be addressed through quality improvement processes.

Disadvantages

A standardized test cannot stand alone as a measure of a child's abilities. Clinical judgment, informal or unstructured

observation, caregiver interviews, and data gathering from other informants are all essential parts of the assessment process. These less structured evaluation procedures are needed to provide meaning and interpretation for the numeric scores obtained by standardized testing.

Several other considerations must be taken into account when performance-based standardized tests are used. For example, a test session provides only a brief “snapshot” of a child's behavior and abilities. The performance a therapist sees in a 1-hour assessment in a clinic setting may be different from that seen daily at home or at school. Illness, fatigue, or anxiety or lack of familiarity with the test materials, the room, or the tester can adversely affect a child's performance. The tester must be sensitive to the possible impact of these factors on the child's performance.

A competent tester can do a great deal to alleviate a child's anxiety about testing and ensure that the experience is not an unpleasant one. However, any test situation is artificial and usually does not provide an accurate indication of how the child performs on a daily basis. Therefore it is important for the therapist to speak to the child's parent, caregiver, or teacher at the time of testing to determine whether the observed behavior is truly representative of the child's typical performance, and the representativeness of the behavior must be taken into account when the child's test scores are interpreted and reported.

Another concern about standardized tests is the rigidity of the testing procedures themselves. Standardized tests specify both particular ways of administering test items and, in many cases, exactly what instructions the tester must give. In view of these administration requirements, children who have difficulty understanding verbal instruction (e.g., with autism, hearing impairment, or attention deficit) or lack control of movement (e.g., with muscle weakness or lack of coordination) may be disadvantaged on performance-based tests. Although this issue is not addressed by all standardized tests, some provide guidelines for administering the test under nonstandard conditions, and some are specifically designed to evaluate functional performance and participation of children with disabilities using performance- and observation-based formats.

It is important to reiterate that although it is permissible to alter the administration procedures of most performance-based tests to accommodate children's individual needs, the child's performance cannot be expressed as a standard score. Rather, the purpose of the testing is to provide a structured format for describing the child's performance ([Case Study 6-1](#)). The test manual should always be consulted for guidelines on alterations in test procedures.

CASE STUDY 6-1 Caitlin

Caitlin is a 5.5-year-old kindergarten student referred for occupational therapy assessment by her teacher, Mrs. Clark, who notes that Caitlin is having difficulty learning to write; she holds her pencil awkwardly and exerts too much pressure on the paper. On the playground she has difficulty keeping up with her peers, falls frequently, appears uncoordinated, and has difficulty learning new motor skills. Her energy level

is low. She is easily overwhelmed by typical classroom activity and often has emotional outbursts, which affect her ability to complete her work and interact with classmates.

The occupational therapist, Debra, spoke to Caitlin's parents and discovered that Caitlin received physical therapy as an infant because of low muscle tone and slow achievement of developmental milestones. Her parents were worried

Continued

CASE STUDY 6-1 Caitlin—cont'd

about her ability to cope with the increase in writing assignments in first grade and her social acceptance by other children.

Debra considered Caitlin's age (5.5 years) and the areas of concern (gross and fine motor skills and social adjustment) in choosing which standardized tests to use. She decided to administer the PDMS-2, along with clinical observations of Caitlin's posture, muscle tone, strength, balance, motor planning, hand use and hand preference, attention, problem-solving skills, and visual skills. She asked Caitlin's teacher to complete the SFA to provide information on Caitlin's performance of functional school-related behaviors. In addition, she had the teacher complete the Sensory Profile School Companion (SPSC) to determine whether sensory processing problems were contributing to Caitlin's motor delays.

Test Results

Caitlin's testing session was scheduled at midmorning to avoid possible effects of fatigue or hunger. She attended well, although she needed encouragement for the more challenging items. By the end of the session she complained of fatigue, but Debra believed she was able to get a representative sample of Caitlin's motor skills and that the scores obtained were reliable.

On the PDMS-2 Caitlin received a gross motor quotient of 81, placing her at the 10th percentile for her age. Her fine motor quotient was 76, placing her at the 5th percentile. In the gross motor area, ball skills were an area of relative strength, but she had difficulty with balance activities and activities involving hopping, skipping, and jumping. In the fine motor area, Caitlin used a static tripod grasp on the pencil, frequently shifting into a fist grasp if the writing task was challenging. Based on the small number of visual-motor items on this test, visual-perceptual skills appeared to be an area of strength, whereas tasks involving speed and dexterity were difficult.

Debra found that Caitlin had low muscle tone overall, particularly in the shoulder girdle and hands, and strength was somewhat decreased overall. Caitlin's endurance was poor. Motor planning difficulties were evident in the way she handled test materials and moved about the environment. She had difficulty devising alternate ways to accomplish tasks that were challenging for her and required manual guidance to complete some tasks.

Debra obtained a functional profile on the SFA based on Mrs. Clark's responses to the items on the test. On the scales of recreational movement, using materials, clothing management, written work, and task behavior and/or completion, Caitlin received scores below the cutoff for her grade level. Other scales were within grade-level expectations, with strengths in the scales of memory and understanding, following social conventions, and personal care awareness.

On the SPSC, scores indicated that Caitlin had definite differences in Environmental Sensations–Auditory and Body Sensations–Movement. She also received definite difference scores in School Factor 1, indicating a need for external support for sensory input, and School Factor 3, a low

tolerance for sensory input. The scale confirmed that she could easily become overloaded by environmental stimuli.

Observations and Recommendations

According to her scores on the PDMS-2, Caitlin had mild delays in her gross motor skills and mild to moderate delays in her fine motor skills. Although Debra believed that the PDMS-2 gave a good indication of what Caitlin could do under optimal circumstances (i.e., a nondistracting environment, individual attention and encouragement, and structuring of tasks to maximize success and minimize frustration), she also thought it did not represent the level of performance that would be seen over the course of a typical day.

In the classroom Debra observed that Caitlin avoided motor activities and completed writing and drawing activities rapidly, resulting in poor quality of the end product. Her materials were disorganized, she required multiple reminders to complete tasks, and she became upset when unable to finish on time. Her SFA results indicated that her performance of tasks involving fine and gross motor coordination and task organization was below grade-level expectations.

Debra met with the teacher, psychologist, principal, and Caitlin's parents to determine a plan of action. The SFA was used to facilitate collaborative problem solving by helping to identify which specific areas of school function could be targeted in the classroom and which skills should be identified as functional outcomes. Based on the collaborative problem solving process, the team developed the following 6-month outcomes for Caitlin:

- Given appropriate seating support, Caitlin will complete written assignments within the time allotted, 75% of the time, no verbal cues required.
- Given appropriate seating support, Caitlin will produce written work of 85% letter legibility, 80% of the time.
- Given verbal reminders, Caitlin will maintain an orderly workspace (desktop clear of extraneous items and supplies stored neatly within the desk), 90% of the school day.
- Caitlin will participate in age-appropriate playground activities with peers for a 20-minute recess period without falling or requiring a rest break, 80% of the time.

The team determined that Debra would provide recommendations to Mrs. Clark about classroom modifications and activities that would increase Caitlin's success and build her motor skills. The team members also collaborated to design strategies and routines that could be used at school and at home to improve Caitlin's on-task behavior, sensory responsiveness, organization, and ability to manage daily tasks at school.

Debra provided a chair that better fit Caitlin and allowed optimal positioning for writing. She provided Mrs. Clark with ideas for appropriate activities and ways of teaching Caitlin new motor skills and addressing her sensory needs. Debra provided Caitlin's parents with suggestions for family activities that would improve general strength and endurance (e.g., bicycle riding and swimming) and provided specific ideas for ways they could build Caitlin's fine motor skills at home. She also agreed to be available to Mrs. Clark for periodic informal

CASE STUDY 6-1 Caitlin—cont'd

consultation. It was agreed that a reassessment would be scheduled at the end of the school year so that the team could make a decision about further intervention and program planning for the next school year.

Summary

Standardized testing, specifically the PDMS-2, SFA, and SPSC, provided a helpful framework for Debra's assessment of Caitlin and gave specific information about areas of strength and difficulty. Debra made use of her clinical observations and information gathering from a variety of sources to recommend interventions she felt would be beneficial, efficient, and

relatively easy to implement. The standardized scores helped her identify Caitlin's problems in fine and gross motor skills, and the test items provided activities that revealed the challenges Caitlin faced when performing motor tasks. However, if Debra had simply relied on the standardized test scores, she would not have acquired the breadth of knowledge that led to her decision-making process for developing intervention options. This example illustrates the important roles of both standardized testing and other methods of data collection in arriving at meaningful and realistic conclusions about children's intervention needs and modes of service delivery.

Summary

- Standardized tests are used by pediatric occupational therapists to assist in the determination of a medical or educational diagnosis, document a child's developmental, functional, and participation status, aid the planning of an intervention program, measure outcomes of programs, and measure variables in research studies.
- Standardized tests have a uniform procedure or protocol for administration, scoring, and interpretation of scores.
- Standardized tests have undergone test development procedures that result in computation of standard scores so that findings can be compared over time and among different domains of function.
- Competency in standardized test administration requires that the user understands basic measurement concepts and is familiar with the test before using it in practice.
- Users evaluate the validity (appropriateness) of a standardized test for specific children and practice contexts.
- Ethical testing procedures include that the examiner considers the purpose of the assessment; adapts procedures to match child and family culture, characteristics, and values; adjusts for the testing context; and is knowledgeable about the test instrument.
- Standardized tests should be administered in conjunction with other methods of data gathering, such as observation and interview.

CHAPTER

7

Application of Motor Control/Motor Learning to Practice

Jane O'Brien

KEY TERMS

Dynamic systems	Motor learning
Degrees of freedom	Feedback
Attractor state	Transfer of learning
Perturbation	Mental rehearsal
Postural control	Skill acquisition
Motor control	

GUIDING QUESTIONS

1. What are the key concepts of motor control and motor learning theories?
2. What are the principles and strategies of contemporary motor control interventions?
3. How do practitioners develop evidence-based interventions for children with motor control deficits?
4. Which child, task, and environmental factors influence motor skill acquisition and occupational performance?
5. How do practitioners apply motor learning concepts to promote children's occupational performance?
6. How are transfer of learning, feedback, practice, sequencing and adapting tasks, modeling or demonstration, and mental rehearsal used to promote children's motor performance?

Typically developing children move into and out of positions fluidly and with ease, exploring their worlds, learning about their bodies, and developing motor, cognitive, sensory, and social skills. They use their hands for feeding, dressing, bathing, play, and academics (Figures 7-1 and 7-2). They practice sitting, walking, jumping, and crawling. They play in a variety of positions and show variability in their movements. Conversely, children who have difficulties with motor control may not have the same opportunities to explore their surroundings; they may take longer and often do not master movements. Because motor control is central to participation, occupational therapists provide interventions to improve children's motor control and ability to engage in occupations.

This chapter delineates the principles of motor control and motor learning related to occupational therapy practice,

beginning with a definition of motor control. A description of contemporary dynamic systems theory is provided, including research evidence to support its use in practice. The author examines the importance of examining the child (e.g., motivation, goals), task (e.g., nature, object properties, goals, and rules), and environment (e.g., setting, terrain) when evaluating movement. A review of motor learning concepts, including practice, feedback, modeling or demonstration, and mental rehearsal, is provided. The author reviews the evidence, principles, and strategies for motor control approaches and provides evidence for current motor control theory as it relates to intervention. Case examples are used to illustrate the application of motor control and motor learning in occupational therapy practice. *Examples of motor control deficits:*

- Teagan is a 4-year-old boy with Down syndrome who loves to play tee-ball. His gross motor skills are awkward and he must take breaks when running around the bases. (See the Evolve website for accompanying video.) Teagan has low muscle tone throughout. He runs with a wide-based gait and holds his arms close to his body for balance. His posture is asymmetric (he elevates his shoulders and leans) when he runs. He holds objects in a palmar grasp and exhibits delayed visual-perceptual skills interfering with his fine-motor performance. Teagan engages in parallel play with other children at the day care center. When he does interact with his peers, he engages at a much younger level and frequently interferes in their play.
- Georgia is a 2-year-old girl who has difficulty playing on the playground. She is diagnosed with cerebral palsy, right hemiplegia. She walks but her movements are awkward and slow. She leans to the left and drags her right toe on the ground. Her right leg is positioned in the "typical" hemiplegic pattern (internally rotated, foot pronated, ankle extended). She does not use her right hand when playing with her toys and has difficulty manipulating objects. The other children run quickly past her. Georgia falls frequently. She looks frustrated at times that her body will not cooperate with her intentions.
- Devin is a 10-year-old boy who has difficulty with fine-motor tasks, such as tying his shoes, buttoning, and writing. He takes longer than his peers to get ready for recess. Devin is awkward in his movements, falls frequently, and experiences difficulty with balance and coordination skills. He cannot skip, hop, or ride a bicycle. Eye-hand coordination is poor as shown in his inability to catch a ball or play games

FIGURE 7-1 Children use their hands for feeding.

BOX 7-1 Description of Developmental Coordination Disorder

Developmental coordination disorder (DCD) refers to children whose acquisition and execution of motor skills is substantially below that expected for their chronologic age and opportunity for skill learning and use. Difficulties are manifested as clumsiness, slowness, and inaccuracy of performance of motor skills. The motor skill deficits must significantly and persistently interfere with activities of daily living and impact academic/school productivity, prevocational and vocational activities, leisure, and play. The motor skills deficits are not explained by intellectual disability, visual impairment, or neurologic conditions affecting movement.

Adapted from American Psychiatric Association. (2013). *Diagnostic and statistical manual of mental disorders* (5th ed., pp. 74–77). Arlington, VA: American Psychiatric Publishing.

such as baseball or Frisbee. Devin has been diagnosed with developmental coordination disorder (DCD) (Box 7-1). He has above average intelligence and enjoys playing with other children, although he tends to stay on the “fringes” of the activity.

These three examples illustrate the diversity of motor control challenges found in children. Motor control is important for occupational performance in activities of daily living, self-care, social participation, play, and academics. Occupational

FIGURE 7-2 Children move in many positions when playing.

therapists help children develop the motor performance required to engage in daily activities. Practitioners develop strategies and interventions to remediate a variety of motor control deficits and therefore therapists must fully understand theories of motor control and the underlying components and mechanisms essential to movement.

Motor Control: Overview and Definition

Motor control is defined as the “ability to regulate or direct the mechanisms essential to movement” (p. 4).⁹³ Motor control refers to how the central nervous system organizes movement, how we quantify movement, and the nature of movement. Practitioners and researchers interested in motor control examine the mechanisms, strategies, and development of movement, as well as causes of motor dysfunction.^{54,70,73,95} Occupational therapy practitioners use this knowledge to design effective intervention so that children with motor control deficits may participate in their desired occupations.

Movement deficits occur in numerous conditions including cerebral palsy, DCD, autism spectrum disorder, Down syndrome, sensory integration disorders, and acquired brain injury.

Motor problems may present as poor coordination, timing, sequencing, bimanual control, force production, balance, sensory processing, and motor planning. These issues interfere with the child's ability to engage in activities of daily living, play, academics, and social events at home, at school, and in the community.

Children with a variety of diagnoses manifest motor problems. Children with cerebral palsy exhibit difficulty with postural control because of neuromuscular and sensory impairments, which leads to motor deficits.⁸⁸ Abnormal muscle tone and spasticity interfere with voluntary muscle control, and children with cerebral palsy exhibit sensory impairments that may result in poor motor planning and body awareness.⁸⁸ Children with Down syndrome experience poor timing, decreased strength, and decreased postural control.¹¹⁰ Given the importance of motor skills to young children's play, early intervention aimed at skill acquisition is recommended to maximize their motor control.^{46,54} A systematic review of the literature showed that the motor deficits of children with autism spectrum disorder fall into two areas: poor integration of information for motor planning and increased variability in sensory inputs and motor output.³⁶ Children with DCD experienced slower reaction times, less accuracy in bimanual tasks, and timing and sequencing problems.^{60,76} In a meta-analysis of studies examining the performance deficits associated with DCD, Wilson et al.¹¹⁷ found that children with DCD experience difficulty with anticipatory movement, rhythmic coordination, executive function (e.g., set shifting, attention, flexibility), gait and postural control, catching and interceptive action, and aspects of sensory-perceptual function (e.g., visuo-sensory processing, tactile perception, kinesthesia, processing speed). Raynor⁸⁷ found that children with DCD experienced strength and power deficits as compared with matched controls in knee extension and flexion tasks. Children with sensory integration deficits experience a host of motor problems including disorders of the vestibular system, body perception and motor planning, and sensory processing and modulation difficulties.^{4,5}

Historically, intervention strategies used by practitioners varied according to the etiology and nature of motor impairments.^{61,93} Therapists used bottom-up approaches, hypothesizing that if they treated the underlying causes of motor dysfunction, the child's function would improve. Therefore, the goals of intervention included normalizing muscle tone, remediating sensory dysfunction, and improving dyspraxia. Bottom-up approaches include sensory integration, neurodevelopmental treatment, reflex integration therapy, and strength training. Table 7-1 describes selected motor control approaches. These interventions focus on addressing the underlying deficit to improve performance.^{3,16,17} These bottom-up frames of reference are based on a hierarchic development model based on neuroscience understandings of the 1970s and 1980s.

Overall, bottom-up approaches appear to have limited effectiveness in improving the occupations of children.^{16,17,25,57,67,75,82,97} Because bottom-up approaches have minimal evidence, they should be used in combination with other approaches, carefully evaluated when used, and continuously monitored to document the child's progress. In contrast, dynamic systems theory describes how systems interact and how these interactions are responsible for motor performance.^{3,17,24,93,102,103}

Dynamic Systems Theory

Dynamic systems theorists propose that movement derives from a variety of sources and takes place within a variety of natural and meaningful contexts.^{93,102,103} This evolving and contemporary theory can be applied to motor control to assist practitioners in framing evaluation and subsequent intervention to facilitate movement in children and youth. Dynamic systems theory suggests that motor control is dependent on nonlinear and transactive person factors (i.e., cognitive, musculoskeletal, neurologic, sensory, perceptual, social-emotional), task characteristics (i.e., goals, rules, object properties) and environmental systems (i.e., contexts).^{102,103} See Figure 7-3.

The principles of dynamic systems theory include:

- The interaction among systems is essential to adaptive control of movement.
- Motor performance results from an interaction between adaptable and flexible systems.
- Dysfunction occurs when movement patterns lack sufficient adaptability to accommodate task demands and environmental constraints.
- Because task characteristics influence motor requirements, practitioners modify and adapt the requirements and affordances of tasks to help children succeed.

According to dynamic systems theory, multiple systems of the person, task, and environment transact for predictive and adaptive control of movement.^{93,102,103} The person factors include the child's cognitive (e.g., attention, motivation, and self-efficacy), musculoskeletal, neuromotor, sensory, perceptual, and social-emotional factors.

Person

Occupational therapy practitioners examine personal factors using knowledge of biomechanics, neurology, and kinesiology to identify areas that may be interfering with motor performance. Practitioners develop goals based on quantitative and qualitative data. Assessments or evaluation tools may provide objective measurements of the child's current level of functioning for purposes of planning intervention and evaluating progress (see Chapter 6). A thorough evaluation of the person factors that influence motor performance includes many of the components described in the following paragraphs.

Cognition

Cognitive factors include a child's attention, motivation, and self-efficacy. Attention is required to explore the environment and move around objects and through space. Children must attend to activity to explore and learn. Typical infants and children are innately motivated to move through the environment; they exhibit interest in activities and enjoy movement. Understanding a child's motivation or interests helps the practitioner design fun and inviting activities to promote effective motor performance. Self-efficacy refers to one's belief in his or her abilities.⁴⁹ Children who feel they will be successful are more apt to attempt new actions leading to improved neural plasticity. They engage in habits and routines that allow them to develop new skills.^{49,52} They may move more confidently and try out new activities freely.

TABLE 7-1 Selected Motor Control Approaches

Approach	Brief Description	Principles	Strategies
Activity-focused motor intervention ¹⁰⁷	Activity-focused motor intervention emphasizes the need for practice and repetition of purposeful motor actions. Provides movement experiences that promote motor learning within the context of the daily routines of the family.	Motor learning principles are a natural fit for therapy if they are complemented by a methodology to address impairments in body function and structure that affect motor learning. Neurologic impairments that affect motor learning can be addressed by: 1. Adapting motor learning guidelines to meet individual needs 2. Integrating activity-focused and impairment-focused intervention	1. Develop activity-related goals with the child and family. 2. Plan activity-focused interventions by adapting knowledge of motor learning to the child's learning strengths and needs. 3. Integrate impairment-focused intervention with activity-focused intervention.
Neurodevelopmental treatment (NDT)	Children who have a brain lesion benefit from “feeling” typical movement patterns. Children with brain lesions (cerebral palsy) experience abnormal muscle tone that interferes with movement, which can be addressed through handling techniques.	The therapist's role is to facilitate normal movement patterns to help children acquire more normal movement. The goal is to provide input to the child to help “normalize” muscle tone. NDT theorists suggest that normalizing muscle tone may improve movement. Although movement is often guided by subcortical brain centers, the role of higher level brain function in guiding movement is acknowledged (e.g., the role of cognition in guiding movement). The principles of this approach are based on dated neuroscientific and hierarchical models for motor development. When children complete adaptive responses, change occurs at the neuronal level (brain plasticity).	The therapist begins by inhibiting or facilitating muscle tone. A variety of strategies is used to inhibit or facilitate muscle tone in children. The therapist uses <i>key points of control</i> and <i>handling techniques</i> to facilitate movement. NDT intervention also considers symmetrical alignment of the body, movement with full range of motion, base of support and weight-bearing, muscle strength, and postural control. ⁷ Provide intervention strategies to integrate reflexes.
Reflex integration therapy	Reflex integration therapy is based on the premise that reflexes that are not integrated in the sequence and rate of typical development interfere with the acquisition of normal movement.		Provide child-directed vestibular, proprioceptive, tactile activities designed to facilitate the “just-right” challenge so the child makes an adaptive response. The use of suspended equipment is required.
Sensory integration	Sensory integration addresses the underlying components of movements by engaging children in intervention in enriched, simulated environments to which they adapt and respond to sensory stimuli (vestibular, tactile, proprioceptive). The practitioner helps the child to engage in activities that provide the “just-right” challenge.		
Strength training	Strength training uses progressively more challenging resistance to muscular contraction to build muscle strength and endurance. ⁷⁵	Strength training programs develop a child's muscle strength to improve quality of movement or performance. The focus of task-specific training is on the functional task, rather than the impairment. Task-specific training resonates with occupational therapy principles.	Increase weight of objects or increase repetition of movements to build strength. 1. Training is relevant to the client and context. 2. Practice sequences are randomly ordered. 3. Training is repetitive. 4. The goal is for the client to complete the whole task (occupation). 5. The client should be positively reinforced.
Task-specific training	Task-specific training involves practicing the specific actions or activity (task) while considering the concepts of motor learning. Clients “practice context-specific motor tasks and receive some form of feedback” (p. 576). ¹⁰¹		

FIGURE 7-3 Dynamic systems theory. (Adapted from Shumway-Cook, A., & Woollacott, M. H. (2007). *Motor control: Translating research into clinical practice* (3rd ed.). Philadelphia: Lippincott Williams & Wilkins.)

Musculoskeletal

Observation of a child's physical appearance provides the practitioner with an overview of musculoskeletal structures required for movement. Physical appearance includes symmetry between the right and left sides of the body, muscular structures, and physical stature. Range of motion of joints allows for effective and full movement.

Muscle tone is defined as the resting state of the muscle.⁶³ Typical muscle tone allows movement into and out of positions with ease, fluidity of movement, and variety in movement. Children with hypertonicity exhibit increased muscle tone, resulting in limited movements; those with hypotonicity exhibit low muscle tone, which results in excessive range of movement and limited control over movement. Some children may experience fluctuating muscle tone, which interferes with quality of motor control. The goal of occupational therapy intervention is not to change the muscle tone but rather to improve the child's ability to perform occupations.

Strength is defined as the voluntary recruitment of muscle fibers. Strength is needed to perform movements against gravity or to pick up objects of varying weights. A degree of trunk strength is required to maintain posture. In strength training programs, the child repeats movements, often with added resistance or weight.

Posture refers to one's core stability and involves the trunk and neck musculature. To demonstrate postural control, a person maintains the center of mass over the base of support.^{43,44,111} Postural control is required for functional

movement and involves an interplay between sensory, motor, and musculoskeletal systems.^{37,111} Children stabilize the head and trunk and remain upright for reaching, feeding, dressing, and play. A stable posture is essential for refined movement and mobility.^{37,111}

Children with cerebral palsy, developmental coordination disorder, or other movement difficulties may have difficulty with postural control and exhibit awkward movements or inadequate balance.^{19,20,88,93} Children with cerebral palsy may not be able to stabilize the shoulder for arm and hand movement; they may walk with a wide or inefficient gait. They may slouch in their seats at school, interfering with writing and academic tasks. Postural stability provides the foundation for simple and complex movements. Core strengthening activities may help children with postural challenges.⁴⁷ Meaningful engagement in a variety of activities can help develop posture and core muscle control for coordinated movement.

Neuromotor Development

The neurologic system (i.e., the peripheral and central nervous systems) is primary in controlling movement. Examining how a child responds to movement helps practitioners better understand the child's neurologic functioning. Infants are born with reflexes that integrate over time and are believed to be the building blocks for functional movement.¹²⁰ Reflexes may remain obligatory for some children who have neurologic deficits. When a primitive reflex remains obligatory over time, it interferes with voluntary movement. For example, an 8-year-old child who is still bound by the Moro reflex or asymmetric

TABLE 7-2 Age of Postural Reactions Acquisition

		Immature (Months)	Mature (Months)
Righting Reactions	Neck on body	Birth	4-5
	Body on body	Birth	4-5
	Body on head		
	Prone	1-2	4-5
	Supine	2-4	5-6
	Landau		
Protective Extension	Flexion	3-4	6-7
	Vertical	2	6
	Forward		6-7
	Lateral		6-11
	Backward		9-12
Equilibrium Reactions	Emerge and continue throughout lifespan		
	Prone		5-6
	Supine		7-8
	Sitting		7-10
	Quadruped		9-12
	Standing		12-21

tonic neck reflex will experience difficulty with voluntary or functional movement. Although some reflexes emerge under stressful situations (e.g., associated movements), they are not obligatory and consistent.

Children tend to develop postural reflexes in a predictable sequence: prone and supine positions to quadruped to standing. There are three major categories of postural reflexes: primitive, righting, and equilibrium and protective reflexes (Table 7-2 provides an overview of postural reactions.)

Primitive reflexes appear within the first year and are thought to serve a survival function. For example, the rooting reflex allows the infant to orient to a food source; the suck reflex enables the infant to receive nutrients. Most primitive reflexes are suppressed early in infancy but may reappear after injury or trauma to the brain.^{39,120}

Righting reflexes are typically observed at about 3 months of age and persist to 6 months of age and are designed to align the head with the body (limbs) and the upper body with lower body. When rotation is imposed on the body, the righting reflexes realign the segments of the body and bring the body into appropriate alignment. They align the head with gravity (keep the child's head upright) and include optical righting, labyrinthine righting reflexes, and Landau. These reflexes realign the head vertically when the body is displaced and are mediated, respectively, by the visual and vestibular systems.

Equilibrium and protective reflexes, the third category, are present at about 6 months of age and persist throughout life to help the child remain upright. Equilibrium and protective reflexes are whole-body responses to postural instability. Protective extension responses are elicited by sudden shoves or pushes to the body. Protective extension helps the child protect the body from injury during loss of balance. For example, in sitting, a toddler extends his or her arm and hand to prevent falling to the side when pushed. Equilibrium responses are elicited when one's center of gravity shifts (e.g., by slowly

tilting surfaces on which the child is standing or sitting). If some instability occurs, the child adjusts by extending limbs or changing muscle tone to remain in position. Children develop equilibrium reactions in supine and prone positions between 5 and 8 months of age and continue to develop equilibrium in more upright positions throughout early childhood.

Equilibrium responses are required to maintain one's upright position or balance. Balance is essential to functional movement. To balance, a child must sense changes in position and respond via movement or muscle tone. These subtle adjustments (equilibrium responses) enable the child to continue a movement and aid in the quality of that movement. Children with motor control deficits may experience balance difficulties.

Soft neurologic signs are often associated with motor control difficulties and provide indicators of brain dysfunction.^{18,38,120} Practitioners can evaluate the presence of the following soft neurologic signs:

- Mild dysfunction in muscle tone
- Dysdiadokokinesis—impairment of the ability to make movements exhibiting a rapid change of motion that is caused by cerebellar dysfunction¹¹²
- Intention tremor—a slow tremor of the extremities that increases on attempted voluntary movement and is observed in certain diseases of the nervous system^{74,112}
- Dysmetria—impaired ability to estimate distance in muscular activity⁷⁴
- Limited force control—limited strength or energy
- Poor bilateral motor coordination—inability to perform movements using both sides of the body (e.g., alternating jumps)
- Difficulty with coordination (fine and gross motor)—inability to complete movements in a smooth manner (e.g., walk on heels, finger opposition)
- Difficulty with balance—inability to maintain one's center of gravity (e.g., stand on one foot)

- Associated reactions (synkinesis)—involuntary movement in one part when another part is moved: an associated movement¹¹²

Children with DCD, acquired brain injury, or mild intellectual disability may exhibit soft neurologic signs.^{18,38} Lundy-Ekman et al.⁶⁰ sought to identify the neurologic systems responsible for soft neurologic signs to shed light on why some children are clumsy or exhibit motor control difficulties.⁶⁰ They found that children with basal ganglia deficits showed difficulty controlling force as compared with matched controls. The children with cerebellum dysfunction were more variable than controls with timing tasks (tapping) and produced less force.⁶⁰

Sensory

The sensory systems that relate to motor control include visual, auditory, vestibular, kinesthesia, proprioception, and tactile. Auditory input may motivate children to respond and explore the environment by turning and locating the source of the noise. Vestibular processing allows the child to sense changes in movement or position that allow the body to respond. Children who under- or overrespond to vestibular sensations may demonstrate ill-timed or awkward responses to position changes. Kinesthesia refers to the sense and direction that one is moving. Children with poor kinesthetic awareness may not realize how their body is performing. Kinesthetic awareness allows children to sense that the body is in motion (e.g., the hand is moving), whereas proprioception provides a sense of the position of one's muscles and joints. Without proprioceptive sense, children are unsure of where they are in space or how the body is positioned. For example, a child may not realize how his or her feet are moving or if his or her feet are positioned on the ground when not looking at the feet. Therefore, poor kinesthetic or proprioceptive perception can result in poor quality of movement and inefficient motor control.

Tactile processing provides children with information about the environment through direct body contact. Children first learn about their environment through tactile sensations. They explore objects and their bodies by putting toys and their hands in their mouths.

Perceptual

Perception refers to the ability to make sense of sensory stimuli and involves cognition and sensory awareness. Visual perception, for example, refers to understanding letter formations (visual closure, figure-ground) and identifying letters (shape recognition). Depth perception refers to an understanding of how far apart things are.

The development of the concept of the physical self involves at least three major components: body schema, body image, and body awareness. Figure 7-4 shows a schematic of the components of the concept of the physical self and the behavioral components specific to body awareness. Body schema is the neural substrate for body awareness. It is present at birth, and as children grow and develop, this so-called diagram of the body (homunculus) in the sensory and motor areas of the brain is modified, in part, through sensory motor experiences and feedback received. Body image refers to the image one has of oneself as a physical entity; it includes the perception that one has of the body's physical or structural characteristics (e.g., "Am I short, tall, heavy, or lean?") and of one's physical performance abilities. Body awareness is defined as the ability to visually discriminate, recognize, and identify labels for various aspects of the body's physical and motor dimensions. Internal aspects of body awareness tend to develop slightly in advance of external components.^{10,13,69,113} External aspects are associated with development and awareness of the relationship of the body to the environment. Understanding one's physical self allows a child to move in many ways through a variety of environments.

FIGURE 7-4 Body Concepts.

Children with poor body awareness may bump into objects; they do not have an internal representation of their body in space. Being unaware of body position, they may stand closer to people. They may not perceive left and right.

Social-Emotional Factors

Emotion is a psychological state that may affect motor performance. Individuals are able to achieve motor challenges for which they attribute positive feelings.^{71,78,86} For example, athletes use the “power of positive thinking” to visualize achievement and subsequently exhibit improved motor performance as a result.⁷¹ Conversely, children may have difficulty performing at their best when they are experiencing negative emotions (such as anxiety or fear). Children may perform less effectively if they are feeling pushed or judged; they may be afraid of failure. Children may want to perform an activity or skill and feel frustrated when they cannot. Watching the child’s expressions during motor performance can provide cues to therapists about the child’s emotions and perceived task difficulty.

When a child is overly stressed or afraid, the sympathetic system is activated, making it difficult for the child to problem solve or learn a new motor skill. Children learn movement best when they are challenged at a level in which success is achievable and they are emotionally ready to engage in problem solving.

Task

Task characteristics refer to the nature, object properties, goals, and rules. The nature of the task may be defined as simple or complex. Generally speaking, simple tasks require minimal attention and brief motor responses. Complex motor tasks require a high degree of attention and are generally more engaging.⁷⁰ Tasks that require precision are often defined as complex and may be more difficult for children (such as handwriting as compared with scribbling). Practice of complex motor tasks results in greater neuroplastic changes than practice of a simple motor task.⁷⁰ When compared with simple motor tasks, adults show greater increase of neural activity during and after practice of a complex task.⁷⁰ Interestingly, these findings are reported after a single practice session. These findings suggest that practice of a more complex task results in greater neuroplastic changes than practice of a simple motor task.⁷⁰

The nature of the task determines the speed, smoothness, force, and accuracy of movement required.^{93,119} Open tasks involve supporting surfaces, objects, or people in the environment that are in motion. Closed tasks involve objects, people, and terrain that are stationary; the learner decides the start and finish.

The properties of the objects (size, shape, weight, texture, sensory aspects) and the ascribed meaning of task (goals, rules) influence motor requirements. Children respond differently when reaching for large as compared with small objects. They orient the hand at the beginning of a reach and adjust the fingers at the end to grasp the small object.³⁰ The shape of the object determines how a person prepares to grasp. Children with motor challenges such as cerebral palsy experience difficulty with these adjustments.¹¹⁸

Object affordance along with the rules and goals associated with the objects help to cue children regarding the expected

movement. Object affordance is a property of an object or an environment that allows an individual to perform an action.¹¹² For example, providing a child with a spoon and food presents a cue of how to use the object and consequently the motor performance required. Research suggests that practitioners should pay attention to several object features: the number of objects required for action, the information conveyed by objects, and the goals.^{42,119} Overall, using the number of objects required for the task along with the actual objects enhances motor responses (as measured by movement time, grasp pattern, and motor performance). Making a clear relationship between the goal and the object(s) enhances motor performance.⁴²

Environmental Contexts

Practitioners evaluate the physical, social, cultural, temporal, virtual, and personal contexts in which movement and occupational performance occur. For example, children may move successfully in a structured clinical setting but have difficulty navigating the uneven terrain outdoors. The light, terrain, setting, gravity, and novelty of the setting may influence a child’s performance.⁵⁶ For example, children were more playful and moved more (as measured by Actiograph measures) at recess when novel objects (e.g., hay bales, tires) were introduced.¹⁵

The social environment can place additional motor requirements on activities. For example, a child may perform “dance moves” in front of his family but show poor quality when in front of classmates at school. The social pressure of “performing” influences the movement. Cultural expectations may influence motor actions. Some family cultures accept less than quality movement, whereas others expect fine and precise movements. Temporal aspects include the developmental stage of the child. Younger children are allowed to be “silly” in their movements, whereas an adolescent may need to control movements more carefully for success. Virtual contexts include motor interactions with a computer screen. Playing video games may help children develop motor skills in a controlled setting. Personal contexts include the features of the child that promote or inhibit movement.

The skilled practitioner considers all these contexts when analyzing a child’s motor performance. Careful analysis of the child’s motor functioning in a variety of contexts allows the practitioner to establish the child’s strengths and weaknesses.²⁴ The Test of Environmental Supportiveness^{14,94} measures the influence of the environment on play and can provide practitioners with a structure when analyzing the play environment. Most often therapists informally assess the environment, with a focus on identifying the factors that seem to most influence the child’s occupational performance.

Motor Performance Results from an Interaction Between Adaptable and Flexible Systems

Movement arises from interactions among many systems. The complexity of movement can be illustrated by examining the system requirements for the complex motor task of handwriting. (Chapter 9 provides more information on handwriting.)

Handwriting involves fine motor skills, visual-motor coordination, motor planning, proprioception, sustained attention, perceptual skills, and tactile and kinesthetic sensitivities; children must hold the pencil and maintain posture, requiring an intact neuromuscular system.^{6,32} Children sit upright (postural control), coordinate fine motor movement, and plan how to move the pencil in relationship to the paper (visual-motor and perception). They feel the object (pencil) in their hand (stereognosis) and detect how it is moving (kinesthesia). As they fluidly draw on the paper, children experience subtle changes in the center of gravity (equilibrium), which they must process and make subtle tone changes in response to (to remain in an upright position). They stabilize the trunk and shoulder muscles to control elbow, wrist, and fingers for writing. They exert pressure (force) on the pencil and paper and use timing and sequencing to form letters in order. They attend to the task along with environmental influences (e.g., teacher or children talking). Cognitive and motivational factors may influence handwriting, as well as feelings of self-efficacy. Handwriting provides an example of the complexity of a motor task and how multiple systems influence movements (Figure 7-5).

Dynamic systems theorists acknowledge the interactions among the systems. The personal aspects such as the child's age, body stature, and neuromotor status interact with the task (e.g., handwriting versus printing) and environment (e.g., classroom with child-sized tables and chairs). Instead of focusing on one component (e.g., hand strength), they propose that practitioners consider multiple systems when designing intervention.

Dysfunction Occurs When Movement Lacks Sufficient Adaptability to Accommodate Task Demands and Environmental Constraints

Performance is affected when components of one or more systems are rigid, impaired, or inflexible. Children with motor deficits who experience difficulty with flexible movements may exhibit timing and sequencing deficits, poor postural control, slow reaction time responses, and/or difficulty with sensory-perceptual function (e.g., tactile perception, visuosensory processing, kinesthesia).^{60,77} Delayed reactions and processing interfere with the accuracy and quality of the movements. Consequently, their movements are not smooth, coordinated, or timely.

Children with motor or processing deficits often lack adaptability and variety in their movements. They move in the same manner and exhibit difficulty maneuvering in unfamiliar ways, such as when navigating an obstacle course. Children with motor impairments frequently move in limited or stereotypical ways and exhibit a small repertoire of movements. For example, a 3-year-old girl who experienced motor planning deficits had only one motor pattern for climbing onto a tricycle and could not get on the tricycle when it was turned at a different angle. This toddler's praxis (ability to process, plan, and execute a movement) was impaired.

Typical children move in a variety of ways so that they can easily navigate through the environment. They process sensory information quickly and correctly, allowing them to move smoothly. They problem solve new movements to address

FIGURE 7-5 Children working on academics.

motor challenges. Variability is a hallmark of efficient movement, therefore occupational therapists work to help children develop a variety of movements they can use in multiple contexts.

Therapists Modify and Adapt the Requirements and Affordances of Tasks to Help Children Succeed

According to dynamic systems theory, the difficulty of planning and executing movement may be changed by altering the degrees of freedom required to accomplish a movement.^{9,51,102,103}

Bernstein⁹ suggested that an essential central nervous system (CNS) function is to control redundancy by minimizing the degrees of freedom for a movement. Degrees of freedom are defined as possible planes of motion in the joints controlled by the musculoskeletal and central nervous systems.^{9,59,93} When multiple systems interact there are many options (degrees of freedom) available to perform the given action.^{9,51,102,103} Therefore, the practitioner can control or limit some of the options to help the child be successful. For example, providing an alternative position (supported sitting, prone) limits the need for the child to control posture, which may allow him or her more success with hand skills.

Decreasing the degrees of freedom required for movement may result in more functional movement.⁵⁹ A child with cerebral palsy may use his hand more effectively if the wrist or thumb is stabilized with a splint. The splint decreases the degrees of freedom the child must control and allows for more accuracy in movements. In a study examining violin playing, Konczak and colleagues (2009) found that expert child or adult violinists decreased the degrees of freedom of movement through practice (e.g., stabilized shoulder flexion-extension), which resulted in greater accuracy and movement at the elbow and shoulder (abduction-adduction).⁵¹ The findings imply that restricting degrees of freedom while leaving other degrees of freedom unconstrained may be an effective strategy for learning complex, precise motor patterns in children and adults.⁵¹

Dynamic systems theorists use the term *attractor state* to describe the tendency to stay in the patterns of the status quo, preferred state, or the state requiring the fewest degrees of freedom to maintain.^{102,103} For example, a child may have a tendency to sit in a posterior pelvic tilt. This pattern may not be most efficient and may even prevent the child from achieving other milestones (e.g., such as reaching with ease). The therapist's role is to identify the attractor state, and when it limits function, facilitate movement away from this state to promote engagement in occupation. Facilitating a child away from an attractor state is often referred to as a *perturbation*—a force that alters the movement pattern. Perturbations can be used to help children move in different ways. They may be psychological (e.g., motivating the child to move to change the task or environment) or physical (e.g., body feels misaligned and therefore the child must right him- or herself).

Functional goals in addition to environmental and task constraints play a major role in determining movement.^{44,81,102} When following a dynamic systems approach, practitioners analyze the task requirements in relation to child and environmental factors so they can adapt the task to help the child successfully perform.⁸¹ Understanding and manipulating task characteristics is an essential feature of occupational therapy intervention planning.

Practice Models That Use Dynamic Systems Theory

Occupational therapy models (e.g., Canadian Occupational Performance⁵⁵; Person, Environment, Occupation, Performance Capacity²¹; Model of Human Occupation⁴⁹) can guide one's thinking and help practitioners develop intervention based on the principles of dynamic systems theory. Each of these models places the client and family at the center while

considering multiple systems. A variety of motor control approaches have been developed to apply dynamic systems theory to practice.

Task-specific training involves practicing the specific actions or activity (task) while considering the concepts of motor learning. Clients “practice context-specific motor tasks and receive some form of feedback” (p. 576).^{90,101} The focus of task-specific training is on the functional task, rather than the impairment. Task-specific training resonates with occupational therapy principles. According to Hubbard et al.,⁴⁵ practitioners using task-specific training follow these guidelines:

1. Training is relevant to the client and context.
2. Practice sequences are randomly ordered.
3. Training is repetitive.
4. The goal is for the client to complete the whole task (occupation).
5. Client should be positively reinforced.

Activity-focused motor intervention emphasizes the need for practice and repetition of purposeful motor actions.^{106,107} The practitioner develops goals with the family and engages the child in repetition of actions in functional movement within the environment. This approach is consistent with current motor control theory, supporting the idea that coordination and motor control emerge in the context of functional activity.^{39,93} Practitioners using the activity-focused approach provide movement experiences that promote motor learning within the context of the daily routines of the family.¹⁰⁷

Framework for Occupational Gradation⁸⁵ provides a systematic process for treating persons with CNS impairments that aligns with dynamic systems theory. The authors suggest ways to manipulate the person, task, or object properties and the environment as ways to decrease the degrees of freedom. The authors base this approach on strength training and practice of meaningful occupations and provide an outline of how to analyze and grade occupations by altering the task, person, and environment.⁸⁵ This framework illustrates how a practitioner may successfully combine strength training with dynamic systems approach.

Case Study 7-1 provides a sample description using the Model of Human Occupation⁴⁹ and a dynamic systems approach to plan occupational therapy intervention.

Translating Dynamic Systems Theory Principles to Occupational Therapy

Dynamic systems theory integrates well with occupational therapy principles. Specifically, a child learns movement more easily and effectively if: (1) The movement is taught as a whole (versus part); (2) the movement is performed in variable situations; (3) the child is allowed to actively problem solve the actions required; and (4) the activity is meaningful to the child.

These principles are described and illustrated in the following sections.

Whole Learning

According to dynamic systems theory, many systems are involved and interact with each other to plan and execute movement.⁹³ Therefore, engaging in a whole activity

**CASE STUDY 7-1 Intervention Plan**

See accompanying video clip on the Evolve website.

Occupational Profile

Teagan is a 4-year-old boy who lives with his mothers and 7-year-old brother in a rural town. Both mothers are employed; one is a teacher and the other is a business manager. Teagan has Down syndrome and had cardiac surgery at 7 months. He has not experienced any other health issues. He receives physical therapy and occupational therapy at preschool.

Volition

Teagan loves to play tee-ball and play outside with his brother. He follows his brother, imitates his play, and indicates what he would like to do. Teagan enjoys being outside at preschool and watches his peers but does not interact with them. They run quickly by him. His parents state that he is an active boy. They are concerned that he does not play with his peers.

Habituation

Teagan attends a preschool for 4-year-olds. Teagan needs help getting dressed and he is not toilet trained. He washes his face and hands. He feeds himself with a spoon (with spillage) and uses a sippy cup to drink. He participates in recreational tee-ball. Teagan's parents report that he goes to bed at a reasonable hour (9 pm) during school days and awakes at 8 am. Teagan has chores to do each day, including picking up his plates after meals, putting his dirty clothes in the hamper, and walking the dog. He takes a 2-hour nap daily.

Performance Capacity

Teagan's gross motor skills are awkward and he must take breaks when running around the bases. He has low muscle tone throughout. He runs with a wide-based gait and holds his arms close to his body for balance. His posture is asymmetric (he elevates his shoulders and leans) when he runs. He falls frequently and shows difficulty moving around obstacles. His movements are slow and he watches his peers play instead of engaging. Teagan climbs up the slide, but does not slide down. Rather, he sits at the top of the slide, frustrating his peers. Teagan engages in some parallel play with other children at day care. When he does interact with his peers, he plays at a much younger level and frequently interferes in their play.

Environment

The preschool is a playful environment with a large fenced-in playground with a large slide, swings, and grassy play area. The inside rooms are full of toys and child-friendly decorations, small tables, and child-sized chairs.

Strengths

Teagan is a physically active 4-year-old who imitates his older brother's play. He enjoys rough play with his brother, playing tee-ball, and water play.

Weaknesses

Teagan does not play with his peers, but rather watches them or interferes in their play (i.e., sits at the top of the slide). He spends outdoor playtime at preschool playing alone.

Assessment

Teagan's motor difficulties are interfering with his ability to engage in play with his peers. He has difficulty initiating movement, as observed by his not moving down the slide. He falls frequently and has poor timing and sequencing of movements. Helping Teagan become more proficient in motor skills may improve his ability to keep up with peers on the playground.

Intervention Plan

Goals: To improve initiation, timing, and sequencing of motor skills for play.

1. At preschool, Teagan will initiate movement by climbing up and sliding down the slide five times consecutively (without stopping at the top for more than 10 seconds) within a 30-minute play session. [initiation]
2. Teagan will complete a 4-step obstacle course (walk on balance board for 5 feet, reach and throw object in container $\times$ 3, crawl through tunnel for 5 feet, and run 10 feet) within 10 minutes without falling or requiring verbal cues. [timing and sequencing]

The practitioner used the Model of Human Occupation (MOHO) to understand Teagan's occupational needs. The model fit well with dynamic systems theory because MOHO provides a framework to examine multiple systems, allowing the therapist to design intervention using motor control/motor learning principles. When developing client-centered goals the occupational therapy practitioner considered Teagan's preference for playing outside and the parents' goal for Teagan to play with his peers. These goals helped Teagan establish positive habits and routines at preschool and provided him with confidence in his ability to play with peers (self-efficacy). The practitioner engaged Teagan in activity in his environment and was able to train the teacher and caregivers through modeling and instruction. The practitioner designed interventions to specifically improve his performance capacity, to allow for occupational engagement by focusing on initiation of movement, sequencing, and timing of motor actions for play.

The practitioner focused on activities in which Teagan would be successful to improve his belief in his skills and abilities (self-efficacy) so that he would engage in play with peers. See Table 7-3 for examples of how a practitioner may consider the child, task, and environment when designing intervention activities.

Therapy sessions were fun and included a variety of games (e.g., follow the leader, obstacle course parades in ride-on cars) where other children could participate. The practitioner determined that person factors (e.g., limited initiation, inadequate timing, and difficulty sequencing) interfered with Teagan's movement for play. Teagan's low muscle tone may

Continued

CASE STUDY 7-1 Intervention Plan—cont'd

result in poor postural control and subsequent difficulty with gross motor activities. Because Teagan engaged in rough play with his older brother at home, the practitioner hypothesized that the social environment at preschool was causing him to be “nervous” or “anxious” because the children ran quickly around him, seldom paying attention to him. The practitioner conducted a task analysis and concluded that activities involving complex motor tasks and multiple children were very difficult for him. The practitioner graded activities to allow Teagan to practice new motor actions in a safe and fun setting. During these sessions, the therapist adapted the course

(environment), task (a car that was easier to move), or child requirements (allowing Teagan to perform a task differently) to help him be successful. Engaging Teagan in play activities that involved other children provided him with opportunities to socialize in nonthreatening and successful ways. For example, the practitioner allowed him to be the leader of the course, allowing him to practice prior to inviting other children. Teagan was proud that he could provide “tips” and directions for his peers. This helped develop his motivation for motor activities, further reinforcing practice and socialization.

TABLE 7-3 Sample Intervention Activities

	Child	Task	Environment
Ride-on-car obstacle course	Require the child to challenge motor skills or perform for longer period of time. Require the child to perform a less challenging motor task but a more challenging social task.	Change the type of “ride-on-car” so that it is easier or more difficult to operate. The car could be operated by pedaling, pushing, or walking or even be motorized. These different cars change the task requirements.	Change the course so that it is a flat or hilly course or a grass-covered or tarred surface.
Follow the leader	Provide a one-on-one assistant to help the child complete the tasks. Provide pictures or cues to the child and vary the time required to follow.	Change the motor movements required when imitating the leader. The leader could walk slowly or hop on one foot. The leader could do bilateral activities or unimanual activities.	Perform game in a structured setting with few distractions. Vary the type of terrain or area that the children must “follow.”
Safari trip	Provide hand-over-hand assistance or modify the tasks so the child can achieve the motor task.	Change the requirements for each stage of the trip. The child may have to reach, pull, throw, or push objects.	Perform the trip in a variety of settings (e.g., ball pit, trampoline, outside, inside).

FIGURE 7-6 Baking with Grandma is meaningful and allows the child to engage in a variety of motor actions.

(occupation) facilitates multiple systems and the interactions required for effective movement (Figure 7-6). Overall, learning the whole motor task is more effective and motivating than learning only a part of the movement.^{62,64,93,108}

Children perform whole tasks more efficiently and with better coordination than when they are asked to perform only a part or component of the movement.^{31,62} Van der Weel and

colleagues found that children with cerebral palsy used more supination when banging a drum than when simply exercising.¹⁰⁸ Not only did children perform the task more efficiently, but they also engaged in the task for longer periods of time and activated more areas of the brain during the activity. In addition, functional magnetic resonance imaging studies indicate that more areas of the brain are activated when subjects engage in meaningful whole tasks versus parts of the tasks.⁵⁰ Van de Winkel and colleagues found significantly more brain activation for both children with cerebral palsy and typically developing children when they were engaged in active movement (grasp and release of an object) compared with passive movements (robot moved finger up and down) and tactile stimulation (stroking back of hand with sponge cotton cloth).¹⁰⁹ The findings suggest engaging children in active tasks results in more brain activation for both typical children and children with cerebral palsy.^{58,109}

Engaging in the whole activity or occupation requires children to process stimuli and respond to changes within and between systems. The ability to respond in variable ways is a hallmark of functional movement. Typically developing children, for example, use multiple strategies when moving, as opposed to children with DCD, who have been found to exhibit limited variability and adaptability in their movement.^{61,91,100} Therefore, one goal of occupational therapy intervention is to promote variability and flexibility in movements.

FIGURE 7-7 The child enjoys playing with marbles in a variety of positions. This activity requires he use a variety of movements.

Variability

Dynamic systems theorists propose that movement requires an ability to adapt to changes within and between systems; in other words, variability is central to functional movement.^{98,102,103} Variability is inherent in activity (e.g., reaching for different objects, environmental stimuli) as well as within and between systems (e.g., interactions between visual and sensory systems).

Movement occurs in a variety of contexts and requires that children adapt to environmental changes (using visual and auditory systems) or internal changes (perceived through vestibular and proprioceptive systems). For example, children may need to adjust movements in response to interpretations of visual input (e.g., the ball is coming quickly versus slowly); children may experience physiologic changes (e.g., low energy) affecting movement patterns. The environment may pose changes (e.g., weather, terrain, peers). Functional movement, the goal of motor control intervention, requires that children possess a variety of motor skills.

Because variability is essential to functional movement, occupational therapists encourage children to move in variable ways while engaging in occupations. Thus the expectation of intervention is that the child performs movements in a variety

of ways versus repeating and learning one pattern of movement. For example, requesting a child who is sitting in a corner seat to repeatedly pick up a block and drop it into a stationary container requires minimal adaptability on the child's part. A better intervention session would include combining the whole task with variability such as engaging the child in playing with marbles scattered on the floor (Figure 7-7).

In certain children, variability of performance is too great and the practitioner's goal is to establish consistency in movements. Variability in movements can be measured by intra-individual variability. In a simple reaction time task to examine intra-individual variability, children with attention-deficit/hyperactivity disorder (ADHD) or dyslexia did not differ from each other but were more variable than typically developing children.¹¹ Children with ADHD produced fewer writing sequences than did the children with dyslexia (controls were not significantly different from children with dyslexia). Excessive variability found in the children with ADHD and those with dyslexia interfered with consistency in handwriting performance. These findings support the need to encourage more accuracy in movements while allowing for variability for functional performance. Understanding the range of typical development and factors influencing movement is essential to designing effective intervention. Performing movements in

multiple ways requires that children problem solve and self-correct. All children use problem solving to develop and refine movement; therefore, problem solving is an important part of motor control.

Problem Solving

Improved retention of motor skills occurs when children problem solve and self-correct for motor errors.^{12,65,68,83} Children learn and retain motor skills better from intrinsically problem solving than they do from receiving external feedback during an action (such as hand-over-hand assistance). For example, to learn to build a sand castle, the child problem solves his or her position in the sand and how to scoop and place the sand (Figure 7-8). The child is more likely to learn a new motor task in a meaningful, socially engaging activity. The child must position his or her body away from the structure and use adequate timing and force to make the castle of choice. Self-correcting enables children to rely on internal cues that indicate the effectiveness of movement and thereby help them adapt and modify movements in a variety of contexts.^{34,41}

Therefore, therapists working to improve a child's motor performance provide many opportunities for the child to actively solve motor problems by doing, rather than repetitive practicing of a part of the movement. Setting up the

environment to facilitate physical, social, and cognitive tasks encourages the child to discover how to move, explore options, and self-correct movement errors beneficial to motor learning. Not only do children benefit from problem solving how to move, they also benefit from engaging in activities that they find meaningful. Participation in meaningful activities is central to occupational therapy practice and also improves the child's motor control.

Meaning

Dynamic systems theory proposes that the interactions between systems (including the emotional system) influence movements. Occupational therapists have historically viewed the meaningfulness of activities as essential to practice and acknowledge the benefits of purposeful activity in motivating clients to perform.^{33,49,105} A child's participation in motor tasks is influenced by the extent to which he or she can identify his or her own interests and goals and believes he or she will be effective in those motor tasks (Figure 7-9, A-C). Children are more motivated to engage in difficult motor skills if they find the activity important and fun and if they believe they can be successful.^{49,52}

In addition, children and youth participate for longer periods of time and perform more repetitions when activities

FIGURE 7-8 Children building sand castles must problem solve.

FIGURE 7-9 A, Sometimes children look very serious while playing as they try to problem solve how to motor plan. B, Children are more likely to engage in a difficult task if they find it meaningful. C, Hopscotch requires motor planning, coordination, timing, and sequencing.

are meaningful.¹¹⁸ Not only do they perform longer, but, in addition, the quality of movement improves when the activity has meaning to the child.³⁵ Meaning may be determined by asking children directly using semistructured interviews. Cohn, Miller, and Tickle-Degnen²² and O'Brien et al.⁷⁶ found that children with motor deficits wanted to participate in “regular” activities with friends. These expressed interests suggest that practitioners promote meaningful physical activity (such as skiing, swimming, cycling, running, and skating) for children who have motor impairments.

Hetu and Mercier⁴² examined the influence of purposeful activity by reviewing 35 articles. They suggest that clinicians use tasks with high object affordance to promote optimal motor performance. They defined object affordance tasks as those in which the objects used conveyed functional information, included functional goals, and consisted of the correct number of actual objects required for the task. The affordance refers to the purposefulness of the object. For example, the object is meaningful to the person (i.e., child’s favorite toy) and the object suggests a specific motor action (e.g., flying a toy helicopter).

Practitioners may also observe children to better understand meaning. The Pediatric Volitional Questionnaire⁸ and the Test of Playfulness⁹⁴ provide observational assessments to measure interest, motivation, and approach toward activity (play). To design effective motor control intervention, occupational therapists acknowledge the meaning a child attaches to the activity by learning the child’s goals and desires.^{1,49,61} Meaning is derived from an individual’s experience and viewpoint; thus therapists involve the child in selecting and designing the

activity. The Child Occupational Self-Assessment (COSA)⁴⁸ provides a measure to help the child identify activities in which he or she would like to engage. The authors suggest that practitioners interviewing children set up a comfortable environment, engage in informal discussion, begin with open-ended questions and follow up with probing questions, pay attention to nonverbal cues, and be aware of how the child perceives the interview. The assessment may be given in multiple sessions and practitioners can adapt or modify the approach to meet the child’s needs. The intent of the COSA is to gain information about the child. In focus group discussions, practitioners using the COSA felt it helped them engage in important discussions with children while providing information on the child’s interests and belief in abilities.⁵³

Therapists use the Cognitive Orientation to daily Occupational Performance (CO-OP) model to engage children in goal setting and problem solving.⁸³ This model is congruent with dynamic systems theory and has been found to be effective for improving movement for children with DCD.^{66,68,116,117} By including children in the process, the therapist empowers the child to make decisions and actively engage. The CO-OP model is explained in Chapter 10. See Box 7-2 for tips to design intervention using motor control concepts.

Development of Motor Control

The development of motor skills occurs in three stages—cognitive, associative, and autonomous—and involves an interaction among three processes (i.e., cognition, perception, and

BOX 7-2 Tips for Designing Intervention Using Motor Control Concepts**Whole Learning**

- Play activities (e.g., crafts, dress-up, cooking, dance moves)
- Games
- Themed activities

Variability

- Develop occupations as goals (e.g., play with peers)
- Provide variety of activities or different ways to do tasks
- Same motor movement in different forms
- Vary the objects or placement
- Vary the requirements of the task
- Consider the social nature of the task
- Vary the environmental context (e.g., clinic versus playground)

Problem Solving

- Set up activities with different degrees of difficulty
- Repeat movements so child must figure it out
- Wait for child to figure it out

BOX 7-3 Strategies for Each Stage of Motor Control

Stage	Strategies
Cognitive	Use simple statements and verbal cues. Use catchy words or pneumonics. Repeat skills. Provide time for problem solving. Allow child to review progress.
Associative	Relate new tasks to past activities. Use the same words or cues for similar tasks. Help child see links to previous successful activity. Allow child to review progress by relating to other activity.
Autonomous	Set up an environment in which the child can be successful. Allow the child to self-reflect. Provide few if any cues. Do not correct or address quality—allow the child to self-evaluate.

action).⁹³ These stages and processes are considered dynamic in that they are constantly changing and interacting with each other in relation to the motor skill or task requirements. Practitioners may change intervention strategies based on the stage of development in which the child is performing. See [Box 7-3](#) for sample strategies as related to stage of development.

The cognitive stage refers to the skill acquisition stage. In this stage the learner practices new movements, errors are common, and movements are inefficient and inconsistent. During this stage, learners need frequent repetition and feedback. Children learning to hold a spoon, for example, may need reminders to take little scoops of food and to move the spoon to the mouth slowly.

FIGURE 7-10 Infants enjoy sensory motor play as they look around and feel things to learn about their environment and movements.

The associative stage involves skill refinement, increased performance, decreased errors, and increased consistency and efficiency. During this stage the learner relates past experiences to the present, thereby “associating” movements (e.g., the child may realize that the last time she moved her hand too quickly, the food dropped off the spoon, so she reminds herself to slow down).

During the autonomous stage, the learner retains the skills and can perform the movement functionally. During this stage, skills are transferred easily to different settings and are refined. For example, during this stage a child can feed himself or herself a variety of foods using a spoon and simultaneously carry on a conversation at the table. At this stage the motor skill has been learned and requires little attention, which supports evidence suggesting that less brain activation is required.⁸⁴

Each stage of movement involves interactions among the processes of cognition, perception, and action⁹³ ([Figure 7-10](#)). Cognition refers to intent or the child’s motivation to move and also to the ability to plan the movement. Cognitive processes are used in decisions about how to use an object (e.g., throw versus catch).

Perception refers to how the individual receives and makes sense of a stimulus (visual, auditory, tactile, kinesthetic, vestibular, or olfactory). Perception involves attributing meaning to sensory input. Perception refers to both peripheral sensory mechanisms and higher level processing that interprets the meaning of stimuli.⁹³ For example, the child must be able to identify the object coming toward him or her or “feel” balance.

The process of action includes muscle contractions, patterns, precision, and nature of the movement (dynamic versus static). Research devoted to the action stage explores how factors such as strength, ability to co-activate muscle groups, reaction time, and timing and sequencing contribute to movement.^{77,80,87}

When looking at skill acquisition, practitioners help clients demonstrate consistency, flexibility, and efficiency in movements. Consistency refers to ability of the child to perform a task consistently over time. Flexibility refers to the ability to adapt and modify the task performance based on changing

environments or conditions.⁷² Efficiency pertains to the cardiovascular and musculoskeletal systems (e.g., Can the child perform the task without tiring?).

Motor Learning

Motor learning refers to the acquisition or modification of motor skills. Motor learning literature explores transfer of learning, sequencing, and adapting tasks, type and amount of practice, error-based learning, timing, type of feedback, and mental rehearsal. These concepts provide useful information on techniques involved in the teaching-learning process of movement. Being knowledgeable and aware of the teaching-learning process enables therapists to incorporate motor learning principles into practice so that children learn and retain motor function for their daily lives. Williams (Box 7-4) provides an overview of motor learning strategies shown to increase motor control. Occupational therapy practitioners are encouraged to use these techniques to promote motor learning. These motor learning strategies can easily be integrated into occupational therapy practice.

Niemeijer and colleagues⁷⁴ examined the outcomes of physical therapy sessions when the practitioners used teaching principles during neuromotor task training. The authors provided 11 practitioners with a taxonomy of principles aimed at improving motor learning for children with DCD. Twenty teaching-learning principles were organized into three categories: giving instructions, sharing knowledge, and providing or asking for feedback. The data revealed that four principles were associated with improved performance as measured by the Test of Gross Motor Development: giving clues, explaining why, providing rhythm, and asking about understanding. Two principles were associated with improved performance on the M-ABC (adjusting body position and explaining why).⁷⁴

Transfer of Learning

Transfer of learning, or generalization, refers to applying learning to new situations. The goal of occupational therapy intervention is that the child transfer learning performed in the clinic or intervention setting to a natural context. For example, after working on maneuvering a new wheelchair through an obstacle course at the clinic with ease, the therapist hopes the child will be able to maneuver the wheelchair through the school hallway.

Children are best able to transfer motor skills when they have practiced the motor skill within the natural context or in the “real world” situation. Therefore, the best way to help the

child successfully maneuver his wheelchair through the school hallway is to practice in that setting. The occupational therapist may initially teach basic wheelchair skills to the child, then practice in the hallway after school hours (to decrease obstacles), and finally work up to maneuvering the wheelchair during class change. Research suggests that children transfer the task more quickly with this intervention strategy than with practicing in a clinic setting only.^{23,99}

In addition, transfer of learning occurs more easily when the motor task is performed during a functional activity or actual occupation.^{23,31,35,79} When selecting activities to practice, the practitioner recognizes that motor skills with similar components are more likely to transfer. For example, a child who has just successfully learned to throw a ball would more easily learn to throw a bean bag at a target.

Sequencing and Adapting Tasks

Grading and adapting motor tasks so that children are successful constitute part of the occupational therapy process (Table 7-4). Generally, discrete tasks are easier to accomplish than continuous tasks. Discrete tasks are those with a definite beginning and end (e.g., picking up an object), whereas continuous task are ongoing (e.g., walking, running). Tasks involving unimanual movements are often learned or mastered before bimanual movements.¹¹⁴ Skills manipulating stationary objects develop before skills with moving objects.

“Closed tasks are those in which the environment is stationary during task performance” (p. 407),⁹³ whereas open tasks are ones in which the environment is changing or in motion and involve some intertrial variability. Closed tasks are generally simpler for most children to accomplish.

Therapists also consider the cognitive demands of activities; children more easily complete simple motor tasks that have fewer cognitive requirements. Tasks with fewer steps are accomplished more readily than those with multiple steps (e.g., throwing at a target is easier than picking up a ball from the container, moving to the starting line, and then throwing at a target). Children acquire tasks that require less precision (e.g., scribbling will be easier than coloring within the lines) more easily than those that require more precision. When sequencing and adapting activities for children, therapists consider the amount of direction required; movement requiring less direction is easier to learn than that requiring multiple directions.

The structure of the environment plays an important role in the nature and complexity of the demands of the activity. For example, environments with variability and extraneous stimuli (e.g., other children) are more challenging and thus more

TABLE 7-4 Grading and Adapting Activity

Uncomplicated	Example	More Difficult	Example
Discrete	Jump over rope × 1	Continuous	Jumping rope
Unimanual	Grasp toy in one hand	Bimanual	Grasping toy with two hands
Stationary	Hold toy	Dynamic	Catching a moving ball
Closed	Scribble on paper	Open	Following with pen moving target on computer
One-step	Write name	Multistep	Writing name and drawing picture
Simple	Place ball in container	Complex	Playing a game of mini-golf

BOX 7-4 Williams' Motor Learning Principles**Transfer of Learning**

- Skill experiences are presented in logical progression.
- Simple, foundational skills are practiced before more complex skills.
- Skill practice includes "real life" and simulated settings.
- Skills with similar components are more likely to show transfer effect.
- Practice in natural context with actual objects is most effective

Feedback

Modeling or demonstration

- Demonstration is best if it is given to the individual before practicing the skill and in the early stages of skill acquisition.
- Demonstration should be given throughout practice and as frequently as deemed helpful.
- Demonstrations should not be accompanied by verbal commentary because this can reduce attention paid to important aspects of the skill being demonstrated.
- It is important to direct the individual's attention to the critical cues immediately before the skill is demonstrated.
- Allow child time to "figure it out."

Verbal Instructions

- Verbal cues should be brief, to the point, and use one to three words.
- Verbal cues should be limited in terms of numbers of cues given during or after performance.
- Only the major aspect of the skill that is being concentrated on should be cued.
- Verbal cues should be carefully timed so they do not interfere with performance.
- Verbal cues can and should be initially repeated by the performer.
- Verbal cues should emphasize key aspects of movement

Knowledge of Results (KR) and Knowledge of Performance (KP)

- A variety of different combinations of both KR and KP typically helps to facilitate learning.
- KP error information may help the performer change important performance characteristics and thus may help facilitate skill acquisition.
- Information about "appropriate" or "correct" aspects of performance helps to motivate the child to continue practicing.
- It is important to balance between feedback that is error-based and that which is based on "appropriate" or "correct" characteristics of the performance.
- KP feedback can also be descriptive or prescriptive; prescriptive KP is more helpful than just descriptive KP in the early or beginning stages of learning.
- KP and KR should be given close in time to but after completion of the task.
- KP and KR typically should not necessarily be given 100% of the time.

- Learning is enhanced if KR/KP is given at least 50% of the time.
- A frequently used procedure for given KR/KP is to practice a skill several times and then provide the appropriate feedback.

Distribution and Variability of Skill Practice

- Shorter, more frequent practice sessions are preferable to longer, less frequent practice.
- If a skill or task is complex and/or requires a relatively long time to perform or if it requires repetitive movements, relatively short practice trials/sessions with frequent rest periods are preferable.
- If the skill is relatively simple and takes only a brief time to complete, longer practice trials/sessions with less frequent rest periods are preferable.
- It can enhance skill acquisition to practice several tasks in the same session.
- If several tasks are to be practiced, divide the time spent on each and either randomly repeat practice on each or use a sequence that aids the overall practice.
- Providing a number of different environmental contexts in which the skill is practiced appears to facilitate learning.
- With regard to the "amount" of practice, more is not necessarily always better.
- Clinical judgment should be used to recognize when practice is no longer producing changes; at this time, a new or different task could and probably should be introduced.

Whole Versus Part Practice

- Whole practice is better when the skill or task to be performed is simple.
- Part practice may be preferable when the skill is more complex.
- If part practice is used, be sure that the parts practiced are "natural units"—that they go together.
- To simplify a task, reduce the nature and/or complexity of the objects to be manipulated—for example, use a balloon for catching instead of a ball.
- To simplify a task, provide assistance to the learner that helps to reduce attention demands—for example, provide trunk support during practice of different eye-hand coordination tasks.
- To simplify a task, provide auditory or rhythmic accompaniment; this may help to facilitate learning through assisting the learner in getting the appropriate "rhythm" of the movement.

Mental Practice

- Mental practice can help to facilitate acquisition of new skills as well as the relearning of old skills.
- Mental practice can help the child to prepare to perform a task.
- Mental practice combined with physical practice works best.
- For mental practice to be effective, the individual should have some basic imagery ability.
- Mental practice should be relatively short, not prolonged.

Adapted from Williams, H. (2006). Motor control. In J. Solomon & J. O'Brien (Eds.), *Pediatric skills for occupational therapy assistants* (2nd ed., pp. 474–480). St. Louis: Mosby.

FIGURE 7-11 Distributed Practice. Taking breaks between swinging is an example of distributed practice.

difficult for children because they must continually adapt and adjust. Occupational therapy practitioners consider how to sequence activities and adapt them accordingly to promote a child's success. Recent research suggests that children with cerebral palsy may have less ability to adapt or vary their movement patterns given different contexts.¹⁰⁴ For example, children with cerebral palsy within the same Gross Motor Function Classification System⁸⁹ exhibited varying degrees of independence depending on the setting and terrain.¹⁰⁴ They performed higher at home and lowest in the outdoors or community. Thus, therapists are encouraged to consider the contextual features that can promote skills when planning interventions.

Practice Levels and Types

Practice is an essential feature of occupational therapy intervention. A considerable amount of research has been conducted on the use of practice to improve or develop motor skills.^{79,99}

Massed practice (also known as blocked) is defined as practice in which the period performing the movement is greater than the rest period. This type of practice works best during the cognitive stage, as the subject is just beginning to learn the movements. An example of blocked practice may include working on grasp pattern and release by asking a child to pick up 10 blocks and put them all in a container before taking a break and then repeating the game again.

Distributed practice is defined as practice in which rest between trials is greater than the time of the trial and is most

useful during the associative stage (Figure 7-11). A clinical example of distributed practice includes asking the child to pick up bean bags placed on the floor while engaged in a game of swinging. In this scenario, the child is still practicing grasp and release, but the child is also working on postural control and processing vestibular input. Therefore, the child grasps and releases a few bean bags, has a rest while swinging in which he must work on other aspects of skill, and then returns to grasp and release.

Variable or random practice is most effective during the autonomous stage. Variable practice requires that learners repeat the same patterns but make small changes as necessary (Figure 7-12). This type of practice increases the ability to adapt and generalize learning. In general, short frequent practice is better than longer, less frequent practice because it decreases fatigue and increases reinforcement.¹¹⁴ Persons with Down syndrome showed improvement in a simple reach (to a target) with variable practice.⁴⁶ An example of random practice includes intervention working on grasp and release while the child is engaged in a variety of play activities. This type of practice is most closely related to the actual occupation. The child must pick up and release toys during the play session. The child picks up a variety of objects: small blocks, large balls, light toys, and heavy scooter boards.

Mental practice includes performing the skill in one's imagination, without any action involved. It consists of role playing, watching a video, or imagining. Mental practice is effective in teaching motor skills and retraining the timing and

FIGURE 7-12 Variable Practice. The child ties her shoes right before she goes outside to play. She is able to tie different sneakers and often she sits on the floor to complete the task.

coordination of muscle group activity.^{26-29,40,78} It is most effective at the early and later stages of learning and may be task-specific. Much of the research on mental practice is conducted on athletes trying to maximize their performance.^{71,78} However, the techniques used may be beneficial to children with motor difficulties.^{91,96,115} For middle school children with mild mental disabilities, mental imagery enhanced their motor performance on a peg board and pursuit rotor task.⁹¹ Some positive results regarding motor performance were reported for children with attention deficit disorder and developmental coordination disorder.¹¹⁵ Taktek and colleagues found performance (in throwing a ball) resulting from mental imagery combined with physical practice was equal during the retention phase, but superior during the transfer of learning phase.¹⁰⁰ The researchers examined visual and kinesthetic imagery in young children and found that they were both effective for children as young as 8 years. Many theorists suggest imagery is effective because it requires cognitive processes and helps children problem solve motor solutions.^{29,40}

Driskell and colleagues suggest that practitioners using mental practice consider the type of task, duration of mental practice, and time between practice and performance for retention.²⁹ Tasks in which the child has experience may be easier to imagine. However, the child may be able to imagine movements after observing them on a video or observing someone

else perform them. Therapists should be cautious not to incorporate a too-long mental practice because this may be difficult for children and result in a lack of motivation. Finally, therapists should incorporate actual performance shortly after the mental practice for the best retention. Techniques of watching a video, pointing out components of the movement, or simply reviewing mentally how the movement will look in combination with physical practice may provide improved motor learning.

In a descriptive study, researchers compared EEG topographic maps in four typically developing children and four children with cerebral palsy while they were engaged in motor execution and motor imagery tasks.⁹² The researchers asked the children to reach and grasp a small ball with their dominant hand, imagine hand movement needed to reach and grasp the ball, observe an animated reaching and grasping movement on the monitor, visualize the right-handed reaching and grasping movement, and create a “mental video” of the virtual hand movement. The authors found that different areas of the brain were activated during the imagery tasks for typical children and those with cerebral palsy.⁹²

Error-Based Learning

Children learn movement by making errors or mistakes and self-correcting.^{6,99} Therefore, clinicians sometimes allow the challenge to exceed the capacity of the child, to give him or her the opportunity to make errors, correct them (if possible), and learn from the experience. Children with disabilities must learn to adapt to new, different, or unexpected situations. In the past, therapists typically have been hesitant to allow children to learn through making errors. However, making errors in controlled settings allows children to resolve problems and is important for facilitating motor skill learning. Encouraging children to explore, adjust movements, and evaluate their responses and reactions helps them learn and refine motor skills.

Feedback

Intrinsic feedback, which allows the child to self-correct, is most effective for sustaining motor performance and should be the goal of intervention sessions. Intrinsic feedback may be elicited through discovery, a situation in which the therapist sets up the environment and the child is allowed to explore and discover, make errors, and consequently learn new ways of moving.

Children may require extrinsic feedback in the early stages of motor skill development. Extrinsic feedback consists of providing verbal cueing or physical guidance. Demonstrative feedback refers to modeling or imitating movements. Demonstrative feedback is best if it is provided before the child actually practices the movement, as well as throughout early stages of skill acquisition. The practitioner provides modeling without verbal commentary, because simultaneous verbal cues can decrease the child's attention to the movement.^{23,99}

Knowledge of Performance

Feedback to improve movement is most helpful when it is specific and clear. Knowledge of performance helps children understand how they performed the desired movement. Knowledge of performance is helpful in refining and adjusting motor

skills and therefore is useful after the child has established basic skills. Therapists may provide descriptive feedback to the child about performance of a specific task (i.e., writing), such as “You held the pencil between thumb and fingers and pressed lightly” or therapists may provide prescriptive feedback, such as “Next time, press a little more.”

Knowledge of Results

Feedback related to the desired outcome helps children understand movement. Providing this knowledge is most effective when specific information on the movement’s goal is stated. Thus, saying “Each button is lined up with its buttonhole” is preferred over “Good job.” Knowledge of results is motivating and encourages children to continue; it is most helpful when learning new motor tasks.

Verbal Feedback

Verbal praise and reinforcement are useful in motivating clients and changing behaviors but may be overused in clinical settings. Allowing children to make their own assessments of their performance is beneficial and will increase their sense of efficacy.⁹⁹ Verbal feedback is best if provided immediately after completion of the task. Using one to three brief cue words that can be repeated easily by the performer is best. Knowledge of

correct performance motivates a child to continue practicing, so such reinforcement may be used frequently. Positive feedback with specific cues improves performance, such as saying “You pressed firmly with the pencil!”

Application of Motor Control/Learning Theory in Occupational Therapy Practice

Case Study 7-2 illustrates how therapists may apply current motor control/motor learning principles to practice. Specifically, this example applies dynamic systems theory from an occupational therapy perspective to intervention of a child’s motor deficits. The practitioner uses concepts from dynamic systems theory with motor learning strategies as outlined by Williams (see [Box 7-4](#)).

Case Study 7-2 shows how a practitioner works within the multiple systems involved in movement to evaluate and design intervention. The therapist used principles of variability, meaning, occupation, and natural context when designing intervention. The therapist incorporated motor learning principles of feedback, demonstration, practice, and sequencing and adapting tasks. All activities were playful and fun for the child so that he would optimally engage in them.

CASE STUDY 7-2 Occupational Profile

Paul is a 7-year-old boy referred to occupational therapy after his mother expressed concern that he has difficulty using his hands, completing school work, and playing on the playground. Paul’s mother states that “he has trouble coloring, doing anything with his hands, and can’t climb up the slide or get on the swing.” She noted that Paul has stomachaches in the mornings and does not want to go to school. She reported that Paul enjoys playing with trucks on the floor in the living room with his friend.

Paul is in the first grade. His teacher is concerned that Paul is not “picking up things” as quickly as his peers and noted he has trouble with handwriting and reading. She acknowledged that Paul verbally contributes in class.

Occupational Performance Living Situation

Paul lives with his parents and 2-year-old sister in a neighborhood with many children who frequently play together outside. Paul stated he has “one good friend” with whom he plays in the afternoons and sees at school. Paul participates in recreational soccer (although he says, “I’m not very good”).

Gross Motor

Paul presented as a thin, small 7-year-old boy, who stood with his shoulders depressed. Range of motion is within normal limits. His muscle tone throughout was slightly low, especially in the trunk. He sat with a rounded back and could not maintain balance with eyes closed. Paul ran with his feet apart and his arms did not swing consistently or in rhythm. He had difficulty changing positions as observed by stopping and reorienting himself as his friend ran around him. Paul showed

poor sequencing and timing of movements—he could not jump with both feet together and or catch a ball. He fell three times on the tires when he tried to balance on them during recess.

Handwriting

Paul held a pencil in a tight pronated grasp and made dark marks on the paper. He did not draw a straight line (3 inches) within the ¼-inch markings—his line went over in more than five places. He printed his name slowly; spacing was inconsistent between letters; the letters were of uneven size; and he did not stay within the large ruled lines. When writing, he sat with his feet on the floor, his back was rounded, and his face was close to the paper. He showed some associated reactions (e.g., facial movements) when writing. He was not able to perform alternating hand movements.

Self-Care

Paul independently donned his coat and hat. He had difficulty with buttoning, and required several minutes to accomplish. He demonstrated beginning skills in tying his shoes, making multiple knots instead. He feeds himself but has difficulty with opening cartons and tearing packages. He washes his face and hands.

Play

Paul was the last child to go outside for recess. He played with his friend and watched others. His friend waited for him and frequently repeated, “Hurry up, Paul.” Paul watched others on the swings and slides, but did not try to interact with others. He played on the tires by himself.

Continued

CASE STUDY 7-2 Occupational Profile—cont'd

Systems Contributing to Performance

Environment

Paul lives in a three-bedroom home. He has access to toys inside and outside. His home is child-friendly. The backyard is fenced in and includes a swing set, slide, and sandbox. He does not ride a bike, swing, or go down the slide. He prefers to play indoors. If he must play outside, he likes to play with his trucks on the deck.

School

Paul attends a local elementary school; there are 15 students in his class. The teacher provides structure and is consistent. She expressed concern that Paul is falling behind his classmates and notes difficulty with handwriting, paying attention, and getting things done in a timely manner. She commented that Paul is always the last one out the door, forgets things in the classroom, and seems frustrated at times. However, she revealed that Paul is verbal, answers questions readily, behaves well, and is polite.

Neuromotor

Paul's low muscle tone, poor postural control, and difficulty with timing and sequencing are interfering with his ability to move in a coordinated fashion. Paul shows some soft neurologic signs, such as associated reactions. He demonstrates poor standing balance with his eyes closed and poor dynamic balance. He fell three times on playground tires within a 30-minute recess.

Sensory

Paul's poor balance and motor planning are interfering with his movement. Paul's body awareness is somewhat affected because he struggles to identify right-left, a skill expected at his age. His internal body awareness is not quite developed.

Assessment

Paul exhibits developmental coordination disorder (DCD), as his motor abilities are interfering with his daily activities of play, self-care, and academics. He is aware of his difficulties and experiencing frustration with an inability to keep up with his peers. He has changed his activity preferences (to indoor activities) and is beginning to resist going to school.

Goals

1. *Academic performance:* Paul will improve fine motor skills for academics.
 - a. Paul will write his first name in a 2 inch by 3 inch rectangle on the upper right hand corner of his paper with 90% legibility.
 - b. Given a verbal prompt, Paul will complete a short writing assignment (three lines) in 15 minutes with 80% legibility.
2. *Play:* Paul will improve motor skills to engage in play on playground with peers.
 - a. Paul will show improved timing and sequencing by pumping a swing consecutively for 5 minutes on the school playground.

- b. Paul will demonstrate posture and balance for play as evidenced by remaining upright while climbing on at least 10 tires (on the playground tire hill) within a 30-minute play session.

Analysis of Intervention Planning

The occupational therapist, Cora, a school-based practitioner, developed an intervention plan to help Paul play with his peers and perform in the classroom. These goals address the parents' concern that Paul is having "difficulty playing on the playground and doing anything with his hands." Cora hypothesized that helping Paul gain postural control, balance, timing, and sequencing through playground activities would provide a foundation for hand skills. Improving the quality, speed, and timing of his motor performance allows him to keep up with his peers. Engaging in successful activities contributes to his sense of competency and leads to a positive view of school. Because children spend so much of their day writing, Cora felt targeting handwriting would significantly effect his occupational performance in school.

Keeping in mind that children learn best when they are presented with the whole versus a part of the activity that is meaningful and carried out in natural contexts, Cora designed a variety of fun gross motor games for the playground. The intervention was designed to help Paul develop postural control, balance, timing, and sequencing while completing fun games with peers and helping him feel better about his abilities. Providing Paul with the opportunity to develop some basic skills will help him succeed on the playground. The therapist graded and adapted activities to promote his success in this context.

Cora spent the first session recording baseline measurements directly related to the established goals. She recorded the time and legibility of Paul's performance of writing his name on his paper and writing three sentences after being given a verbal prompt ("Tell me about your favorite animal."). She also measured how many consecutive swings (back and forth) Paul could complete on the swing in 5 minutes and how many times he fell on the tires. Cora videotaped the baseline measurements, recorded the results, and documented her observations of the quality of his motor performance. This data provided her with solid measurements to determine the effectiveness of occupational therapy intervention.

During the subsequent sessions, Cora designed fun activities to target postural control, balance, timing, and sequencing play by setting up a five-step obstacle course on the playground, which included that Paul:

1. Climb over three tires (lined up on flat surface)
2. Run to the slide (10 feet)
3. Pick up an object sitting on the fourth rung of the slide
4. Swing back and forth two times on the swing
5. Stand in the center of the hula hoop

Cora used motor learning principles by demonstrating the movement for each step before asking Paul to perform. Once she reviewed each step, she asked him to complete them in order. Paul made many mistakes but started to problem solve how to better perform toward the end of the course. On

CASE STUDY 7-2 Occupational Profile—cont'd

completion, he said, “Let me try it again and see if I can go faster.” Cora provided some key points about the part of the course with which he had trouble (e.g., swinging). She cued him using one to three key words to “Pump back and forth.” Providing one to three key words as verbal feedback after the child has performed is recommended for motor learning. Furthermore, allowing Paul to make and learn from his own motor mistakes allowed him to internalize the motor learning. This technique has been found to improve generalization. The therapist periodically changed the format, allowing Paul to make some revisions in the course, to ensure that the course was meaningful. For example, Paul added more tires to the course and requested that the toy be placed higher on the ladder.

Cora was fortunate to be able to provide intervention in the natural context, which provides cues to the child and allows for transfer of learning. Cora waited to invite peers to join Paul so that he could develop competence in skills before the added social “pressure” and stimuli.

Cora continued the session in her classroom space by talking to Paul about his writing and discussing strategies that might help make it easier for him in terms of motor functioning. Paul decided his writing would improve if he held the paper down with his left thumb; he liked the idea of using a mechanical pencil with a new pencil grip. Research suggests that discussing handwriting performance may help children improve motor performance.⁶ For example, Banks and colleagues found that discussing strategies (so the children come up with the solutions) helped four children with developmental coordination disorder to improve handwriting performance more than physical practice alone.⁶ Problem solving with the child may not work with all groups of children and requires an adequate level of cognition. Using mental practice

strategies, Cora asked Paul to visualize how he would complete his writing tasks in school. She suggested that he visualize his handwriting immediately before beginning the writing task.

In the therapy session, they played with a spirograph, using it to help Paul improve his handwriting grasp. The spirograph requires repetitive movement and is fun for children. It improves sequencing and allows the child to work on grip strength. This proved to be a nice activity to work on the mechanics of writing. Later in the intervention sessions, Cora purchased a set of colored pencils, an art book, and some stencils that Paul found interesting. Paul brought his “art portfolio” to class and home, which allowed him practice time.

Cora provided Paul with a variety of activities to promote postural control, coordination, timing and sequencing, and handwriting that were meaningful and fun for him. Periodically, she stopped the spirograph activity and reviewed how to hold the pencil or reinforced correct posture. On the playground she spent time explaining pumping and working on songs to improve timing and rhythm. Cora paid close attention to the nonverbal and verbal cues Paul gave her. If activities were too challenging, she adapted them almost effortlessly. She used humor and paid attention to therapeutic use of self so she could optimize the session. Cora was attentive to Paul, provided positive facial expressions, and encouraged gently.

She used a block practice schedule to teach the new skills, such as climbing to the top of the slide alternating one’s feet and hands (bilaterally). As Paul became more competent, she used a distributed practice schedule and later a random or variable schedule. She focused on her goal to enable Paul to participate in play on the playground with peers and complete handwriting assignments with better quality and speed.

By capturing the child’s interest in playing with friends and the parent’s goal of helping him play with his peers and school, the therapist targeted intervention to help the child improve occupational performance in a meaningful way. The practitioner addressed his fine motor skills for handwriting. This approach promotes practice and learning by empowering children to meet their own occupational goals.

Summary

- Motor control refers to the “ability to regulate or direct mechanisms essential to movement” (p. 4).⁹³ It includes examination of the mechanisms, strategies, development of movement, and causes of motor dysfunction. Motor learning refers to how people learn and retain motor skills. It helps practitioners understand how to instruct and teach children to perform movements.
- Contemporary motor control interventions support a dynamic systems approach that movement derives from an interaction of person factors, task characteristics, and environmental systems. The principles of dynamic systems theory include:
 - The interaction among systems is essential to adaptive control of movement.
 - Motor performance results from an interaction between adaptable and flexible systems.
 - Dysfunction occurs when movement patterns lack sufficient adaptability to accommodate task demands and environmental constraints.
 - Because task characteristics influence motor requirements, practitioners modify and adapt task requirements and affordances to help children succeed.
- The research evidence supports a dynamic systems approach to motor control intervention by considering the multiple systems in which the child moves. Using an occupation-based model of practice can frame the occupational therapist’s use of a dynamic systems approach. Interventions that allow the child to perform meaningful whole activities using real objects in the natural setting promote motor performance.
- An understanding of the stages of motor control (cognitive, associative and automatic) helps guide practitioners when developing intervention. The practitioner analyzes child, task, and environmental systems to determine how the components and systems interact for purposeful movement.

Child factors include cognitive, musculoskeletal, neuro-motor, perceptual, and social-emotional influences. Task characteristics consider nature of task, object properties, goals, and rules. Environmental systems include physical, social, cultural, virtual, and personal contexts.

- Practitioners use knowledge of motor learning concepts during intervention to teach children motor actions.
- Motor learning strategies (such as transfer of learning, feedback, practice, sequencing and adapting tasks, modeling or

demonstration, and mental rehearsal) are techniques to promote motor acquisition and motor control. Motor learning strategies help practitioners decide how and when to provide feedback and how to promote generalization of skills (transfer of learning). Practice information helps define which type of practice to provide at each stage of learning. Practitioners are encouraged to use evidence-based motor learning strategies to enhance a child's occupational performance.

CHAPTER

8

Hand Function Evaluation and Intervention

Jane Case-Smith • Charlotte E. Exner

KEY TERMS

Hand function	Neurodevelopmental therapy
Reach and carry	Motor learning
Grasping patterns	Constraint induced movement therapy
In-hand manipulation	Adaptation and assistive technology
Bimanual skills	
Biomechanical approaches	

GUIDING QUESTIONS

1. What is the sequence of hand function development in infants and children?
2. Which factors contribute to development of hand function?
3. How do hand function problems affect children's occupational performance?
4. Which assessment tools and methods are useful in evaluating children's hand skills?
5. How are intervention practice models and principles used by occupational therapists to promote hand function?
6. Given a range of diagnoses, how do occupational therapists use specific intervention strategies to improve hand function?
7. How do assistive technologies and adapted techniques improve children's hand function and increase participation in play, school, and activities of daily living?
8. How does research support occupational therapy practice models for hand function interventions?

Hand function is critical to children and youth's interaction with objects (e.g., tools), materials, and other persons within everyday environments. Hands are the dynamic "tools" most often used to accomplish activities of daily living (ADLs), school, work, and play activities. The child who has a disability affecting hand function has less opportunity to interact with, explore, and act on the environment.

Components of Hand Skills

Effective use of the hands to engage in a variety of occupations depends on a complex interaction of hand functions, postural

mechanisms, cognition, social-emotional function, and visual perception. The term *visual-motor integration* refers to the interaction of visual skills, visual-perceptual skills, and motor skills. The term *hand function* is used interchangeably with the terms *fine motor coordination*, *fine motor skills*, and *hand skills*, and this chapter uses the term hand function to refer to all of these skills.

Although a child's development of hand functions depends on adequate postural functions and sufficient visual-perceptual and cognitive development, these areas are described in other chapters and not in detail in this chapter. Patterns of hand function include reach, grasp, carry, and voluntary release, as well as the more complex skills of in-hand manipulation and bimanual skills. These terms are briefly defined:

- Reach: extension away from the body and movement of the arm for grasping or placing objects
- Grasp: attainment of an object with the hand; holding within the hand
- Carry: transportation of a hand-held object from one place to another
- Voluntary release: finger extension allowing intentional release of a hand-held object at a specific time and place
- In-hand manipulation: adjustment or movement of an object within the hand
- Bimanual skills: coordinated use of two hands together sequentially or simultaneously to accomplish an activity

Factors That Contribute to the Development of Hand Function

Occupational therapists often use occupation-based models and dynamic systems theory to understand development of inter-related performance areas. Through the lens of these conceptual models, a child's performance reflects his or her innate developmental abilities and the contextual opportunities and barriers that affect performance. As described in [Chapters 2](#) and [8](#), performance is dynamically influenced by intrinsic variables, including motivation, cognition, and social-emotional function as well as extrinsic variables, including the social, physical, and cultural context. These models are used to guide analysis of hand function by identifying potential factors associated with a child's delay or impairment in hand function. Using a top-down approach, this section describes factors that influence the development of hand function, recognizing that as a child develops, the factors associated with efficient hand use

and skilled manipulation of objects have greater or lesser influence.

Social and Cultural Factors

Knowledge of contextual factors is critical for understanding, evaluating, and providing interventions to enhance hand functions. Social and cultural factors, in particular, are likely to play important roles in the acquisition and use of various hand skills. Social factors that can affect the development of hand functions include socioeconomic status, gender, and role expectations. These cultural and social factors may not influence the development of basic hand skills but can influence the development of complex manipulation of objects and tool use. For example, children who live in conditions of poverty may not have access to writing utensils, scissors, and other materials common to children from middle-class environments.

The objects that are important to the child's cultural group influence the development of object manipulation. Because tools that are important in one culture may not be available in another, children may not have the opportunity to develop some tool-specific skills. For example, eating utensils vary from chopsticks to forks and spoons. Scissors use may be important for school performance in some cultures but not in others. As explained by Flynn and Whiten,⁵³ children's pattern of tool use is influenced by observing the actions of familiar individuals using tools over time, thereby reinforcing the significance of that action to the child. Children learn to use tools through repeated observation of adults and their peers, suggesting that tool use may be delayed when models are not available and most often reflect patterns within their immediate environments.

In addition, the age at which children are expected to achieve skills in object manipulation can vary. Safety concerns influence parents in some cultural groups to delay introduction of a knife to a child, whereas parents in other cultural groups encourage early independence in knife use.¹⁰⁹ Some cultures introduce children to the use of writing materials before 1 year of age. Parents from other cultures and socioeconomic groups do not provide children with these materials until they can be expected to adhere to requirements such as using them only on paper (rather than on the wall or on clothing).

Culture also influences the perception of children's need for manipulative materials and the cultural group's view of the importance of play. Play materials that provide opportunities for the development of manipulative skills (e.g., building sets, beads, puzzles, table games) are highly valued in some cultural groups, whereas in other groups, play with gross motor objects (e.g., balls, riding toys) or play with animals is more valued. Some cultural groups do not view children's play as important; therefore few play materials of any type are available.⁶

Although the types of activities encouraged can promote the development of specific skills, acquisition of the basic hand functions of reach, grasp, release, and manipulation does not rely on the availability of any particular materials; rather, it relies on reasonable exposure to a variety of materials with the opportunity to handle them. In a comparative study of children in Hong Kong and those in the United States, children in Hong Kong demonstrated higher level manual dexterity and, at earlier ages, more proficient writing.²³ Hong Kong children's

proficient hand skills at early ages may relate to using chop sticks to eat, having less access to gross motor activities, or attending early childhood programs that emphasize writing. Although dexterity of children in Eastern cultures may be higher than that of American children, hand strength may be lower. Studies have found that on average, children from Eastern cultures, such as Korea, demonstrate lower hand strength than children of Western cultures.¹³¹

Although contextual variables influence a child's development of hand function, intrinsic variables, including the child's somatosensory functions, visual perception, and cognition, have strong, direct association with the child's rate of development, level of performance, and proficiency across tasks. Musculoskeletal integrity also influences patterns of hand function, coordination, and dexterity. As hand functions mature beyond grasp and release patterns, children learn to coordinate visual skills with hand skills, develop praxis and dexterity, and later, coordinate visual-perceptual and motor planning skills.^{37,98}

Somatosensory Functions

The role of somatosensory information and feedback is critical in the development of hand functions, particularly those involving isolated movements of the fingers and thumb. Practitioners acknowledge that intact somatosensory functioning is required for development of precise and dexterous hand and finger movements. Haptic perception is the child's interpretation of somatosensory information (through active touch) for purposes of understanding object properties and characteristics. Although haptic perception emerges by 6 months when grasping patterns are immature, full haptic perception (perception of object texture, shape, and hardness through active touch) does not mature until 5 or 6 years when the child can manipulate objects within the hand.¹³ As a more direct sense than vision, haptic perception allows for immediate feedback on the child's use of force, accuracy of movement, and precision of movement.¹¹¹ A 6-year-old can identify three-dimensional common objects and all aspects of objects' characteristics by active touch alone.²¹

The fingertips gather precise information about many types of object qualities. Children with impaired control of finger movement have limited access to somatosensory information, and/or the impaired control of finger movement may reflect their difficulties in perceiving and using sensory information. Initiating and sustaining grasp force requires tactile and proprioceptive input and integration, and the ability to hold objects in the hand (i.e., without dropping them) is related primarily to intact somatosensory functioning.^{55,58,59} Hand functions and accurate use of force clearly relate to tactile sensibility; for example, in children with cerebral palsy, tactile information was found to be critical for anticipating the amount of force needed to grasp and lift an object.⁵⁶

Somatosensory functioning is difficult to assess in children, particularly in young children (e.g., less than 4 years) and those with disabilities. When testing haptic perception (e.g., using stereognosis) or tactile sensitivity (e.g., using two-point discrimination), a child's performance often varies within a session or from one session to another. Although formal testing may be unreliable, therapists informally evaluate somatosensory functioning to understand delays or impairment in

hand function. For example, a child with poor somatosensory registration may engage in few activities involving active manipulation. A child with tactile hypersensitivity may avoid contact with certain materials, thus limiting exposure to various objects. Limitations in somatosensory function are associated with poor coordination, problems in timing and speed of response, and clumsiness, including dropping objects or use of excessive force.⁵⁷ In particular, children with cerebral palsy^{55,56} and developmental coordination disorder (DCD)⁷⁸ often demonstrate these somatosensory perception difficulties and associated impaired hand function.

Visual Perception and Cognition

Visual perceptual and visual-motor development has a major role in the development of hand function.^{9,21,71} Vision is particularly important for learning new motor skills. The 4-month-old infant uses vision as a dominant sense to guide arm and hand movements in reaching for objects and making differentiated finger movements. The visual-motor development required for accurate reach matures by approximately 6 months of age. During the first 6 months, the infant demonstrates emerging skills in using visual and tactile perception to guide reach, object carry, and object placement.¹¹⁰ The infant's visual-motor coordination continues to refine, and by 9 months of age the infant guides his or her hand movements using visual-somatosensory integration (i.e., these sensory inputs are combined and compared as the infant anticipates and plans arm and hand movements).

Because the child acquires knowledge about objects through object manipulation, hand use and cognitive development seem to be particularly linked in infancy and very early childhood.⁵⁰ Early manual exploratory behavior plays an important role in the development of visual-spatial skills and learning about the environment.^{96,112} Object manipulation in infants between 6 and 12 months of age leads to learning about object characteristics and understanding of spatial relationships. For example, by 9 to 10 months of age, infants adapt their arm positions to horizontal versus vertical object presentations and shape their hands appropriately for convex and concave objects.¹¹⁰

During the second year, infants learn to relate objects to one another with more accuracy and purpose. Before 18 months of age, infants modify their movement approach in anticipation of the weight of the object.^{13,27} As eye-hand coordination continues to develop, the toddler learns movements that require precise guidance by vision (e.g., stringing small beads or putting together a puzzle). For example, in the second half of the first year the infant adjusts the actions of the hand in response to object characteristics, such as size, shape, and surface qualities.²⁷ By preschool age, the development of hand function allows for more complex interaction with objects, and the child uses well-developed visual-perceptual skills to guide manipulation of objects in the course of play and social interaction.

Like visual-perceptual skills, cognitive skills are associated with the development of hand function in the young child.⁸² Changes in attentional control and the development of problem-solving strategies are seen in the infants' gradual improvement in handling two objects simultaneously. The infant attends to two objects simultaneously when, at 10

months, he or she bangs two objects together and, at 15 months, he or she stabilizes an object with one hand while manipulating with the other. With further cognitive development, the toddler, at 18 to 20 months, manipulates two or more objects simultaneously. As attention and planning skills increase, the child develops facility in using two hands together to manipulate objects.^{17,27}

Musculoskeletal Integrity

The integrity of the hand's joint and bone structures is an important consideration in hand function. Children with congenital hand anomalies may be missing one or more digits, a condition that significantly affects the variety of possible prehension patterns. Refined finger movements and in-hand manipulation skills may also be limited or absent. Congenital anomalies in which the thumb is missing or contracted significantly affect grasp. Children with congenital anomalies affecting hand structures often undergo orthopedic surgeries to optimize grasp and hand function.

Limitations in joint range of motion (ROM) can occur as a result of abnormal joint structure, muscle weakness, abnormal muscle tone, or joint inflammation. These limitations can affect the child's range of reach and carry, active supination for tool uses, and hand and finger mobility. Effective hand function depends on adequate mobilization of distal muscle groups that control palmar arches. ROM limitations or hand contractures affect a child's ability to grasp small or large objects, use dynamic grasp and release patterns, and move objects within the hand.

Aspects of muscle functions include muscle power (strength), muscle tone, and muscle endurance. Sufficient strength is necessary to initiate all types of grasp patterns and to maintain these patterns during lifting and carrying. Children's grasp strength gradually increases through the preschool years,⁸⁰ the elementary school years,¹³¹ and adolescence.²⁵ This increase allows them to engage in activities with objects of increasing weight and to use greater resistance.

Children with poor strength may be unable to initiate the finger extension or the thumb opposition pattern necessary before grasp. They also may not have the flexor control to hold a grasp pattern. Many children with diminished strength are unable to use patterns that rely on the intrinsic muscles for control and therefore are unable to use thumb opposition or metacarpophalangeal (MCP) joint flexion with interphalangeal (IP) joint extension. Children with fair strength may be able to initiate a grasp pattern but may be unable to lift an object against gravity while maintaining the grasp. Children with mildly diminished strength may demonstrate limited activity endurance, particularly in situations in which they must use a sustained grasp pattern or hold an object against resistance (e.g., during eating with utensils, coloring, handwriting, and scissors activities).

When children with cerebral palsy demonstrate increased or decreased muscle tone in the upper extremity, arm and hand movements tend to be unstable and motor control is diminished. Finger and hand movements are often limited or missing. Children with spasticity or hypertonicity frequently demonstrate limited ROM, poor control, and decreased movement efficiency. Children with hypotonia or low muscle tone often exhibit exaggerated joint ROM and decreased stability. With

fluctuating tone, a child may have full ROM but attains joint stability only at the extreme end of a joint position (full flexion or full extension). With fluctuating tone, movements are less controlled and appear to be random or unrelated to the child's goal.

Although intrinsic and extrinsic factors influence the development of hand function, the sequence of hand skill development is remarkably similar in typical children. The sequence of development guides the occupational therapist in evaluating hand function and fine motor skills, establishing goals that reflect the next developmental steps, and selecting developmentally appropriate activities as the context for intervention.

Development of Hand Skills

Developmental theories and principles are used in conjunction with other practice models to select appropriate goals, design intervention activities, and assess the child's progress. The occupational therapist uses comprehensive knowledge of hand function development to select tasks that challenge the child's emerging skills and provide or fade out supports that enable the child to reach the next developmental level. Hand functions develop through childhood, continuing into the adolescent years.^{4,46} This long course of development mirrors other aspects of development and reflects the complexity of hand skills as humans interact with objects and their environments. Developmental theories are further described in [Chapter 3](#); this section describes the sequence of hand function development by considering its components.

Reach and Carry

An important sequence in the development of motor control is the use of linear movement patterns before the emergence of controlled rotation patterns. As illustrated in the development of reach and carry, the infant first develops controlled stability and mobility in basic flexion and extension of the shoulder, elbow, and wrist. Within the first year, control of internal and external rotation of the shoulder and pronation and supination of the forearm emerges and these rotational arm movements characterize the reaching patterns required in functional tasks (e.g., reach to be picked up, reach for a bottle or cup). The goal of reach is to transport the hand to the target, with precision in both time and space,^{110,117} and therefore requires control of the hand's movement toward the object and the preparation of the hand for grasp.

Within the first several days of life the neonate shows visual regard of objects close to him or her and activation of the arms in response to objects.¹²⁶ Over the next few months of life the arms become more active and the infant swipes or bats at objects with the arm abducted at the shoulder. Reach with an extended arm to contact an object with the hand is likely to occur between approximately 12 and 22 weeks of age.^{126,127} Objects are rarely grasped and then only by accident. If grasped, they are released at random, generally in association with arm movements.

By 3 to 4 months a midline orientation of the hands develops. Initially the hands are held close to the body. Soon, with an increased desire for visual regard of the hands and greater proximal arm stability, the 4- to 5-month-old infant holds the

hands further away to view them. This pattern precedes the onset of symmetric bilateral reaching, which usually occurs first in the supine and then in the sitting position. At this stage the infant initiates reach with humeral abduction, partial shoulder internal rotation, forearm pronation, and full finger extension.¹¹⁰

As the infant shows increasing dissociation of the two body sides during movement, unilateral reaching begins. Abduction and internal rotation of the shoulder are less prominent in reach. The hand opens in preparation for grasping the object and is usually more open than necessary for the size of the object.¹²⁸

As scapular control and trunk stability mature, the infant begins to use shoulder flexion, slight external rotation, full elbow extension, forearm supination, and slight wrist extension during reaching. Active supination of the forearm requires some external rotation of the shoulder to stabilize the humerus. In addition, well-controlled elbow extension evolves as control of shoulder rotation develops. Mature reach is usually seen with sustained trunk extension and a slight rotation of the trunk toward the object of interest. Over the next few years the child refines this unilateral reaching pattern, increasing the accuracy of arm placement and the grading of finger extension as appropriate to the size of the object ([Figure 8-1](#)), as well as the timing of the various movement elements. With increasing age, reaching patterns become direct, highly accurate, and highly consistent. The quality of reach with grasp continues to mature until approximately 12 years of age, at which time the child prepares the hand with the optimal hand opening for the object size at the initiation of reach.⁷⁵

Carrying (moving and lifting) involves a smooth combination of body movements accompanied by stabilization of an object in the hand. When carrying objects to perform a task, small ranges of movements are used and adjusted in accordance with the demands of the activity. The child carries an object by maintaining co-contraction of the forearm, wrist, and hand and may modify the forearm and wrist positions to correctly orient the object. Similarly, the child uses shoulder rotation movements with shoulder flexion and abduction to orient the object during carry.

FIGURE 8-1 A 2-year-old shows refinement of unilateral reach with graded finger extension.

Grasp Patterns

Broadly, grasp patterns are determined by whether a person needs to perform with precision or power to accomplish an activity. Precision grasps involve opposition of the thumb to fingertips. Power grasps involve the use of the entire hand. In a power grasp, the thumb is held flexed or abducted to other fingers, depending on control requirements. In most cases the activity and the object's characteristics determine the grasp pattern used. Small objects are generally held in a precision grasp, using the extensive sensory feedback available through the fingertips and the fine control of intrinsic muscles. Medium objects can be held with either pattern, and large objects are generally held with a power grasp. The child uses interplay between precision and power handling of objects based on the activity demands.^{17,98} Specific grasp patterns are described in Table 8-1.

Sequential Development of Grasp Patterns

The sequences of grasp pattern development reflect three types of progression: (1) Ulnar fingers show activation before radial fingers and thumb; (2) palmar grasp (proximal) patterns precede finger grasp (distal) patterns; and (3) extrinsic muscle activation dominates before intrinsic muscle activation. These progressions interact and overlap as the infant develops. The infant's growing interest in objects and desire to attain and

explore them and relate them to other objects interact with motor and sensory development to influence the grasp patterns. Haptic development and visual-perceptual development contribute to the infant's ability to shape the hand to the object's form and to approach the object with optimal orientation of the arm and hand.

Another aspect of motor development that contributes to the infant's use of increasingly mature and more varied patterns is the arm's internal stability to hold a position of forearm supination and wrist extension. Stability of wrist and forearm allow controlled thumb opposition and isolated finger movements for precision grasp patterns. The ability to stabilize the wrist in a slightly extended position is important for grasp patterns that use distal (fingertip) control. Slight forearm supination positions the hand so that the thumb and radial fingers are free for active object exploration and allows the infant to view fingers and thumb during grasp.¹⁷

The typical sequence of grasp development begins with the neonate appearing to have no voluntary hand use. A newborn infant's hands alternately open and close in response to sensory input. Within the first 3 months the automatic traction response and grasp reflex decrease, and a voluntary palmar grasp emerges (Figure 8-2). By approximately 6 months the infant exhibits a radial palmar grasp when prehending objects.

The second 6 months is a significant period for the development of hand skills. The ability to grasp a variety of objects

TABLE 8-1 Mature Grasping Patterns Used in Functional Activities

Grasp Pattern	Functionality	Description
Power grasp	Used to control tools or other objects. Used with hand strength is required in activity	The object is held obliquely in the hand; ulnar fingers are flexed; radial fingers are less flexed. Thumb is in extension and adduction. The child stabilizes the object with the ulnar side of the hand and controls the object using the radial side of the hand.
Hook grasp	Used to carry objects such as a purse or briefcase	The transverse metacarpal arch is flat; the fingers are adducted with flexion at the interphalangeal (IP) joints. The metacarpophalangeal (MCP) joints may be flexed or extended.
Spherical grasp	Used to hold a small ball	The wrist is extended, fingers abducted, with some flexion at the MCP and IP joints. Stability of the longitudinal arch is needed to use this pattern to grasp a larger ball. The hypothenar eminence assists in cupping the hand for control of the object.
Cylindrical grasp	Used to hold a glass, cup, or can with hand around the object	The transverse arch is flattened to allow the fingers to hold against the object. The fingers are only slightly abducted, and IP and MCP joint flexion is graded according to the size of the object. When additional force is required, more of the palmar surface of the hand contacts the object.
Disk grasp	Used to hold a disk such as a jar lid	The fingers hold the disk with extension of the MCP joints and flexion of the IP joints. The wrist flexes and thumb extends when objects are larger, and only the pads of the fingers contact the object. This pattern involves dissociation of flexion and extension movements and use of a combination of wrist flexion with MCP extension and IP flexion.
Lateral pinch	Used to exert power on or with a small object	The index finger is slightly flexed and the thumb is flexed and adducted. The pad of the thumb is placed against the radial side of the index finger at or near the distal interphalangeal (DIP) joint.
Pincer grasp	Used to hold and handle small objects and precision tools (e.g., a pencil)	The thumb is opposed to the index finger pad and the object is held within the finger pads. The ulnar fingers are often flexed.
Three-jaw chuck or tripod grasp	Used to hold and manipulate a writing utensil or eating utensil	The thumb is simultaneously opposed to the index and middle finger pads. These fingers provide stability for prehension of a tool. The thumb forms an oval or a modified oval shape with the fingers. When using a tripod grasp on a tool, the forearm is slightly supinated.
Tip pinch	Used toprehend and hold tiny objects	The thumb is opposed with thumb tip meeting index finger tip, forming a circle. All joints of the index finger and thumb are partly flexed.

FIGURE 8-2 A 4-month-old exhibits voluntary palmer grasp. (From Case-Smith, J. (2013). Applying occupation and motor learning principles in pediatric CIMT: Theoretical foundations and conceptual framework. In S. L. Ramey, P. Coker-Bold, & S. C. DeLuca (Eds.). *Handbook of pediatric constraint-induced movement therapy (CIMT)* (pp. 41–54). Bethesda, MD: AOTA Press.)

FIGURE 8-3 This child uses a radial-digital grasp to hold a rattle. (From Case-Smith, J. (2013). Applying occupation and motor learning principles in pediatric CIMT: Theoretical foundations and conceptual framework. In S. L. Ramey, P. Coker-Bold, & S. C. DeLuca (Eds.). *Handbook of pediatric constraint-induced movement therapy (CIMT)* (pp. 41–54). Bethesda, MD: AOTA Press.)

increases significantly between 6 and 9 months of age. During this time grasp patterns with active thumb use emerge. Crude raking of a tiny object is present by about 7 months of age, and by 9 months of age the infant holds a tiny object between the finger surface and the thumb. By 8 to 9 months of age the infant grasps a larger object between the thumb and the radial fingers (Figure 8-3) and readily varies the grasping pattern according to the shape of the object. However, intrinsic muscle control is not yet effective because the infant does not use grasp with MCP flexion and IP extension. Between 9 and 12 months of age, refinement occurs in the ability to use thumb and finger pad control for tiny and small objects. More precise preparation of the fingers before initiation of grasp, more inhibition of the ulnar fingers, and slight wrist extension and forearm supination are characteristics of this refinement.

After 1 year of age the infant further refines grasp patterns and more sophisticated patterns emerge. By 15 months the infant can hold crackers, cookies, and other flat objects, signifying increasing control of the intrinsic muscles. Between 18 months and 3 years of age most children with typical development acquire the ability to use a disk grasp, a cylindrical grasp, and a spherical grasp with control (see Table 8-1). Control of a power grasp continues to develop through the preschool years. The pattern for a lateral pinch may be present by 3 years of age, but children generally do not use this pattern with power until later in the preschool years. Overall grasp patterns for a variety of objects are well developed by 5 years of age, but those involving tools may continue to mature into the early school years.^{88,98}

In addition to refinement of grasp patterns, strength of grasp increases throughout childhood. Strength for palmar

grip, key (lateral) pinch, and tripod (three-point) pinch significantly increase in children between 3 and 5 years of age.⁸¹ Strength appears to continue to increase in grip, lateral pinch, palmar pinch, and tip pinch until children reach 12 years, with differences in grip strength between boys and girls common.⁸⁶ Isometric force gradually increases during the 5- to 10-year-old age span, reflecting corticospinal system maturation.^{119,120} Compared with 10- to 12-year-olds, adults exhibit greater isometric strength and use alternative strategies for selecting and monitoring the hand strength needed during a task.⁵¹

In-Hand Manipulation Skills

In-hand manipulation includes five basic types of patterns: finger-to-palm translation, palm-to-finger translation, shift, simple rotation, and complex rotation.⁴⁴ All skills require the ability to control the arches of the palm (Figure 8-4, A and B). In finger-to-palm translation, the child grasps the object with the pads of the fingers and thumb and moves it into the palm.⁴⁴ The finger pad grasp is released so that the object rests in the palm of the open hand or is held in a palmar grasp. The child moves the object in a linear direction within the hand, and the fingers move from an extended to flexed position during the translation. An example of this skill is picking up a coin with the fingers and thumb and moving it into the palm of the hand.

Palm-to-finger translation is the reverse of finger-to-palm translation and requires isolated control of the thumb.^{43,99} In palm-to-finger translation, the child begins with finger flexion and moves to finger extension (see Figure 8-4, B). This pattern is more difficult for the child to execute than finger-to-palm translation. An example of this skill is moving a coin from the

FIGURE 8-4 A, In emerging in-hand manipulation skills, child demonstrates increasing control of isolated finger movements. B, In buttoning, child uses palm-to-finger translation.

palm of the hand to the finger pads before placing the coin in a vending machine.

Shift involves linear movement of the object on the finger surface to allow for repositioning of the object on the pads of the fingers.^{44,98} In this pattern the fingers move just slightly at the MCP and IP joints, and the thumb typically remains opposed or adducted with MCP and IP extension throughout the shift. The object usually is held solely on the radial side of the hand. Examples of this skill are separating two pieces of paper, moving a coin from a position against the volar aspect of the DIP joints to a position closer to the fingertips (e.g., to insert a coin into the slot of a vending machine), and adjusting a pen or pencil after grasp so that the fingers are positioned close to the writing end of the tool. This skill is used frequently in dressing tasks such as buttoning, fastening snaps, lacing shoes, and putting a belt through belt loops.

The two patterns of rotation are simple rotation and complex rotation. In simple rotation the child turns or rolls an object held at the finger pads approximately 90 degrees or less.⁴⁴ The fingers act as a unit, without differentiation of action, and the thumb is in an opposed position. Examples of simple rotation are unscrewing a small bottle cap, reorienting a puzzle piece in the hand by turning it slightly before placing it in the puzzle, and picking up a small peg and rotating it from a horizontal to a vertical position for insertion into a pegboard.

In complex rotation, the child rotates a small object 180 to 360 degrees once or repetitively.^{44,100} During complex rotation the fingers and thumb alternate in producing the movement, and the fingers typically move independently of one another. An object may be moved end over end, such as in turning a coin or a peg over or in turning a pencil over to use the eraser.

In-hand manipulation skills also are used when a child has two or more pieces of cereal in his or her hand and moves one piece to the finger pads before placing it in the mouth. The term *with stabilization* refers to the use of an in-hand manipulation skill while other objects are stabilized in the hand. In-hand manipulation skills with stabilization are generally more difficult to perform than the same skill without the simultaneous stabilization of other objects in the hand.

Developmental Considerations

Postural and motor skill prerequisites for in-hand manipulation and dynamic grasping patterns include that the child demonstrates:

- Active forearm supination with stability when moving hand and fingers
- Wrist extension with stability
- Controlled and dynamic thumb opposition
- Fingertip prehension of objects with control of fingertip forces
- Isolated thumb and radial finger movement
- Stability with mobility of the transverse MCP arch
- Dissociation of the radial and ulnar sides of the hand⁴⁴

Children with delayed or limited in-hand manipulation skills are likely to substitute other patterns. Typical patterns that compensate for limited in-hand manipulation include (1) changing hands, (2) transferring from hand to hand, or (3) stabilizing the object on a table surface to reorient its position. The child uses these patterns after the initial grasp when he or she realizes that the object needs to be repositioned for use. For example, a child picks up a crayon with the right hand but is unable to shift it to place the fingers near the writing end; therefore, he or she grasps the object with the left hand and then transfers it back to the right hand. Some children preplan for this by picking up the crayon with the non-preferred hand and changing it to the preferred hand. Children commonly use two hands to compensate for limited shift and complex rotation.

In-hand manipulation skills develop after primary grasp and release skills have matured. By approximately 12 to 15 months of age, infants use finger-to-palm translation to pick up and “hide” small pieces of food in their hands. By 2 to 2.5 years of age, children use palm-to-finger translation and simple rotation with some objects.⁹⁹ Complex rotation skills are observed in children at 2.5 to 3 years of age, although children of this age group often have difficulty with them. By 4 years of age, children consistently use complex rotation without using an external support.¹⁰⁰ Children between 3.5 and 5.5 years of age

develop skills in rotating a marker (regardless of its initial orientation) and shifting it into optimal position for coloring and writing.⁶⁹ Children 3 and 3.5 years old demonstrate shift, although use is inconsistent.⁴³

After 3 years of age, a child's in-hand manipulation skills become more proficient and consistent. For example, objects are seldom dropped during in-hand manipulation tasks.⁹⁸ In-hand manipulation speed and accuracy continue to improve during the preschool years. By 6 years of age children develop the ability to use a variety of in-hand manipulation skills with stabilization.⁹⁷ Between 6 and 7 years of age, children more consistently use combinations of in-hand manipulation skills in complex fine motor activities (e.g., palm-to-finger translation with stabilization followed by complex rotation with stabilization). These skills continue to refine and speed improves through 12 years of age, at which time skills are similar to those of adults.⁵⁵

Object characteristics influence the in-hand manipulation pattern used. In general, medium-sized objects (e.g., standard crayons) are easier for children to manipulate than slightly larger objects (e.g., larger-diameter crayons) or tiny objects. Tiny objects require precise fingertip control, whereas medium-sized and larger objects require control with more fingers. Other factors that contribute to a child's use of in-hand manipulation skills include the cognitive-perceptual demands of the activity and the objects' shape and texture. The child's motor-planning skills, strength, and tactile sensibility can influence development of in-hand manipulation skills.

Voluntary Release

Voluntary release, like grasp, depends on control of arm and finger movements. To place an object for release, the arm must move into position accurately and then stabilize as the fingers and thumb extend. Object release requires precise coordination of fingertip forces and timing for predicting accurate object placement (e.g., on a surface).⁶⁰

Initially the infant does not voluntarily release an object; objects either drop involuntarily from the hand or must be forcibly removed from the hand. As the infant's tactile and proprioceptive perception, eye-hand coordination, and cognitive development improve, volitional control of release emerges. The infant first demonstrates object release when transferring objects from one hand to another. Initially the child stabilizes the object in the mouth during transfers or pulls it out of one hand with the other. By 5 to 6 months the infant transfers the object from one hand to the other by fully opening the releasing hand.

By 9 months of age the infant begins to release objects without stabilizing them with the other hand. Typically, the arm (i.e., elbow and wrist) extends during release. The infant exhibits increasing shoulder control as he or she moves the arm to drop objects in different locations. With the development of dissociation of arm and hand and increasing elbow stability, the infant begins to release with the elbow in mid ranges (i.e., with some degree of flexion). To control release, the child may stabilize the arm or hand on the surface during release. At about 1 year of age, the child can release objects with shoulder, elbow, and wrist stability; however, the MCP joints remain unstable during this pattern, therefore the infant continues to show excess finger extension (Figure 8-5). Gradually the child

FIGURE 8-5 A 10-month-old infant exhibits object release with full finger extension.

FIGURE 8-6 A 2-year-old exhibits precision release with partial finger extension.

develops the ability to release objects into smaller containers and to stack blocks. The release pattern is refined over the next few years until the child can release small objects with graded extension of the fingers, indicating control over the intrinsic hand muscles (Figure 8-6). Between 7 and 13 years of age, children acquire effective modulation of fingertip force when grasping lighter and heavier objects to accurately time their release and placement.^{39,97} Development of precision release, similar to precision grasp, illustrates the integration of perceptual, motor, cognitive, and sensory functions.

Bimanual Skills

In typical development the infant gradually learns to use both sides of the body together in effective ways and to use each side of the body independently of the other. Initially the newborn moves his or her arms in asymmetrical patterns that are not coordinated. Movements of one arm often elicit reflexive, nonpurposeful reactions in the other arm. Gradually the infant develops the ability to move the two arms together in the same pattern. As skilled use of symmetrical hand and arm patterns is refined, the infant begins to use the two arms independently of one another to perform different roles in an activity.^{27,47,48} For example, one hand stabilizes an object while

the other hand manipulates it. Overflow and associated movements gradually decrease to allow separate but coordinated action of the two hands.

As discussed previously, infants progress from asymmetry to symmetry to differentiated asymmetrical movements for bilateral hand activities. Asymmetry is a characteristic of movement patterns until almost 3 months of age. Symmetric patterns predominate between 3 and 10 months of age, when bilateral reach, grasp, and mouthing of the hands and objects are primary activities. Control of these movements originates proximally at the shoulders, allowing the hands to engage at midline. By 9 to 10 months of age the infant can hold one object in each hand and bang them together. This ability to hold an object in each hand at the same time is critical for further bimanual skill development. By 10 months of age bimanual action is well differentiated, with one hand grasping the object and the other exploring parts of it (Figure 8-7).^{48,49}

Differentiated bimanual action, first as reciprocal or alternating hand movements, then as simultaneous hand movements, allows the child to engage in ADLs and object interactions of increasing complexity. By 17 to 18 months of age, infants frequently use role-differentiated strategies (i.e., one hand stabilizes or holds the materials and the other manipulates or activates them).¹⁷ For these skills to emerge, the infant must be able to dissociate the two sides of the body and begin to use the two hands simultaneously for different functions (see

FIGURE 8-7 This 10-month-old shows emerging bimanual skills with one hand holding the object and the other manipulating it.

Figure 8-7). Effective stabilization of materials also depends on adequate shoulder, elbow, and wrist stability.

Between 18 and 24 months of age, the child begins to develop skills that are precursors to simultaneous manipulation. Continuing development of reach, grasp, release, and in-hand manipulation skills complements bimanual skill refinement. Skills in visual-perceptual, cognitive, and motor areas become more integrated, leading to the child's effective use of motor planning for task performance. Simultaneous manipulation using both hands together—that is, opposing hand and arm movements for highly differentiated activities (e.g., cutting with scissors)—emerges at about 2.5 years of age.^{27,47} This mature pattern is refined, including increases in speed and efficiency, as the school-age child engages in increasingly complex manipulation tasks.

Ball-Throwing Skills

Ball-throwing skills reflect the child's ability to use shoulder strength and control with release skills. In throwing a small ball, the child must sequence and time movements throughout the entire upper extremity. The child brings the arm into a starting position, then prepares for projection of the ball into space by moving the trunk with the scapulohumeral joint, stabilizing the shoulder while beginning to extend the elbow, stabilizing the elbow while moving the wrist from extension to a neutral position, and simultaneously forcefully extending the fingers and thumb.

Children progress through a series of skill levels before they can smoothly sequence these movements and project the ball to the desired location. Research on the development of ball-throwing skills is quite limited and has primarily been identified in the context of standardized test development.^{12,54} By 2 years of age the child can throw a ball forward and maintain balance so that his or her body does not also move forward. At this age the child uses arm extension without sustained shoulder flexion to fling the ball.⁵⁴ The child dissociates trunk and arm movement but does not completely dissociate humeral and forearm movements. By 2.5 to 3 years of age, the child projects the ball approximately 3 feet forward toward a target. This ability to control the direction of the ball to some degree implies that the child can control the humerus so that the elbow is in front of the shoulder when the ball is released. Thus the shoulder has sufficient stability to support controlled elbow and finger movement. By 3.5 years of age, the child throws a ball 5 to 7 feet toward a target with little deviation from a straight line.⁵⁴ To accomplish this level of throwing accuracy, the child positions his or her elbow in front of the shoulder before releasing the ball.

Further refinement of ball-throwing skills continues over the next few years. Distance and accuracy improve as the child gains scapulohumeral control, the ability to sustain the humerus above the shoulder, and the ability to control the timing of elbow, wrist, and finger extension. Thus at approximately 5 years of age, the child uses an overhand throw to consistently hit a target at 5 feet. Children between 6 and 7 years of age can hit a target 12 feet away using an overhand throw.⁵⁴ Children 5 years of age or older also use underhand throws to contact a target. Underhand throwing requires the ability to move the humerus into flexion while sustaining full external rotation.

FIGURE 8-8 A 2-year-old experiments with using a marker (**A** and **B**) and a crayon (**C**), exhibiting a variety of transitional grasping patterns.

Tool Use

Tool use is part of everyday life and is an essential method for children and adults to interact with their environment. It involves purposeful, goal-directed manipulation of a tool to interact with other objects or materials.^{26,105} Proficient tool use is essential to participation in a variety of self-care, play and leisure, and school and work tasks. Tool use competence for eating and play typically emerges during the second year, after the child has mastered the basic skills of reach, grasp, and release.²⁷ These skills emerge concurrently with in-hand manipulation skills that allow the tool to be dynamically held with fingers adjusting it within the hand.

A child's acquisition of tool-use skills highly relates to cognitive development. In proficient tool use, an individual understands the goal of the task (the intentional aspect of the task) and knows how to accomplish it (the operational aspect of the task).^{82,105} Acquisition of tool use follows the stages of motor learning (later defined in the motor learning section). Initially, the child experiments with a tool (e.g., a marker) by trying a wide variety of actions (e.g., holding in either hand, with fist or fingers, at top or base of marker). Experimenting with a tool is an important stage in the skill-acquisition process. As skill acquisition progresses, practice allows the skill to progress from

the child demonstrating a high level of attention to his or her action to performing at a more automatic level. With practice, performance becomes faster, more accurate, and smoother (i.e., more automatic), resulting in proficient tool use for daily life tasks (Figure 8-8, *A* to *C*).

The first tools that a child learns to use with proficiency are those required for eating. A toddler uses a spoon by 18 months of age, a fork by 2.5 years of age, and a knife by 6 years of age.⁶⁵ In a longitudinal study on development of spoon use skills in infants between 11 and 23 months of age, 17- to 23-month-old toddlers showed a clear hand and grasping pattern²⁶ preference for eating. Between these ages, children used 10 different grasp patterns, none of which was typical of an adult pattern. The most commonly used pattern was a transverse palmar grasp with all four fingers flexed around the handle of the spoon. By 17 months toddlers held the spoon primarily in their fingers and used some degree of finger extension to hold and orient the spoon. This pattern, which continues to refine through the second year, improves eating efficiency.

Another example of tool use that emerges in young children is cutting with scissors.⁵⁴ Early cutting is actually snipping, a process of closing the scissors on the paper with no movement of the paper and with no ability to repetitively open and close the scissors while flexing the shoulder and extending the elbow

TABLE 8-2 Developmental Sequence for Scissors Skills

Age (years)	Scissors Skill	Arm Actions
2	Snips with scissors	Hand holding paper is minimally involved; may hold paper awkwardly or with lateral pincer; hand with scissors often pronated.
2.5	Cuts across a 6-inch piece of paper	Hand holding paper in active supination; holds paper with stability; hand with scissors supinated.
3 to 3.5	Cuts on a line 6 inches long	Hand holding paper with stability, forearm in partial supination; hand holding scissors supinates to 90 degrees.
3.5 to 4	Cuts out a circle*	Hand holding paper moves it in coordination with cutting; hand holding scissors is supinated 90 degrees or more.
4 to 5	Cuts out a square	Hand holding paper moves it in coordination with cutting; hand holding scissors is supinated 90 degrees or more.
6 to 7	Cuts a variety of shapes	Both hands cooperate in synchronous and reciprocal interaction during cutting actions.

*The research of Rodger, Ziviani, Watter, Ozanne, Woodyatt, & Springfield (2003) suggests that cutting a circle is more difficult than cutting a square. Adapted from Folio, R. M., & Fewell, R. (2000). *Peabody developmental motor scales—revised*. Chicago: Riverside.

to move across the paper. Three-year-old children may use a pronated forearm position or a forearm-in-mid-position placement, or they may alternate between the two forearm positions. By 4 years of age children typically hold both forearms in mid position for the cutting activity.⁹² Table 8-2 describes the typical sequence for the development of scissors skills.

The child's grasp on the scissors changes over time. The thumb position in one hole remains consistent, but the finger positions change according to the child's level of maturation and the type of scissors used. Although grasp pattern is determined by the type of scissors, by 6 years of age a child demonstrates a mature grasp with the ulnar two fingers flexed (inside or outside the lower hole, depending on its size) and the radial fingers within the top scissor hole to provide the cutting action.

One component of tool use is the role of the assisting hand. For example, in using scissors and eating, the assisting hand has an active role, while in writing and drawing, the assisting hand primarily stabilizes the paper. In cutting, the assisting hand holds the paper and orients it using rotational movements in the same or the opposite direction as the hand with the scissors. In eating, the child's assisting hand may be involved in a variety of activities, depending on the child's age and the utensils used. Infants between 18 and 23 months of age appear to have significantly more involvement of the assisting hand in stabilizing a dish during spoon feeding than do infants between 12 and 17 months of age.²⁶

Hand Preference

Hand preference, sometimes termed *hand dominance*, is a complex concept. In typical children hand preference evolves over a long period of time and gradually becomes more consistent, as do other expressions of motor functioning. In children 6 to 24 months of age, use of a preferred hand is inconsistent in about 60% of the children performing a simple grasp task. When one hand is used as a stabilizer and one as a manipulator, 65% or more of the children over 18 months use the right hand as the manipulator. Inconsistency of preferred hand was noted in some children in the 2.5- to 3-year-old group but not in the 4-year-old group. Handedness is highly

influenced by the task demands; for example, 18- to 36-month-old infants show a preferred hand in bimanual manipulation tasks that mandate a dominant hand but not in simple grasping tasks. When exploring objects, infants tend to use both hands and not demonstrate a preferred hand.⁴⁹

Hand preference continues to develop until at least 8 years of age, as illustrated in a study of a reaching activity that involved crossing the midline of the body. Carlier, Doyen, and Lamard¹⁵ found that with increasing age, children used the preferred hand with greater frequency to pick up cards in various locations, including crossing the midline with the preferred hand. As with other areas of hand skill development, some degree of variability and inconsistency is the typical pattern for young children. It is worrisome and atypical when infants (less than 7 months) consistently use one hand, and these infants should be further evaluated for possible neurologic impairment.

Relationship of Hand Skills to Children's Occupations

Hand skills are vital to the child's interaction with the environment. Engagement in most occupations requires object and material handling with one's hands.

Play

Although infants engage with people and objects through their visual and auditory senses, these are distant senses and do not readily bring the infant essential information that can be gained only through touch. In early exploratory play with objects, an infant learns object properties through manipulating them.^{17,17} The interaction of touching, grasping, and manipulating, while visually inspecting, allows the infant to integrate sensory information and to learn that objects remain the same regardless of visual orientation.

With increasing age, until at least the early school years, participation in play depends on hand function and fine motor skill competence. These skills are reflected in the child's interest in activities such as cutting with scissors, dressing and

undressing dolls, putting puzzles together, constructing with various types of building materials and model sets, participating in sand and water play, completing craft projects, and engaging in imaginary play with objects. Playing video games and using computers also require fine motor control. Dramatic play with dolls or figurines in doll houses and vehicles involves precision hand movement including in-hand and bimanual manipulation.

Activities of Daily Living

Activities of daily living (ADLs) often entail a sequence of steps using a variety of hand functions. Specific hand functions needed for ADLs include (1) precision and power grasps of objects and materials; (2) complementary and reciprocal bimanual skills; (3) hand movements, including in-hand manipulation, with and without vision; (4) complex action sequences; and (5) development of automaticity.⁶⁵ In-hand manipulation speed, grasp strength, motor accuracy, and tool handling are correlated with self-care skill development.¹⁶

Dressing skills (i.e., donning shirts, pants, socks, and shoes) involve complex grasping patterns and in-hand manipulation skills to fasten and a variety of bimanual skills to manipulate the clothing. Donning jewelry requires the ability to use delicate grasp patterns and in-hand manipulation. Bathing, showering, and other personal hygiene skills depend on the child's increasing control of dynamic grasping patterns to handle slippery objects (e.g., soap). In addition, these skills are likely to be needed when an individual is in a standing position, such as when putting toothpaste on a toothbrush, brushing the teeth, shaving, or applying makeup. Youth need high competency in precision grasp, in-hand manipulation, and dynamic tool use to perform complex hygiene activities such as shaving, applying makeup, using tweezers, cutting nails, and styling hair (applying barrettes or rubber bands and using a curling iron, a brush, and a hair dryer).

Eating skills require refinement of the ability to use forearm control with a variety of grasp patterns and tools. The ability to use both hands together effectively is necessary for spreading and cutting with a knife, opening all types of containers, pouring liquids, and preparing food. In-hand manipulation skills are used to adjust eating utensils and finger foods within the hand, to handle a napkin, and to manipulate the opening of packaged food and utensils.

Typically developing children 8 years of age and older are independent in self-care skills and the manipulation skills required to perform eating, dressing, and hygiene tasks. In contrast, children with DCD and poor coordination are frequently delayed in development of dressing, personal hygiene, toileting, and independent eating skills.^{91,108} Older children with DCD perform similarly to younger typical children. Because older children with DCD demonstrate delays in self-care, parents continue to support their self-care participation by providing cues, assistance, and substitutions.¹⁰⁸

School Functions

Independent functioning in the school environment requires effective hand function and competence in fine motor skills. In preschool classrooms, children engage in a variety of manipulative activities, for example, using crayons, scissors, small

building materials, and puzzles, and participate in simple cooking and art projects. During kindergarten and the early elementary school years, children use fine motor skills most of the school day. McHale and Cermak⁸⁹ found that first and second grade children spend 45% to 55% of the school day engaged in fine motor activities. Fourth grade children spend approximately 30% of their school day participating in fine motor activities, primarily paper-pencil tasks. Writing activities include preparing one's paper, obtaining a writing tool, and using an eraser. Other typical fine motor activities in children's classrooms include cutting with scissors, folding paper, using paste and tape, carrying out simple science projects, assuming responsibility for managing one's own snack and lunch items, and organizing and maintaining one's desk.²⁸ Elementary school children also need computer and keyboarding skills to function in the classroom.

Older children and adolescents use high-level fine motor skills for science projects, vocational courses (e.g., woodworking, metal shop, and home economics), art classes, music classes (other than vocal music), managing a high volume of written work and notebooks, keyboarding, and maintaining a locker. Greater speed (e.g., in writing and keyboarding) and greater strength (e.g., for physical education and vocational courses) are required. As demands in high school increase, proficiency and speed in using keyboards, calculators, and writing utensils is expected. Children and adolescents with hand function difficulties often demonstrate limited productivity and require accommodations for written communication tasks, managing school-related materials, and manipulating learning materials.⁷

Evaluation of Hand Skills in Children

The developmental sequence provides a backdrop for evaluation of hand function. The occupational therapist evaluates a child's hand skills in the context of play, self-care, and school occupations when the evidence suggests that problems with performance are associated with delays or impairment in hand function. Based on the evaluation purpose, a variety of standardized and non-standardized assessments can be used (see [Chapter 6](#)). Parents, teachers, and the child often are the best sources of information about difficulties with participation at home and in the community; this information is obtained through the development of an occupational profile.

When a problem with occupational performance that implies hand function delays has been identified, the occupational therapist plans a full evaluation of fine motor, visual-motor, and hand function performance. To fully analyze hand function and potential reasons for difficulties, related performance areas may need to be screened and/or assessed using standardized methods. Postural alignment and stability, gross motor skills, cognitive and perceptual skills, sensory processing, social skills, and emotional functioning are associated performance areas that can contribute to hand function.

Analysis of the identified hand function problems follows administration of specific assessments or scales that define the basis of the problem and the extent of the impairment. A sample analysis of an occupational performance problem in the area of constructive play associated with delayed and impaired hand function is presented in [Box 8-1](#). The occupational

BOX 8-1 Analysis of Performance Components Potentially Associated with Delays or Impairment in Constructive Play

Occupational therapists apply clinical reasoning to analyze potential reasons for a child's delay or limitation in constructive play activities. Constructive activities vary by the child's age and may include completing puzzles, building with blocks and Legos, stacking toys, and participating in games that involve moving and combining small objects. When the basis for a child's performance delay is identified, these components can be targeted in designing play activities for intervention.

1. Delayed or limited in-hand manipulative skills may be associated with:
 - a. Unstable wrist in neutral position or extension, uses wrist flexion
 - (1) Decreased tone in wrist extensors
 - (2) Increased tone in wrist flexors
 - b. Unstable metacarpophalangeal (MCP) joints and limited stability of finger joints
 - (1) Increased tightness of extensor digitorum muscles
 - c. Inability to identify finger being touched; decreased tactile discrimination
 - d. Lack of midrange movements of finger joints
 - (1) Poor co-contraction of MCP and interphalangeal (IP) flexors and extensors
 - (2) Tightness in intrinsic muscles and long finger flexors
2. Breaking materials, often by dropping and crushing them, may be associated with:
 - a. Inability to sustain finger pad grasp; may be associated with:
 - (1) Poor tactile or proprioceptive awareness
 - (2) Poor co-contraction of muscle groups
 - b. Excessive finger flexion in grasp may be associated with:
 - (1) Poor proprioceptive awareness of size and weight of object
 - (2) Increased finger flexor tone
 - (3) Associated reactions
 - (4) Inactivity in intrinsic muscles
3. Ineffective bilateral handling may be associated with:
 - a. Weakness and limited control of movement in one arm and hand
 - (1) Unstable grasp because of poor wrist extension caused by increased flexor tone
 - (2) Learned nonuse of one hand
 - b. Delays in bimanual coordination, reciprocal and simultaneous use of two hands together
 - (1) Difficulty in motor planning of sequential, coordinated movements
 - (2) Limited or inaccurate tactile and kinesthetic feedback from arm and hand movement.
 - (3) Delays in performance of cooperative, precise hand and finger movements, possibly related to delayed somatosensory or visual motor integration.

therapist analyzes potential sensory, musculoskeletal, and neuromotor functions that may contribute to a child's difficulties in construction activities. To support analysis of the child's performance in specific tasks and interpret which sensory, motor, perceptual, and cognitive factors influence performance,

therapists administer a combination of standardized assessments. Examples of measures used in comprehensive evaluation of hand function are listed in [Table 8-3](#).

Intervention Models, Principles, and Strategies

Occupational therapists use a variety of evidence-based practice models to guide interventions to improve a child's hand function. The child's diagnosis (e.g., cerebral palsy, developmental coordination disorder), severity of involvement (e.g., mild, moderate, severe), context for intervention (e.g., clinic, home, school), service delivery model (e.g., direct, consultation), and phase of intervention (e.g., preparation, practice, generalization) influence which practice approach is used. Practice models used by occupational therapists to improve children's hand function can be categorized as biomechanical/neurodevelopmental, occupation-based, and adaptation/ecologic and are described in the following sections. These practice models, with their corresponding principles and strategies, are generally used in combination or sequentially throughout a course of interventions to improve a child's hand function.

Biomechanical and Neurodevelopmental Approaches

Practice models that focus on the child's musculoskeletal and neuromotor systems are considered to be bottom-up approaches because they focus on enhancing specific components of performance. The approaches are based on an understanding of normal movement patterns and body alignment and incorporate handling and positioning of the child to inhibit and facilitate posture and movement. The occupational therapist embeds these techniques in specific activities that promote strengthening and motor control of targeted movements. These approaches require careful, in-depth analysis of performance to identify missing, atypical, or delayed body functions that are the basis for hand function problems. Biomechanical approaches focus on the musculoskeletal system, including spinal alignment, joint alignment throughout the body, muscle tone, and muscle strength as foundational elements of a child's motor skill. In neurodevelopmental therapy, therapists use facilitation and inhibition handling techniques within activities designed to enhance the child's motor control.

Biomechanical Practice Model

The biomechanical approach or practice model is used primarily to assess and provide intervention activities that improve a child's ROM, strength, or endurance. Biomechanical approaches focus on postural alignment, joint stability and relationships, and musculoskeletal problems. For example, biomechanical principles explain the basis for tenodesis grasp (i.e., automatic finger flexion when the wrist is extended) and the relationship of intrinsic and extrinsic muscle control for grasp and in-hand manipulation patterns.

Types of Children Who Benefit from Biomechanical Approaches

Children with musculoskeletal and neuromotor disorders associated with prenatal or perinatal central nervous system lesions or anomalies often receive interventions that use biomechanical

TABLE 8-3 Comprehensive Hand Function Evaluation

Evaluation Objective	Examples of Tools
Measurement of active and passive range of motion (ROM)	Goniometer
Evaluation of strength	Observation of ADL tasks Muscle testing (modified for children) Grip and pinch strength testing Observation of strength and endurance across motor tasks
Evaluation of tactile perception/sensibility	Two-point discrimination ⁴⁰ Finger identification with vision occluded
Stereognosis	Identification of common objects with vision occluded Matching of object in hand (with hand behind barrier) to one visualized
Postural alignment and postural stability	Observation of posture when trunk is unsupported. Postural tilt with observation of equilibrium responses.
Classification of hand function to document outcomes	Manual Abilities Classification System (MACS) ⁴¹

approaches. Primary features of neuromotor disorders such as cerebral palsy are abnormal muscle tone, muscle weakness, and sensory loss. Muscle tone may be lower or higher than the normal muscle tension (e.g., hypotonia or spasticity) and is associated with shortening and tightness of muscle groups and malalignment or contracture of joints. With imbalance of muscle groups around joint structures, upper extremity joints can tighten into a position of flexion or extension that counters full hand function.

The biomechanical problems associated with hypotonia include poor postural stability that affects hand function in a seated or standing position and poor control of arms in space (i.e., when posture is unsupported). Therefore, children with hypotonia may need seating supports such as a high chair back, lateral supports, firm seating, and strapping to maintain a midline, upright posture when sitting in a chair or wheelchair to effectively use their arms and hands. When children with cerebral palsy have spasticity, they exhibit limited ROM, stiffness that restricts movements, asymmetrical postures and movements, and difficulty maintaining upright postures. Arm and hand function is often limited to small ranges of movement with reduced isolated thumb and finger movements and limited control of their arms when not stabilized on a surface. Children with spastic quadriplegia may exhibit primitive reflexes, such as the asymmetrical tonic neck reflex, and stereotypical patterns of movement (e.g., a pattern of pronation, elbow, wrist, and finger flexion when bringing hands to mouth). Patterns of hip adduction and internal rotation may dominate in the low

extremities. These movement problems are associated with poor postural alignment and significantly delayed motor skill development.

Biomechanical Model Principles and Strategies

Biomechanical approaches consider postural alignment, postural stability, the level of motor skill performance, effects of gravity, effects of the supporting surface, and the most efficient postures for functional performance. Biomechanical approaches for children with cerebral palsy and neuromotor disorders as described previously often focus on minimizing spinal asymmetries and optimizing support of posture. [Box 8-2](#) defines key concepts of the biomechanical approach. The occupational therapist often implements biomechanical techniques that support optimal function before making activity demands on the child or before need for performance. Principles and examples for the biomechanical model are listed in [Table 8-4](#).

In selecting the positioning of the child for hand function interventions, the occupational therapist must consider the optimal position for eliciting the particular skills desired, given activity demands and environmental contexts. Positions are carefully selected and optimally supported to promote the child's alignment, postural stability, and control of arm and hand movements. Supported side-lying, prone, sitting, or standing may be optimal positions to elicit and practice fine motor skills. For example, a child with significant weakness or spasticity may achieve hands-to-midline or reach only in the side-lying position. The side-lying position may reduce the effects of gravity on overall body posture and may make it

BOX 8-2 Biomechanical Model Concepts**Range of Motion (ROM)**

ROM requires joint movement and flexibility. Strength and coordination of arm movement relates to ROM, and optimal position for function is usually midrange of the joint. Joints may be limited in ROM because of muscle tightness, soft tissue contracture, or fascial restrictions.

Base of Support

The body's base of support includes the areas of the body that are in contact with the supporting surface. The center of pressure in standing or sitting depends on the characteristics of the base of support. Postural activity is initiated at the base of support (e.g., when sitting, pelvic movement allows the trunk to shift forward or laterally for reach).

Changes in the base of support influence alignment of the spine and limbs.

Alignment of the Body

The alignment of shoulders, pelvis, and feet is influenced by gravity. Body alignment reflects the interaction of gravity, postural tone, position, and supporting surfaces. Alignment of the trunk influences the possible ROM and control of head, arms, and legs.

Muscle Strength and Postural Control

The musculoskeletal system maintains posture and movement through muscle force (muscle fiber activation). Postural control requires spinal alignment, muscle tone (active muscle tension), and muscle strength.

Mobility

Movement of the body through space requires postural control, muscle strength, and muscle control.

Adapted from Adolph, K.E., Vereijken, B., & Shrout, P. E. (2003). What changes in infant walking and why? *Child Development*, 74(2), 475–497.

TABLE 8-4 Biomechanical Model Principles and Examples

Principles	Description and Examples
Optimal positioning of the child includes natural spinal alignment with trunk stable or well supported.	The child's head is aligned over the pelvis. When the child is in a prone stander, head and pelvis are aligned over the feet. A straight line can be drawn from head to feet.
Central control at shoulders and pelvis is prerequisite to control of arm and hand movement in space.	The pelvis anchors the trunk and provides a base of support for shoulder and arm movement. The shoulder and scapula complex anchor the arms' movement in space and allows for rotational movement in reach and carry.
Postural control is influenced by the child's postural tone, spinal alignment, and gravity and supporting surfaces.	When sitting square on buttocks on a firm surface, postural tone is likely to be neutral with extension against gravity dominating.
Midline position of the head, arms, and hands is optimal for most functional tasks.	Many positioning devices facilitate midline position of head and arms. Lateral supports on a wheelchair or feeder chair can guide arms to midline.
Equipment to support a child's alignment and trunk control should be firm, stable, and solid.	A firm seat such as that of a Rifton chair or wheelchair allows the child to sit in a neutral pelvic position (i.e., square on buttocks). A firm seat can prevent adduction of hips and reduce posterior pelvic tilt.
For optimal function, a child should feel stable, able to move against gravity, able to shift weight, and able to flexibly adjust his or her position when needed.	Strapping on a wheelchair should allow weight shift, movement of arms, and reach in all directions. For optimal function, the child sits with dynamic stability and can move his or her arms overhead and across the midline.
For optimal function, the child's postural tone should be relaxed, allowing him or her to actively maintain upright posture and flexibly maintain functional postural alignment.	A child's postural tone may be optimal when sitting on a firm surface, when feet are well supported, and when a midline position is facilitated. See Chapter 20 for additional information on seating and positioning.

possible for the child to more easily open his or her hands. However, side-lying positions tend to limit most hand functions, and in general children exhibit more varied and skillful hand function in supported sitting positions.

The occupational therapist can use certain body positions to elicit specific hand skills. The supine position is effective for working with infants on initial control of arm movements with visual regard of the hands during movement. Supine positioning can be used to reinforce midline movements of hands and reach against gravity; however, a supine position is not functional for most activities and is most appropriate for infants (less than 12 months). A prone position with weight bearing on

the forearms can elicit and reinforce shoulder stability and co-contraction, dissociation of the two sides of the body during weight bearing on one arm while manipulating with the other, bilateral manipulation of objects, and visual regard of the hands. By placing a child prone on a wedge, the effect of gravity is reduced, allowing for more trunk and neck extension. Prone positioning can be an advantageous position for the child to visualize his hands but limits the child's viewing of the environment. Use of prone positioning for play activities is always fatiguing and should be used only for brief periods with the occupational therapist or caregiver present to support the child's actions.

Through assessment of the child's alignment, postural control, and arm/hand control, the occupational therapist identifies and recommends positioning and seating that offer sufficient stability and mobility for optimal hand function across a range of home and school activities. For optimal hand use in sitting, the child needs a chair that provides appropriate shoulder, pelvis, leg, and foot support.^{24,113} Even young children without motor disabilities benefit from sitting in furniture that fits appropriately. Children demonstrate higher level manipulation skills when seated in chairs and at a table fitted to them than when seated in chairs and at a table that do not fit. Appropriately fitted furniture may enhance hand function by supporting proximal stability, thereby allowing the child to focus more on the manipulative tasks and less on postural readjustments.¹²⁹

To promote optimal alignment and control of hand function for children with disabilities, adapted seating and positioning may be needed. When in a seated position, the child should be able to shift weight in the anterior-posterior and lateral directions; his or her trunk should be aligned over the pelvis or leaning slightly forward; and the pelvis and shoulders should be stable. Spinal alignment with trunk stability and mobility is important to functional movement of the head and arms. Examples of adaptations for sitting, such as lateral supports, pelvic straps, pelvic stabilizers, and chest harnesses, can provide

the just-right support for a child to competently perform fine motor activities.¹¹³ In a systematic review of the effect of positioning on upper extremity function, Stavness¹²¹ found that upper extremity function was optimal when the child was in a functional sitting position with slight (0 to 15 degrees) forward orientation, a pelvic strap, footrests, and a cutout tray. Caregivers of children with cerebral palsy report that adapted seating is useful to their families and enables the child's participation in important everyday activities.¹⁰⁷ Rigby and colleagues¹⁰⁷ found that adaptive seating was particularly important to the child's ability to participate in eating, self-care, play, and recreational activities. **Case Study 8-1** illustrates use of the biomechanical approach to improve hand function in a child with spastic cerebral palsy (**Figure 8-9**).

In addition to supportive and functional seating, children with neuromotor disabilities may benefit from a wheelchair tray in supporting the upper extremity during fine motor activities. For optimal support, the tray or table surface should be only slightly above elbow height, because a lower table may cause trunk flexion and a higher surface can cause abduction and internal rotation of the arms. The tray's height can be adjusted to meet specific goals; for example, children with muscle weakness more effectively reach and carry objects when the table or tray surface is at or slightly above elbow height. With this biomechanical advantage, the child's control in manipulating

CASE STUDY 8-1 Biomechanical Model for Child with Cerebral Palsy

Zeza with Spastic Quadripareisis

Zeza was 3 years old and had severe spastic quadripareisis. She received occupational therapy each week through an outpatient clinic; she also received occupational therapy in her early childhood program. She was dependent in all of her self-care skills. Her parents fed her most meals, although she independently self-fed finger foods. She also drank from a sippy cup with handles with minimal assistance. She did not sit independently but she sat with minimal assistance when provided full back support. She used a Rifton chair in the early childhood program and is transported in an umbrella stroller. Her occupational therapist discussed with the family the purchase of a manual wheelchair that would offer her more support. Recognizing that a wheelchair, if well-fitting and adapted to her postural needs, could become a more functional sitting device at home and school, the family agree to purchase a wheelchair that would replace the stroller.

The occupational therapist with the family selected a manual wheelchair that offered features to support her posture and enhance hand function. The therapist and family selected a new chair that would facilitate Zeza's achievement of the following Individual Education Program goals:

1. Eat yogurt and other thickened foods using a spoon with enlarged handle and suction bowl with minimal support in grasping the spoon.
2. Successfully activate her iPod or CD player using a button switch on her wheelchair tray.
3. Participate in circle time songs and activities by imitating the teacher's gestures with arms and hands, turning to greet her peers, and vocalizing when appropriate.

The manual chair that the occupational therapist and family selected had the following features:

1. The back extended to the top of her head to support her head in neutral and midline.
2. A neck support helped to align her head in midline but did not prevent full head turning and neck ROM.
3. Shoulder straps that gently maintained neutral, upright trunk.
4. A pelvic strap held her buttocks against the back of the chair and maintained neutral pelvis.
5. Lateral supports helped to maintain her trunk in neutral.
6. Arm rests that supported her arms in neutral forearm and wrist positions; the arm rests also supported a tray.
7. A tray supported her arms and gave her a surface to stabilize her hand in fine motor activities.
8. A foot rest fully supported her feet with hips, knees, and ankles at 90 degrees.

The new wheelchair offered positioning that increased her function in hand function activities, including eating and use of switches. The wheelchair enabled Zeza to achieve the established objectives. In her new chair, she more fully participated in the early childhood program including circle time, story time, art, and snack. Although she did not sit in her new wheelchair all day, it was her optimal seating device for activities that required her highest level hand function. Often a child's well-fitting wheelchair, because it has adapted features that support postural alignment, gives the child a biomechanical advantage and is an optimal seating device for hand function and fine motor activities.

See **Figure 8-9** for an example of manual wheelchair.

FIGURE 8-9 This manual wheelchair provides optimal supports for a child with spastic quadruparesis to effectively participate in visual-motor and fine motor activities.

objects can increase. Another biomechanical advantage that supports hand postures for effective tool use and other hand functions (e.g., for writing or fine motor activities) is use of an elevated or slanted table or tray surface. An elevated surface, such as a slant board positioned at an angle of 20 to 30 degrees, can facilitate a hand position of wrist extension, increasing the child's control of finger flexion for grasping activities⁹² (Figure 8-10). Table 8-5 presents characteristics of optimal postural support for fine motor tasks when sitting.

For children with mild to moderate motor involvement, standing may be an appropriate position for practice of fine motor activities. Standing facilitates extension through the trunk and neck and may promote more active postural tone when compared with sitting. Many daily living skills that rely on hand skills, such as brushing the teeth, zipping and buttoning clothing, shaving, applying makeup, and cooking, are most commonly done while standing. For children who have substantial difficulties with standing, the occupational therapist should use this position only after the child has mastered the skills in a sitting position.

Neurodevelopmental Therapy

Neurodevelopmental therapy (NDT) uses biomechanical principles in addition to a range of handling and positioning techniques that promote motor function in children with cerebral palsy. Originally termed neurodevelopment treatment, NDT

FIGURE 8-10 A slanted surface for writing promotes wrist extension and active grasping patterns.

was proposed by the Bobaths in the 1960s and has been widely used by occupational and physical therapists since that time. The Bobaths were innovative in their understanding of cerebral palsy and the effects of abnormal muscle tone (e.g., spasticity) on postural control and movement. They recognized that spasticity interfered with normal movement patterns and that inhibition of spasticity was important to improving a child's movement patterns. They also believed that through sensory feedback, a child with atypical muscle tone and movement patterns could learn normal movement patterns. The goals of therapeutic handling are to inhibit spasticity, facilitate more normal muscle tone, and guide the child with cerebral palsy in using more normal movement patterns.⁶⁶

Types of Children for Whom Neurodevelopmental Therapy Principles and Techniques Are Appropriate

The NDT practice model was specifically designed for children with cerebral palsy who have abnormal muscle tone. The Bobaths characterized spasticity as tonic reflexes, muscle co-contraction, and stereotypic movement patterns and specified that an important goal of therapy was to reduce spasticity and its associated abnormal movement patterns. NDT theories and postulates have enabled occupational therapists to understand how abnormal muscle tone, primitive reflexes, abnormal movement patterns, loss of strength, and impaired muscle synergies interfere with motor control.^{66,125} By analyzing these components of posture and movement in children with cerebral palsy, occupational therapists have conceptualized new methods to improve these elements of the child's motor function.

When a child has cerebral palsy, control of arms in reach and carry; development of precise hand and finger movements; bimanual coordination; and sequential, reciprocal, fluid movement patterns are delayed, limited, or missing. Gordon and Duff^{35,57,58} described the characteristics of hand function in children with cerebral palsy, explaining that they have difficulty grading force and sustaining force during grasping, holding, and carrying objects. Children with cerebral palsy also have difficulty releasing objects with control and grading hand movements.⁶⁰ The characteristics associated with cerebral palsy and related effects on hand function are described in Table 8-6.

TABLE 8-5 Characteristics of Sitting Supports for Optimal Hand Function in Children with Cerebral Palsy, Spastic Quadriplegia

Characteristic	Rationale	Example
The pelvis is supported on a solid surface.	Solid support promotes trunk symmetry and trunk extension	Chair seat is a firm cushion or wooden surface.
The back support ends at the scapula unless shoulder and head support is needed.	Support through the scapula area can enhance shoulder stability for distal (hand) function.	Most wheelchair backs end at the scapula, although chair backs can extend to include head support.
A pelvic strap holds the pelvis in place. The pelvis is in a neutral position and the hips are at 90 degrees.	With hips at 90 degrees, the pelvis is upright or in a neutral position (without anterior or posterior tilt). A neutral pelvis supports an upright trunk.	The strap holds hips at 90 degrees with a 45 degree angle across the hips.
The chair promotes symmetric weight bearing on thighs.	Symmetric weight bearing results in symmetric posture, facilitating midline movement of arms and hand.	Chair may include hip guides. A firm seat also promotes symmetrical weight bearing.
Knees and ankles are positioned at 90-degree angles.	Solid foot support anchors the lower extremity, giving the trunk, head, and hands a firm base of support. When knees and ankles are at 90 degrees, muscle tone tends to be neutral; tension on the hamstrings is optimal; and a stable, neutral pelvis can be maintained.	Foot supports on wheelchair or other chair that angle at 90 degrees. A well-fitting chair seat that does not extend beyond knee angle.
Lateral trunk supports can provide lateral stability and increase midline alignment of trunk.	Lateral support guides the trunk but do not support or hold the trunk. Lateral supports can promote symmetry and midline.	Lateral supports on wheelchair. Lateral supports on floor sitter or other chair.
A lap tray can improve shoulder and trunk position.	A lap tray can provide a surface to support arms and hands.	Wheelchair tray.
A harness may be needed to promote an upright trunk and to guide child's weight shift when moving arms.	A harness helps the child maintain an upright and symmetric posture. When using a harness, the child should be dynamically stable (stable with mobility to move arms and hands).	When fitting appropriately, most harnesses firmly support the chest and pelvis while allowing the child to shift weight and reach.

TABLE 8-6 Characteristics of Cerebral Palsy and Associated Hand Function Limitations

Characteristic of Cerebral Palsy	Associated Hand Function Limitations
Muscle tone characterized by hyper- or hypotonicity	Limited ROM at wrist, forearm, and fingers. In hypertonicity, the finger flexors may be tight; the child cannot fully extend fingers. In hypotonicity, the joints may be hypermobile and the hand lacks stability. Over time, joints stiffen owing to limited or minimal joint movement.
Excessive co-contraction at joints (with spasticity)	Wrist, forearm, and metacarpals are stiff; wrist and finger joint movements are limited. Hand may tighten when child attempts to move fingers.
Muscle synergies are inefficient and stereotypical	Excessive thumb adduction. Flexor synergies may dominate upper extremity movement. These include shoulder internal rotation with elbow flexion, forearm pronation, and wrist flexion.
Muscle weakness	The hand may not have sufficient force to hold or move heavy objects. The hand may not generate appropriate forces to hold and use writing utensils, scissors, eating utensils.
Limited dissociated movement	Fingers move together in full flexion or extension; child has difficulty moving isolated fingers with control. Reciprocal, precise finger movements are limited. Inability to initiate or sustain thumb opposition. Intrinsic muscle action is limited.
Impaired sensory feedback	Tactile, kinesthetic, and proprioceptive feedback is limited; sensory feedback is not available to guide precise hand and finger movements

CASE STUDY 8-2 Use of Neurodevelopmental Therapy Techniques to Promote Hand Function in a Young Child with Cerebral Palsy

Susan, 5-Year-Old with Spastic Quadriparesis

Susan was currently in regular kindergarten where she received special education, occupational therapy, and physical therapy. She had a power wheelchair that gives her mobility in the classroom and school. Susan spent 20 to 30 minutes each day in her prone stander and 30 minutes twice a day in her Rifton chair. Most of the day she stayed in her power chair using the tray that supports her fine motor activities.

The occupational therapist and physical therapist often worked together to provide NDT techniques in their clinic space. The occupational therapy goals were:

1. Given minimal physical assist at her shoulder, Susan will use a spoon with enlarged handle and scoop bowl on her wheelchair to feed herself applesauce.
2. Given preparation using upper extremity weight bearing, Susan will demonstrate hand opening sufficient to turn pages of her book.
3. Given preparation using upper extremity weight bearing and trunk rotation, Susan will use her open hand to consistently activate a button switch.

Each session began with Susan lying on the mat, stretching and practicing trunk rotation. This trunk rotation was followed by weight bearing on her hands while kneeling beside a bench. She moved from tall kneeling to trunk rotation in

side sitting. She moved into side sitting to the right and left to reinforce the trunk rotation patterns. Frequently the occupational therapists placed her in a prone position over a therapy ball and rolled the ball forward to allow her to place her hands on the floor. This activity helped her develop full shoulder flexion range, equilibrium reactions in prone, and weight bearing on her hands.

After these preparatory activities, often Susan elected to sit in her Rifton chair with a tray. She practiced prehending and manipulating puzzle pieces to complete a puzzle with assistance from the occupational therapist supporting her shoulder, and she practiced using different switches to activate her favorite toys. The occupational therapist gave her graded support, that is, the just-right support that she needed to accomplish the isolated (dissociated) arm and hand movements. Although she held her hand in a more open position, she continued to demonstrate difficulty in isolating and controlling finger movements.

After the occupational therapy and physical therapy session, the occupational therapists discussed with the teacher Susan's successes in completing the puzzles and in activating the switches, noting the level of support and the position in her chair that were optimal for achieving these activities. They recommended that she continue to practice in the classroom.

Principles of Neurodevelopmental Therapy Used to Promote Hand Function

Principles of the neurodevelopmental approach have evolved since the Bobaths originated the intervention concepts. At its inception and as practiced through the 1970s and 1980s, NDT involved extensive handling by a trained occupational therapist.⁶⁶ More recently, NDT-trained occupational therapists have adopted motor learning principles and dynamic systems theories.⁶⁶ Many of the principles have been integrated into other practice models and approaches; for example, Howle⁶⁷ defines how the goals and principles of NDT and motor learning are integrated in current practice. Child goals include:

- Postural alignment and postural tone that allows fluid transitional movements through a variety of positions
- Improved foundational postural stability to support optimal hand function
- Efficient weight shift and equilibrium responses in upright positions
- Improved control of isolated and dissociated extremity movements
- Enhanced mobility and dynamic stability within and between body positions

Occupational therapists implement NDT techniques to inhibit spasticity and primitive reflexes and facilitate normal movement patterns. Specifically, the occupational therapist uses sensory input such as deep pressure and upper extremity weight bearing with the spine and body in good alignment. These techniques facilitate postural tone to increase dynamic stability, that is, postural tone that supports movements through different planes (e.g., lateral weight shifts when sitting or rotational

movements in a quadruped position). Specialized handling of children with cerebral palsy is believed to allow the development of new patterns of more normal movement and provide the basis for ongoing motor skill development. [Case Study 8-2](#) explains how the NDT approach can be applied to improve a child's development of hand function.

Postural stability is important to hand function, and a child's ability to control isolated movements of fingers, thumb, and hand arches requires a stable base of support that allows these precise and coordinated movements. Stability of all proximal structures—the pelvis, trunk, shoulders, elbow, forearm, and wrist—allows these fine hand movements. Occupational therapists facilitate postural tone through therapeutic handling at key points (most often, the shoulders and pelvis). By handling in a play activity, the occupational therapist guides the child through small weight shifts and movements in different planes that specifically activate or modulate postural tone. When a child learns to control weight shifts and equilibrium responses, he or she may gain improved control of arm movement for reach and bimanual tasks. The occupational therapist primarily facilitates rotational patterns of movement as the basis for normal movement patterns. For example, the occupational therapist can facilitate slow rotary movements in small ranges of motion in shoulder rotation and forearm pronation and supination to inhibit the child's arm tone before implementing a fine motor activity.

Weight bearing on hands during intervention activities is particularly useful for improving postural control and improving stability in the scapulohumeral area ([Figure 8-11](#)). The occupational therapist can also use upper extremity weight bearing to encourage the child to maintain elbow co-contraction

FIGURE 8-11 Weight bearing on hands improves shoulder and arm stability. It also promotes wrist extension and, for certain children, finger extension.

FIGURE 8-12 Weight bearing on forearms or hands can be practiced using functional activities. This child maintains an upper extremity weight-bearing position on his affected arm while engaged in a computer tablet activity.

and wrist extension.¹⁰ Depending on the child's skill level, the occupational therapist can carry out weight-bearing activities with the child in a prone position on forearms, a prone position on extended arms, or a side-sitting position (Figure 8-12).

For the child who has tightness in wrist flexion, a position of upper extremity weight bearing on hands with the arms extended may be difficult, if not impossible, to achieve. The most appropriate positions for children with wrist tightness to use for weight bearing include prone on the forearms and side-lying. If the child's thumb is tightly adducted and flexed, the occupational therapist can apply firm pressure over the first MCP joint and use slow, small, rotary movements to relax the child's hand before this activity.

Important functional outcomes of NDT include improved control of isolated arm, hand, and finger movements required in manipulation and bimanual activities.¹²⁵ For example, often children with cerebral palsy lack control of supination and forearm muscles can be spastic. Active supination is easiest to

perform in an elbow flexed position, and the child can first practice active supination in activities that position the elbow in greater than 90 degrees of flexion (e.g., eating finger foods, donning dress-up hats, and putting lotion on the face). Supination of 90 degrees or more is needed to accomplish functional activities such as drinking, eating with utensils, or turning a doorknob.

As noted above, manipulation is often optimal when the child is positioned with good postural stability and support, including support of shoulder stability and a working surface that fully supports forearm and hand. The MCP joints (i.e., the palmar arch) can be key points of control to promote isolated fingers movements. The occupational therapist may offer support of palm at the MCP joints as the child practices activities that specifically require isolated movements in a supportive surface.¹²⁵ Games that include grasping chips, marbles, small boxes, or pick-up sticks provide practice of isolated finger movement. The occupational therapist may handle the child during these activities by supporting the shoulder, guiding the wrist into extension, supporting the palmar arch, or guiding the forearm into supination.

Research of Neurodevelopmental Therapy Related to Hand Function Interventions

Although understanding of cerebral palsy and diagnoses in which muscle tone and function are impaired has increased because of Bobath's work and that of NDT-trained therapists, the trials of NDT principles and handling techniques have not demonstrated strong efficacy. NDT handling techniques by occupational therapists were examined in two randomized trials by Law and colleagues in the 1990s. Neither study found support for NDT in improving the hand function of children with cerebral palsy more than regular (usual care) intervention. In the second trial the preschool children received more NDT sessions than regular occupational therapy but did not differ in hand function or quality of movement after the interventions.⁷⁹ Both groups made significant gains in hand function. Three systematic reviews^{11,20,94} synthesized the research evidence for NDT and concluded that NDT does not appear to result in positive benefit and functional improvement in children with cerebral palsy. Of 15 studies, Novak found only three that demonstrated benefit from NDT and concluded that the evidence does not support NDT for improving contractures, muscle tone, or functional outcomes. These studies suggest that the specific handling techniques used in NDT may not result in significant improvement in motor function, and use of NDT techniques in occupational therapy should be carefully monitored and evaluated to determine if the child is benefitting and making expected progress.

Despite lack of evidence, the principles introduced by the Bobaths have deepened therapists' understanding of cerebral palsy and disorders that include muscle tone impairments. As explained by Howle,⁶⁷ certain NDT practices translate to other practice models and have validity through clinical practices with children with cerebral palsy. Therapists recognize the importance of enhancing postural stability as the child's base of support for control of hand function. The occupational therapist can provide activities and handling that inhibit stereotypic movement patterns or reduce joint stiffness. The goals that were originally identified within the NDT practice model are often achieved in current practices through positioning and

seating, Botox or baclofen treatments, electrical stimulation, practice opportunities, and motor learning techniques.

More recently developed practice models are based on learning and behavioral theories. These models have emerging evidence of effectiveness and translate well into occupation-based interventions. Efficacious practice models, such as motor learning, that use occupation-based theories are described in the following section.

Occupation-Based Approaches

Occupation-based approaches emphasize the interaction of person, environment, and occupation and use holistic methods to support the child's skill development. Using this approach, an occupational therapist selects and creates activities that facilitate the child's functional performance by considering (1) the child's motivation and interests; (2) the context of performance, including activity demands, constraints, and natural supports; and (3) the child's performance strengths and limitations. The interaction of child, environment, and occupation determines how well and at which developmental level the child participates in play, mobility, social relationships, and ADLs. Interventions may focus on any or all of these variables, and in typical practice the focus shifts among them. Occupation-based models are congruent with dynamic systems theories (see Chapters 2 and 7) in understanding the multiple child-related and context-specific variables that influence performance. Key to these approaches is appreciation of meaningful and preferred play occupations, particularly social play, as the context for intervention and the context for much of the child's learning and development. Two practice models that reflect occupation-based approaches to improve children's hand function are (1) motor learning and (2) pediatric-constraint induced movement therapy. Two other occupation-based models are frequently used to promote children's hand function: Cognitive Orientation to daily Occupational Performance (CO-OP) and occupational therapy using sensory integration (OT-SI). CO-OP is described in Chapter 10 and OT-SI is explained in Chapter 9; therefore these practice models and associated strategies are not described in this chapter.

Motor Learning Practice Model

Motor learning is an occupation-based approach that helps the child achieve motor goals using problem solving, practice with reinforcement, whole task activities, and refinement of skill in everyday activities.¹⁸ Using motor learning principles, the occupational therapist assists the child in acquiring motor skills through structured activities, practice of targeted skills, and specific types of feedback. The occupational therapist selects the type of practice and feedback based on the child's level of performance and response to intervention. Using the child's interest to guide activity selection, the child is engaged in meaningful whole tasks that have embedded targeted movement patterns. Through practice of these activities with reinforcement that specifically guides the child's learning, the child masters new skills.

Types of Children Who Benefit from Motor Learning Approaches

Because motor learning approaches are based on general learning theories, many types of children can participate in and benefit from this practice model. Children who have aptitude

to follow a model or instructions, engage in repetitive practice, and understand specific, descriptive reinforcement can benefit from motor learning interventions. Although infants may have difficulty staying engaged and repeating action, most preschoolers and older children are easily motivated to engage in activities with high repetition and some challenge.

Application of motor learning approaches and principles has been examined in children with developmental coordination disorder,⁹⁰ children with cerebral palsy,⁷³ and adults with brain injury.⁸⁷ Interventions that explicitly access learning principles appear to be effective in promoting hand function for children with developmental coordination disorder.⁹⁰ Mastos and colleagues⁸⁷ studied the effects of goal-directed therapy using motor learning principles on individuals post brain injury. The two participants met their goals using task-oriented therapeutic practice that included whole tasks, repetition (intense practice), and structured feedback. In a randomized controlled trial, children with cerebral palsy, including those with hemiparesis, diplegia, and quadriplegia, made gains in functional performance following 6 months of physical therapy using a functional program that included motor learning principles.⁷³ Although this trial's primary focus was on gross motor skills, the children, most of whom had upper extremity impairments, improved in self-care, suggesting improvement in hand function. Using case reports, Eliasson³⁶ explained how the complexity of hand function in children with cerebral palsy warrants holistic approaches such as occupation-based and motor learning models. These models incorporate the multiple variables that she identified influence hand function, that is, self-efficacy, attention, cognition, motivation, sensorimotor systems, perception, and musculoskeletal/biomechanical structures. The case reports^{36,73} and small trials suggest that motor learning models can have positive effects on hand function in children and youth with a variety of diagnoses.

Motor Learning Principles and Techniques

Motor learning theories posit how children develop motor skills in the course of daily activity¹³² and include both foundational theories that explain how children learn movement and transformational principles that form the basis for intervention principles and strategies. For our purposes, foundational motor learning theories are (1) schema theory, (2) dynamic systems theory, and (3) stages of learning. These basic concepts about motor development and learning provide a context for designing interventions and are briefly described below. They are further explained in this chapter and in Chapter 2. Schema theory defines how a child learns movement patterns by building new movements on established motor patterns.^{116,132} To improve efficiency of learning and to allow automatic movements, humans use similar movement patterns repeatedly, albeit with variation and flexibility, to accomplish everyday tasks. For example, similar movement patterns are used to brush teeth, comb hair, and wash the face. Dynamic systems theory and occupation-based theories recognize how multiple variables in the child, the activity, and the environment influence performance. When interventions use motor learning theories, constraints and resources of environment, activity demands, and child strengths and limitations are considered and purposely manipulated to promote new learning and skill development.

The child's stage of learning (i.e., cognitive, associative, or automatic) also provides a foundation for selecting an appropriate intervention activity and planning how to elicit and support

TABLE 8-7 Principles and Examples of Motor Learning Theory

Principle	Application
Learning a whole motor task is more effective and motivating than learning part of a movement.	Whole motor tasks can provide the child with a meaningful goal, sustain his or her attention, and become the context for repetition.
A meaningful, preferred activity is selected.	When a preferred activity is selected, the child is more likely to remain engaged. ⁶¹
Frequent, repetitive practice is required to learn new motor skills.	Children must practice motor actions repeatedly to reach the automatic stage of learning. Generally, the number of repetitions required is underestimated. For example, children take thousands of steps with supports before they achieve independent ambulation ³ (Adolf, Vereijken, & Shrout, 2003). Practice is equally important for learning hand functions.
Practice should include variability and should be distributed across time	Children retain more when motor practice is varied within the context of the activity. This generally happens naturally when building a structure, playing a game, or performing ADLs.
The occupational therapist provides structured reinforcement that includes specific feedback about performance.	Specific feedback reinforcement learning by increasing the child's understanding of his or her performance. "You reached higher that time!" "You made a perfect letter B."
Feedback or reinforcement is provided frequently and consistently.	Children appear to perform best when they receive consistent reinforcement. ¹²²
Specific activities are structured to support transfer of learning to a variety of natural environments.	Learning of specific motor skills in a therapy session may not generalize to natural environment and varied contexts. Therapists encourage practice of new skills in a variety of environments with supports as needed. Caregivers and teachers reinforce the child attempting new motor skills in a variety of environments.

practice of the child's highest level skills. Understanding these stages helps the occupational therapist identify the next step in the child's learning and select appropriate challenges and supports for each stage.^{18,52} In the cognitive stage of learning the child is highly attentive to the activity, learning how to approach it, often using trial-and-error to develop a strategy for accomplishing the activity goal (e.g., creating a bridge out of Legos). In the associative stage of learning, movements are less variable and the child refines the movements that accomplish the goal. In the automatic stage, the child practices his or her skills with less cognitive effort and less attention required. Performance that is automatic (e.g., putting on a coat, opening a jar) allows people to perform efficiently and attend to meaningful goals. The stages of learning also suggest that learning processes extend over time, requiring repeated practice in varied environments.

The transformation principles used to design motor learning interventions are listed in [Table 8-7](#) with examples. These principles define how to select intervention activities, structure practice and reinforcement, and help the child generalize new motor skills. To apply motor learning principles to occupational therapy intervention, first the occupational therapist selects a meaningful goal-directed activity that is preferred by the child. The activity selected allows practice of movements that are missing, delayed, or difficult for the child and a just-right challenge for his or her emerging hand functions. For example, a therapist may select building a train track with a 4-year-old child who has unilateral cerebral palsy. Fitting together train track pieces requires two hands working together with precision grasp, stable wrists, and forearm supination. Pressing the train track pieces together using weight bearing on hands requires shoulder strength and bimanual coordination ([Figure 8-13](#)). The child selected this activity because he loves trains

and wanted to build an entire track to show his father. Building the track required 22 repetitions of placing pieces together, naturally requiring repetition. Therefore this activity exemplifies a good choice using motor learning principles. [Case Study 8-3](#) illustrates use of motor learning principles with a child with cerebral palsy.

Repetition and practice are important to establishing and retaining new motor skills and hand functions.³⁶ Therefore, eating activities and toys and games with many pieces can be particularly useful and enjoyable for developing precision grasping skills ([Figures 8-14](#)). Eating is often motivating and if designed to provide the just-right challenge, for example, using a spoon with a new food (such as blueberries) that is challenging to scoop, the child will engage in the challenging activity repeatedly. The occupational therapist reinforces the child's actions and praises how she is holding the spoon and scooping blueberries onto the spoon.

Although children with cerebral palsy can acquire new hand function, including more precise grasp and release, they require more practice than do typically developing children.⁵⁷ Research has demonstrated that as children with cerebral palsy learn new skills, each stage of learning (i.e., cognitive, associative, and automatic) takes longer and requires more practice than these learning stages require for typical children.^{36,37}

For children with autism spectrum disorder (ASD) or DCD, hand function goals may include managing fasteners to dress independently each morning or legible handwriting for school assignments. Because children with ASD or DCD often struggle with higher level hand function, such as in-hand manipulation and bimanual coordination, one component emphasized in designing intervention activities are tasks that facilitate in-hand manipulation skills. [Box 8-3](#) lists examples of specific activities that can be incorporated in games, ADLs, and play to

FIGURE 8-13 This child with unilateral cerebral palsy puts together the train cars and places them on the track. This activity inherently has repetition and requires bimanual skill.

CASE STUDY 8-3 Use of Motor Learning Principles to Improve Hand Function

Simon: Use of Motor Learning Principles with Child with Hemiparesis

Simon was 4 years old and had right hemiparesis cerebral palsy following preterm birth and a grade III intraventricular hemorrhage. He was bright and cooperative, although he struggled to use his right hand and typically performed activities using only his left hand. Simon's father was an airplane pilot, and Simon loves airplanes and airports.

Simon's occupational therapist provided services in the home. In this session Simon and the occupational therapist decided to build an air control tower that included a garage for airplanes to trolley through and park for repairs. They used medium-sized Legos that required firm fingertip grasp with stable wrist and arm to fit the pieces together. The occupational therapist assisted Simon intermittently in fitting pieces together and allowed him to sometimes press them together using one hand with the Lego stabilized on the floor surface. The tower required that 40 Legos be pressed together; it required 30 minutes to complete the tower with the occupational therapist providing some assistance with stabilizing the

Legos and giving frequent reinforcement and encouragement. As the tower became taller, Simon did not have a supporting surface and was challenged to hold both arms in space. The occupational therapist suggested ways to place the Legos to make the task easier when he observed that Simon was fatiguing and to make the task more challenging when he wanted to push Simon to the next skill level.

The 30-minute activity was fatiguing but Simon remained engaged because the occupational therapist was encouraging and airports were a favorite activity. He knew that when the air control tower was completed, he could play with his airplane, driving through the port at the base and flying by it.

When the air control tower was completed, the occupational therapist discussed with Simon's father how to use Lego activities to encourage bimanual hand skills. The father planned to build another tower with Simon that weekend, to continue his practice and to generalize his skills to play with partners who would offer different levels and types of reinforcement. See [Figure 8-11](#).

promote in-hand manipulation. The occupational therapist can guide and support repeated practice of dressing skills in pretend dress-up play, doll dress-up, or morning dressing. Because dressing most often occurs with caregivers, the occupational therapist recommends to parents how to arrange dressing tasks

to promote success and how to motivate the child to practice the tasks (e.g., fastening) that are most difficult.

Handwriting is also a frequent goal for children with ASD or DCD. Denton et al.³⁴ found that intensive handwriting practice was more effective in promoting handwriting legibility

FIGURE 8-14 This child completes a two-hand activity of cutting play fruit with a plastic knife. The occupational therapist suggests which hand should hold the knife and helps him position the knife and fruit for success. Associated movements suggest that the task is a challenge for this boy.

than practice of sensorimotor performance components. Case-Smith et al.¹⁹ also used motor learning principles to enhance handwriting legibility in first grade students. They incorporated handwriting practice into meaningful activities (e.g., small group activities with playful, social elements) and encouraged peer supports. The occupational therapist and teacher team structured handwriting practice, provided immediate reinforcement, solicited peer feedback, and guided transfer of handwriting skills to writing tasks. These learning strategies resulted in significant improvement in handwriting legibility when compared with traditional handwriting instruction.¹⁹

For children with mild delays in hand function who have limited in-hand manipulation, games and crafts with small objects and dynamic use of tools (e.g., scissors) can be used to practice, reinforce, and gain control of isolated finger movements. The occupational therapist selects manipulative tasks that require practice of dissociated movements, translation of small game pieces in and out of the hand, and rotation of small objects within the hand.⁴⁴ Games with marbles, pick-up sticks, or chips require that children practice and repeat in-hand manipulation. Children often experience more success when their hand is stabilized on a surface. As skills progress they should be encouraged to manipulate objects without the forearm and wrist supported. Table 8-8 lists games and activities that can be practiced to develop dynamic grasping

patterns and in-hand manipulation skills for children with developmental coordination disorder or mild delays in hand function.

Motor Learning Research

Motor learning interventions have been researched in adults⁸⁶; however, few studies of motor learning interventions for children have been published. In a descriptive study, Eliasson³⁶ explains how to design interventions that incorporate motor learning principles, using examples of tasks for children with cerebral palsy. Using case reports, she explains how to structure meaningful, child-selected tasks, elicit distributed practice, and provide reinforcement. Each case demonstrated qualitative improvement in hand function.

Several group comparative studies of motor learning principles have been completed. In a study of “neuromotor task training” in which motor learning principles were applied to children with DCD, therapists were trained to teach children whole motor tasks by giving explicit instruction, sharing specific information about the child’s performance, and providing feedback when the task was completed.⁹³ The children who received this intervention improved more in motor coordination and gross motor function than children who received no intervention. In a second study of children with DCD who received a task-oriented treatment program using motor learning principles, the intervention group improved more in

BOX 8-3 In-Hand Manipulation Activities That Can Be Embedded When Using Motor Learning Principles

Preparation Activities

- Activities involving general tactile awareness (easily repeated, generally not a skill challenge)
 - Using Crazy Foam
 - Using shaving cream
 - Applying hand lotion
 - Finger painting
 - Activities involving proprioceptive input (increases cocontraction, strength, endurance; easily repeated)
 - Weight bearing (e.g., wheelbarrow, activities on a small ball)
 - Pushing heavy objects (e.g., boxes, chairs, benches)
 - Pulling (e.g., tug-of-war)
 - Pressing different parts of the hand into clay
 - Pushing fingers into clay or therapy putty
 - Pushing shapes out of perforated cardboard
 - Tearing open packages or boxes
 - Activities involving regulation of pressure
 - Rolling clay into a ball
 - Squeezing water out of a sponge or washcloth
 - Pushing snaps together
 - Activities involving tactile discrimination
 - Playing finger games and singing songs
 - Playing finger identification games
 - Discriminating among objects or textures by manipulating with vision occluded
-
- #### Specific In-Hand Manipulation Activities
- Translation (fingers to palm)
 - Prehending coins from a container
 - Hiding pennies in the hand (magic trick)
 - Crumpling paper
 - Picking up small pieces of food
 - Taking chips attached to a magnetic wand
 - Picking up pegs or paper clips for use in a game or craft
 - Picking up several utensils one at a time
 - Translation (palm to fingers)
 - Moving pennies from the palm to the fingers
 - Moving game pieces to place onto a game board
 - Moving small food items into the mouth
 - Holding several chips to put on a wand
 - Handling money to put it into a coin bank
 - Shift
 - Turning pages in a book
 - Picking up sheets of paper, tissue paper, or dollar bills
 - Separating playing cards
 - Stringing beads (shifting string and bead as string goes through the bead)
 - Shifting a crayon, pencil, or pen for coloring or writing
 - Shifting paper in the nonpreferred hand while cutting
 - Playing with Tinker Toys (long, thin pieces) or pick-up sticks
 - Adjusting a spoon, fork, or knife for appropriate use
 - Holding a pen and pushing the cap off with the same hand
 - Holding chips while flipping one out of the fingers
 - Holding fabric in the hand while attempting to button or snap
 - Simple or complex rotation (depending on object orientation)
 - Removing or putting on a small jar lid
 - Putting on or removing bolts from nuts
 - Rotating a crayon or pencil
 - Removing crayons from the box and preparing for coloring
 - Rotating a pen or marker to put the top on it
 - Rotating toy people to put them in chairs, a bus, or a boat
 - Rotating a puzzle piece for placement in the puzzle
 - Feeling objects or shapes to identify them
 - Handling construction toy pieces
 - Turning cubes that have pictures on all six sides
 - Constructing twisted shapes with pipe cleaners
 - Handling parts of a small-shape container while rotating the shape to put it into the container
 - Holding a key ring with keys, rotating the correct one for placement in a lock

TABLE 8-8 Examples of Activities That Promote Hand Function in Children 3 to 8 Years Old

Activity	Child Goal	Specific Hand Functions Targeted
Basket weaving Repetition of pulling yarns through basket frame	Make a basket for mother; share yarn colors with friends	In-hand manipulation simple rotation as child moves basket while pulling through yarn
Sponge painting	Create colorful painting using small sponges, making favorite animals	Precision grasp of sponge, carry of sponge; translation when prehending sponge
Nuts and bolts	Make box with nuts and bolts around top; make design with nuts and bolts	Rotation and translation
Eye dropper painting	Make multicolor painting for parents or for holiday	Precision grasp, precision release
Cleaning the white board with water spray	Helping the teacher with classroom cleanup	Isolated finger strength and coordination to operate spray bottle
Perfection game	Play with peers; social elements promote motivation and effort	Translation to move piece in and out of hand; precision placement; precision release, repetition
Tissue paper mural	Create a mural for classroom with peers, tearing small pieces of tissue paper and pasting to a large piece of paper	Precision grasp; hand strength, bimanual hand skills

handwriting, dexterity, and ball skills performance when compared with a control group.¹¹⁸

In a study of typical children, Sullivan, Kantak, and Burtner¹²² provided different frequencies of feedback as children learned a task involving arm movements. Compared with adults who perform optimally with intermittent feedback, the children performed optimally with continuous feedback and required longer periods of practice. This emerging but promising research evidence supports the use of motor learning principles to improve hand function in children with a variety of diagnoses.¹³²

Pediatric Constraint-Induced Movement Therapy

Pediatric constraint-induced movement therapy (P-CIMT) is a well-researched, widely used intervention for children with hemiparesis cerebral palsy (i.e., unilateral cerebral palsy). P-CIMT evolved from constraint-induced movement therapy for adults post stroke, which was originally developed and researched in the 1980s.^{95,130} Research applying CIMT to young children with cerebral palsy emerged after 2000 with studies in New York, Alabama, and Sweden.^{22,29,42} Currently many variations of P-CIMT have been studied, and virtually all studies have produced positive effects on hand function in children with unilateral cerebral palsy. The core elements of P-CIMT are (1) constraint of the child's less impaired upper extremity, (2) selection of activities and techniques to elicit specific movements of the more impaired arm and hand, (3) high intensity intervention with repetition of targeted movements, (4) sessions in the child's natural environment (note: sessions are sometimes held in clinics, hospitals, or schools), (5) systematic reinforcement that directs the child to attempt higher level skills or demonstrate increased strength and endurance, and (6) transfer of the intervention program to caregivers and the child's daily routines. Although constraint is an essential part of P-CIMT, virtually all programs include sessions without constraint (most often in the final weeks or days of the intervention) that emphasize integration of bimanual skills. The variations of these essential components are explained in the following sections.

Types of Children Who Benefit from P-CIMT

P-CIMT was originally developed for children with hemiparetic cerebral palsy and hemiparesis caused by acquired brain injury.⁷² Research findings suggest that P-CIMT is successful with children across age groups (15 months to 20 years).^{66,103} Eliasson et al. found that older children improved more with P-CIMT than younger, but this finding has been inconsistent across studies, with most showing no difference in improvement based on age. Recent studies have shown benefits for infants with unilateral cerebral palsy.⁸³ Although practitioners recognize that neuroplasticity is greatest in infancy, certain scholars are concerned about use of constraint at early stages of bimanual development; therefore, careful monitoring for potential negative effects is warranted when applying P-CIMT to infants less than 12 months.

One rationale for using P-CIMT with infants is the potential to prevent the phenomenon of “developmental disregard.” Developmental disregard refers to a pattern observed in children with congenital hemiparesis in which they neglect their affected arm and hand.^{31,103} This pattern seems to evolve from repeated experiences when the child attempts to use the hemiparetic hand and fails to achieve his or her goal. Therefore,

early on in development the child learns adapted techniques for accomplishing his goals by using only the skillful or unaffected arm and hand. Intervention such as P-CIMT that can promote and help integrate bimanual skills during infancy may prevent this pattern of disregard.

P-CIMT has been used with children with a wide range of impairment (i.e., severe to moderate) with equivalent benefit across level of involvement. Citing one exception, DeLuca et al.³⁰ found that children with dystonia did not improve with P-CIMT and suggested that children with dystonia may not benefit from P-CIMT. Because a child with dystonia has very poor control of extremity movement with fluctuating tone, gains with intervention may be limited, and such a child may benefit most from adapted techniques and assistive technology.

In recent examples, occupational therapists have implemented P-CIMT with children recovering from brachial plexus injuries. In two case reports, P-CIMT was applied to children with Erb-Duchenne palsy (brachial plexus injury with impairment to spinal nerves C5 and C6 resulting in paralysis of shoulder muscles, elbow flexors, and forearm supinators).^{115,124} In Santamato et al.¹¹⁵ the children (age 6 and 7 years) had contractures and were treated with botulinum toxin injections before the P-CIMT program. Both studies reported significant improvement in arm movement and hand function with P-CIMT, suggesting potential benefit for children with brachial plexus injuries.¹⁰⁶

P-CIMT Principles and Strategies

As noted, a feature of P-CIMT is use of constraint of the child's less affected or unaffected upper extremity. Researchers and practitioners have used different types of constraints, including mitts,²² splints inserted into gloves, slings,¹ and full arm casts.¹⁹ Although the effects of constraints cannot be compared across studies, the principles supporting type of constraint are distinctly different. When splints and mitts are used, the child wears these forms of constraint only during the intervention sessions. In P-CIMT using full-arm casts, the child wears the cast continually (i.e., full time), “forcing” him or her to primarily use the affected arm and hand throughout the day and beyond the intervention session (Figure 8-15).

FIGURE 8-15 In P-CIMT often a full arm cast is used as the constraint. The child wears a typical CIMT full-arm cast.

TABLE 8-9 Pediatric Constraint-Induced Movement Therapy (P-CIMT) Principles and Strategies

Principle	Explanation and Examples
Intervention takes place in the child's natural environment.	The child's home is a comfortable environment for intensive practice of skills, allows selection of meaningful and preferred activities, and allows easy engagement of the caregiver in the intervention sessions.
The child's less-affected arm and hand are constrained.	Constraints include mitts, splints, slings, gloves, or casts. A full-arm cast limits sensorimotor input to the less affected arm, potentially inhibiting brain activity in the nonimpaired hemisphere.
The occupational therapist guides intensive practice or targeted movements in whole tasks.	The occupational therapist encourages the child to repeat specific, targeted movement patterns in meaningful (fun) play activities and family-selected self-care activities.
The occupational therapist encourages the child to master emerging skills or the just-right challenge.	Using a process termed "shaping," the occupational therapist encourages the child to attempt challenging skills, reinforces the child's efforts, reinforces repetition, monitors performance, and guides activity to refine movement patterns.
The occupational therapist uses reinforcement that is specific and positive and supports the child's learning about performance.	The occupational therapist uses immediate reinforcement (i.e., praise) that encourages sustained performance, guides higher level performance, and results in skills refinement.
The occupational therapist collaborates with the parents in establishing goals, assessing and monitoring the child's progress.	The occupational therapist establishes goals with the caregiver at the initiation of the P-CIMT program. The goals are assessed and monitored routinely (e.g., each week). Formal communication methods are established to communicate the child's performance during therapy sessions and at home after therapy sessions.
The occupational therapist transfers the intervention program to the caregiver.	At the conclusion of the P-CIMT session, the occupational therapist develops a home program that extends the original goals and suggests activities that encourage the child's practice of bimanual skills and the next developmental steps.

Emerging evidence suggests that by inhibiting sensorimotor functions of the less affected arm and hand for an extended period (e.g., 3 weeks), the brain may reorganize. A neuroimaging study found that inhibiting the unaffected hemisphere was associated with activation in the impaired hemisphere.¹²³ The slowing of neural input to the unimpaired hemisphere may allow the development of new pathways within the impaired hemisphere.¹⁸ Although emerging evidence from imaging studies suggests benefit¹²³ and the full-time full arm cast results in more practice with the affected arm and hand, it may reduce opportunities for bimanual integration during the intervention period. Some researchers believe that intensive, highly structured bimanual interventions in which the child is not constrained better align with the goal of increasing bimanual function. Intensive bimanual interventions,⁶¹ when provided with high structure, appear to be as effective as P-CIMT.⁶²

Most often P-CIMT is provided in an intensive (3-6 hour) daily program of 2 to 4 weeks.¹⁰³ Short-term, intensive occupational therapy services allow the child and family to focus on specific functional goals, engage in daily goal-directed practice, and assess intervention outcomes. Pediatric hospitals and clinics across the United States are implementing short-term intensive occupational and physical therapy services as a service delivery model that may be more effective, more accountable, and more family-friendly than continuous (year round) weekly therapy services. Short-term, intensive P-CIMT has resulted in significantly improved hand function and bimanual hand use with sustained outcomes at follow-up.¹⁹

The occupational therapist incorporates both motor learning and shaping techniques in the P-CIMT sessions. These

principles that guide intervention with example strategies are presented in Table 8-9. After analysis of the missing or impaired components of arm and hand movements, the occupational therapist designs play and social activities that elicit and provide a context for practice of specific hand functions. With sessions of 2 to 3 hours, the occupational therapist can select meaningful activities that may require many steps to complete (e.g., making muffins, building a castle of Legos, a morning dressing and bathing routine). The child repeats targeted movements within the play or self-care activity that are reinforced by the occupational therapist's praise, descriptive feedback, and encouragement. The occupational therapist prompts and cues the child to attempt movements that are higher level (e.g., to reach higher, supinate more, grasp multiple pieces). Using continual activity analysis, the occupational therapist judges when the child needs supports or encouragement and when the child can be further challenged. The intervention sessions provide continuous cycles of (1) selecting an activity that presents a motor challenge (elicits the targeted movement), (2) observing the child's performance, (3) reinforcing the child's performance, (4) encouraging the child to repeat the action, and (5) monitoring how the child refines the movement pattern.³⁰ For example, during the bimanual intervention phase the occupational therapist designs a folding, cutting, and pasting activity that includes easy shapes and more difficult shapes to cut with scissors. The occupational therapist initially helps the child stabilize the paper, then encourages the child to stabilize it. The child is positioned at a table for the activity; however, the occupational therapist encourages the child to cut without using the table as a support, facilitates movement of

FIGURE 8-16 Bear crawling on carpet allows more weight bearing on hands than does the quadruped position. The occupational therapist demonstrates and joins in the race.

the affected arm into different planes, and encourages active supination. The occupational therapist increases or fades out supports depending on the complexity and challenges inherent in each cutting and folding task.

For young children, scooping and eating with a spoon can be challenging and is naturally repetitive. Eating can be a motivating activity with multiple steps that the occupational therapist can grade to challenge the child's current skill level. Crawling through the living room over carpet and pillows elicits wrist extension, open hand (finger extension), and shoulder external rotation (Figure 8-16). Sustained crawling requires upper extremity stability and strength. The carpet texture may be beneficial to children whose hands are hypersensitive to touch. Crawling games can include siblings, can be extended by playing hide and seek, can provide a break from intensive practice of grasp in fine motor activities, and are appropriate across age groups.

Although P-CIMT is provided in clinics and outpatient hospital settings, Ramey et al.¹⁰³ recommend that therapists provide the sessions in the child's home and other natural environments. Services in the home with parents present during some or most of the sessions promote easier transfer of learning. Using the child's own toys and objects ensures that he or she can continue to practice new skills after the intervention session. The occupational therapist can model techniques that elicit the child's highest level skills (Figure 8-17). Parent education is an essential element of P-CIMT. Parent education is most likely to result in behavioral change when (1) the occupational therapist first develops a positive relationship with the family; (2) the parents' learning styles and motivation are considered; (3) the family's routine and time demands are considered; and (4) the occupational therapist is responsive and sensitive to the family's needs and priorities. When services are provided in the home, the occupational therapist can model for the parent, interact on a regular basis, discuss the child's progress, and provide education about the intervention according to the pace that is most comfortable for the parent. [Case Study 8-4](#) describes P-CIMT for a child with unilateral cerebral palsy.

P-CIMT Research

Since 2000, more than 50 studies of P-CIMT have been published. Research has been completed in more than 10 countries,

FIGURE 8-17 This child demonstrates his emerging strength and highest level skill using two hands to lift his Lego construction.

suggesting that this intervention has been broadly adopted. Although almost all studies have shown that P-CIMT has positive effects on hand function for children with unilateral cerebral palsy, the studies have been criticized for lack of follow-up measures and differences in intensity between the intervention and control groups that may account for differences in

CASE STUDY 8-4 P-CIMT for a Child with Unilateral Hemiparesis

P-CIMT Camp

Many hospitals and clinics offer P-CIMT during the summer using a camp model with groups of children with hemiparesis cerebral palsy participating. Examples of camps are those with specific themes, such as a rock 'n' roll P-CIMT camp or one that is held outdoors and includes many adapted outdoor activities (e.g., scavenger hunts, boating, animal exploration, obstacle courses).

Camps offer many positive social elements, making it easy to create fun activities while promoting shaping and repetitive practice. Once an age range is selected, the types of activities can be selected. Most camps offer all-day activities that include eating, social activities, fun yet challenging activities, and housekeeping activities. For example, using a rock 'n' roll theme with children 8 to 12 years, the camp provides dancing, singing, playing musical instruments, making collages of rock 'n' roll images, and performing for families. These fun activities are scheduled before and after preparing and eating lunch with cleanup.

A preschool camp may include a Disney theme with pretend play activities focused on Disney characters, singing and dancing, Disney arts and crafts, and gross motor play.

Aarts, Jongerius, Geerdink, Limbeek, and Geurts¹ described a group intervention for children with unilateral cerebral palsy (ages 2.5-8 years) that included 6 weeks of constraint and 2 weeks of bimanual task-specific training. The

theme of their intervention program was "Pirates," and it took place in the Netherlands. The children attended the camp for 3-hour sessions, 3 days per week, and daily activities included the following:

- As a group they dressed in pirate costumes that included a sling for their less affected arm (during the constraint weeks).
- They practiced targeted movement with a plastic sword while singing pirate songs.
- Each then had an individualized session to target specific tasks.
- As a group they participated in eating and drinking, reinforcing use of their more affected arm and hand.
- In small groups they participated in board games, card games, puzzles, and arts and crafts according to their developmental level and targeted goals.
- At the conclusion they changed into their own clothes to prepare to go home.

The pirate group intervention resulted in significant positive effects on individualized goals as measured by Goal Attainment Scaling and standardized measures (the Assisting Hand Assessment and the ABILHAND-Kids).

Aarts et al. concluded that "the Pirate group provided a meaningful and challenging environment for the children, who enjoyed the playlike treatment and the provocative activities with peers."

outcomes. As noted earlier, researchers have used widely varied forms of constraint (mitt, sling, splint, cast) and different intensities (2-6 hours/day over 2 to 4 weeks). Because studies have used different measures and study samples have different characteristics, comparison of these important variables across studies is not possible.¹⁰⁰

Four systematic reviews that included P-CIMT have been published since 2007.^{18,66-68,114} Each review included three randomized controlled trials and concluded that although most studies reported positive evidence, the trials remained small and differences in procedures prevented comparability across studies. Among the recent studies, Aarts et al.¹ examined the effects of a group intervention that combined constraint and bimanual interventions with usual care. The children in the CIMT/bimanual groups demonstrated improved function in the affected hand (including improved effectiveness as an assisting hand and increased bimanual performance during self-care and leisure activities) but did not improve in strength and automaticity.² In a randomized controlled trial reported by DeLuca et al.³⁰ and Case-Smith et al.,¹⁹ the effects of 3 hours per day P-CIMT was compared with 6 hours per day P-CIMT for a sample of preschool children. This team used continuous full-arm casting, home-based services, and shaping/motor learning principles in the intervention sessions. The children who received P-CIMT 3 hours per day, when compared with those who received 6 hours per day, made comparable improvements in affected hand function and bimanual hand skills at 1 and 6 months post intervention. Effect sizes on hand function measures for both groups were large. This small study concluded

that a program of 3 hours per day may yield as many benefits to a child's hand function as a program of 6 hours per day.

A recent large randomized trial completed in Italy⁴⁵ compared three groups of children with hemiplegic cerebral palsy ($N = 105$): P-CIMT, bimanual training, and standard treatment. The children in the P-CIMT group wore a glove with a splint 3 hours per day for 10 weeks. The P-CIMT and bimanual interventions were provided in a clinic, 3 days per week for 3 hours a day over 10 weeks, and the parents were instructed to provide 3 hours per day on the other 4 days. Standard treatment occurred once or twice a week. The two intensive interventions resulted in significant effects on isolated arm and hand movements, grasp, and bilateral manipulation. ADLs improved for the younger (2- to 6-year-old) but not older (7- to 8-year-old) children. With positive results for most P-CIMT studies, occupational therapists should prioritize translation of this intervention to clinic and program. Although major pediatric hospitals and some clinics provide CIMT using intensive schedules, modified intervention models that obtain similar results are needed. Further study of P-CIMT models, including those that vary by types of constraint, dosage, individual or group, and types of children who benefit, is needed.

A barrier to broad use of CIMT is the intensive therapy schedule that translates into commitment of therapist resources and family time. Clinics have begun to provide group P-CIMT to maximize therapist resources.³⁸ Home-based models are family-friendly models; however, they are most costly for therapy resources. With positive outcomes, expansion of P-CIMT is anticipated.

Adaptation Models

In many cases, children with neuromotor or musculoskeletal disorders experience hand function impairments that remain limiting despite interventions focused on remediation. Children with congenital orthopedic disorders (e.g., arthrogryposis), trauma resulting in permanent hand impairments (e.g., spinal cord injury or amputation), or severe neuromotor disorders (e.g., spastic quadriplegia cerebral palsy), may benefit from adapted techniques or assistive technology to increase their participation in hand function activities. Adaptation models reflect ecologic practice models in which contextual features of the environment and activity are modified to increase the child's participation in play, school functions, social interaction, and ADLs. When a child has impaired hand function of anticipated long duration, occupational therapists recommend, select, and implement adapted techniques, adapted equipment, and assistive technology to improve the child's participation in everyday activities.

To select appropriate adapted equipment or assistive technology, the occupational therapist analyzes the child's performance and the activity demands and, using this information, identifies potential devices or technology that can compensate for the gap between the child's performance and activity demands. Application of assistive technology to support a child's hand function and participation also includes the occupational therapist's involvement in purchasing, fitting, problem solving or troubleshooting, adjusting, and training to successfully use equipment or technology. Following analysis of performance and desired activities, the occupational therapist identifies available technology and assesses its potential usefulness, fit to the environment, cost, durability, and usability for a particular child's hand function limitations and routine activity demands. Once the family (or school), based on the occupational therapist's recommendations, decides to purchase a specialized device, the occupational therapist adjusts or fits the device; explains how it is used; models and instructs the child in how to use it; trains the family, teachers or other caregivers; and assesses its functionality. These roles in selecting, training, and assessment may be minimal or extensive depending on whether the technology is simple or complex (see [Chapter 20](#)). This section describes the adaptation practice model, including use of adapted equipment and assistive technology, to support and improve hand function.

Types of Children Who Benefit from Activity Adaptation

For children with significant loss of hand function, therapists and families select adapted techniques and assistive technology to increase their participation in play, self-care, and school activities. Although technology is used to support hand function for children with a broad range of disabilities, to illustrate how technologies can support play, self-care, and school occupations, this section focuses on three types of children. Children and youth with (1) orthopedic conditions that restrict upper extremity function, (2) neuromuscular disorders with significant weakness or loss of movement, and (3) cerebral palsy with severe spasticity and limited ROM often benefit from adapted techniques and assistive technology.

Children born with congenital orthopedic disorders, such as arthrogryposis, may have significant limitations in hand

function beginning at birth with limited increase in function over the course of development. Arthrogryposis multiplex congenital is characterized by abnormal fibrosis of muscle tissue, causing contracture of upper and lower extremity joints.⁶³ Often the child's elbow is locked in extension with forearm pronated, creating difficulty in eating and activities that require bringing hands to face. Because children with arthrogryposis experience limited ROM from birth, they often learn adapted methods for accomplishing their goals and tend to be good problem solvers.

Congenital limb deficiencies can also affect hand function. Conditions such as polydactyly (more than 5 fingers [including an extra finger with bone but no joints]), syndactyly (webbed or fused fingers) or amelia (missing fingers or limbs) can result in participation limitations for activities involving hand and finger function. Children with congenital anomalies such as polydactyly or syndactyly generally undergo reconstructive surgeries to increase hand function (see [Chapter 29](#)). Depending on the extent of involvement and success of the surgery, these children may benefit from adapted techniques and equipment. Often children who are missing hands or parts of the hand learn to perform ADLs and school activities with other body parts, rather than learn to use prostheses. When a child determines that use of other body parts is more efficient than use of a prosthesis, these adapted methods need to be respected.

When a child or youth experiences a spinal cord injury that results in quadriplegia, hand function can be permanently impaired. When high-level injuries resulting in minimal arm and hand movement (e.g., at cervical vertebrae C3 or C4) occur, children benefit from assistive technologies such as joysticks, switches, or mobile arm supports. When the spinal cord injury is lower and the child retains wrist movement and partial hand function (e.g., at C6 or C7), adapted equipment, such as universal cuffs, built up handles, or handles on cups, allows independence in specific ADLs. Children and youth with spinal cord injury with quadriplegia can benefit from both low technology, such as adapted spoons and writing utensils, and high technology, such as computer tablets, adapted computers, and electronic aids for daily living.

Children with quadriplegia spastic cerebral palsy whose movement is restricted or poorly controlled may benefit from use of assistive technologies such as switches and electronic devices. When severe muscle tone and muscle weakness limit range of reach and motor control is minimal, adapted equipment and technology become important to the child's participation in play and ADLs. Children with severe athetoid cerebral palsy and minimal control of extremity movements, particularly in midranges, often need switches or adapted interfaces to access computers, tablets, and other devices.⁸⁴ Examples of assistive technology for children with severe cerebral palsy and limited hand function are described in the following sections.

Assistive Technology to Enhance Children's Participation in Play Activities

Children with severely limited upper extremity ROM or hand function can increase their participation in play activities with application of assistive technology.⁷⁷ Lane and Mistrett⁷⁷ recommend the family access lending libraries to explore different options in adapted toys and play activities. Toy adaptations

TABLE 8-10 Switches and Computer Devices for Children with Limited Hand Function

Switch or Device	Examples of Use	Functionality Required to Operate
Button switch	Operates a battery powered toy; can interface with a computer; can be used with online scanning	The child presses down with hand or arm. Releases by lifting hand and arm Can operate with fist or open hand
Grasp switch	Turns devices on and off, can interface with computer and operate online scanning; operates a battery-powered toy	The child squeezes the switch using palmar grasp. Must be able to release the grip to prevent switch latching
Ribbon or leaf switch	Turns devices on and off; operates a battery-powered toy	The child activates by swiping against the switch and bending it. A child who reaches and swipes with fair accuracy can operate this switch.
Plate switch	Turns on and off other devices; operates a battery-powered toys	The child activates with very light touch. A child with poor strength and minimal hand movement can activate this switch.
Joystick	Turns devices on and off; can be used as the computer's mouse; because it has directionality can be used to operate a power wheelchair	The child can operate without full grasp if positioned in thumb web space. Usually the full arm is used to push the joystick forward and backward. Backward pull requires grasp, but child with minimal strength can operate a joystick. Child must have directionality sense. Sensitivity of joystick can be adjusted for a child with poor control of arm movements.
Head proximity switches, mouth-activated switches (e.g., pneumatic)	Turns devices on and off; can include activate computer	For a child with no hand movement or extremely poor control of arm and hand movement, the head or mouth can be used to activate a switch.
Adapted mouse: joystick	Provides mouse functions	For a child with poor control of arm movement or limited grasp. Child controls the mouse movement by moving joystick in different directions. Joystick can be calibrated to become more or less responsive to child's movements.
Adapted mouse: trackball	Provides mouse functions	For a child with limited hand strength and movement, or a child with limited arm control. Computer's cursor moves with minimal movement of hand on trackball.
BigKeys keyboard	Provides large, easily visible keys to access the computer's keyboard	For a child with limited fine motor control who needs a bigger key target. Child with poor hand coordination or ataxia is more accurate with BigKeys.
Membrane keyboard	Provides alternative keyboard for computer access and word processing	For a child with poor strength and limited arm and hand movement

See Ablenet at <http://www.ablenetinc.com>.

include easy-to-grasp handle extensions or handles on puzzle pieces, methods to stabilize the toy by placing on a nonslip material or materials, and attaching toys to the hand using Velcro or a strap. Campbell et al.¹⁴ summarized 12 studies that examined young children's use of switches to activate toys or a computer. These studies demonstrated that young children with a variety of disabilities can learn to use a switch and that switch-activated toys are motivating and reinforcing. Children with minimal arm and hand function can activate switches using an arm swipe, full hand grasp, or pressing motion with hand open. Once a reliable and controlled arm or hand movement is identified, an appropriate switch is selected and placed optimally for the child to activate. When a child can consistently activate a switch, it can be used to operate different battery-operated toys and computer play activities. For children with limited reach and minimal manipulation, switch-activated toys can offer an engaging and meaningful play activity that reinforces the child's motivation and self-initiation. Table 8-10 lists

different types of switches and the arm and hand function required to activate them.

Adapted Equipment for Activities of Daily Living

For children with limited reach, grasp, and manipulation, use of adapted equipment and simple devices can significantly increase their independence in ADLs. When selecting adapted equipment to improve the child's participation in ADLs, the occupational therapist selects and recommends devices that the child can (1) easily use to achieve the ADL goal with minimal caregiver supports, (2) independently don and doff, (3) learn to use without extensive training, and (4) use in different circumstances and environments. The device or adapted materials need to easily fit into the family daily life and should be durable and reliable. Examples of adapted equipment that can support a child eating independently include Dycem underneath the plate to stabilize it, a scoop bowl that allows easy scooping with a spoon, a spoon or fork with built-up handle, bent

spoon or fork, a cup with handles and lid, or a long straw to a stabilized cup.

Adapted equipment helpful for dressing includes reachers, hooks to pull up pants, button hooks, and long-handled shoe horns. Choice of clothing can also make dressing tasks easier. Although family and child preference in clothing must always be considered, therapists often recommend pants with elastic waistbands, looser fitting clothing, shirts with large open necklines, large zipper pulls, Velcro closures, and stretchy materials. Adapted equipment for hygiene includes bath mitts, liquid soap instead of a soap bar, easy grip handles for the toothbrush, and easy-to-dispense toothpaste.

Assistive Technology for School Functions

School-based occupational therapists frequently consider and, when appropriate, recommend technology and device solutions for children with limited hand function. The Individuals with Disabilities Education Act requires that schools provide assistive technology devices and services to students who can benefit from these services, and in the past 20 years assistive technologies have become an important resource for students with disabilities. Fifty percent of students who use assistive technology receive occupational therapy services to support that use,¹⁰² and occupational therapists are frequently part of a school's interdisciplinary assistive technology team. These teams assess the student's functional performance relative to environmental and activity demands, decide as a team which technology is needed, and work with the school and family to obtain the technology.⁷⁶ These teams also fit or adjust the technology, troubleshoot when needed, and train school personnel in its use.

Among school functions, children with limited hand skills often need assistive technology to support writing tasks. Adapted pencils or pens with larger grasping surfaces can be used with a supportive writing surface (e.g., correct height, supporting the forearm and wrist). Children with a tight or fisted grasp on the pencil may benefit from a pencil grip to encourage a tripod grasp.

Children and youth with severely limited hand function often abandon handwriting and transition to word processing using a computer. Adapted computers and tablets may be recommended to optimize the student's function in classroom tasks. When accessing a keyboard, a child with poor arm and hand control may benefit from using a keyguard or forearm stabilizer. The keyguard is a clear plastic cover for the keyboard with key holes over the letters; therefore, it offers a surface for stabilizing the hand when using isolated finger movements to access the keys. For a student with limited control and some

isolated finger movement, a larger keyboard, such as Intellikeys or BigKeys, may improve accuracy. Use of a typing stick may improve the child's accuracy on the keyboard. In addition, the responsiveness of the mouse and keyboard can be slowed to accommodate a child whose performance is slower or error-prone. Using an adapted mouse can be helpful to children with weak hands or poor control of hand function. A large track ball may be easier to use than a regular mouse, or a joystick can replace the mouse (see Table 8-10). For students with minimal arm and hand control, a switch can be used to access an online keyboard. A rocker or button switch can be optimal for scanning to a word processor (Case Study 8-5). Chapter 20 describes for examples of computer programs to support school functions.

Students also use assistive technology and adapted equipment to manage materials, (e.g., math cubes, rulers, books). Occupational therapists may recommend or obtain dividers or containers that are easy to open and stable when handling. Placement of enlarged handles, large zipper pulls, and Velcro fasteners can help the student manage his or her materials with less support from caregivers and aides.

Assistive Technology Research

Because the types of technology vary according to the activity and the hand performance problem, few studies of assistive technology use have been completed. In pre- to post-test, repeated-measures study of students who received assistive technology services in school, their individualized education program goals and objectives improved.¹²⁸ Frequently applied technology to support limited hand function included adapted devices for computer access (e.g., Intellikeys) and adapted keyboards for word processing (e.g., AlphaSmart word processors).¹²⁸

Isabelle and colleagues⁷⁰ explained that because children mature quickly, their need for assistive technology changes quickly, therefore limiting opportunities to collect outcomes data on assistive technology use. Assistive technology application appears to be very fluid with children, and often devices are used to help them reach the next developmental level and then are no longer needed. Therefore, one indicator of assistive technology success may be that the device is not used and is replaced with a simpler device or no device. Although research on the effectiveness of assistive technology to augment and increase hand function is limited, the tools presented in this section are widely used in practice. Occupational therapists who combine adapted techniques and assistive technology with interventions to improve performance can optimize children's participation in school and home activities.

CASE STUDY 8-5 The Use of Assistive Technology

Suzanne, at 8 years old, had infantile spinal muscular atrophy. Spinal muscular atrophy is a genetic disorder that affects neuronal cells in the anterior horn of the spinal cord, causing atrophy of motor neurons. Spinal muscular atrophy progresses from birth, and often children die in infancy. Generally, lower extremity muscles are first affected, then upper extremities,

trunk, and neck; the disease progresses from proximal to distal muscle. Although Suzanne was diagnosed in the first months of life, at 8 she continued to be healthy despite profound weakness throughout her body. She was on a respirator and had limited head movement, no functional movement in her trunk and legs, and minimal movement of her right arm and

Continued

CASE STUDY 8-5 The Use of Assistive Technology—cont'd

hand, with some active range in supination, wrist extension, finger flexion, and extension. Suzanne operated her power chair with an adapted joy stick calibrated to require minimal movement to activate the chair's movement.

Suzanne was very bright and social. She did well in her academic work and in particular enjoyed drawing and art. The following adaptations were made to enable her mobility in school, her participation in art, and her participation in second grade academic work. The second grade curriculum was adapted for her with significant reduction in written work, emphasis on reading/literacy, and emphasis on adapting leisure activities. Suzanne's attendance in school was intermittent because the family was very cautious about maintaining her health. She spent most of her day in her wheelchair because it offered full pelvic, trunk, head, and foot support and had a tray to support her arms. The wheelchair tray was also used to support her computer, computer tablet, switches, and other materials. She received occupational therapy at home and at school.

Goals for Suzanne included:

1. With supervision and an obstacle-free environment, she will operate her power chair for short distances at home and school.
2. With minimal assistance and setup, she will operate painting programs on her computer and her computer tablet using a touch mouse and an adapted joystick.
3. With setup of the book on her book stand, she will turn pages using a mouth stick.

Power Mobility

Suzanne was fitted for an adapted joystick on her power wheelchair's right arm rest (she is stronger on the right). Although Suzanne could not raise her arm at this time, she moved her arm forward when it was resting on the arm rest and she cupped her hands on the joy stick to move it to the right and left. This adapted joystick responded to very subtle movements, and although Suzanne was profoundly weak, she had precise control of her arm movements within a limited range. At times the occupational therapist or parents needed to readjust her arm on the joystick and a small platform was placed over her arm rest to give her a larger surface for sliding her arm (and to keep her arm from falling).

Although Suzanne traveled short distances in her chair, she had limited neck ROM and therefore needed adult guidance when turning or when she needed to avoid obstacles in her environment.

Computer Painting

Suzanne received great pleasure from painting using computer and tablet programs. These programs allowed her to select different colors and make designs on the computer screen with movements of her hand over the touch pad or with the adapted joystick. She loved to select different colors. The touchpad was mounted on a gooseneck mount on her wheelchair to position it for her right hand in the range where she had the most control of her movement (to the right of midline and near her body). She rested her hand on the pad and used the movement of second and third fingers, where she had the greatest active range. She required assistance to print her paintings. Family and staff were most pleased when Suzanne shared her artwork with them.

Turning Pages of a Book

The occupational therapist had to problem solve where to place Suzanne's book stand for her to easily visualize the page and to use her hand to turn pages. He originally set up computer books for Suzanne to use on the computer and to turn pages by lightly hitting a switch. Although computer books worked well, not all of Suzanne's required reading was available on the computer with page-turning capacity, and therefore a set up for paper books was needed. Using a mounting system on her wheelchair tray, the books were placed to the right at the height of her arm rest. She was fitted with a pointer with rubber end on a U-shaped universal cuff. The point angled from her palm and she used a rocking motion of her hand and a sliding motion of her arm (across the tray) to turn the pages. With this system Suzanne sometimes required multiple tries, but she was successful 90% of the time. The book holder had a small bar that holds down the page once it was turned.

Although these adapted activities required teacher or therapist support, they gave Suzanne great pleasure, enabled social and academic participation, and promoted her overall quality of life.

Summary

Occupational therapists are experts in children's hand function and often take the lead in providing interventions to improve hand function. The typical sequences of development for basic skills of reach, carry, grasp, and release, as well as advanced functions of in-hand manipulation and bilateral hand use, were reviewed. A deep understanding of hand skill development and the factors associated with hand function enable occupational therapists (1) to analyze performance in play, social, school, and ADLs; (2) to determine the variables associated with performance, including contextual factors; and (3) to prioritize and plan interventions. The chapter includes description of

intervention principles and strategies, based on primary occupational therapy practice models, and research that supports these practice models.

- Children rapidly develop basic hand functions of reach, carry, grasp, release, and bimanual skills in the first 2 years of life. They continue to refine these hand functions, with emphasis on increasing strength and coordination, development of in-hand manipulation and dynamic grasping patterns, and increasing competency of bimanual skills through elementary school ages.
- Factors that contribute to hand function development include musculoskeletal systems, somatosensory function, visual perception, and cognition. Social cultural context also influences hand function development.

- The child's proficiency in tool use, ADLs and school functions is highly influenced by competency in bimanual skills, dynamic grasping patterns including precision grasp and release, and in-hand manipulation.
- Biomechanical and neurodevelopmental therapy practice models are used with children with cerebral palsy and neuromotor disorders. These approaches emphasize body alignment, ROM techniques that influence muscle tone, facilitation of postural stability and equilibrium, and techniques that facilitate normal patterns of posture and movement.
- Motor learning principles and strategies include (1) engaging the child in a meaningful, preferred activity; (2) using frequent, repetitive practice; (3) systematically varying the practice; (4) providing a just-right challenge to elicit emerging skills; (5) providing structured reinforcement that includes specific feedback about performance; and (6) structuring activities to facilitate the transfer of newly learned skills to the natural environment.
- Pediatric constraint-induced movement therapy (P-CIMT) is the most extensively researched intervention for children with unilateral cerebral palsy. In P-CIMT, occupational therapists provide (1) systematic constraint of the child's less-affected arm and hand either continuously throughout the intervention program or during intervention sessions, (2) high-intensity intervention that engages the child in activities to improve function of the more involved arm and hand, (3) systematic repetition and reinforcement based on motor learning principles, (4) activities that challenge the child's skills and elicit emerging skills, and (5) transfer of intervention program (generally at 2 to 4 weeks) to the caregivers.
- Children with significant hand function impairments may benefit from acquiring and using adapted equipment and assistive technology. A range of assistive technologies can increase the child's participation in play, ADLs and school functions.

CHAPTER

9

Sensory Integration

L. Diane Parham • Zoe Mailloux

KEY TERMS

Ayres Sensory Integration (ASI)	Perception
Adaptive response	Sensory discrimination
Neural plasticity	Praxis
Sensory integration	Dyspraxia
Sensory modulation	Ideation
Under-responsiveness	Motor planning
Sensory registration	Sensory seeking
Over-responsiveness	Intervention fidelity

GUIDING QUESTIONS

1. What does the term “sensory integration” mean, as a term referring to neurobiologic processes and as a frame of reference in occupational therapy practice?
2. Which sensory systems are emphasized in Ayres Sensory Integration (ASI), and why are they considered important?
3. How do sensory experiences support brain functions, and what are the conditions under which they optimally influence neuroplastic changes?
4. What are the key hallmarks of development in the tactile, proprioceptive, and vestibular systems, and how does each developmental achievement in each system contribute to mastery of occupations from early infancy through childhood?
5. Does evidence exist for the different types of sensory integration problems in childhood, and if so, what type of evidence is available and where can this evidence be found?
6. What are the key indicators of problems in sensory modulation, perception, vestibular-bilateral functions, and praxis, and how does each of these areas affect child behavior?
7. What are the primary methods and specific instruments used to assess sensory integration?
8. How are assessment data from different sources and contexts organized to make recommendations that will benefit the child and family?
9. What are the active ingredients of occupational therapy applying a sensory integration approach (OT-SI), and what are the benefits and drawbacks of this intervention approach?
10. What is the purpose of the Fidelity Measure for Ayres Sensory Integration Intervention?
11. Which children are appropriate for OT-SI, and what are the expected outcomes of OT-SI?
12. Does evidence exist for effectiveness of OT-SI intervention, and if so, what type of evidence exists and where can it be found?
13. What are alternative interventions that may be used in conjunction with or instead of OT-SI intervention to help children with sensory integration problems, what are the benefits and limitations of each, and what evidence exists for each?

The term *sensory integration* has held significance for occupational therapists for more than 50 years. Recognized as a way of viewing the neural organization of sensory information for functional behavior, this term also refers to a clinical frame of reference that includes theoretic tenets, assessment methods, and intervention principles and strategies. Both the biobehavioral and the clinical meanings of this term originated in the work of A. Jean Ayres, an occupational therapist and psychologist whose brilliant clinical insights and original research revolutionized occupational therapy practice with children and in many ways led the way for theory development and evidence-based practice for the profession as a whole.

The ideas developed by Ayres ushered in a new way of looking at children and understanding many of the developmental, learning, and emotional problems that arise during childhood. When introduced in the late 1960s and 1970s, her innovative practice and groundbreaking research met some resistance from within the profession, as well as from outside fields. The intervention methods that she pioneered continue to be questioned and investigated today. However, the substantial and evolving body of research and practice applications that have emanated from her work leave little doubt that the Ayres’ perspective has had a profound influence on occupational therapy. The presence of sensory integration concepts in many of the chapters of this book attests to the extent to which these ideas have affected the thinking of pediatric occupational therapists. Even more broadly, the research base of the sensory integration approach has elevated many aspects of assessment, intervention planning, and outcome monitoring in the profession of occupational therapy.

The practice approach that occupational therapists call *sensory integration* is now trademarked through the Franklin B. Baker/A. Jean Ayres Baker Trust as *Ayres Sensory Integration* (ASI).²⁰⁹ According to the trademark document, ASI

encompasses the theory, assessment methods, patterns of sensory integration and praxis problems, and intervention concepts, principles, and techniques developed by Ayres.²⁰⁸ This chapter uses the abbreviation OT-SI (occupational therapy using a sensory integration approach) when discussing the clinical methods developed by Ayres, to emphasize that this kind of intervention generally is provided within the context of occupational therapy.

This chapter provides an in-depth orientation to this fascinating and important aspect of occupational therapy practice for children. The reader will gain a general sense of how sensory integration as a brain function is related to everyday occupations, how sensory integration is manifested in typically developing children, and how some children experience difficulties with sensory integration that may lead to daily life problems. Research on sensory integration problems is reviewed to give the reader a perspective on the evolving research base of this field and how we currently classify patterns of sensory integration problems. We discuss OT-SI practice with respect to methods of clinical assessment, key principles of individual intervention, and other interventions that may be used in conjunction with or in place of individual OT-SI intervention. Effectiveness research on individual OT-SI intervention is reviewed, and case examples of children who have been helped by occupational therapists using an OT-SI approach are provided.

Introduction to Sensory Integration Theory

Ayres understood that brain function is a critical factor in human behavior.¹⁴ She reasoned, therefore, that knowledge of brain functioning would give her insight into the ways children develop, learn, and interact in the world. However, Ayres also had a pragmatic orientation that sprang from her professional background as an occupational therapist. She was concerned particularly with how brain functions affected the child's ability to participate successfully in daily occupations. Consequently, her work represents a fusion of neurobiologic insights with the practical, everyday concerns of human beings, particularly children and their families.

As Ayres developed her ideas about sensory integration, she used terms such as *sensory integration*, *adaptive response*, and *praxis* in ways that reflected her concern with child occupations. Ayres coined some of these terms, whereas others were drawn from the literature of a variety of fields of study. When Ayres borrowed a term from another field, however, she imparted a particular meaning to it. For example, Ayres did not use the term *sensory integration* to refer solely to intricate synaptic connections within the brain, as neuroscientists typically do. Rather, she applied it to neural processes as they relate to functional behavior. Hence, her definition of sensory integration is the "organization of sensation for use" (p. 5).²⁰ It is the inclusion of the final clause "for use" that is Ayres' hallmark, because it ties sensory processing to the person's occupation.

Ayres introduced a new vocabulary of sensory integration theory and synthesized important concepts from the neuroscience literature to organize her views of child development, as well as the types of difficulties she observed in children. Many of these ideas were first published in her seminal book, *Sensory*

Integration and Learning Disorders.¹⁴ Later she wrote a book for parents, *Sensory Integration and the Child*,^{20,23} which identified the ways in which sensory integration develops as well as the ways in which inefficient sensory integration affects behavior, learning, and participation. Major points made in these books regarding neurobiological concepts in relationship to child development and the ontogeny of sensory integration are presented in the following sections.

Neurobiologically Based Concepts

Role of Sensory Experiences in Development and Brain Function

Sensory input is necessary for optimal brain function. The brain is designed to constantly take in sensory information, and it malfunctions if deprived of it. The classic sensory deprivation experiments conducted in the 1950s and 1960s made it clear that without an adequate inflow of sensation, the brain generates its own input in the form of hallucinations and subsequently distorts incoming sensory stimuli.²³¹ If adequate sensory experiences are not available at critical periods in development, neuronal and brain connectivity abnormalities emerge that influence behavior, limiting the ability to function.^{90,116,126,242} It is now well established that persistent, serious impairments in cognitive, social, and emotional functioning often result when infants and young children are institutionalized in environments that are impoverished with respect to availability of a wide range of sensory experiences, the presence of a nurturing caregiver, and opportunities for sensorimotor exploration.^{38,40,75}

Ayres considered sensory input to be *sensory nourishment* for the brain, just as food is nourishment for the body.²⁰ Wilbarger, a colleague of Ayres, built on this concept with the term *sensory diet*, an intervention program that involves provision of individualized sensory experiences and activities throughout the day to support optimal functioning of the child with sensory integration challenges.²⁴⁴ The therapeutic sensory diet provides an optimal combination of sensory-based activities at the appropriate intensities for the specific child. For most typically developing children, the naturally occurring sensory diet does not require conscious monitoring by caregivers. The environment continuously "feeds" the child a variety of nourishing sensations in the flow of everyday life.

As critical as input is to the developing brain, the mere provision of sensory stimulation is limited in value. Too much stimulation can generate stress that is detrimental to brain development and may reduce the person's subsequent ability to cope with stress.¹⁰⁵ To have an optimal effect on development, learning, and behavior, the sensory input must be actively organized and *used* by the child to act on and respond to the environment.

Sensory Integration and Adaptive Responses

A child does not passively absorb whatever sensations come along. The child actively selects the sensations most useful at the time and organizes them in a fashion that facilitates accomplishing goals. This involves brain processes of *sensory integration*, "the organization of sensation for use" (p. 5).²⁰ When these processes are going well, the child also organizes a successful, goal-directed action on the environment, which is called an *adaptive response*. When a child makes an adaptive

FIGURE 9-1 Adaptive responses help the child acquire skills such as riding a bicycle. Amelia's nervous system must integrate vestibular, proprioceptive, and visual information adequately for her to successfully steer the bicycle while it is moving.

response, he or she successfully meets some challenge presented in the environment. The adaptive response is possible because the brain has been able to efficiently organize incoming sensory information, which then provides a basis for action (Figure 9-1). Adaptive responses are powerful forces that drive development forward. When a child makes an adaptive response that is more complex than any previously accomplished response, Ayres hypothesized that the brain attains a more organized state, and its capacity for further sensory integration is enhanced. Thus, sensory integration leads to adaptive responses, which in turn result in more efficient sensory integration.

Ayres provides the example of learning to ride a bicycle to illustrate this process.²⁰ The child must integrate sensations, particularly from the vestibular and proprioceptive systems, to learn how to balance on the bicycle. The vestibular, proprioceptive, and visual senses must accurately and quickly detect when the child begins to fall, and then must be rapidly integrated with each other to produce motor reactions that counteract the direction of the fall. Eventually, often after many trials of falling, the child integrates sensory information efficiently enough to make the appropriate weight shifts over the bicycle to maintain balance. This adaptive response, and those that follow, enable the child to balance effectively to ride the bike. The child's nervous system has changed in how it integrates multisensory information to produce refined, dynamic balancing, so the child is now more adept at bicycle riding.

In making adaptive responses, the child is an active doer, not a passive recipient. Adaptive responses come from within the child. No one can force a child to respond adaptively, although a situation may be set up that is likely to elicit adaptive responses from the child. Typically developing children and most children with disabilities have an innate drive to develop sensory integration through adaptive responses. Ayres called this *inner drive* and speculated that it is generated primarily by the limbic system of the brain, a network of neural structures known to be critical in both motivation and memory.²⁰ Ayres

designed therapeutic activities and environments to engage the child's inner drive (to elicit adaptive responses) and, in so doing, advance sensory integrative development and the child's occupational competence.

Neural Plasticity

It is thought that when a child makes an adaptive response, change occurs in neural synapses and circuits. This change is a function of the brain's neural plasticity. *Plasticity* is the ability of a structure and concomitant function to be changed gradually by its own ongoing activity.¹⁴ The term *neuroplasticity* is used to refer to specific changes in neuron structure and function that last longer than a few seconds and are not simply part of a periodic cycle. The processes of habituation, experience-dependent learning and memory, and cellular recovery after injury all provide examples of types of neuroplasticity.²²⁵ It is well established in the neurobehavioral literature that when organisms are permitted to explore interesting environments, significant increases in dendritic branching, synaptic connections, synaptic efficiency, and size of brain tissue result.¹²⁶ These changes are most dramatic in a young animal and probably represent a major mechanism of brain development,¹¹⁶ although it is clear that such manifestations of plasticity are characteristic of optimal brain functioning throughout the life span.^{28,74,143}

Studies of the effects of enriched environments on animals indicate that the essential ingredient for positive brain changes is that the organism actively interacts with a meaningful and challenging environment.^{43,126} Passive exposure to sensory stimulation does not produce these same positive changes.^{74,79} Recent research suggests that neural circuit reorganization is more extensive and optimal when an animal actively engages in goal-directed activity rather than being passive, for example, when an owl is allowed to hunt instead of being fed.²¹² It can be hypothesized from this body of research that adaptive responses activate the brain's neuroplastic capabilities. Furthermore, the brain's plasticity makes it possible for an adaptive response to increase the efficiency of sensory integration at a neuronal level.

Central Nervous System Organization

Ayres looked to the organization of the central nervous system (CNS) for clues to how children use sensory information and how sensory integration develops over time.¹⁴ Her postdoctoral studies in neuroscience led her to hypothesize that critical aspects of sensory integration are seated in parts of the brain that are phylogenetically older and more primitive than the neocortex.¹⁴ For example, most of the CNS processing of vestibular information occurs in the brainstem, and a great deal of somatosensory processing takes place in the thalamus. One of the basic propositions of Ayres' theory is that, because older parts of the brain integrate and filter information before it is relayed to the cortex, increased efficiency in structures such as the brainstem and thalamus enhance⁵ higher-order functioning.¹⁴ This view differs from traditional neuropsychology and education models, which have tended to emphasize the direct study and remediation of high-level, cortically directed skills such as reading and writing, without attention to more basic modes of processing information.

Ayres also assumed that the more primitive parts of the CNS develop before maturation of higher brain centers.¹⁴ At the

time that Ayres was developing her theory, this was somewhat speculative, although generally accepted by neuroscientists. In later research, the use of positron electron tomography (PET) scans with infants provided direct support for the notion that postnatal brain development proceeds in a bottom-to-top direction.⁶⁵

Her view of the interdependence between the more primitive and more refined processing centers of the brain led Ayres to emphasize the more primitive vestibular and somatosensory systems in her work with young children. These systems mature early and are seated in the lower CNS centers (particularly the brainstem, cerebellum, and thalamus).^{14,149} Ayres reasoned that the refinement of primitive functions, such as postural control, balance, and tactile perception, provides a sensorimotor foundation for higher-order functions, such as academic ability, behavioral self-regulation, and complex motor skills (e.g., those required in sports). Thus, she viewed the developmental process as one in which the more primal body-centered functions serve as building blocks upon which complex cognitive and social skills can be scaffolded. This view undergirds a basic premise of the therapy approach that she developed: enhancing lower-level functions related to the proximal senses might have a positive influence on higher-level cortical functions. In many ways, Ayres was ahead of her time in suggesting that the brain operates in a holistic manner.

Sensory Integrative Development and Childhood Occupations

One of the most distinctive contributions that Ayres made to understanding child development was her focus on the role of primary sensory motor experiences in early childhood, with a unique and original view of the proximal senses (vestibular, tactile, and proprioceptive). From the sensory integration viewpoint, these senses are emphasized because of their importance in shaping a child's interactions with the world early in life. The distal senses of vision and hearing are also critical and become increasingly more dominant as the child matures. Ayres believed, however, that the body-centered senses provide a foundation on which complex occupations are scaffolded. Furthermore, when Ayres began her work, consideration of the vestibular, tactile, and proprioceptive senses was virtually absent in the literature on child development. She devoted her career to studying the roles played by these overlooked senses in development and the genesis of developmental problems of children.

Ayres believed that the first decade of life is a period of rapid development in sensory integration.²⁰ She drew this conclusion not only from her many years of observing children, but also from research in which she gathered normative data on tests of sensory integration.²² By the time most children reach 7 or 8 years of age, their scores on standardized tests of sensory integrative capabilities reflect almost as much maturity as an adult's.

Development, from a sensory integrative standpoint, occurs as the brain organizes sensory information and the child forms adaptive responses with increasing degrees of complexity in order to respond to and interact with early sensory experiences. Sensory integration, of course, enables adaptive responses to occur, which in turn promote the *development of sensory integration* and the emergence of occupational engagement and

social participation.^{184,232} As this process unfolds in infancy, the developing child begins to attach meaning to the stream of sensations experienced. The child becomes increasingly adept at shifting attention to what he or she perceives as intriguing and essential, tuning out that which is irrelevant to current needs and interests. As a result, the child can organize play behavior for increasing lengths of time and gains control in the regulation of emotions.

Inner drive leads children to search for opportunities in the environment that offer “just-right” challenges to their emerging abilities and are aligned with their temperament and interests. These are challenges that are not so complex that they overwhelm or induce failure nor so simple that they are routine or uninteresting. The just-right challenge is one that requires effort but is accomplishable and satisfying. Because there is an element of challenge, a successful adaptive response engenders feelings of mastery and a sense of oneself as a competent being.

It is fascinating to watch this process unfold. Most children require no adult guidance or teaching to acquire basic developmental skills such as manipulating objects, sitting, walking, and climbing. Children need little, if any, step-by-step instruction to learn daily occupations, such as playing on playground equipment, dressing and feeding oneself, drawing and painting, and constructing with blocks. These achievements seem to just happen. They are the product of an active nervous system busily organizing sensory information and searching for challenges that bring forth more complex behaviors, all shaped within the context of a world saturated with sociocultural expectations and meanings.¹⁸⁴

In this section, developmental hallmarks of sensory integration are identified and connected to the occupations attained during childhood. The proximal senses dominate early infancy and continue to exert their influence in critical ways, as the visual and auditory systems gain ascendancy. Although there is some variability across children in the sequence in which developmental achievements unfold during the first year of life, this variability becomes increasingly apparent after this first year. By kindergarten age, skills vary tremendously among children because of differences in environmental opportunities, familial and cultural influences, personal experiences, and genetic makeup. It is important to keep in mind that, throughout development, sensory integrative processes contribute to children's construction of their identities, but many other influences are powerful as well—the family and cultures that shape occupational routines, the interpretations given to behaviors by others, individual talents and abilities, and even chance events that carry special meaning for children and families.¹⁸⁴

Prenatal Period

The first known responses to sensory stimuli occur early in life, at approximately 5.5 weeks after conception.¹²⁵ These first responses are to tactile stimuli. Specifically, they involve reflexive avoidance reactions to a perioral stimulus (e.g., the embryo bends its head and upper trunk away from a light touch stimulus around the mouth). This is a primitive protective reaction. It is not until a gestational age of about 9 weeks that an approach response (moving of the head toward the chest) occurs,¹²⁵ probably as a function of emerging proprioception.

The first known responses to vestibular input in the form of the Moro reflex also appear at about 9 weeks after conception. The fetus continues to develop a repertoire of reflexes such as rooting, sucking, Babkin, grasp, flexor withdrawal, Galant, neck righting, Moro, and positive supporting in utero that are fairly well established by the time of birth. Thus, when the time comes to leave the uterus, the newborn is well equipped with the capacity to form a strong bond with a caregiver and to actively participate in the critical occupation of nursing. These innate capacities require rudimentary aspects of sensory integration that are built into the nervous system. However, even in this earliest period of development, environmental influences, such as maternal stress, can have a significant impact on the quality of sensory integrative development. For example, Schneider and her colleagues found that infant rhesus monkeys born to mothers who had experienced stress in early pregnancy had signs of diminished responses to vestibular input, such as impaired righting responses, weak muscle tone, and attenuated postrotary nystagmus (i.e., normal reflexive back-and-forth movements of the eyes that occur following rotary movement and reflect central vestibular function).^{220,221}

Neonatal Period

Touch, smell, and movement sensations are particularly important to the newborn infant, who uses these to maintain contact with a caregiver through nursing, nuzzling, and cuddling. Tactile sensations, especially, are critical in establishing a primary attachment relationship with a caregiver and fostering feelings of security in the infant. This is just the beginning of the important role that the tactile system plays in a person's emotional life because it is directly involved in making physical contact with others (Figure 9-2). Proprioception is also critical in the mother-infant relationship, enabling the infant to mold to the adult caregiver's body in a cuddly manner. The phasic movements of the infant's limbs generate additional proprioceptive inputs. Together, all of these tactile and proprioceptive inputs set the stage for the eventual development of body scheme (the brain's map of the body and how its parts interrelate).

The vestibular system is fully functional at birth, although refinement of its sensory integrative functions, particularly its integration with visual and proprioceptive systems, continues through childhood.¹⁵⁸ Most caregivers who use rocking and carrying to soothe and calm the infant instinctively appreciate the influence of vestibular stimuli on the infant's arousal level. Ayres pointed out that sensations such as these, which make a child contented and organized, tend to be integrating for the child's nervous system.²⁰

Experiences that activate the vestibular sense have other integrating effects on the infant as well. Being lifted into an upright position against the caregiver's shoulder is known to increase alertness and visual pursuit.¹⁰³ While being held in such a position, the young infant's vestibular system detects the pull of gravity and begins to stimulate the neck muscles to raise the head off the caregiver's shoulder. This adaptive response reaches full maturation within 6 months. In the first month of life, head righting may be minimal and intermittent with much wobbling, but it will gradually stabilize and become firmly established as the baby assumes different positions (first when the baby lies in a prone position and later in the supine position).

FIGURE 9-2 Tactile sensations play a critical role in generating feelings of security and comfort in the infant and are influential in emotional development and social relationships throughout the life span.

The visual and auditory systems of the newborn are immature. The newborn orients to some visual and auditory inputs and is particularly interested in human faces and voices, although meaning is not yet attached to these sensations. Visually the infant is attracted to high-contrast stimuli, such as black-and-white designs, and the range of visual acuity for most stimuli is limited to approximately 10 inches. The infant's visual acuity and responsiveness to visual patterns expand dramatically over the first few months of life.¹⁵⁸ During this time the infant begins to sustain eye contact with the caregiver, further strengthening the bond between them.

Stimulation in each of the sensory systems potentially affects the infant's state of arousal. The infant's capacity to behaviorally adapt to changing sensations is another important aspect of sensory integrative development—the development of self-regulation. It is relatively easy to overstimulate young infants, for example, with changes in water temperature, changes in body position, or an increase in auditory or visual stimuli.²¹³ However, as sensory integration develops, the older child is better able to self-regulate his or her responses to changing stimuli by initiating behaviors that facilitate calming and soothing (e.g., thumb sucking or cuddling with a favorite blanket) or exciting and energizing (e.g., jumping or singing).¹⁹⁵ This process of self-regulation begins in the neonatal period and develops throughout early childhood.

FIGURE 9-3 Strong inner drive to master gravity is evident in this infant's efforts to lift her head and shoulders off the floor. This is an early form of the prone extension posture.

First Six Months

By 4 to 6 months of age, a shift occurs in the infant's behavioral organization. The sensory systems have matured to the extent that the baby has much greater awareness and interest in the world, and developing vestibular-proprioceptive-visual connections provide the beginnings of postural control. During the first half of the first year, the infant begins to show a strong inner drive to rise up against gravity (Figure 9-3), and this drive is evident in much of the baby's spontaneous play. Body positions during the first 6 months characteristically involve the prone position, with gradually increasing extension from the neck down through the trunk as the arms gradually bear more weight to help push the chest off the floor. By 6 months of age, many infants spend much of waking playtime in the prone position with full active trunk extension, and most are able to sit independently, at least if propped with their own hands. These body positions usually are the infant's preferred positions for play and reflect the maturing of the lateral vestibulospinal tract. Head control is well established by 6 months of age and provides a stable base for control of eye muscles. The development of head control reflects the growing integration of vestibular, proprioceptive, and visual systems, which becomes increasingly important in providing a stable visual field as the baby becomes mobile.

Somatosensory maturation at this time is particularly evident in the infant's hands. The infant uses tactile and proprioceptive sensations to grasp objects, albeit with primitive grasps. Touch and visual information are integrated as the baby begins to reach for and wave or bang objects. The infant has a strong inner drive to play with the hands by bringing them to midline while watching and touching them. Connections between the tactile and visual systems pave the way for later hand-eye coordination skills. Midline hand play is a significant milestone in the integration of sensations from the two sides of the body.

By now, neonatal reflexes no longer dominate behavior; the baby is beginning to exercise voluntary control over movements during play. The earliest evidence of motor planning is observed as the infant produces simple novel actions, that is, handling objects and initiating transitions from one body position to another. Although reflexes play a role in such actions

(e.g., grasp and neck righting reflexes), the infant's actions have a goal-directed, volitional quality and are not stereotypically reflex-bound. The emergence of intentionality is a marker of the beginning of occupational engagement.

Six to Twelve Months

Another major transition occurs during the latter half of the first year. Infants become mobile in their environments, and by the first birthday they can willfully move from one place to another, many walking while others creep or crawl. These locomotor skills are the product of the many adaptive responses in prior months, resulting in increasingly more sophisticated integration of somatosensory, vestibular, and visual inputs.

As the infant explores the environment, greater opportunities are generated for integrating a variety of complex sensations, particularly those responsible for developing body scheme and spatial perception. The child learns about environmental space and about the body's relationship to external space through sensorimotor experiences.

During the second 6 months after birth, tactile perception becomes further refined and plays a critical role in the child's developing hand skills. The infant relies on precise tactile feedback in developing a fine pincer grasp, which is used to pick up small objects. Proprioceptive information is also an important influence in developing manipulative skills, and now the baby experiments with objects using a variety of actions. These somatosensory-based adaptive responses contribute to development of motor planning ability. Growing evidence indicates that these early sensory motor experiences not only inform children about their own actions, but also the actions of others.²⁵² Further development of midline skills is also apparent as the baby easily transfers objects from one hand to the other and may occasionally cross the midline while holding an object.

Through the first year, auditory processing plays a significant role in the infant's awareness of environment, especially the social environment. Auditory information is integrated with tactile and proprioceptive sensations in and around the mouth as the infant vocalizes. The fruits of this process begin to blossom in the latter half of this first year, when the infant experiments with creating the sounds of the language used by caregivers. Vocalizations such as consonant-vowel repetitions ("baba" and "mamama") are common. Parents often attach meaning to these infant vocalizations and strongly encourage them, thus leading the infant also to attach meaning to these sounds. By their first birthday, many infants have a small vocabulary of words or wordlike sounds that they use meaningfully to communicate desires to caregivers.

Another major landmark toward the end of the first year is beginning independence in self-feeding. This complex achievement requires refined somatosensory processing of information from the lips, the jaw, and inside the mouth to guide oral movements in the chewing and swallowing of food. Taste and smell sensations are also integral to this process, but self-feeding involves more than the mouth. All of the acquired sensory integrative milestones involving hand-eye coordination are important to self-feeding. The infant at this period of life uses the fingers directly to feed him- or herself and to explore the textures of foods. At this stage, use of a spoon is not very functional and is messy because motor planning skills have not progressed to the point that the child can manipulate it successfully. However, many infants begin to demonstrate a drive

FIGURE 9-4 Because somatosensory processing and visual motor coordination strongly influence self-feeding skills, sensory integration is an important contributor to the development of dining, a fundamental occupation.

to use the spoon in self-feeding by the end of the first year. For many contemporary U.S. infants, use of a spoon is the first experience in using a tool (Figure 9-4).

The occupation of eating, then, begins to emerge in infancy as sensory integrative abilities mature, allowing the child to engage in self-feeding. As an occupation, eating in its fullest sense goes far beyond the physical, sensorimotor act. Mealtime usually takes place within a social context, whether at a family dinner at home or in a formal restaurant, so social standards for acceptable behavior and etiquette become increasingly important as the child develops. Partaking in a meal and sharing certain types of food gradually come to take on powerful symbolic meanings. The sensory integrative underpinnings of the eating experience influence how the child experiences meal-times and how others view the child as a dining partner, thus playing a role in shaping the social and symbolic aspects of this vitally important occupation.

Second Year

As the child moves into the second year, the basic vestibular-proprioceptive-visual connections that were laid down earlier continue to refine, resulting in growing finesse in balance and fluidity of dynamic postural control. Discrimination and localization of tactile sensations also become much more precise, allowing for further refinement of fine motor skills.

FIGURE 9-5 As motor planning develops during the second year of life, the infant experiments with a variety of body movements and learns how to transition easily from one position to another. These experiences are thought to reflect the development of body scheme.

Increasingly complex somatosensory processing contributes to the continuing development of body scheme. Ayres hypothesized that as body scheme becomes more sophisticated, so does motor planning ability.¹⁴ The child draws on knowledge of how the body works to program novel actions (Figure 9-5). Throughout the second year, the typically developing toddler experiments with many variations in body movements. Imitation of the actions of others contributes further to the child's movement repertoire. In experiencing new actions, the child generates new sensory experiences, thus building an elaborate base of information from which to plan future actions.

Although motor planning ability becomes increasingly more complex in the second year, another aspect of praxis, ideation, begins to emerge. Ideation is the ability to conceptualize what to do in a given situation. Ideation is made possible by the cognitive ability to use symbols, first expressed gesturally and then vocally during the second year of life.⁴⁹ Symbolic functioning enables the child to engage in pretend actions and to imagine doing actions, even actions that the child has never before done. By the end of the second year, the toddler can connect several pretend actions in a play sequence.¹⁶⁵ Furthermore, the 2-year-old child demonstrates that he or she has a plan before performing an action sequence, either through a verbal announcement or through a search for a needed object.¹⁶⁵ Thus, a surge in praxis development occurs in the second year as the child generates many new ideas for actions and begins to plan actions in a systematic sequence.

The burgeoning of praxis abilities plays an important role in the development of self-concept. Infant psychiatrist Daniel Stern suggests that the sense of an integrated core self begins in infancy as an outcome of the volition and the proprioceptive feedback involved in motor planning.²³³ The consequences of the child's voluntary, planned actions add to the developing sense of self as an active agent in the world. Because praxis takes giant leaps during the second year, so does this sense of self as an agent of power. The child feels in command of his or her own life when sensory integration allows the child to move freely and effectively through the world.²⁰

FIGURE 9-6 Blowing bubbles requires motor planning of oral movements to blow with the right amount of force, in coordination with upper extremity actions to manage the object.

Third Through Seventh Years

The child's competencies in the sensorimotor realm mature in the third through seventh years of life, which Ayres considered a crucial period for sensory integration because of the brain's receptiveness to sensations and its capacity for organizing them at this time.²⁰ This is the period when sensorimotor functions become consolidated as a foundation for higher intellectual abilities. Although further sensory integrative development occurs beyond the eighth birthday, changes are fewer and less dramatic than in infancy and early childhood.

In the third through seventh years, children have strong inner drives to produce adaptive responses that not only meet complicated sensorimotor demands but also sometimes require interfacing with peers. The challenges posed by children's games and play activities attest to this complexity. In the visual-motor realm, sophistication develops through involvement in crafts, drawing and painting, constructional play with blocks and other building toys, and video games (Figure 9-6). Children are driven to explore playground equipment by swinging, sliding, climbing, jumping, riding, pushing, pulling, and pumping. Toward the end of this period they enthusiastically grapple with the motor-planning challenges posed by games such as jump rope, jacks, marbles, and hopscotch. It is also during this period that children become expert with cultural tools such as scissors, pencils, zippers, buttons, forks and knives, pails, shovels, brooms, and rakes (Figure 9-7). Many children begin to participate in occupations that present sensorimotor challenges for years to come, such as soccer, softball, karate, gymnastics, playing a musical instrument, and ballet.

FIGURE 9-7 By the time a child reaches school age, sensory integrative capacities are almost mature. The child now can devote full attention to the demands of academic tasks because basic sensorimotor functions, such as maintaining an upright posture and guiding hand movements while holding a tool, have become automatic.

Furthermore, children develop the ability to organize their behavior into more complex sequences over longer time frames. This makes it possible for them to become more autonomous in orchestrating daily routines, such as getting ready for school in the morning, completing homework and other school projects, and performing household chores.

As children participate in these occupations, they must frequently anticipate how to move in relation to changing environmental events by accurately timing and sequencing their actions.⁵³ This is particularly challenging in sports when peers, with their often unpredictable moves, are involved. Their bodies are challenged to maintain balance through dynamic changes in body position. In fine motor tasks, children must efficiently coordinate visual with somatosensory information to guide eye and hand movements with accuracy and precision while maintaining a stable postural base.

Children meet these challenges with varying degrees of success. Some are more talented than others with respect to sensory integrative abilities, but most children eventually achieve a degree of competency that allows them to fully participate in the daily occupations that they are expected to do and wish to do at home, in school, and in the community. Furthermore, most children experience feelings of satisfaction and self-efficacy as they master occupations that depend heavily on sensory integration.

When Problems in Sensory Integration Occur

Not every child develops sensory integration in the same way, and for some children, differences in sensory integrative functions create challenges in daily life. When some aspect of sensory integration does not work well, the child may experience difficulties in the course of everyday occupations because processes that should be automatic or accurate are not. It may

be stressful, for example, to get dressed in the morning before school, attempt to play jump rope, or eat lunch in a socially acceptable manner. The child may be aware of these difficulties and become frustrated by frequent failure when confronted with ordinary tasks that come easily for other children. Many children with sensory integrative problems develop a tendency to avoid or reject simple sensory or motor challenges, responding with refusals or tantrums when pushed to perform. If this becomes a long-term pattern of behavior, the child may miss important experiences, such as playing games with peers, which are critical in building feelings of competency, mastering a wide repertoire of useful skills, and developing flexible social strategies. Thus, the capacity to participate fully in the occupations that the child wants and needs to do is compromised.

Often behavioral, social, academic, or motor coordination concerns are cited when a child with sensory integrative challenges is referred for occupational therapy. The occupational therapist evaluates whether a sensory integration problem may underlie these concerns. The therapist then must decide on a course of action to help the child move toward the goal of greater success and satisfaction in engaging in meaningful occupations. These challenges to the occupational therapist—to identify a problem that may be hidden and decipher how to best help the child—were the challenges to which Ayres devoted most of her career.

Beginning in the 1960s, Ayres⁶ conducted research over several decades to develop her theory of sensory integration and evaluate the assessment and intervention methods that she created to help children who have difficulty processing sensory information. She also mentored many occupational therapists who used her theory in practice and conducted research to evaluate, expand on, or modify her theory. While conducting her research, she maintained a private practice; thus, she had many years of firsthand clinical experience on which to ground her theoretical work.

As a step toward better understanding the difficulties of children with learning and behavior problems, Ayres developed standardized tests^{12,22} that measured visual, tactile, and kinesthetic perception, as well as central vestibular processing, motor planning, and other sensorimotor abilities. She statistically analyzed test scores and behavior observations to identify different patterns of sensory integration functioning among children with a variety of learning and behavior difficulties.

Ayres found similar patterns of sensory integration functions as well as problems across multiple studies involving diverse samples of children. The key factors discovered by Ayres were replicated by Mulligan in a confirmatory factor analytic study of more than 10,000 children across the United States who had been clinically referred to occupational therapists.¹⁷⁹ Mailloux et al.¹⁵⁵ also replicated most of the factors identified by Ayres and Mulligan. Tables 9-1e and 9-2e in *Evolve* summarize these studies and other studies of sensory integration patterns. The robustness of patterns across many studies strengthens the hypothesis that these patterns are generalizable and relevant to a child's ability to be successful in everyday life. Evidence-based practice in sensory integration assessment, therefore, includes a comprehensive effort to evaluate these patterns. Knowledge of these patterns provides the therapist with critical information to accurately interpret assessment data and develop individualized intervention that addresses the child's specific strengths and limitations in the various patterns

of sensory integration functions and problems. In the following sections, the general categories of sensory integrative problems that concern clinicians today, based on research findings and clinical experience, are discussed.

Types of Sensory Integration Problems

The results of research, combined with the experiences of practitioners and the ongoing work of scholars in the field, have led to the identification of patterns of individual differences in sensory integration. The terms *sensory integrative problems*, *sensory integrative disorder*, *sensory integrative dysfunction*, and *sensory processing disorder* do not refer to one specific type of difficulty but to a heterogeneous group of patterns that emerge developmentally (i.e., not owing to trauma) and are thought to reflect subtle neural processing differences involving sensory and motor systems. This chapter uses words such as *dysfunction* or *disorder* primarily when referring to particular work in the field that has used these terms. In general, however, we use the terms *sensory integrative patterns*, *problems*, *differences*, or *difficulties*, instead of *disorders* or *dysfunction*, to emphasize our view that differences in sensory integration are part of being human, rather than pathologies. All of us encounter problems or difficulties in life, and for those of us who have difficulty with sensory integration, the problems often fall into predictable patterns. Familiarity with these patterns, and with the related research, assists the occupational therapist in determining how sensory integration problems should be addressed when planning intervention for a particular child.

Most discussions of sensory integrative problems assume normal sensory receptor function. In other words, sensory integrative differences involve central, rather than peripheral, sensory functions. This assumption has been supported in several well-designed studies. For instance, Parush and her colleagues found that the somatosensory-evoked potentials of children with attention deficit hyperactivity disorder (ADHD) differ from those of typically developing children with respect to indicators of central tactile processing but not peripheral receptor responses.¹⁸⁹ Many of the children with ADHD in this study were also identified as having tactile defensiveness, a sensory integrative problem. In another study, researchers found that children with learning disabilities, compared with nondisabled children, had impaired postural responses involving central integration of vestibular, proprioceptive, and visual inputs, whereas measures of peripheral receptor functions were normal.²²³ Thus, when sensory integrative problems involving the vestibular system are discussed, these problems are generally thought to be based within CNS structures and pathways (i.e., the vestibular nuclei and its connections) rather than the vestibular receptors (i.e., the semicircular canals, utricle, or saccule).²⁵¹ In this chapter, the discussions of sensory integrative problems assume that peripheral receptor function is normal.

As noted, different conceptualizations of sensory integrative problems have been generated over the years. Although perfect consensus on how to categorize these problems does not exist, clearly there are recurring themes across authors. Distinct but overlapping taxonomies and models of sensory integrative problems include, for example, those of Bundy and Murray⁵³ and Kimball.¹³⁰ Bundy and Murray presented a taxonomic model that depicts sensory integrative dysfunction as

manifested in two major ways: poor sensory modulation and poor praxis.⁵³ Miller, Anzalone, Lane, Cermak, and Osten¹⁶⁹ proposed use of the term *sensory processing disorder* to include three main types of problems: sensory modulation disorder (i.e., over-responsiveness, under-responsiveness, and sensory seeking), sensory-based motor disorder (incorporating the postural-bilateral and dyspraxia patterns identified by Ayres),²¹ and sensory discrimination disorder (perceptual problems identified by Ayres). Some models specifically focus on sensory modulation. For example, Cermak⁶⁰ and Royeen²¹¹ hypothesized that sensory responsiveness follows a continuum, with hypo-responsiveness at one end and hyper-responsiveness at the other. Dunn later presented a quadrant model that takes into account the potential roles of various neural processes in generating patterns of under-responsiveness and over-responsiveness.^{80,82}

For the purposes of this chapter, four general categories of sensory integration problems are discussed:

1. Sensory modulation problems
2. Sensory discrimination and perception problems
3. Vestibular-bilateral functional problems
4. Praxis problems

These four categories are used here because they are consistent with research that has accumulated from the 1960s to the present. Although variations were reported across studies, these patterns of sensory integration problems emerged in research on different samples of children over many decades. This research indicated that the patterns are interrelated and often coexist in individual children. When planning intervention, occupational therapists need to carefully analyze assessment data to discern whether one or more specific patterns of sensory integration problems seem to be affecting an individual child's participation in activities.

Sensory-seeking behavior is often seen in conjunction with these four main types of sensory integration problems. Although sensory seeking sometimes is addressed as a type of sensory integration problem, this chapter discusses it as a set of diverse behaviors that often co-occur with the four main types of SI problems. Sensory seeking may serve a variety of adaptive purposes for a child who is struggling with some aspect of sensory integration. When planning intervention for children whose sensory-seeking behavior is a concern, the therapist must carefully analyze why the behavior may be occurring, in light of assessment data on SI functioning as well as other factors such as temperament and events in the child's life. In the next section of this chapter, we discuss each of the four main categories of sensory integration problems. This is followed by a discussion of sensory-seeking behaviors and some of the diverse reasons why these behaviors may occur.

Sensory Modulation Problems

Modulation refers to CNS regulation of its own activity.²⁰ The term *sensory modulation* refers to the tendency to generate responses that are appropriately graded in relation to incoming sensory stimuli, rather than under-responding or over-responding to them.

Sensory modulation has been widely studied in the past decade. Most studies of the sensory characteristics of children use sensory questionnaires completed by adults, which are valuable instruments but rely on the reports of parents and teachers.

Sensory questionnaires tend to focus on over-responsiveness (one type of modulation problem that involves strong reactions to ordinary stimuli), because the child behaviors associated with this condition are easily noticed and relatively easy to report in a reliable manner. Consequently, it has become commonplace for many professionals outside occupational therapy (and some inside the profession) to think of sensory modulation problems, and over-responsiveness in particular, when they hear the terms *sensory processing* or *sensory integration*. Prevalence of sensory modulation problems among 4- to 6-year-old children in the general population, as determined through parent questionnaire data, is estimated to be about 5%.¹ No large epidemiological studies have been conducted for children with developmental challenges, but prevalence estimates based on smaller studies consistently indicate a relatively high incidence of modulation problems. It may be greater than 80% among children with autism.^{34,144}

Research on patterns of sensory modulation and their manifestations in everyday activities is an area of focused investigation in occupational therapy^{32,86,172} and in interdisciplinary research on children with diagnoses such as autism^{42,139,140,148} and attention deficit disorder.^{85,253} Many children (e.g., children with autism spectrum disorder [ASD]) demonstrate behavioral characteristics of both under-responding and over-responding, often within the same sensory system.^{33,41,138,235} In addition, the relationship between physiologic measures and patterns of behavior that characterize sensory modulation problems continues to be explored through studies of brain electrical activity⁷⁶ and autonomic responses^{64,170,214,215,222} to sensory input.

Although much remains to be learned about sensory modulation, a general consensus exists among sensory integration experts regarding the behaviors that characterize different kinds of sensory modulation difficulties. These behaviors are described in the following sections.

Under-responsiveness and Sensory Registration Problems

As noted previously, sensory integration is the “organization of sensory input for use” (p. 184).²⁰ However, for sensory information to be used functionally, it must first be registered within the CNS. When the CNS is working well, it knows when to “pay attention” to a stimulus and when to “ignore” it. Most of the time, this process occurs automatically and efficiently. For example, a student may not be aware of the noise of traffic outside the window of a classroom while listening to a lecture, instead focusing attention on the sound of the lecturer's words. In this situation, the student registers the auditory stimuli generated by the lecturer but not the stimuli generated by the traffic. The process of sensory registration is critical in enabling efficient function so that people pay attention to stimuli that enable them to accomplish desired goals. Simultaneously, if the process is working well, energy is not wasted attending to irrelevant sensory information.

Traditionally, occupational therapists, beginning with Ayres,^{20,27} have used the term *sensory registration* problem to refer to the difficulties of the person who frequently does not notice or “register” relevant environmental stimuli. This kind of problem is considered to be a form of modulation difficulty involving under-responsiveness (also called *hypo-responsiveness*). It is often seen in individuals with autism^{33,42,204} but may also

be seen in other individuals. Under-responsiveness appears to be one of the earliest developing features of autism, particularly lack of response to social signals from others, such as the sound of a caregiver calling the child's name.^{31,98} When a pervasive sensory registration problem is present, the child often seems oblivious to touch, pain, movement, taste, smells, sights, or sounds. The key point is that the child is not aware that the stimulus is present. Usually more than one sensory system is involved, but for some children one system may be particularly affected. Among children with ASD, a common finding is that the child does not register socially relevant stimuli but is over-focused on irrelevant stimuli. Children with developmental problems, including ASD, may lack sensory registration in some situations but react with extreme sensory over-responsiveness in other situations.^{33,101}

Safety concerns are frequently an important issue among children with sensory registration problems. For example, the child who does not register pain sensations may not have learned that certain actions naturally lead to the negative consequence of pain, and therefore may not withdraw adequately from dangerous situations. Instead of avoiding situations likely to result in pain, the child may repeatedly engage in activities that may be injurious, such as jumping from a dangerous height onto a hard surface or walking over toys with sharp edges. Other children with sensory registration problems may not register noxious tastes and smells that warn of hazards. Similarly, sights and sounds such as sirens, flashing lights, firm voice commands, and hand signals or signs that are meant to warn of perils go unheeded if not registered. This can be a life-endangering problem in some circumstances (e.g., when a child is at risk for stepping into traffic).

When a child appears to not notice or respond to certain stimuli, it is important to consider whether the underlying problem is a perceptual or cognitive difficulty, rather than a lack of registration. For example, a child who has a tactile perception problem may register the sensation of a tactile stimulus in the hand, but have so much difficulty with stereognosis (a form of tactile perception) that she does not actively manipulate objects. She is unable to interpret the complex, changing three-dimensional tactile sensations that occur when an object moves in her hand, so she has not learned to use object manipulation to gain tactile information as a guide to movement. To the novice therapist, it may appear that this child does not notice the stimulus and therefore is under-responsive, when actually the child may be aware that the stimulus is present but is not able to accurately perceive the complex three-dimensional tactile information provided by the object. In this example, the child's lack of active object manipulation is caused by tactile perception or cognitive limitations rather than under-responsiveness (i.e., a registration problem).

A sensory registration problem interferes with the child's ability to attach meaning to an activity or situation because critical information is not being noticed. Consequently, in severe cases, the child lacks the inner drive that compels most children to master ordinary childhood occupations (e.g., the child who is generally unmotivated to engage in play activities or to practice skills). Symbolic play and language development may be impeded, particularly if auditory and visual stimuli related to social meanings and messages are not registered.²⁴¹ Therefore the long-term effects on the child's development can be profound.

Over-responsiveness

At the opposite end of the sensory modulation continuum are problems associated with over-responsiveness, sometimes called *hyper-responsiveness* or *sensory defensiveness*. The term *sensory defensiveness* was first introduced by Knickerbocker¹³² and later used by Wilbarger and Wilbarger¹⁵³ to describe sensory modulation difficulties involving over-responsiveness in multiple sensory systems, such as over-reactions to touch, movement, sounds, odors, and tastes, that are often associated with discomfort, avoidance, distractibility, and anxiety. The child who is over-responsive is overwhelmed by ordinary sensory input and reacts defensively to it, often with strong anxiety¹⁹² and activation of the sympathetic nervous system.⁶⁴ This condition may occur as a general response to all types of sensory input, or it may be specific to one or a few sensory systems.

A large study of tactile and auditory over-responsiveness in randomly selected elementary school-aged children with no disabilities produced a prevalence estimate of about 17%.⁴² In this study, most of the children who were scored as over-responsive demonstrated difficulty specifically with tactile sensations but not auditory. Similarly, a large study of twin toddlers found that tactile and auditory over-responsiveness appear to be distinct conditions, with tactile over-responsiveness particularly likely to have a genetic influence.¹⁰⁰ However, sociodemographic factors such as poverty, minority ethnicity, low birthweight, and exposure to environmental toxins may also play a significant role in the prevalence of over-responsiveness.^{42,200,210}

Anxiety is so common among children with sensory over-responsiveness that the relationship between these two conditions has been given increasing scrutiny in recent years. Unusually high rates of coexisting sensory over-responsiveness and anxiety disorders have been documented for children with attention deficit disorders,^{141,198} children with autism,¹⁰² and children and adults with obsessive-compulsive disorder.²⁰¹ Both anxiety and sensory over-responsiveness involve states of over-arousal in response to stimuli, perhaps because of neurophysiologic mechanisms such as abnormal amygdala activity.^{102,192} Green and Ben-Sasson¹⁰² proposed three possible theories that could explain the association between sensory over-responsiveness and anxiety disorders: (1) anxiety causes sensory over-responsiveness, (2) sensory over-responsiveness causes anxiety, or (3) these two conditions are associated through a common risk factor, such as abnormal amygdala activity. Because an understanding of the underlying causal mechanisms for these conditions will inform decisions regarding appropriate interventions, ongoing research on this issue is imperative.

Over-responsiveness to particular sensory stimuli is very common among children with autism and, as noted earlier, often coexists with under-responsiveness.^{33,42,204} In other words, a child may be unusually over-responsive to certain types of stimuli, but does not register other types of stimuli that peers notice. Over-responsiveness in autism is very often manifested as tactile defensiveness, for example, avoidance of certain textures of clothing or food, or as auditory defensiveness, as in showing distress or holding hands over the ears in reaction to certain sounds.

Tactile Defensiveness

Tactile defensiveness involves a tendency to over-react to ordinary touch sensations.^{7,14,20} It is one of the most commonly

observed sensory modulation problems. Individuals with tactile defensiveness experience irritation and discomfort from sensations that most people do not find bothersome. Light touch sensations are especially likely to be disturbing. Common irritants include certain textures of clothing, grass or sand against bare skin, glue or paint on the skin, the light brush of another person passing by, the sensations generated when having one's hair or teeth brushed, and certain textures of food. Common responses to such irritants include anxiety, distractibility, restlessness, anger, throwing a tantrum, aggression, fear, and emotional distress.

Common self-care activities such as dressing, bathing, grooming, and eating are often affected by tactile defensiveness. Classroom activities such as finger painting, sand and water play, and crafts may be avoided. Social situations involving close proximity to others, such as playing near other children or standing in line, tend to be uncomfortable and may be disturbing enough to lead to emotional outbursts. Thus, ordinary daily routines can become traumatic for children with tactile defensiveness and for their parents. Individuals with tactile defensiveness can be stressed when they realize that others do not share their discomforts and may actually enjoy situations that they find so upsetting. Teachers and friends are likely to misinterpret the child with tactile defensiveness as being rejecting, aggressive, or simply negative.

An occupational therapist working with a child who is tactually defensive must become aware of the specific kinds of tactile input that are aversive and the kinds that are tolerated by that particular child. Usually, light touch stimuli are aversive, especially when they occur in the most sensitive body areas such as the face, abdomen, and palmar surfaces of the upper and lower extremities. Generally, tactile stimuli that are actively self-applied by the child are tolerated much more easily than stimuli that are passively received, as when being touched by another person. Tactile stimuli may be especially threatening if the child cannot see the source of the touch. Most individuals with tactile defensiveness feel comfortable with deep touch stimuli and may experience relief from irritating stimuli when deep pressure is applied.

Knowledge of these characteristics of tactile defensiveness helps the occupational therapist identify strategies that help the child and others who interact with the child to cope with this condition. For example, the occupational therapist may recommend to the teacher that if the child needs to be touched, it should be done with firm pressure in the child's view, rather than with a light touch from behind the child. Helping a child prepare for sensory experiences in advance can lower stress and anxiety for many children. For example, showing pictures of children getting haircuts may make the situation less anxiety-provoking for some children, as it may help them to know what to expect. Using other forms of sensory feedback, such as a mirror for teeth brushing or hair washing, may also reduce the aversion felt by some children in these tasks. Deep touch pressure is a naturally calming and overriding sensation (e.g., when we rub a place on the body that hurts). Helping a child by rubbing away ticklish or irritating sensory input with soothing words that Dr. Ayres used, such as, "Sometimes rubbing will make that bothersome feeling go away," are still useful today.

Gravitational Insecurity

Gravitational insecurity is a form of over-responsiveness to vestibular sensations involving linear movement, particularly

sensations from the pull of gravity and from vertical movement through space.²⁰ Children with this problem have an insecure relationship to gravity characterized by excessive fear during ordinary movement activities. The gravitationally insecure child is overwhelmed by changes in head position and movement, especially when moving backward or upward through space. Fear of heights, even those involving only slight distances from the ground, is a common problem associated with this condition. Research evidence suggests that some children with autism have this distinct type of over-responsiveness to movement.^{139,140}

Children with gravitational insecurity often display signs of inordinate fear, anxiety, or avoidance in relation to stairs, escalators or elevators, stepstools or ladders, playground equipment that moves, and uneven or unpredictable surfaces. Some children are so insecure that only a small change from one surface to another, as when stepping off the curb or from the sidewalk to the grass, is enough to send them into a state of high anxiety or panic.

Common reactions of children with gravitational insecurity include extreme fearfulness during low-intensity linear movement or when anticipating movement, and avoidance of tilting the head in different planes (especially backward). They tend to move slowly and carefully, and they may refuse to participate in many gross motor activities. When they do engage in movement activities such as swinging, many of these children resist lifting their feet off the ground. When threatened by simple motor activities, they may try to gain as much contact with the ground as possible or they may tightly clutch a nearby adult for security. These children often have signs of poor proprioception in addition to the vestibular over-responsiveness. May-Benson and Koomar developed a Gravitational Insecurity (GI) Assessment (see Evolve website) and found that scores on this standardized tool, which involves activities such as performing a backward roll and stepping off a chair with eyes closed, significantly discriminated between children with gravitational insecurity and typical children.¹⁶¹

Playground and park activities are often difficult for children with gravitational insecurity, as are other common childhood activities such as bicycle riding, ice skating, roller skating, skateboarding, skiing, and hiking. The ability to play with peers and explore the environment is therefore significantly affected. Functioning in the community may also be affected when the child needs to use escalators, stairs, and elevators.

A distinction may be made between gravitational insecurity and a similar condition called *postural insecurity*. Postural insecurity refers to fearfulness of full body movement resulting from limited postural stability or motor control. The fears of children with postural insecurity result from a learned, realistic appraisal of their motor limitations, not a modulation problem per se. Often it is difficult to discern whether a child's anxiety during movement activities is primarily sensory, that is, caused by vestibular over-responsiveness, or primarily resulting from limited motor control, because these two conditions can coexist in the same child. Sometimes, however, the distinction is clear. Children with mild spastic diplegia, for example, commonly have postural but not gravitational insecurity. These children typically (and appropriately) react with anxiety when faced with a minimal climbing task because they are aware that they lack the refined motor control needed to safely climb. However,

these same children may show pleasure at receiving vestibular stimulation, including movement of the head in different planes, as long as they are securely held and do not have to rely on their own motor skills to maintain a safe position.

Over-responsiveness in Other Sensory Modalities

Over-responsiveness in other sensory systems can also have a significant influence on a person's life. For example, most people interpret the raucous sounds found at birthday parties, parades, playgrounds, and carnivals as happy sounds, but these can be overwhelming and distressing to a child with auditory defensiveness. Similarly, a visually busy and unfamiliar environment may evoke an unusual degree of anxiety in a child with visual defensiveness. The variety of tastes and odors encountered in some environments may be disturbing to a child with over-responsiveness in these systems.

Auditory defensiveness is very common among children with autism or other developmental disabilities³² and probably contributes greatly to difficulties with social participation. Lane and colleagues have documented that a subgroup of children with autism have extreme taste and smell sensitivities.^{139,140} These types of problems, like over-responsiveness to touch and movement, may create discomfort, avoidance, distractibility, and anxiety.

Sensory Discrimination and Perception Problems

Sensory discrimination and perception allow for refined organization and interpretation of sensory stimuli. *Discrimination* refers to the brain's ability to distinguish between different sensory stimuli, such as two points touched on the skin simultaneously. *Perception* is the brain's process of giving meaning to sensory information, as when the complex visual stimuli from a person's face are integrated and interpreted as a particular facial expression of emotion. Some types of sensory integrative disorders involve inefficient or inaccurate organization of sensory information (e.g., difficulty differentiating one stimulus from another or difficulty perceiving the spatial or temporal relationships among stimuli). A classic example involving the visual system is that of the older child with a learning disability who persists in confusing a *b* with a *d*. A child with an auditory discrimination problem may be unable to distinguish between the sounds of the words *doll* and *tall*. A child with a tactile perception problem may not be able to distinguish between a square block and a hexagonal block using touch only, without visual cues.

Some children with perceptual problems have no difficulty with sensory modulation. However, modulation problems often coexist with perceptual problems. It is reasonable to expect that these two types of problems are associated, because a child who has registration problems may have limited perceptual skills owing to a lack of experience interacting with sensory information. The child who has sensory defensiveness may exert energy trying to avoid certain sensory experiences. Defensive reactions may make it difficult to attend to the detailed features of a stimulus and thereby may impede perception.

Discrimination or perception problems can occur in any sensory system. They are best detected by standardized tests, except in the case of proprioception, which is difficult to measure in a standardized manner. Although most factor

analytic studies of the Sensory Integration and Praxis Tests (SIPT) scores revealed patterns that linked perception with motor functions, certain patterns reflected perception factors that were specific to a particular sensory system (e.g., a visual form and space perception factor or a tactile perception factor as well as a somatosensory perception factor). Professionals in many fields, such as clinical psychology, special education, and speech language pathology, are trained to evaluate perceptual problems, and their focus usually is on the visual and auditory systems. Most of the clinical assessment tools in visual and auditory perception focus on literacy-related perceptual functions, such as visual discrimination of two-dimensional diagrams or letters and auditory discrimination of phonemes. In contrast, occupational therapists have expertise in the functional aspects of lesser known areas of perception such as tactile, proprioceptive, and vestibular processing.

Tactile Discrimination and Perception Problems

Poor tactile perception is a common sensory integrative problem. Children with this disorder have difficulty interpreting tactile stimuli in a precise and efficient manner. For example, they may have difficulty localizing precisely where an object has brushed against them or using stereognosis to manipulate an object that is out of sight. Fine motor skills are likely to be affected when a tactile perception problem is present, especially if tactile defensiveness is also present.⁵⁸

As discussed, the tactile system is a critical modality for learning during infancy and early childhood. Tactile exploration using the hands and mouth is particularly important. If tactile perception is vague or inaccurate, the child is at a disadvantage in learning about the different properties of objects and substances. It may be difficult for a child with such problems to develop the manipulative skills needed to efficiently perform tasks such as connecting pieces of constructional toys, fastening buttons or snaps, braiding hair, or playing marbles. Inadequate tactile perception also interferes with the feedback that is normally used to precisely guide movement during activities such as writing with a pencil, manipulating a spoon, or holding a piece of paper with one hand while cutting with the other.

Tactile perception is associated with visual perception²⁵; thus, it is fairly common to see children with problems in both of these sensory systems. Not surprisingly, these children tend to have concomitant problems with hand-eye coordination. A discrete somatosensory perception factor emerged as a pattern in analyses of the SIPT,²² but a more striking finding in the factor analytic studies of sensory integration tests over many decades was the link between tactile perception and motor planning, which recurred in many different studies.^{8-10,12,13,18,25,179}

These findings led Ayres to hypothesize that tactile perception is an important contributor to the ability to plan actions. She speculated that the tactile system is responsible for the development of body scheme, which then becomes an important foundation for praxis.

Ordinarily, tactile perception operates at such an automatic level that, when it is not working well, compensation strategies take a great deal of energy. For example, a child who cannot make the subtle manipulations to fasten a button needs to use compensatory visual guidance; as a result, the task of buttoning, usually performed rapidly and automatically, becomes tedious, tiring, and frustrating. The necessity of using such

compensatory strategies throughout the day tends to interrupt the child's ability to focus on the more complex conceptual and social elements of tasks and situations.

Proprioception Problems

Another type of perceptual problem involves proprioception, wherein the muscles and joints inform the brain about the position of body parts. Research on this sensory system is limited because specific measures of proprioception with adequate normative data are not available. However, the experiences of master clinicians suggest that many children have serious difficulties interpreting proprioceptive information.

Children who do not receive reliable information about body position often appear clumsy and awkward. Children with inadequate feedback about body position must often rely on visual cues or other cognitive strategies (e.g., use of verbalizations) to perform simple aspects of tasks, such as staying in a chair or using a fork correctly. Other common attributes of children with poor proprioception include using too much or too little force in activities such as writing, clapping, marching, or keyboarding. Breaking toys, bumping into others, and misjudging personal space are other consequences of poor proprioception that have strong social implications.

Many children thought to have proprioception problems seek firm pressure to their skin or joint compression and traction. These sensation-seeking behaviors may be an attempt to gain additional feedback about body position, or they may reflect a concomitant hypo-responsiveness to tactile and proprioceptive sensations. In any case, if these behaviors are done in socially inappropriate ways or at inopportune times, such as leaning on another child during circle time or hanging from a doorway at school, the child's behavior may be misinterpreted as being willfully disruptive.

For many years, occupational therapists have hypothesized that children with autism have difficulty with proprioception.⁴⁸ A recent study of adolescents with autism found no deficits in simple proprioception of isolated limb position.⁹⁹ This finding indicates that peripheral proprioceptors probably function normally in autism. However, it is plausible that the proprioceptive problems of concern to occupational therapists are related to integration of proprioceptive information from the entire body to guide complex action. Praxis difficulties in ASD may relate to proprioceptive inefficiencies and are discussed later in this chapter.

Visual Perception Problems

Visual perception is an important factor in the competent performance of many constructional play activities and fine motor tasks. Early factor analyses of sensory integration test scores revealed a form and space perception factor. Tests are available to measure figure-ground perception, spatial orientation, depth perception, and visual closure, to name just a few of the many aspects of visual perception that have been of concern to professionals in many disciplines.

Problems with visual perception are commonly seen in children with sensory integrative difficulties, particularly when poor tactile perception or dyspraxia is present.^{22,25} Whereas some children have only a specific visual perception problem without any other sign of sensory integrative difficulty, many others who have visual perception problems also have broader sensory integration difficulties. Henderson, Pehoski, and Murray point

out the many relationships between visual spatial abilities and functions such as grasp, balance, locomotion, construction, and cognition.¹⁰⁹ As these authors note, low scores on tests of visual perception can occur for a variety of reasons and in some cases will represent a problem that therapists would not view as reflective of a sensory integrative issue.

A sensory integrative intervention approach, as described later in this chapter, may be appropriate for the child who demonstrates visual perception problems along with other indicators of sensory integrative difficulties, such as poor tactile perception or praxis. However, if the child has a discrete problem with visual perception, an alternative intervention may be more helpful. When other sensory integration issues are not present or have been resolved with intervention, the occupational therapist may choose to work with the child using another approach, such as visual perception training, use of compensatory strategies, or skill training in specific activities.

Many children with autism have strengths in visual perception, especially in regard to ability to perceive visual details.^{34,177} However, children with these talents may also have difficulty with more global, gestalt-type visual perception as well as decreased perception of moving visual stimuli.

Other Perceptual Problems

Many other dimensions of perception and sensory discrimination exist. For example, perception of movement through space involves the integration of vestibular, proprioceptive, and visual sensations and may be affected in children with vestibular-proprioceptive problems. Auditory perception is an important function that may, when impaired, contribute to sensory integrative disorders in some children. The field of speech pathology has introduced the term *central auditory processing disorders* in reference to problems with auditory perception and modulation, and some authors have suggested that more attention should be given to the role of the auditory system in the sensory integration literature.⁵⁶ However, because so much of the function of the auditory system is related to the functions of hearing, speech, and language, this area of study in sensory integration may be most appropriately pursued in collaboration with speech-language pathologists and audiologists. Although auditory perception problems are not usually considered to be a type of sensory integrative condition when seen in isolation, difficulties with auditory perception and language development often coexist with signs of sensory integrative difficulties. The relationship between these processes warrants further research.

Vestibular-Bilateral Problems

A type of sensory integration problem that was identified early in Ayres' research involves difficulty with functions that are closely associated with the vestibular system. As research emerged using different measures across several decades, different terms were used to refer to this type of problem, including *postural and bilateral integration* disorder,¹⁴ *vestibular-bilateral integration* (VBI) disorder,¹⁹ *bilateral integration and sequencing* (BIS) pattern,²² and *vestibular bilateral integration and sequencing* (VBIS) pattern. These terms refer to the same general constellation of clinical signs and test scores that involve motor outcomes of vestibular processing. This

chapter uses the term *vestibular-bilateral problems* to refer to this type of sensory integration pattern.

Vestibular-bilateral functions are assessed primarily using informal and formal clinical observations, as well as standardized tests. Observations of head and trunk control, balance and bilateral coordination, and vestibular-ocular functions during spontaneous, naturally occurring activities are informative. Clinical observations such as the ability to assume and maintain a prone extension (“superman”) body position are valuable as well. Relevant SIPT tests include Standing and Walking Balance, Bilateral Motor Coordination, and Postrotary Nystagmus (PRN). Postrotary nystagmus, a normal reflexive back-and-forth movement pattern of the eyes following rotary vestibular stimulation, may be shorter than average in duration. Shortened duration of postrotary nystagmus is associated with other signs of vestibular processing difficulty, including limitations in smooth sequencing of bilateral movements.^{22,95,155} A recent study indicated that the PRN test is feasible to administer to infants and toddlers when they are seated on an adult’s lap and that PRN scores for these young children are comparable to those of typical 5-year-olds. These findings suggest that the PRN test may be valid to use in assessment of infants and toddlers.¹⁵⁶

Inefficient balance and equilibrium reactions, as well as poor bilateral coordination, are likely to affect competence in performing activities such as bicycle riding, roller-skating, skiing, and playing games like hopscotch. In addition, difficulty with bilateral coordination may make activities such as cutting with scissors, buttoning a shirt, or doing jumping jacks especially challenging. Bilateral motor difficulties are sometimes associated with delays in body midline skill development, such as hand preference, spontaneous crossing of the body midline, and right-left discrimination.

Children with vestibular-bilateral signs, and no other sensory integration problems, typically do not appear to have a disability so they are seldom referred to a health professional for assessment. When they are referred, the reasons for referral usually include clumsiness or incoordination, difficulty with team sports, slumping or slouching when sitting and doing academic tasks, and attention difficulties.

Although some children with vestibular-bilateral problems have no other sensory integration difficulties, research has shown that vestibular functions such as postural control may be impaired in children with sensory modulation difficulties.²³⁴ The limited research that has examined vestibular functions of children with ASD suggests that postural control in these children may be underdeveloped.¹⁷⁶ A prospective study of infants who were siblings of children with autism, and therefore at high risk for autism, showed that delayed head lag (a measure of emerging head control and postural stability) was a predictor of diagnosis of autism at age 36 months.⁹⁶

Praxis Problems

Praxis is the ability to conceptualize, plan, and execute a non-habitual motor act.²⁰ Problems with praxis are often referred to as *dyspraxia* or *problems in motor planning*. When the term *dyspraxia* is used in regard to children, it usually refers to a condition characterized by difficulty with motor planning that emerges in early childhood and cannot be explained by a

medical diagnosis, developmental disability, or environmental constraint.

Ayres was struck with the relationship between tactile perception and praxis that emerged in her studies. She hypothesized that tactile perception contributes to development of an accurate and precise body scheme, which is necessary for planning new actions. Ayres introduced the idea that praxis problems may be manifested in different forms, not all of which are sensory integrative in nature.²² She coined the term *somato-praxis* to refer to the aspect of praxis that is sensory integrative in origin and grounded in somatosensory processing. At the same time she introduced the term *somatodyspraxia* to refer to a sensory integrative deficit that involves poor praxis and impaired tactile and proprioceptive processing. By definition, somatodyspraxia involves poor tactile perception in conjunction with signs of poor motor planning.⁶¹ This pattern of sensory integrative dysfunction was identified by Ayres and replicated in recent factor analytic studies.^{155,179}

The child with somatodyspraxia typically appears clumsy and awkward. Novel motor activities are performed with great difficulty and often result in frustration. Transitioning from one body position to another or sequencing and timing the actions involved in a motor task may pose a great challenge. These children typically have difficulty relating their bodies to physical objects in environmental space. They often have difficulty accurately imitating actions of others. Precision of movement may be poor, resulting in unintentional knocking down of toys or inefficient placement of materials and objects. Many of these children have difficulties with oral praxis, which may affect eating skills or speech articulation.

Ayres also demonstrated the relationship between visual perception and visually directed praxis in numerous studies. She used the term *visuopraxis* to describe this relationship and the term *visuodyspraxia* for patterns in which these functions were paired as areas of difficulty. In both the studies conducted by Ayres as well as subsequent research, visuodyspraxia was shown to sometimes occur in conjunction with somatodyspraxia.²⁵ Some children with dyspraxia have problems with *ideation* (i.e., they have difficulty generating ideas of what to do in a novel situation or conceiving play possibilities when presented with unfamiliar toys or objects). When asked to simply play, without being given specific directions, these children may not initiate any activity or they may initiate activity that is habitual and limited or seems to lack a goal. Typical responses may include wandering aimlessly; performing simple repetitive actions such as patting or pushing objects around; randomly piling up objects with no apparent plan; or, for the more sophisticated child, waiting to observe others doing an activity and then imitating them rather than initiating a new activity independently. The work of May-Benson highlighted the role of language and the social environment in the development of ideation as an aspect of praxis.¹⁵⁹

For children with dyspraxia, skills that most children attain rather easily can be excessively challenging (e.g., donning a sweater, feeding oneself with utensils, writing the alphabet, jumping rope, completing a puzzle). These skills may be mastered only with high motivation on the part of the child, coupled with a great deal of practice, far more than most children require. Participation in sports is often embarrassing and frustrating, and organization of schoolwork may be a problem

of particular concern. Children who have somatodyspraxia and are aware of their deficits often avoid difficult motor challenges and may attempt to gain control over such situations by assuming a directing or controlling role over others.

Praxis may be a significant area of concern for children with autism. Ideation may be affected¹⁴⁶ and could be related to the repetitive, stereotyped behaviors that comprise one of the defining characteristics of this diagnosis. Motor planning difficulties are well documented in this population. For example, many studies have demonstrated that children with autism have difficulty imitating gestures.^{88,107,203} In one recent study, children with autism were shown to have worse praxis than typical controls, after accounting for age, IQ, and basic motor skills.⁷⁸ In another study, children with Asperger's syndrome who were tested with the SIPT demonstrated evidence of poor proprioceptive and vestibular processing, as well as motor planning impairment, leading the investigators to suggest that these sensorimotor impairments exacerbate the limited social participation of individuals with Asperger's.²²⁴

Praxis in children is best evaluated using the SIPT, which is very sensitive to detecting differences in several aspects of praxis. Five standardized tests on the SIPT—Oral Praxis, Sequencing Praxis, Postural Praxis, Constructional Praxis, and Design Copying—measure motor planning aspects of somatoprasia and visuoprasia. However, parent interview, questionnaires, and informal observations also provide critical information in the assessment process, particularly in the assessment of the ideational aspects of praxis, which are difficult to appraise using conventional standardized tests. A recently developed instrument, the Test of Ideational Praxis, is promising as a standardized, objective means for assessing ideation.¹⁶⁰ In addition, emerging work on assessments of praxis for younger children will hopefully contribute valuable new options in the future for assessment of praxis.²³⁷

Sensory-Seeking Behavior

Some children seek intense stimulation in particular sensory modalities. For example, a child may jump excessively, make sounds frequently, or want to swing or spin his body more often and more intensely compared with most children. Traditionally, in the field of sensory integration, sensory seeking often has been considered to be a sign of under- or over-responsiveness, and accordingly, previous editions of this textbook discussed it as a modulation disorder. However, as new research emerges and more in-depth case examples become available (e.g., personal reflections by individuals with autism),⁶³ it is becoming clear that sensory-seeking behaviors probably occur for diverse reasons. This section reviews the plausible explanations for behaviors that are generally considered to reflect sensation seeking. These potential explanations for what we call *sensory-seeking behaviors* are that they: (1) generate additional sensory input to compensate for weak processing in a particular sensory system, (2) regulate general arousal level, (3) modulate over- or under-responsiveness in other sensory systems, (4) are part of a multifaceted modulation disturbance, (5) reflect limited praxis and are not really sensory-seeking behaviors, and (6) are an expression of temperament and not related to sensory integration problems. These proposed reasons currently serve as tentative explanations that should be

examined in future research. Underlying many of these potential explanations is the hypothesis that sensory-seeking behavior may serve an adaptive function for particular sensory integration difficulties.

One kind of adaptive function that sensory-seeking behaviors may serve is generating additional sensory input to compensate for weak processing in a particular sensory system. For example, some children seek very strong proprioceptive input in the form of active resistance to muscles, deep touch pressure stimulation, or strong joint compression and traction (e.g., by stomping instead of walking, jumping forcefully, intentionally falling or bumping into objects and people, pushing against large objects, or pushing and throwing objects with excessive force). In such cases, the occupational therapist might hypothesize that the child is not aware of the positions of body parts without intense proprioceptive stimulation. For example, when assessment data indicate that the child has tactile perception and proprioceptive difficulties, demonstrates signs of poor body awareness, and frequently initiates jumping and throwing movements with excessive force, the practitioner might interpret the sensory-seeking behaviors as strategies for obtaining additional touch pressure and proprioceptive sensations to compensate for inefficient processing in these sensory systems. The forceful movements can be viewed as proprioceptive-seeking behaviors, which may serve to provide enhanced feedback about dynamic changes in body position during action.

Similarly, some children who have signs of poor tactile perception are observed to touch things and people excessively. This tactile seeking behavior might be a way to compensate for inadequate tactile information by increasing the flow of tactile sensations into the central nervous system, to enhance interpretation of touch sensations during object manipulation and social contacts. Vestibular sensation seeking may also serve a similar function. For example, some children who have difficulty processing vestibular sensations seek large quantities of intense stimulation by swinging or spinning on suspended equipment in a therapy setting, but do not easily become dizzy or show the expected autonomic responses demonstrated by most peers. This intense vestibular seeking behavior may serve the adaptive function of increasing the intensity of vestibular input to adequately activate responses such as maintaining head and trunk stability during movement.

Sensory seeking may also serve the purpose of regulating arousal level. For example, intense vestibular sensation seeking may serve to increase the arousal level of a nervous system that is generally under-aroused. It is well documented in research that vestibular stimulation involving fast changes in head position or movement through space has a generally arousing effect.^{151,194,230} So again, sensory seeking may be playing an adaptive role. That is, children with low baseline arousal may be engaging in vestibular seeking behaviors to reach levels of alertness that help them to perform more optimally.

Another potential reason for sensory seeking is that it may serve to help dampen or override over-responsivity in a particular sensory system. Children who seek intense proprioceptive input sometimes demonstrate concomitant signs of tactile defensiveness or gravitational insecurity. Because animal research as well as clinical experience indicates that proprioceptive and deep touch pressure sensations have an inhibitory effect on light touch¹⁶⁶ and vestibular⁹⁷ sensations, these

children may be seeking increased proprioceptive input to help themselves modulate the overwhelming touch and movement sensations that they often experience.

Sensory-seeking behavior is prevalent among children with autism. In their recent review of sensory characteristics in autism, Baranek and her colleagues separate sensory seeking from hypo-responsiveness (which they treat as low sensory registration).³⁴ These authors categorize sensory features in autism as falling into four main categories: (1) hypo-responsiveness; (2) hyper-responsiveness; (3) sensory interests, repetitions, and seeking; and (4) enhanced perception. Examples of “sensory interests, repetitions, and seeking” in autism often involve visual, tactile, and auditory-seeking behaviors such as fascination with flickering lights, repeatedly rubbing textures, or wanting to listen to the same sound over and over. Proprioception seeking is also very common in this population.¹⁴² Because sensory-seeking behaviors are associated with under- and over-responsiveness in children with autism, it is plausible that sensory-seeking behaviors in this population serve arousal modulation functions.^{34,80,148} For example, a child who is over-responsive to environmental sounds may find that staring at flickering lights helps to block out the disturbing stimuli by focusing attention on the light stimuli. In this example, the visual sensory seeking may be viewed as a strategy for modulating disturbing auditory stimuli or as a direct reflection of a sensory modulation disturbance.

Children who have difficulty with praxis may also appear to have sensory-seeking behavior. Those who struggle with ideation, imitation, sequencing, timing, and multistep planning tend to use play equipment in very simple, repetitive ways because they lack the ability to conceptualize and plan novel and complex actions. These children typically perform familiar actions excessively, such as swinging, jumping, throwing, hitting, or splashing. When these behaviors occur in a child with signs of poor praxis, the possibility exists that these are the only movement strategies available to the child, given the limited repertoire of play skills.

The behaviors generated by sensation-seeking children may be disruptive or inappropriate in social situations. Safety issues frequently are of paramount concern, and often these children are labeled as having social or behavioral problems. A challenge for the occupational therapist working with these children is to identify strategies by which they can receive the high levels of stimulation they seem to need without being socially disruptive, inappropriate, or dangerous to themselves or others.

Finally, occupational therapists should bear in mind that people of all ages (including children) have natural, individual proclivities for certain sensory experiences. Although some children inherently love the thrill of fast rides and high vistas, others prefer slow movements and do not find pleasure in speedy movement or ascending to high places. If no other indicators of a sensory integration difficulty are present, then the sensation-seeking behavior probably is an expression of temperament, and not a manifestation of a sensory integration problem, so a sensory integration approach to intervention would not be appropriate. However, if occupational therapy is indicated to support self-care, play, school, or work skills, the child’s inclination toward sensory seeking should be addressed when considering daily activity routines to ensure that the child’s preferences for intense sensations are met in ways that are safe and socially acceptable.

Impact on Participation

Research tells us that sensory integration difficulties may limit the quality of children’s participation in occupations that they want or need to do as a member of a family, classroom, or community. A systematic review of research on the occupational performance challenges of children with sensory integration difficulties identified 35 studies that addressed difficulties in the areas of play, leisure, and social participation; activities of daily living and instrumental activities of daily living; rest and sleep; and education and work.¹³⁴ Results indicated that sensory problems were related to occupational performance difficulties in all of these areas.

The severity of the sensory difficulties and the presence of other disabilities very likely have an impact on the degree to which participation is affected and the aspects of participation that are impacted. Research has shown that Sensory Profile scores of high functioning children with autism are significantly correlated with scores on a social competence measure, indicating that more extreme sensory differences—especially those involving over-responsiveness—are related to more severe social problems.¹¹⁸ For children with sensory processing problems but no identified disability, the social impact may be milder. For example, a study of these children compared with closely matched typical peers found that, in many ways, these children were very similar to peers in activity preferences and participation. However, they were less involved with team sports, reported less enjoyment and intensity of involvement in general, and had more limited social networks.⁷¹ Qualitative research suggests that sensory experiences of children with autism have a powerful effect on family occupations and daily routines.³⁰ Tactile defensiveness, in particular, seems to strongly affect family routines and self-care activities, even in children with no medical, developmental, or learning disabilities.¹⁹⁷ For example, sensory processing problems can be a significant source of child-related parenting stress.¹²⁷

How others, especially parents, respond to a child’s struggles with sensory integration challenges may have a powerful effect on the child’s developing competence and self-image. First-hand parent accounts provide vivid illustrations of the challenges involved in raising a child with significant sensory issues.¹⁸¹ Sensory integrative difficulties can be both “invisible” (i.e., their presence or origin may not be obvious, especially for children who have no medical or developmental diagnosis) and fluctuating (i.e., their presentation may vary from one time and situation to another). These features often lead parents, teachers, neighbors, and even strangers to assume that the child is capable of performing or behaving better and more consistently and is willfully refusing to do so. Consequently, the child may be punished or responded to inappropriately for behavior not under voluntary control, which may lead to chronic feelings of hopelessness. Moreover, the variability of the sensory integrative problems across time, events, and environments makes it difficult to predict which situations cause problems for a particular child, how much discomfort results, and when distress is likely to occur. Parents and teachers of children with these disorders often find the unpredictability of the child’s behavior to be frustrating and difficult to understand.

Sensory integration difficulties can also have a negative influence on skill development, secondary to limited participation

in the typical childhood occupations that afford children with opportunities for practice and exposure to challenges. The child who avoids finger painting because of tactile defensiveness or who rarely attempts climbing on the jungle gym because of poor praxis not only misses these singular experiences, but also misses opportunities to hone underlying functions such as tactile discrimination, hand strength and dexterity, shoulder stability, balance and equilibrium, hand-eye coordination, bilateral coordination, ideation, and motor planning. If the child misses a substantial number of such experiences over time, the gap between the child's sensorimotor skills and the skills of peers may grow.

In addition, typical interactions that occur in the context of sensorimotor play and are important to the development of communication and social skills may be limited. Thus, some children with sensory integrative problems may lack the ability to play successfully with peers partly because they have not participated fully in the childhood occupations in which sensory, motor, cognitive, and social skills typically emerge and develop. The fear, anxiety, or discomfort that accompanies many everyday situations is also likely to work against the expression of the child's inner drive toward growth-inducing experiences. Therefore, lack of experience and diminished drive to participate can compound the direct effects of a sensory integrative disorder. A qualitative case study of "Jake," a young man with praxis difficulties and sensory modulation problems, illustrates how sensory integration challenges can strongly influence activity and lifestyle choices from childhood into adulthood.¹⁹¹

Sensory integrative problems can also undermine self-esteem and self-confidence over time. Autobiographical accounts by people with sensory integration difficulties provide concrete examples of how this negative cycle may unfold.^{101,164} Children with sensory integrative problems are often aware of their struggles with commonplace tasks, so it is natural for them to react with frustration. Chronic frustration, compounded by fear of failure and humiliation, can negatively affect the child's feelings of self-efficacy. Instead, the child may develop feelings of helplessness. This leads to further limitations in the child's experiences because the child becomes less likely to attempt challenging activities.

These obstacles to participation may actually have a more powerful impact on the child's life outcomes than the original sensory integration difficulty. In some cases, minor sensory integration difficulties can become magnified by losses in self-efficacy and limitations in social relationships, ultimately leading to significant barriers to life satisfaction.

This kind of negative cycle is not inevitable. Children's resilience and capacity to grapple and cope with challenging experiences will influence their occupational lives over the years.¹⁸⁴ Resilient families and children find successful strategies on their own. For many others, however, professional support may provide critical experiences that alter the child's life trajectory in a positive direction. How occupational therapists may help through assessment, intervention, and other supportive approaches is the next topic in this chapter.

Assessment of Sensory Integrative Functions

Assessment of sensory integration, like all other areas addressed in occupational therapy, requires a multifaceted approach

because of the need to understand the child's presenting problems in relation to the family and environments in which that child participates. Assessment by the occupational therapist begins with a general exploration of the occupations of the child and family, focusing on their concerns and hopes in relation to the child's strengths and challenges. A variety of tools is needed to help the occupational therapist discern whether problems in sensory integration are relevant to the child's life situation, to understand the nature and scope of these difficulties, to consider how the difficulties may be offset by the child's talents and strengths, and to decide whether intervention should be recommended. Assessment tools employed by occupational therapists using a sensory integration perspective include interviews and questionnaires, informal and formal observations, standardized tests, and consideration of services and resources available to and appropriate for the family. Smith Roley¹⁷² explained how this process of assessment is consistent with the Occupational Therapy Practice Framework.⁴

Interviews and Questionnaires

The need for an occupational therapy assessment of sensory integration usually arises when a parent, teacher, physician, or other person who knows the child notices difficulties that are not easily explained by some known condition or circumstance. The referral source, family members, and others who work with the child may all be valuable sources of information through interviews or questionnaires (Figure 9-8). This initial phase of evaluation identifies the main concerns about the child and begins the process of determining if examination of sensory integration functions might help to explain some of the child's challenges.

The initial interview with the parent, teacher, or other referral source provides an opportunity for the therapist to gather important information about sensory integration problems that may be present. For example, the teacher may report that the child seems to frequently become agitated while standing in line and cannot seem to stay seated during reading circle time. Further questioning may reveal signs of tactile defensiveness

FIGURE 9-8 Because parents know their child better than anyone else, they are invaluable sources of information to the therapist, especially in beginning phases of the assessment process. (Photo © istock.com.)

that explain the child's behavior, but may not have been considered by a teacher unfamiliar with this condition. A parent may provide critical information about the child's development, which may be helpful in identifying early signs of sensory integrative difficulties. For instance, parents may have noticed that specific tasks, such as cutting with scissors or pedaling a tricycle, were especially difficult for the child. Because difficulty coordinating the two sides of the body is common when vestibular processing difficulties are present, this type of information can inform the therapist about additional observations and tests that are needed to determine whether this is the case. Another important role of the interview is to uncover alternative explanations of the child's difficulties that may rule out sensory integration problems, such as when a recent emotional crisis (e.g., a divorce or death) coincides with the onset of problems.¹⁷³

Cohn⁶⁸ identified the themes of child abilities, activities, and re-establishment of self-worth as important priorities for parents seeking intervention for their children with sensory integration challenges. These themes may be strategic areas to address in initial parent interview questions or conversations with the child. Discussion of these topics goes beyond identification of sensory integration problems and lays the groundwork for intervention planning. When possible, it is also useful to talk with the child directly. Children with sufficient verbal skills to discuss their own abilities, perceptions, and difficulties can sometimes provide invaluable insight into their sensory experiences, challenges, skills, and interests.

Questionnaires, checklists, and histories given by caregivers and other adults who know the child well are other means for gathering information that aids in identifying presenting problems and strengths, and in clarifying the priorities of the family. One such instrument is a sensory history or similar questionnaire. Originally developed by Ayres as an unpublished questionnaire, this type of instrument asks parents questions regarding specific child behaviors indicative of sensory integrative problems, and parents respond by rating the child using a Likert-style scale. These types of questionnaires were subsequently developed using normative samples to produce reliable and valid scores.

The Sensory Profile⁸¹ and the Sensory Processing Measure (SPM)¹⁸⁷ are two sensory questionnaires used extensively in pediatric occupational therapy. The Sensory Profile is normed in versions for parents of infants and toddlers⁸³ and children in early and middle childhood,⁸¹ as well as for self-reports of adolescents and adults.⁵⁰ Additionally, a Sensory Profile School Companion is available for teacher report of child behavior at school.⁸⁴ The SPM has two forms, Home¹¹⁵ and Main Classroom,¹⁷⁵ that are normed on the same sample of 5- to 12-year-old children and can furnish a score that aids the therapist in discerning whether a child's sensory issues are manifested differently in the contexts of home versus school. In addition, the SPM contains separate rating scales for school personnel other than the main teacher, such as art teacher, music teacher, or bus driver. The SPM-Preschool (SPM-P)¹⁷⁴ is normed for ages 2 to 5 years old, and is structured similarly, with separate Home and School forms for parents and day care providers or preschool teachers, respectively. Normative data for 2-year-olds are separate from that of 3- to 5-year-olds, because this instrument is sensitive to developmental changes in sensory processing of young preschoolers.

The information garnered through the initial interview process and, when available, through review of the educational or medical records is used to decide whether further assessment is warranted and, if so, which evaluation procedures are most appropriate. This information is also critical in interpreting the final pool of information gathered through assessment and in prioritizing goals for the child in light of the main concerns and wishes of the family and child.

Direct Observations

Direct observation of the child is essential to the evaluation of sensory integration. Both unstructured observations within natural environments as well as more structured clinical observations are essential for a comprehensive assessment and a full understanding of the child's strengths and challenges.

Naturalistic Observations

When feasible, informal observation of the child during familiar routines in natural settings, such as a classroom, playground, or home, is informative and helpful. Informal observation influences the conclusion as to whether sensory integrative challenges are present and, if so, helps to clarify how the child's difficulties, as well as capabilities, are affecting the child's participation in daily occupations. For example, an experienced therapist can often detect signs of poor proprioceptive body awareness by observing the child at school. Such signs may include exerting too much pressure on a pencil, standing too close to classmates in line, using poor foot placement when climbing on a jungle gym, or sitting in an ineffective position in a chair while completing class assignments. Teachers may not report these behaviors to the therapist if they perceive them as signs of inattentiveness or clumsiness.

Observation of the child in the clinical setting can also be useful for discovering how the child responds to situations that are novel or unpredictable. A child with praxis problems may struggle to mount an unfamiliar climbing structure in a therapeutic setting, even though performance is adequate on play equipment at home or in school, on which the child has practiced familiar actions. The novelty of the specialized therapy room elicits responses from children that may be diagnostically relevant. For children with good ideation and sensory processing abilities, the endless opportunities afforded by sensory integration equipment in the clinic can be exhilarating. For the child who experiences difficulty with praxis or bilateral integration, the same environment may be confusing, puzzling, or frustrating. A child with gravitational insecurity may be terrified by the prospect of equipment that moves, whereas a child with autism may be distressed by the clinic environment because of its unpredictability and discrepancy from familiar settings. Parham has provided some guidelines for organizing informal observations in a therapeutic setting, with special attention to issues related to praxis.¹⁸³ Although focused on the assessment of preschoolers, these suggestions can also be applied to older children and may be particularly helpful in evaluating children who are unable to cooperate with standardized testing. Roley²⁰⁷ and Windsor, Roley, and Szklut²⁵⁰ provide additional guidelines for assessing praxis through informal observations. May-Benson and Cermak¹⁶⁰ offer guidance for specifically assessing ideational aspects of motor planning.

BOX 9-1 Examples of Commonly Used Clinical Observations

- **Crossing body midline:** Intentional movement of a body part (usually the hand) to reach for or manipulate an object in contralateral space. This capacity typically emerges during toddlerhood and early childhood and is related to the development of hand preference. Delays in midline crossing may be related to inadequate hand preference and bilateral integration.
- **Equilibrium reactions:** Automatic postural and limb adjustments that occur when the body's center of gravity is displaced enough to cause potential loss of balance. These adjustments serve to restore the body's center of gravity over its base of support so that balance is maintained or restored. Difficulties with equilibrium reactions are associated with vestibular processing problems.
- **Muscle tone:** The readiness of a muscle to contract. Force with which a muscle resists being lengthened.
- **Prone extension:** Ability to assume and hold an "airplane" position (neck, upper body, and hips extended to lift head, arms, and legs off the floor) while lying prone. Difficulty maintaining this position for 30 seconds is related to inefficient vestibular processing in children 6 years of age and older.
- **Supine flexion:** Ability to assume and hold a curled position (neck, upper body, hips, and knees flexed so that knees are drawn close to the face) while lying supine. Difficulty maintaining this position for 30 seconds is related to poor praxis in children 6 years of age and older.

Structured Clinical Observations

Formal observations that are highly structured and similar to test items are often used in an occupational therapy assessment of sensory integration. Usually referred to as *clinical observations*, these typically involve a set of specific procedures that allow the therapist to observe signs of neurologic system integrity that are associated with sensory integrative functioning. Ayres developed a set of clinical observations that she used in clinical practice. These unpublished, non-standardized evaluation tools were intended to supplement standardized test scores and subsequently were revised, expanded on, and studied by many other therapists over the years.^{46,52,249} Examples of some of the most commonly used clinical observations are presented in [Box 9-1](#). Recently, Blanche and colleagues reported on a developing scale, the Comprehensive Observations of Proprioception (COP), specifically for assessment of proprioceptive functions in children.⁴⁸

Because these types of clinical observations usually involve administration and scoring criteria that are not rigorously standardized, different procedures are often applied from one clinician to another. Furthermore, most of these observations lack normative data to aid in interpretation of the scores, although some clinical observations are supported by research using standardized administration and data on typically developing children.^{48,104,150,160,161,250} In light of the limited information available regarding expected performance across age, gender, and other demographic characteristics, clinical observations are generally considered supplemental rather than stand-alone information within a comprehensive assessment.

FIGURE 9-9 Constructional praxis is the ability to motor plan actions in order to create a 2- or 3-dimensional design or structure, as when drawing or building with blocks. This ability is used when children engage in constructional play. It is evaluated by the Constructional Praxis Test of the Sensory Integration and Praxis Tests (SIPT).

Standardized Testing

Occupational therapists frequently use standardized tests to evaluate sensory integration. Although several tests are available that contribute incidental information regarding sensory integrative functions, the Sensory Integration and Praxis Tests (SIPT) comprise the gold standard for comprehensive, in-depth evaluation of sensory integration. The SIPT evolved from a series of tests that Ayres developed in the 1960s^{6,7,9,10,20} and later published as the SCSIT¹⁵ and the SCPNT.¹⁷ The standardization process used in the development of the SIPT was rigorous, involving normative data on approximately 2000 children in North America and extensive reliability and validity studies.²² Its 17 tests measure tactile, vestibular, and proprioceptive sensory processing; form and space perception and visuomotor coordination; bilateral integration and sequencing abilities; and praxis.²⁶ A list of the 17 tests and the functions measured by each is presented in [Table 9-1](#).

Administration of the SIPT by an experienced examiner requires about 1.5 to 2 hours with an additional 30 to 45 minutes for scoring ([Figure 9-9](#)). Raw scores are translated into standard scores through a computerized scoring program available from the test publisher. After standard scores are obtained for both the major and subtests of the SIPT, the therapist critically reviews them, keeping in mind the patterns of sensory integration problems that were identified in research. The SIPT scores are integrated with observations of the child's behavior during testing, as well as all other sources of assessment information, so as to reach a conclusion regarding the status of the child's sensory integrative functioning.

Other pediatric tests include items or subtests from which inferences regarding sensory integration may be drawn. For example, the Miller Function & Participation Scales include tests that challenge praxis, visual-motor integration, figure-ground perception, and some vestibular functions.¹⁶⁸ The

TABLE 9-1 Functions Measured by the Sensory Integration and Praxis Tests

Function	Description
Space visualization	Motor-free visual space perception; mental manipulation of objects
Figure-ground perception	Motor-free visual perception of figures on a rival background
Manual form perception	Identification of block held in hand with visual counterpart or with block held in other hand
Kinesthesia	Somatic perception of hand and arm position and movement
Finger identification	Tactile perception of individual fingers
Graphesthesia	Tactile perception and practice replication of designs
Localization of tactile stimuli	Tactile perception of specific stimulus applied to arm or hand
Praxis on verbal command	Ability to motor-plan body postures on the basis of verbal directions without visual cues
Design copying	Visuopraxis ability to copy simple and complex two-dimensional designs, and the manner or approach one uses to copy designs
Constructional praxis	Ability to relate objects to each other in three-dimensional space
Postural praxis	Ability to plan and execute body movements and positions
Oral praxis	Ability to plan and execute lip, tongue, and jaw movements
Sequencing praxis	Ability to repeat a series of hand and finger movements
Bilateral motor coordination	Ability to move both hands and both feet in a smooth and integrated pattern
Standing and walking balance	Static and dynamic balance on one or both feet with eyes opened and closed
Motor accuracy	Hand-eye coordination and control of movement
Postrotary nystagmus	Central nervous system processing of vestibular input assessed through observation of the duration and integrity of a vestibular-ocular reflex

From Mailloux, Z. (1990). An overview of the sensory integration and praxis tests. *American Journal of Occupational Therapy*, 44, 589–594.

Bruininks-Oseretsky Test of Motor Proficiency (BOT-2)⁵¹ measures aspects of fine and gross motor skills (such as bilateral coordination) that are related to sensory integrative functions. Other tests, such as the Developmental Test of Visual Motor Integration,³⁹ provide specific information related to visual-perceptual and perceptual-motor skills.

Some instruments geared toward the broader evaluation of occupation can provide critical information, such as the School Function Assessment (SFA),⁷² the Goal-Oriented Assessment of Lifeskills (GOAL),¹⁷¹ or the Social Participation Scale of the SPM.¹⁸⁷ These tools are useful for identifying the extent to which sensory integrative difficulties may be affecting the child's participation in occupations within specific settings. For the child with suspected sensory integrative problems, tests such as these are most effectively used along with specific measures of sensory integration. When combined, these tests assist the therapist in identifying the child's functional strengths and challenges, as well as the underlying reasons for the child's difficulties and accomplishments, to target in intervention.

Interpreting Data and Making Recommendations

Once the information from interviews, questionnaires, informal and formal observations, and standardized tests has been collected, the occupational therapist must integrate and interpret these data to reach meaningful conclusions and appropriate recommendations for the individual child. Conclusions and recommendations are framed with an overriding consideration of the presenting problems and concerns from the family and other professionals (such as teachers), the occupations of the child and family, and the contexts that influence occupational engagement.^{4,206} Burke, Schaaf, and Hall advocate the strategy of creating a narrative, or story, to form an integrated understanding of the child and family to focus assessment and intervention planning on issues that are most meaningful and

important to them.⁵⁵ In using such a future-oriented outlook, the therapist not only generates a picture of the child and family in the present, but also imagines how changes might unfold over the next few years.¹⁸⁴ Occupational therapists use research as well as training and experience to formulate conclusions and recommendations.

One of the important steps in interpretation of assessment findings is to evaluate whether a sensory integrative problem may contribute to the occupational challenges of the child. To do this, data are classified into categories that either support or refute the presence of particular types of sensory integrative problems. After a detailed analysis of the constellation of assessment findings, a hypothesis is generated as to whether any sensory integrative issues appear to affect the child's daily functioning, and if so, what kinds of difficulties appear to be present. For example, a child may present as having difficulties in the classroom with sitting still, staying upright at his or her desk, and losing his or her place when copying from distances. If the interviews, observations, questionnaires, and standardized assessments reveal signs of a vestibular bilateral integration problem (e.g., depressed postrotary nystagmus, poor extensor muscle tone, inefficient postural and ocular control, low scores on balance and bilateral coordination tests), then the therapist forms a hypothesis that this child's classroom struggles relate to vestibular bilateral difficulties. This type of analysis requires both advanced knowledge and skills about these complex sensory integrative functions and patterns, as well as the ability to translate the relationship of these functions to everyday childhood activities.

As the preceding example illustrates, the relationships between sensory integrative functions and daily occupations can be difficult to understand without advanced training. As in any aspect of occupational therapy, it is critical to relate the assessment findings to the presenting problems and initial concerns of the family or referral source, and when applying the sensory integrative framework, therapists will often find that

they need to take some extra steps to make the connections understandable and meaningful.¹⁵³ For example, an assessment may uncover signs of tactile defensiveness in a child described by the parents as destructive and impulsive. It may not have occurred to the parents that difficulty responding to touch input has any relationship to the child's behavior. The evaluating therapist will likely not only need to explain the concept of tactile defensiveness, but also to present a description of how and why tactile defensiveness may be related to the child's behavior problems. An interpretation of how the assessment findings are linked to the daily life experiences and occupations of the child and family also lays the foundation for intervention recommendations.

In addition to the information that is gathered about the child, an occupational therapy assessment of sensory integration takes into consideration the services and resources that are available to the child and family. Information regarding the types of services that the child is currently receiving, how he or she is responding to these services, and which services, programs, and resources are available to the child need careful consideration in light of the purpose and findings of the evaluation before recommendations can be formulated. For example, a child who lives in an area where no occupational therapists are qualified to provide sensory integration intervention needs a program recommendation different from one for a child who has easy access to this type of service. Understanding family aspirations and values, caregivers' concerns, child interests and talents, and resources such as funding, transportation, and time are also critical in identifying the types of services that will be most helpful to the child and family. These issues are as important to the assessment process as the child factors that are addressed in a sensory integration evaluation.

If an assessment leads to a recommendation for occupational therapy intervention, it generally includes an estimate of the duration of time that the child should receive therapy, some indication of prognosis, and a statement regarding expected areas of change. The anticipated gains can be further clarified through the establishment of specific goals and objectives. Writing and explaining goals will provide the occupational therapist with an opportunity to illuminate the ways in which the identified sensory integration issues relate to the presenting problems and desired functional outcomes.¹⁵³ The format in which goals are specified is often a function of the setting in which therapy is delivered. For example, a school district may mandate a particular format for goals in an individualized education plan, whereas a hospital setting may require medically related outcomes. Goal attainment scaling may be useful in many settings.¹⁵⁴ Regardless of the types of goals that are written, goals are established in a manner that is culturally relevant for the family and considers the needs, wishes, talents, and interests of the individual child.

Interventions for Children with Sensory Integrative Problems

Planning an occupational therapy program around a child's strengths and sensory integrative challenges requires the same careful analysis that is used in applying any theoretical framework in therapeutic practice. As for any occupational therapy practice, the aim of sensory integration intervention is

"supporting health and participation in life through engagement in occupation."⁴ When a sensory integration approach is used in occupational therapy, intervention decisions are based on an understanding of the unique ways in which sensory integrative problems affect the engagement and participation of children and their families.²⁰⁶ Intervention is continually planned and evaluated in relation to the occupations that the child wants and needs to do in the contexts of home, school, and community.

The comprehensive assessment process, combined with knowledge of available evidence, helps the therapist to evaluate whether intervention is indicated and, if so, which kinds of approaches are likely to be of the most benefit to the child and family. Regardless of the form in which intervention is delivered, theory-based reasoning regarding the nature of sensory integration should be applied in services to children with sensory integrative difficulties. Therapists who plan interventions for children with sensory integrative problems are responsible for developing their professional expertise through advanced training, mentorship, and ongoing review of evidence. The field of sensory integration is a complex, specialized area of occupational therapy practice that demands that the occupational therapist synthesize information from many sources. Because it is a dynamically changing field, it is important that the therapist stay abreast of research evidence, as well as new developments in sensory integration theory and practice, to guide practice decisions.

The remainder of this chapter provides a description of Ayres sensory integration intervention (OT-SI), including intervention principles, effectiveness research, methods for measuring outcomes, and expected child outcomes. In addition, we discuss several other types of intervention approaches that are often used along with OT-SI or as alternatives to OT-SI: specific sensory strategies and regimes, individual skill development training, group skill development interventions, and consultation, including individualized coaching and modification of everyday activities, routines, and environments.

Ayres Sensory Integration Intervention

The term *Ayres Sensory Integration* (ASI) intervention refers to the individualized occupational therapy practice approach that Ayres developed specifically to remediate sensory integrative problems of children.²⁰⁹ ASI intervention is also called OT-SI to emphasize that it is occupational therapy. In this intervention, the occupational therapist presents activity challenges that are individually tailored to improve sensory integration capacities of the child. Ultimately, this intervention is designed to help a child gain competencies and confidence in performing everyday occupations at home, in play, at school, or in the community ([Case Study 9-1](#)). Although Ayres originally designed this therapy for children with learning disabilities who presented signs of sensory integration difficulties,¹⁴ she and many other expert practitioners have used this kind of intervention, alongside other compatible occupational therapy intervention frameworks, to help children with other disabilities, including autism.^{152,157}

In designing this specialized form of occupational therapy, Ayres was influenced by the neuroscience literature, which shows that the nervous system has plasticity or changeability, particularly when the organism has opportunities to explore

CASE STUDY 9-1 Karen

History

Karen was born after a full-term pregnancy complicated by gestational diabetes. Labor, which was induced at 40 weeks, was prolonged, and it was believed that Karen broke her right collarbone during delivery. Karen achieved her early motor and language milestones within average age ranges. However, she was described as an irritable baby who had difficulty breastfeeding, startled easily, and could be calmed only by swinging. Karen attended a parent cooperative child development program as a toddler, and at 4 years of age she was eligible for a special education preschool program through her school district. She has not been given any specific medical or educational diagnosis.

Reason for Referral

Karen's mother expressed concern about Karen's fine and gross motor skills to a neurologist, who referred Karen for an occupational therapy assessment when she was 4 years of age. When asked why she was seeking an evaluation for Karen, her mother wrote, "Up until recently I had been very patiently waiting for normal development to occur (for example, handedness, fine motor). The school psychologist feels that this still may occur, but I am convinced that something isn't right. Karen's increasing frustration and decreasing belief in herself prompted me to seek evaluations. While a part of me wishes to have a 'normal child,' the other part will be relieved to find that the child I have had so many doubts about since infancy does indeed have some behaviors and actions that are unusual."

Evaluation Procedure

The Sensory Integration and Praxis Tests (SIPT) were administered in one testing session. Karen was also observed in a clinical therapy setting and at home. In addition, Karen's mother was interviewed, and she completed a developmental and sensory history on which she provided detailed accounts of Karen's early and current sensorimotor, language, cognitive, social, and self-care development.

Evaluation Results

On the SIPT, Karen scored below average for age expectations on 7 of 17 tests. This profile was generated through computer scoring by the test publisher. The unit of measure represented by the scores is a statistical measure called a *standard deviation*, which represents how different the child's score is from that of an average child of the same age. The closer a child's score is to 0 on the horizontal axis, the closer to average is the child's performance on that test. Karen's scores are plotted as solid squares that are connected by a dark line on the computer-generated profile. Scores falling below -1.0 on the horizontal axis are considered to be possibly indicative of dysfunction.

One of Karen's scores was low on a motor-free visual perception test (space visualization), and it was noted that she had difficulty fitting a geometric form into a puzzle board during this test. Her mother reported that Karen knew colors at 18 months of age but had trouble learning shapes. However,

she was reported to have a strong visual memory for roads, signs, and faces. These findings suggested difficulty with spatial orientation of objects but relative strengths in visual memory.

Karen had several low scores and showed signs of difficulty performing on several of the tests of somatosensory and vestibular processing. A low score on finger identification suggested inefficient tactile feedback involving the hands. This was corroborated by observations of poor manipulative skills during activities such as buttoning and using utensils. She was also observed to have signs of tactile defensiveness, also corroborated by her mother's report. Her low score on Kinesesthesia, as well as her difficulty in exerting the appropriate amount of pressure on a pencil and in positioning her body for dressing, suggested problems with proprioceptive feedback. Karen's lowest score on the SIPT was on the Postrotary Nystagmus test (-2.2 standard deviations). This low score, as well as below-average scores on Standing and Walking Balance, observations of poor functional balance in dressing and playground activities, a tendency not to cross her body midline, poor bilateral coordination in activities such as cutting, and reports that she never appeared to get dizzy, pointed to the probability of vestibular processing problems.

Karen showed above-average performance on a praxis test on which she could rely on verbal directions. However, tests of motor planning that were more somatosensory dependent (Oral Praxis and Postural Praxis) were substantially more difficult for her. Karen was unable to ride a tricycle, pump a swing, or skip. She had extreme difficulty planning her movements to dress herself or even letting someone else dress her. She also had a great deal of difficulty using utensils during eating and often choked on food and drinks. Writing skills were particularly difficult for Karen, and her lack of hand preference, immature grasp, and hesitancy to cross her midline hampered her attempts at drawing or writing.

Karen was reported to be a social child who was liked by adults and younger peers. However, her mother worried that she did not seem able to "pick up on the hints and unwritten rules of her peers" and was "definitely starting to march to her own beat." She noticed increasing signs of frustration that she thought were beginning to impinge on Karen's willingness to participate with peers.

Overall, the evaluation results suggested problems in sensory processing of some aspects of visual, tactile, proprioceptive, and vestibular sensory information. These difficulties were seen as related to somatodyspraxia, poor balance and bilateral integration, difficulties with specific gross and fine motor skills, and emerging concerns around socialization. Karen's strengths included age-appropriate cognitive and language skills, good ability to motor plan actions using verbal directions, and an exceptionally supportive and involved family.

Recommendation

Based on the evaluation results and a meeting of Karen's IEP team, who met shortly after the assessment, it was

CASE STUDY 9-1 Karen—cont'd

recommended that Karen receive individual occupational therapy using a sensory integration approach to enhance foundational sensory and motor processes. Because of her significant sensory integrative problems and need for a specialized approach, the therapy was recommended to initially occur in a setting equipped for Ayres Sensory Integration (ASI) intervention.

Occupational Therapy Program

In the first 6 months of individual occupational therapy, an ASI approach was used that included individualized, carefully selected therapeutic activities aimed at enhancing visual, tactile, proprioceptive, and vestibular sensory processing. As part of her intervention program, Karen's occupational therapist provided her with graded challenges to praxis, bilateral coordination, and balance.

After 6 months of therapy, Karen has shown decreasing tactile defensiveness, a reduced tendency to choke on food,

acquisition of the ability to ride a tricycle, and an improved ability to plan new or unusual motor actions. Although these are significant gains for Karen, she continues to exhibit substantial difficulties with many aspects of sensory processing, general motor planning ability, and many age-appropriate fine and gross motor skills. If she continues to respond to occupational therapy using an ASI approach, it is expected that by the beginning of the next school year (in about 6 months), she will have improved in basic sensory and motor functions to the extent that some specific skill training will become more appropriate. It is likely that at that time some therapy will occur at school with the introduction of a consultation program for her teacher. Her parents have already begun a home program, which appears to support the gains she is making through direct services. Karen's young age and initial positive response to therapy make her an optimal candidate for application of the sensory integration approach, and her long-term outlook is excellent.

and engage in activities within an enriched environment. Plasticity is particularly characteristic of the developing young child. This led Ayres to hypothesize that neural system functions can be improved with active engagement in an enriched environment that presents activity challenges, especially for the young child. Accordingly, she set out to design therapy that capitalized on the plasticity of the nervous system to improve sensory integrative functioning. This is *not* to say that OT-SI cures conditions such as learning disability, autism, or developmental delays. Rather, the intent is to improve the efficiency with which the nervous system interprets and uses sensory information for functional use. Therefore OT-SI promotes underlying capabilities to the greatest degree possible. Recently, Reynolds, Lane, and Richards reviewed five decades of animal studies on the effects of enriched environments on brain structure and function and concluded that essential features of enriched environments historically have been incorporated into OT-SI and should continue to do so.¹⁹⁹ These essential features are multiple sensory experiences, novelty in the environment, and active engagement in challenging cognitive, sensory, and motor tasks. Thus, the basic science research on effects of enriched environments studies provides empirical support for the underlying assumptions and strategic intervention strategies of OT-SI intervention.

Some basic assumptions underlying the OT-SI approach are summarized in [Box 9-2](#), drawn from the classic work of Ayres.^{14,20} The principal ideas behind these assumptions were introduced previously in this chapter in the sections on neurobiologically based concepts, sensory integrative development, and types of problems.

OT-SI is applied on an *individual* basis because the therapist must adjust therapeutic activities moment by moment in relation to the individual child's interest in the activity or response to a specific challenge or sensory experience.^{66,130,136} This requires the occupational therapist to continually focus attention on the child while being mindful of opportunities in the environment for eliciting adaptive responses. Of particular importance is the delicate interplay between the potential

BOX 9-2 Basic Assumptions Underlying Ayres Sensory Integration Intervention

1. Sensory input can be used systematically to elicit an adaptive response.
2. Registration of meaningful sensory input is necessary before an adaptive response can be made.
3. An adaptive response contributes to the development of sensory integration.
4. Better organization of adaptive responses enhances the child's general behavioral organization.
5. More mature and complex patterns of behavior emerge from consolidation of simpler behaviors.
6. The more inner-directed a child's activities are, the greater the potential for the activities to improve neural organization.

therapeutic value of an activity and the child's motivation to engage in it. Therefore, the occupational therapist's session plan is fluid, changing according to the child's behaviors. The occupational therapist establishes a relationship with the child that fosters the child's inner drive to actively explore the environment and to master challenges posed by the environment. Because of the high degree of personal attention continuously given to the child during the therapy session, a fine gradient of complexity can be built into therapeutic activities while simultaneously ensuring that the child's interests are prioritized and the child experiences success and a growing sense of "I can do it!"

The occupational therapist's job is to create an environment that evokes increasingly complex adaptive responses from the child. To accomplish this, the occupational therapist respects the child's needs and interests while structuring opportunities to help the child successfully meet a challenge. An example is a child who needs to develop more efficient righting and equilibrium reactions and chooses to sit and swing on a platform swing. The occupational therapist may allow the child to swing

FIGURE 9-10 Individual OT-SI intervention requires the therapist to attend closely to the child on a moment-by-moment basis to ensure that therapeutic activities are individually tailored to changing needs and interests of the child.

awhile to become accustomed to the vestibular sensations. Once the child seems comfortable, the occupational therapist steps in to jiggle the swing to stimulate the desired responses. However, if the child responds to this challenge with signs of anxiety or fear, the occupational therapist needs to intervene quickly to help the child feel safer. For example, the occupational therapist might set an inner tube on the swing to provide a base to stabilize the lower part of the child's body and increase feelings of security while the child's upper body is free to make the required righting reactions. Therapeutic activities thus emerge from the interaction between the occupational therapist and the child. Such individualized treatment can be fully realized only with one-to-one interaction between the occupational therapist and the child (Figure 9-10).

Occupational therapy using a sensory integration approach intervention capitalizes on the *inner drive* of the child during intervention.^{14,20,66,136} Self-direction on the part of the child is encouraged because therapeutic gains are maximized if the child is fully invested as an active participant. This is not the same as permitting the child to engage in free play with no adult guidance. The optimal therapy situation is one in which a balance is struck between the structure provided by the occupational therapist and freedom of choice on the part of the child.^{14,20} Drawing on the child's interests and imagination is often key to encouraging greater effort on a difficult task or staying with a challenging activity for a longer time. However, because children with sensory integrative problems do not always demonstrate inner drive toward growth-inducing activities, it may be necessary to modify activities and find ways to entice such children toward interaction. When facilitating engagement in children with autism or other children whose inner drive is limited, the occupational therapist may need to frequently initiate activities and guide the child on how to perform them. Occasionally an occupational therapist may use a greater degree of directedness within the context of a particular activity to show a child that the challenging activity is possible not only to achieve, but also to enjoy. In situations in which the occupational therapist intervenes by directing the child, the occupational therapist always looks for opportunities in which the child can increase his or her active engagement

FIGURE 9-11 Rather than passively imposing vestibular input on the child, classic sensory integration treatment emphasizes active participation and self-direction of the child.

and control of the activity, including supporting the child's initiation of a new activity.

Active participation is also emphasized because the brain responds differently and learns more effectively when an individual is actively involved in a task, rather than merely receiving passive stimulation. Therefore, in OT-SI intervention, the occupational therapist actively engages the child to the greatest degree possible. For example, sensory integration theory posits that a child experiences a greater degree of integration from pumping a swing or pulling on a rope to make it go than from being swung passively.

Maximal active involvement generally takes place when therapeutic activities are at just the right level of complexity, at which the child not only feels comfortable and non-threatened but also experiences some challenge that requires effort. The course of therapy usually begins with activities with which the child feels comfortable and competent and then moves toward increasing challenges. For example, for children with gravitational insecurity, therapy usually begins with activities close to the ground and with close physical support from the therapist to help the child feel secure. Gradually, over weeks of therapy, activities that require higher level surfaces and moving away from the floor are introduced as the therapist subtly withdraws physical support. Introducing the "just right" level of challenge, while respecting the child's need to feel secure and allowing the child to have degree of control, is a key to maximizing the child's active involvement in therapy (Figure 9-11).

At times, sensory experiences may be initiated and provided by the occupational therapist to help prepare a child for more complex or challenging activities that he or she may later perform. For example, a child with autism may show improved awareness of and interest in movement activities after receiving passive vestibular sensation on a swing that the occupational therapist has moved in a linear or rotary fashion.²³⁰ The improved awareness of the joys and affordances of movement will also likely mean that the child has greater awareness of the environment. In this way, therapist-initiated sensory experiences can be a stepping stone toward active involvement in an activity. Another example is the use of carefully introduced

tactile activities as a means for reducing tactile defensiveness and improve the child's comfort in situations and activities that involve frequent tactile contact with objects and people.¹⁴ Overall, therapist-directed or induced sensory experiences are a limited component of a sensory integrative treatment program and are used only as a step toward facilitating more active participation.

The setting in which OT-SI takes place, including the availability of specialized therapeutic equipment, is another important aspect of this type of intervention.^{163,229,239} Consistent with research that shows that brain structure and function are enhanced when animals are permitted to actively explore an interesting environment,^{126,199} a sensory-enriched environment is designed to evoke active exploration on the part of the child. A therapy room that is designed for OT-SI contains large activity areas with an array of specialized equipment.¹⁶³ The availability of suspended equipment is a hallmark of this treatment approach.^{66,136} Suspended equipment provides rich opportunities for engaging and challenging the vestibular system. In addition, equipment and materials are available that provide a variety of somatosensory activities, including tactile, vibratory, and proprioceptive input. Mats and large pillows are used for safety. Overall, this special environment provides the child with a safe and interesting place in which to explore his or her capabilities. At the same time the equipment and setting provide the occupational therapist with a tool kit and workshop for creating sensory experiences that are enticing to the child and for gently guiding the child toward activities that challenge perception, dynamic postural control, and motor planning (Figure 9-12).

FIGURE 9-12 The setting in which OT-SI intervention takes place provides a variety of sensory experiences. Immersion in a pool of balls presents challenges to sensory modulation.

A few cautionary words are in order regarding responsible use of vestibular and tactile stimulation as therapeutic tools. These are powerful tools that can have profound effects on the physiologic state. For example, activation of the vestibular system, usually in the form of linear movement, is commonly introduced early in the course of treatment for many children because it is believed to have an organizing effect on other sensory systems.^{14,20} However, it can have a disturbing and disorganizing effect on the child if used without careful monitoring of the child's response. Vestibular system activation may produce strong autonomic responses, manifested as blanching and nausea. It directly influences arousal level and, if not regulated carefully, may produce hyperactive, distractible states or lethargic, drowsy states. Because OT-SI intervention emphasizes active participation on the part of the child, vestibular stimulation is rarely passively imposed on the child. Whenever vestibular stimulation is used, the occupational therapist constantly monitors the child's responses and frequently adjusts the activity in response to the child's state. For example, if a child is actively rotating while sitting in a tire swing and begins to exhibit mild signs of autonomic activation, the occupational therapist might intervene by acting to reduce the intensity of the swinging, guide the child to shift to slow linear swinging, or increase proprioceptive input by offering the child a trapeze to pull. This latter strategy (increasing proprioceptive input) is derived from animal research showing that proprioceptive input has an inhibitory effect on vestibular activation.⁹⁷ Therefore, knowledge of the effects of vestibular stimulation and its interactions with other sensory systems is critical in this treatment approach.

Similarly, tactile stimulation during OT-SI is informed by knowledge about this sensory system and how it interacts with arousal processes as well as other sensory systems. Passive tactile stimulation is not often used. Imposing tactile stimulation on a child who is tactile defensive may lead to a state of sensitization, in which the child becomes increasingly more defensive instead of habituating to the sensation. Instead of using passive tactile stimulation, tactile stimuli are usually incorporated into the materials and surfaces that the child contacts while engaging in activities under his or her active control, for example, through manipulation of objects with varying shapes and textures or through contact with surfaces that have diverse textures.

To summarize the critical features of OT-SI intervention, therapeutic activities are neither predetermined nor are they simply free play. The flow of the treatment session involves collaboration between the occupational therapist and child in which the therapist encourages and supports the child in a way that moves the child toward therapeutic goals. This all takes place within a special environment that is safe yet challenging. To determine if a child can benefit from OT-SI intervention, a comprehensive occupational therapy assessment, including in-depth evaluation of sensory integration, must be conducted. Assessment findings are used to determine whether OT-SI is appropriate and desirable for the individual child. If so, assessment findings guide treatment planning.²¹⁷ Because challenges in sensory integration are often identified early in life and can affect occupational performance over many phases of development, OT-SI intervention may be appropriate for extended or intermittent periods across childhood.

After Ayres developed OT-SI intervention,^{14,20} her colleagues and students continued to further develop and expand on her intervention concepts. Koomar and Bundy provided a particularly thorough description of the application of sensory integration procedures for specific types of sensory integrative disorders.¹³⁶ Holloway imported OT-SI concepts into the neonatal intensive care unit (NICU), where the treatment principles are used to help young infants when their developing nervous systems are most plastic.¹²¹ Others have adapted OT-SI intervention to address the needs of infants and toddlers who are developmentally at risk,²¹³ as well as the needs of children with visual impairments,²⁰⁵ cerebral palsy,⁴⁷ environmental deprivation,⁷⁵ and fragile X syndrome.¹¹⁷

Application of the OT-SI approach requires special training beyond the entry level of practice in occupational therapy.²⁴⁰ Koomar and Bundy advocated a mentorship process as the best preparation for learning how to clinically apply sensory integration principles.¹³⁶ Ayres also advocated this and established a 4-month course in which therapists receive both didactic instruction and intensive hands-on experience treating children under close supervision. Ayres believed that this level of intensity was required to master the sensory integration approach. Because of the highly specialized and complex nature of the OT-SI approach, it is important that occupational therapists gain post-professional education and mentored experience in this area before independently engaging in this form of practice. Self-study of professional and scholarly resources relevant to this area of practice is also important in developing professional competencies. A list of these resources is available on the Evolve website.

In addition, ongoing personal study and discussion with peers are highly recommended after acquiring advanced training, to hone clinical expertise and explore emerging evidence in the field. Although OT-SI intervention often occurs within specialized therapy centers, many of the concepts can be applied in other settings as well. School-based occupational therapists have found ways to incorporate the central principles of OT-SI into the educational setting, including bringing specialized equipment into classrooms, therapy rooms, and playgrounds in ways that help to organize and prepare a child for learning. Successful therapy programs frequently involve helping families to understand and use the sensory integration concepts that support and facilitate their children's success by developing activities at home and identifying resources within the community that reinforce the experiences emphasized during therapy.¹⁹⁰

Evidence of Effectiveness of Ayres Sensory Integration Intervention

Occupational therapists who wish to use an OT-SI approach in practice need to keep up-to-date on research in this field to ensure that intervention is informed by the growing knowledge base. Research on the effectiveness of OT-SI is particularly critical to evidence-based practice in this specialty area. May-Benson and Koomar¹⁶² conducted a systematic review of 27 effectiveness studies that were published in peer-reviewed journals over a span of 37 years. Two meta-analyses were included: an early one that found a large, significant, positive treatment effect for motor outcomes in children with learning and intellectual disabilities¹⁸² and a later one that found moderate motor and psychoeducational benefits across different populations but

no significant difference from interventions that used other approaches.²³⁸ These findings, taken together with the results of other studies, led these authors to conclude that sensory integration intervention leads to positive results, especially compared with no intervention.¹⁶²

However, these encouraging findings must be interpreted with caution because of a variety of methodologic limitations that are common in research on interventions for children with developmental, learning, and behavioral challenges.^{162,167,180} For example, a common limitation in outcomes studies of OT-SI is that children may have been provided this intervention without confirming whether they actually have any problems with sensory integration. Another common limitation is that the intervention provided in a study may have been called sensory integration but was not actually provided in a manner that matches the defining characteristics of OT-SI.¹⁸⁵ This type of limitation is called a fidelity problem. In intervention research, fidelity refers to the extent to which the intervention provided in a study is faithful to the key elements of the intervention approach.

A reliable and valid fidelity instrument, the Fidelity Measure for ASI Intervention, was developed recently to provide researchers with a systematic method for ensuring fidelity of OT-SI intervention^{163,188} (Box 9-3). Table 9-2 presents evidence from group design studies that used the Fidelity Measure for ASI Intervention or a similar fidelity instrument to document that the intervention provided in the study was delivered in a manner that reflects OT-SI principles. As shown in Table 9-2, several studies examining the effectiveness of OT-SI have demonstrated positive outcomes of this approach for children with autism. In a randomized controlled trial (RCT) comparing fine motor intervention with OT-SI, Pfeiffer et al.¹⁹³ reported that children with ASD had greater gains in individual goals using Goals Attainment Scaling (GAS) as well as a significant decrease in autistic mannerisms. Similarly, Schaaf et al.²¹⁶ conducted an exceptionally well-designed RCT involving 32 children with ASD. The group who received OT-SI for 10 weeks, three times per week, showed statistically significant improvements in primary outcome measures using GAS, as well as improved performance in self-care and social activities and decreased caregiver assistance, which were secondary outcome measures. Both the Pfeiffer et al. and Schaaf et al. studies used the Fidelity Measure for ASI Intervention throughout the study to ensure adherence to the intended intervention.

An important issue in intervention trials is the maintenance of long-term gains after completion of a period of OT-SI intervention. An encouraging finding reported by Wilson and Kaplan²⁴⁷ suggests that children who receive sensory integration intervention may obtain long-term benefits that are not obtained by children who receive other interventions. Although this study was published before development of the Fidelity Measure for ASI Intervention, a systematic review of fidelity in sensory integration research found that the intervention in this study included most of the key fidelity elements of OT-SI identified by Parham et al.¹⁸⁵ Although no significant differences in outcomes were found between the two intervention groups in the original study (i.e., both the OT-SI and tutoring groups made significant gains),²⁴⁸ at follow-up 2 years later only the children who had received OT-SI maintained the gains that they had made after intervention. Maintenance of intervention gains is a critical issue that is relevant to cost-effectiveness of

TABLE 9-2

Effectiveness Studies Using Group Comparison and Fidelity Measure to Verify Occupational Therapy Using a Sensory Integration Approach Intervention

Author/Year	Purpose	Study Design and Subjects	Intervention and Outcome Measures	Results and Limitations	Conclusions
Iwanaga, Honda, Nakane, Tanaka, Toeda, & Tanaka ¹²³	Investigate the effectiveness of OT-SI for high-functioning children with ASD	Level III—Cohort study of two groups <i>Subjects:</i> 20 children with ASD (IQ > 70), ages 2-6 yr. Children received individual OT-SI (N = 8) if standard group therapy (GT) (N = 12) was not available. Groups were similar for gender and age.	<i>Intervention:</i> All participants received 8-10 mo of intervention, 1 session per week. GT focused on social skills. OT-SI included all elements in Fidelity Measure for ASI. <i>Measures:</i> JMAP before and after intervention.	OT-SI group made treatment gains in JMAP Total and 4 subscale scores. GT group made gains only on total score. Group differences in changes found for Total and 3 subscale scores, with OT-SI group benefitting more. Results may be biased by non-blinded ratings.	High-functioning young children with ASD may benefit from OT-SI in motor, nonverbal cognitive, and complex perceptual-motor functions.
Miller, Coll, & Schoen ¹⁷⁰	Determine whether OT-SI is more effective than a placebo treatment or no treatment	Level II—Small RCT <i>Subjects:</i> 24 children with SMD. N = 7 in OT-SI group, 10 in placebo group, and 7 no treatment. Groups equivalent for gender, ethnicity, parent education, & age. Mean age 6 yr in each group.	<i>Intervention:</i> Individual OT-SI twice per week for 10 weeks. Placebo was child-selected tabletop play activities in 1:1 sessions. Structured assessment to monitor fidelity. <i>Measures:</i> Leiter Parent Rating Scales, SSP, VABS, CBC, GAS, electrodermal reactivity.	OT-SI group made significantly greater gains than other groups on GAS and Leiter scales. Very large effect size found in OT-SI group for GAS. Parent involvement in OT-SI sessions may have biased results.	Children with sensory modulation problems may benefit from OT-SI. GAS outcomes may be especially sensitive to gains owing to OT-SI.
Pfeiffer, Koenig, Kinnealey, Sheppard, & Henderson ¹⁹³	Establish model RCT, identify appropriate outcome measures, and examine effectiveness of OT-SI for children with ASD	Level II—Small RCT <i>Subjects:</i> 32 boys and 5 girls with ASD, age 6-12 (mean = 8.8 yr) attending therapeutic activities program; 21 with autism and 16 with PDD-NOS. All scored ≥ 60 on the SPM. 20 received OT-SI & 17 received OT individualized fine motor (FM) intervention.	<i>Intervention:</i> Individual 45-min sessions for 18 days over a 6-week period. Fidelity Measure for ASI and a fidelity measure for FM group were used to monitor and manualize interventions. <i>Measures:</i> SPM, SRS, QNST-II, GAS, VABS-II. All evaluators blinded to group assignment.	SI group had more gains than FM group in GAS goals rated by parents and teachers. No differences found for SPM or QNST-II scores. Sample heterogeneity and short intervention period may have limited outcomes.	Short-term intensive OT-SI (3 $\times$ per week for 6 weeks) is more effective for children with ASD than fine motor intervention for attaining GAS goals. SPM and QNST may not be sensitive to short-term OT-SI gains.
Schaaf et al. ²¹⁶	Evaluate the efficacy of OT-SI for children with autism	Level II—Small RCT <i>Subjects:</i> 32 children randomly assigned to OT-SI (N = 17) + usual care or usual care control group (N = 15). All had confirmed diagnosis of ASD, ages 4-7 yr, IQ > 65, and assessment indicating SI problems. Groups similar for gender, race, parent education, age, autism severity, cognition, and non-study related services.	<i>Intervention:</i> Individual 1-hr OT-SI, 3 times per week for 10 weeks, provided by SI-certified OTs. Fidelity Measure for ASI used to monitor manualized OT-SI intervention. <i>Measures:</i> Primary measure was GAS. Goals set by independent evaluators using standard questions for parents. Secondary measures were PEDI, PDDBI, and VABS-II. All evaluators blinded to group assignment.	OT-SI group made significantly greater gains than control group on GAS and PEDI scores for Self-Care Caregiver Assistance and Social Function Caregiver Assistance.	Children with ASD + SI problems, and mild or no intellectual disability, are likely to benefit from OT-SI. Benefits include gains in daily life functioning and decreased need for caregiver assistance during self-care and social activities.

Note: Levels of evidence are rated using the AACAPDM² Methodology for quantitative group designs (AACAPDM, 2008) or for single-subject research designs (Logan, Hickman, Harris, & Heriza, 2008). ASD, autism spectrum disorder; CBC, Child Behavior Checklist; GAS, goal attainment scaling; JMAP, Japanese version of Miller Assessment for Preschoolers; OT-SI, occupational therapy using Ayres Sensory Integration (ASI) intervention; PDDBI, Pervasive Developmental Disorders Behavior Inventory; PDDNOS, pervasive developmental disorder not otherwise specified; PEDI, Pediatric Evaluation of Disability Inventory; QNST-II, Quick Neurological Screening Test (2nd ed.); RCT, randomized controlled clinical trial; SMD, sensory modulation disorder; SPM, Sensory Processing Measure; SRS, Social Responsiveness Scale; SSP, Short Sensory Profile; VABS, Vineland Adaptive Behavior Scales (VABS-II = 2nd ed.).

BOX 9-3 Fidelity Process Elements of Occupational Therapy Using Ayres Sensory Integration Intervention

OT-SI intervention is implemented with moment by moment adjustments that are made based on the child's responses and choices in concert with the occupational therapist's clinical reasoning. The fidelity elements listed here describe the process of therapy, that is, what the therapist is responsible for doing throughout OT-SI therapy sessions.¹⁸⁸ In action, these elements occur simultaneously and interactively. Additionally, structural elements are required for the appropriate implementation of OT-SI.^{163,188} These include specified therapist qualifications and training, space and equipment requirements, safety monitoring measures, and assessment and documentation procedures.

1. *Ensures physical safety:* The physical space arrangement and materials in the therapy room, as well as the occupational therapist's actions, ensure the child's physical safety.
2. *Presents sensory opportunities:* Using therapeutic equipment, materials, and activities, the occupational therapist provides the child with sensory-rich activities, particularly those that involve body-centered (tactile, proprioceptive, and vestibular) sensory experiences
3. *Supports sensory modulation for attaining and maintaining a regulated state:* The occupational therapist modifies sensory conditions and activity challenges to help the child attain optimal arousal, alertness, and affect for engagement in activities.
4. *Challenges postural, ocular, oral, and/or bilateral motor control:* Using assessment data regarding areas of need, the occupational therapist introduces, supports, or modifies activities to provide challenges to these areas of motor control.
5. *Challenges praxis and organization of behavior:* Using assessment data regarding areas of need, the occupational therapist introduces, supports, or modifies activities to challenge the child's motor planning, ideation, and/or ability to plan and engage in organized activities.
6. *Collaborates in activity choice:* The occupational therapist strives to share control with the child in choosing, modifying, or changing activities; ultimately the goal is that activities are chosen collaboratively by the occupational therapist and child.
7. *Tailors activity to present just-right challenge:* To ensure the child's optimal engagement, the occupational therapist tailors activities so that they are at the "just-right" level of challenge, by suggesting or supporting an increase or decrease in task complexity so that the activity is not too difficult or too easy for the child to do independently or with therapist support.
8. *Ensures that activities are successful:* The occupational therapist strives to provide challenges in which the child will experience feelings of success.
9. *Supports child's intrinsic motivation to play:* The child's intrinsic motivation to play is prioritized in the OT-SI approach, so the occupational therapist creates a setting that supports play as a way to fully engage the child in the intervention.
10. *Establishes a therapeutic alliance with the child:* In OT-SI, a strong positive relationship between the child and occupational therapist is essential; therefore, the occupational therapist establishes an interpersonal connection with the child, forming a therapeutic alliance that entails working together in a mutually enjoyable partnership.

From Parham, L. D., Roley, S. S., May-Benson, T., et al. (2011). Development of a fidelity measure for Research on Ayres Sensory Integration. *American Journal of Occupational Therapy*, 65, 133–142.

intervention. Additional studies are needed to measure long-term outcomes of OT-SI.

Although randomized clinical trials are considered to be the gold standard of effectiveness studies, other research designs examining intervention outcomes also make valuable contributions to understanding the potential effects of sensory integration intervention. In research using single-subject designs, a child serves as his or her own control and is monitored repeatedly before intervention (the baseline phase) and during intervention. An advantage to this approach is that behavioral outcomes can be highly individualized and tracked over time to provide an understanding of each child's response to intervention. For example, Linderman and Stewart measured three behavioral outcomes of OT-SI for two preschool children with pervasive developmental disorders.¹⁴⁷ Each outcome was observed in the child's home and was tailored to address functional issues for each child (e.g., response to holding and hugging for one child and functional communication during mealtime for the other). Results indicated significant improvements between baseline and intervention phases for five of the six outcomes measured. These results are encouraging, but should be considered tentative because of the small number of participants and the absence of a fidelity measure.

Future studies can build on current research to explore new questions regarding who is a good candidate for OT-SI

intervention and what kinds of outcomes can be expected. For example, it would be reasonable to expect different intervention outcomes for children with different kinds or different levels of severity of sensory integration difficulties, yet this has not been systematically studied since Ayres' early work.^{13,19,24,27} Research addressing this issue could help practitioners predict who will best respond to individual OT-SI intervention and who may be better served by other intervention approaches. The effectiveness of systematically combining individual OT-SI intervention with other interventions, such as sensory strategies at home or in the classroom, specific skill training, group programs, or consultation, also needs further research. Finally, long-term maintenance of gains, particularly those related to social participation outcomes, is an important question that should be addressed in future research.

Expected Outcomes of Ayres Sensory Integration Intervention

Occupational therapy aims to improve a child's health and quality of life through engagement in meaningful and important occupations or activities. To accomplish this with a young child who has sensory integrative problems, the occupational therapist usually first aims to improve sensory integrative functions through direct OT-SI intervention. Based on the premise of neuroplasticity in the young and developing brain,

sensory integration theory holds that many of the child's sensory integration functions improve with individually tailored therapeutic activities that provide opportunities for exploration and challenge. In addition to addressing the underlying sensory integration problems, occupational therapists also often help the child to develop specific skills and strategies, to minimize the effects of the problems the child is experiencing and help the child to cope with the current day-to-day demands. Finally, consulting with parents and teachers to allow for carry-over of direct intervention and to plan modifications of activities, routines, and environments is an important component of any intervention program involving children. Often direct intervention, specific skill training, and consultation are thoughtfully combined in a treatment plan that is designed to meet the particular needs of the child and family.

The child's goals and objectives target specific occupations, such as eating, play, rest, work, and self-care, in which positive changes are expected. For example, a toddler who tends to be overstimulated much of the time because of severe sensory modulation problems may consequently have difficulty falling and staying asleep. Sleep deprivation can aggravate over-responsiveness and behavior problems for the child and can also disrupt occupational performance of other family members. A goal may be for the child to acquire more predictable sleep patterns with adequate amounts of sleep. A related objective might be that the child will tolerate unpredictable sensations such as household sounds, change in room temperature, or the texture of sheets and blankets in order to successfully nap without interruption for at least 1 hour for 3 days per week. The intervention could involve direct remediation to reduce the sensory defensiveness, as well as parent consultation on strategies such as calming activities, a predictable activity schedule including a specific rest time ritual, and creation of an arousal-reducing environment after lunch (e.g., lights dimmed and noise reduced and screened with rhythmic sounds or "white noise").

Sometimes specific objectives that address performance skills are appropriate as a way to monitor progress toward the desired changes in daily occupations. Expected outcomes are summarized in Box 9-4; more detailed descriptions of each category follow.

Increase in the Frequency or Duration of Adaptive Responses

As discussed in the introduction of this chapter, adaptive responses occur when an individual responds to environmental

challenges with success. A priority for an occupational therapist applying OT-SI principles is to create opportunities for the child to make adaptive responses. Ensuring that the sensory experiences inherent in activities are organizing rather than disorganizing and integrating rather than overwhelming requires careful monitoring on the part of the occupational therapist, who must be sensitive to the child's response to each aspect of an activity and to each type of sensory input involved. The OT-SI intervention approach intensively focuses on the child's acquisition of higher level adaptive responses.

Increasing the duration and frequency of adaptive responses is an important outcome of sensory integration because functional behavior and skills are developed by mastering simple adaptive responses. For example, a child who has difficulty staying with an activity for more than a few seconds tends to shift from one activity to another, thus never having the chance to fully process the sensation and develop purposeful actions in response to it. A desirable outcome for that child might be to remain involved in a simple activity, such as swinging, for longer periods of time. The specific goal might be worded as, "The child will sustain engagement for two minutes in a simple movement activity, such as remaining seated in a swing while holding onto the side ropes as it moves, with therapist providing verbal and physical cues for support." Achievement of this simple adaptive response can lead to increased postural control and emerging motor plans such as holding on and using rhythmic, coordinated trunk and leg flexion movements to move the swing. These basic adaptive responses may contribute to the functional behavior of staying seated in an upright position during circle time in the school classroom or participating with peers on a playground swing, thus contributing to engagement in important childhood occupations. In a case study of a child with autism who participated in the Schaaf et al. clinical trial,²¹⁶ such improvements in basic adaptive responses are called proximal outcomes of OT-SI.²¹⁷ These proximal outcomes are thought to lead to distal outcomes related to participation in daily routines.

Development of Increasingly More Complex Adaptive Responses

Adaptive responses can vary in complexity, quality, and effectiveness.¹⁹ As noted, a simple adaptive response might be simply holding on while sitting on a moving swing. An example of a more complex adaptive response would be releasing grasp while swinging on a trapeze, and then at just the right moment, jumping off to land on a pillow. This type of action requires timing and sequencing, as well as integration of various sensory functions such as proprioceptive awareness of changes in body position, tactile perception in the hands, vestibular sense of motion through space, and visual perception of the intended target. Over time, effective OT-SI intervention is expected to enable the child to make increasingly more complex adaptive responses. This outcome is based on the assumption that sensory integrative procedures promote more efficient organization of multisensory input at elementary levels of functioning, which in turn is expected to enhance functions that are more complex. The result is an improvement in the child's ability to make judgments about the environment, what can be done with objects, and which specific actions need to be taken to accomplish a goal. Increase in complexity of adaptive responses is another example of proximal outcomes, which lead to long-term distal outcomes of OT-SI.²¹⁷

BOX 9-4 Expected Outcomes of Occupational Therapy Using a Sensory Integration Approach Intervention

1. Increase in the frequency or duration of adaptive responses
2. Development of increasingly more complex adaptive responses
3. Improvement in gross and fine motor skills
4. Improvement in cognitive, language, and academic performance
5. Increase in self-confidence and self-esteem
6. Enhanced occupational engagement and social participation
7. Enhanced family life

Improvement in Gross and Fine Motor Skills

The child who makes consistent and more complex adaptive responses shows evidence of improved sensory integration. Moreover, this child meets new challenges with greater self-confidence. A net result of these gains frequently is greater mastery in the motor domain. An example is the child with a vestibular processing problem who exhibits greater competency and interest in playground activities and sports after individual OT-SI intervention, even though these activities were not practiced during therapy. Motor skills may be among the earliest complex skills to show measurable change in response to an OT-SI approach, probably because extensive motor activity is inherent in this intervention approach.¹⁸²

Improvement in Cognitive, Language, or Academic Performance

Although cognitive, language, and academic skills are not usually the specific objectives of OT-SI, improvement in these domains has been detected in some effectiveness studies involving the provision of ASI intervention.^{13,19,24,151,194,244} Application of OT-SI therapeutic procedures is thought to generate broad-based changes in these areas secondary to enhancement of sensory modulation, perception, postural control, or praxis.^{20,57} For example, a child with autism may be helped through a sensory integrative approach to respond in a more adaptive way to sights, sounds, touch, and movement experiences. This improvement in sensory modulation may lead to a better ability to attend to language and academic tasks; thus, improvements in these areas may follow. A child who has a vestibular processing disorder may improve in postural control and equilibrium, freeing the child to concentrate more efficiently on academic learning, without the distraction of frequent loss of sitting balance or loss of place while copying from the blackboard. This child's vestibular-related improvements are also likely to have a positive effect on playground and sports activities because effects of classic sensory integration intervention are expected to generalize to a wide range of outcome areas.

Increase in Self-Confidence and Self-Esteem

Ayres asserted that enhanced ability to make adaptive responses promotes self-actualization by allowing the child to experience the joy of accomplishing a task that previously could not be done.²⁰ The outcome of therapy that encourages successful, self-directed experiences is a child who perceives the self as a competent actor in the world. Individual and group programs and direct and indirect services can help the child master the activities that are personally meaningful and essential to success in the world of everyday occupations. Mastery of such activities is expected to result in feelings of personal control that, in turn, lead to increased willingness to take risks and try new things.²⁰ For example, a child with gravitational insecurity may experience not only fear responses to climbing and movement activities, but also feelings of failure and frustration when limited in participating in the play of peers. In such a case, an increase in self-confidence and comfort in one's physical body is often accompanied by a general boost in feelings of self-efficacy and worth. Cohn, Miller, and Tickle-Degnen noted that parents' perceptions of the benefits of occupational therapy using a sensory integrative approach included enhancing feelings of self-worth, in addition to improving abilities and activities.⁷⁰ Parents in this study perceived that this intervention enabled their children to take more risks and try new activities, which opened the door to greater possibilities.

Enhanced Occupational Engagement and Social Participation

Occupational therapy programs that address sensory integrative problems encourage the child to organize his or her own activity, particularly in the OT-SI intervention approach. As the child develops general sensory integrative capabilities and improved strategies for planning action, gains are seen in relation to the ability to master self-care tasks, cope with daily routines, and organize behavior more generally.²⁰ As a result, the child often is able to participate more fully in the occupations that are typical for peers. Anticipated gains in social participation are often specified as individualized goals. For example, intervention may help the child who is overly sensitive to touch or movement to respond to sensations in a more adaptive manner. As a result, the child approaches and engages in the challenges of everyday occupations, such as getting ready for school in the morning, sharing a table with others in the school cafeteria, behaving appropriately in the classroom, and playing with friends on the playground with greater security and confidence. As noted previously, Cohn et al.⁷⁰ reported that parents viewed their children as more willing to try new experiences following intervention, thus enhancing their opportunities for social participation. Not only is participation in daily occupations performed with greater competency and satisfaction, but relationships with others are likely to become more comfortable and less threatening. It is noteworthy that randomized clinical trials of OT-SI using the OT-SI fidelity measure have consistently found significant gains in individualized goals related to social participation and occupational engagement.^{170,193,216}

Enhanced Family Life

When children with sensory integrative problems experience positive changes during intervention, their lives and the lives of other family members may be enhanced. One possible by-product of intervention based on OT-SI principles is that parents gain a better understanding of their children's behavior and begin to generate their own strategies for organizing family routines in a way that supports the entire family system. This kind of change can be particularly powerful for parents of children with autism, whose perceptions of child behaviors may be reframed as they become familiar with the sensory integrative perspective. For example, behavior that is interpreted as bizarre, such as insisting on wearing tight rubber bands on the arms, may be reframed as a meaningful strategy that the child uses to obtain deep pressure input for self-calming.⁵ Instead of viewing the behavior as a frustrating sign of pathology that should be eliminated, reframing may lead the parents to explore other ways that they could provide the child with the deep pressure experiences that he or she seeks. An important outcome of sensory integrative intervention, then, may include changes in parents' understanding of the child, leading to new coping strategies and alleviation of parental stress.⁶⁹ In her studies of parental perspectives, Cohn has found that an important outcome of the sensory integrative approach is that parents tend to "reframe" their view and expectations of their children in a positive manner.^{67,68}

Measuring Outcomes of Ayres Sensory Integration Intervention

Because every child with a sensory integrative problem is unique, the expected outcomes of an OT-SI approach are

individualized and diverse. As noted in the preceding section on expected outcomes, goals are often stated as objectives that target particular observed behaviors of the child. These objectives should contain a specific description of the desired behavior, including the context of the behavior and an objective way to measure it, for example, by timing how long the child can sustain an activity or with what percentage of success she can perform it after a number of attempts. Some good examples of measurable outcomes that target child-specific behaviors are provided by single subject studies.^{59,147}

Additionally, outcomes are sometimes measured using standardized tests. In fact, some of the SIPT tests (e.g., Design Copying, Standing and Walking Balance, and most of the praxis tests) are good measures of change because of their strong test-retest reliability, in addition to being relevant to concerns that are commonly voiced by parents and teachers. However, standardized tests often do not address key occupational issues. When used, care must be taken to select a test that is likely to be sensitive to the kinds of changes expected for the particular child. Sometimes changes in raw scores are more informative than changes in standardized scores, because raw score change is a direct measure of the child's improvement in skill relative to performance at initial assessment. Comparing the child's performance to normative data may not detect actual changes in performance.

Goal attainment scaling (GAS) is an alternative to standardized tests that addresses the uniquely individualized nature of expected outcomes of OT-SI. Goal attainment scaling provides a means to prioritize goals that are specifically relevant to individuals and their families and to quantify the results using a standard metric that allows comparison of achievement across different types of goals (see Chapter 24). Emerging evidence indicates that this approach is useful for capturing outcomes of OT-SI intervention programs.¹⁵⁴ In three randomized, controlled clinical trials, GAS detected significant improvements among children who received OT-SI intervention, compared with those receiving alternative conditions.^{170,193,217} This procedure for systematic monitoring of meaningful goals aligns well with current recommendations of the American Academy of Pediatrics³ regarding sensory integration therapies for children with developmental and behavioral disorders.

Sensory Stimulation Protocols

This section discusses specific sensory protocols that are provided by the therapist or by the teacher or parent under the guidance of the therapist. In this discussion, we use the term *sensory stimulation protocol* to refer to interventions that involve application of specific types of sensory stimuli that are controlled by the therapist and delivered in a predetermined manner, usually according to a prescribed schedule or sequence. Examples include brushing the skin using a specific technique and sequence to provide tactile input, spinning in a prescribed sequence to provide controlled vestibular input, or having the child wear headphones while listening to selected music or other sound stimuli as part of a packaged sequential program. The sensory stimulation is applied in a non-contingent manner, that is, specific procedures used are not dependent on the child's behavior.

As described earlier, sensory stimulation techniques are used on a limited basis within OT-SI intervention sessions, where

they are embedded within ongoing activities and are constantly modified based on the child's response. Whenever possible, control of the sensory input is given to the child. Within OT-SI sessions, the common purpose of these strategies is to support the child's sensory and arousal modulation. For example, swinging might be introduced by the therapist to increase or decrease arousal level by constantly adjusting the sensory qualities of the swinging activity (e.g., velocity, direction, intensity, predictability) according to the child's ongoing responses. Another example is the introduction of deep touch-pressure stimulation, such as having the child wear a weighted vest during activities, or playing a game of making a pretend "sandwich" by having the child lie inside two large pillows or mats. This kind of sensory strategy generally has a short-term calming effect, which may serve to help decrease sensory defensiveness, anxiety, or heightened arousal in the immediate situation.⁸⁹ Such sensory strategies are usually initiated at moments when the therapist judges that they may help move the child into a more organized state for making adaptive responses. Within the context of an OT-SI session, the therapist constantly monitors the child's response and accordingly adjusts the stimulus, shares control of the stimulus with the child, or discontinues the stimulus.

In contrast, sensory stimulation protocols are often used as stand-alone interventions that are performed in a prescribed manner and sequence, according to a particular schedule or sequenced program. Probably the most regimented examples are the Wilbarger Protocol and the Astronaut Program. The Wilbarger Protocol involves application of touch pressure in a particular sequence via brushing arms and legs with a surgical scrub brush using stroking motions, followed by manual compression of specific joints, every 2 hours.²⁴⁵ The Astronaut Program is a protocol involving application of rotary vestibular combined with sound stimulation.¹²⁹ Expected outcomes for the Wilbarger and Astronaut protocols include improved sensory modulation and self-regulation, and general improvements in attention, learning, and behavior. Evidence on effectiveness of the Wilbarger protocol is inconsistent and limited to a few case studies,^{44,77} and evidence regarding the Astronaut protocol currently is not available.

The strongest research support at this time for sensory stimulation protocols is for use of massage protocols. Two randomized controlled trials (RCTs) using a massage protocol developed by Tiffany Field indicated some improvements in tactile modulation and reductions in problem behaviors among children with autism, perhaps related to improved sleep after massage.^{91,94} More recently, RCTs of a type of Qigong massage, based in traditional Chinese medicine, have also found positive effects. This intervention was designed to improve sensory processing, physiologic self-regulation, and sleep of children with autism. Significant improvements in behavior of children with autism were indicated after individualized delivery of a Qigong massage regimen over a 5-month period by trained occupational therapists or parents who were trained and coached by occupational therapists.^{226,227}

Sound-based interventions (also called sound therapy or auditory programs) involve complex applications of auditory stimulation, specifically music delivered through headphones or other listening systems. These interventions usually involve multiple sessions in which a specific sequence of filtered music is presented over time. Generally, the child is not guided or

prompted to make any responses to the stimulation beyond simply listening. Originally developed by physicians as an individual therapy, occupational therapists have used and developed versions that can be used either alone, during OT-SI intervention sessions, or during other sensory-based interventions. Sound-based interventions target a variety of outcomes, including sensory modulation, self-regulation, attention, improved language, and adaptive functioning. These interventions have been tested in single-system studies, small group comparison designs, and RCTs with mixed findings for children with diverse conditions.^{45,106,178,202,228}

Sensory-Based Strategies

We use the term *sensory-based strategies* to refer to specific sensory interventions that are less regimented than sensory stimulation protocols, with more flexible guidelines for use in daily life. Examples include wearing a weighted vest for touch pressure and enhanced proprioceptive input, sitting on a therapy ball for augmented vestibular-proprioceptive input, or use of body compression devices such as the Grandin hug machine. In practice, these sensory strategies are usually integrated into daily routines and are delivered by parents or teachers or are self-administered by the child, following instruction by a professional. Expected outcomes vary depending on diagnosis and the specific intervention used, but generally they include better self-regulation, improved attention, and decreased behavior problems such as self-stimulatory or aggressive behaviors.

The sensory strategy that has been researched most often is the use of weighted vests to improve attention to task and in-seat behaviors in the classroom, but most of these single-subject studies did not find expected improvements in behavior.^{73,93,119,120,128,145,196} However, positive short-term effects of sitting on a therapy ball chair (also called stability ball) in the classroom have been documented in a few single-system studies of children with autism spectrum or attention deficit disorders, with immediate benefits related to in-seat behavior, attention to task, and productivity in academic tasks for many but not all children.^{29,92,218,219} Data from a study conducted by Bagatell and her colleagues suggest that therapy balls may be most effective when used selectively with consideration for the sensory processing characteristics of the individual child.²⁹ In their study of children with autism, the best responder to a ball chair was a child who demonstrated strong vestibular-proprioceptive sensory seeking. Perhaps this strategy was effective because therapy balls generate more sensory input via vestibular and proprioceptive systems compared with conventional classroom chairs. Conversely, use of a therapy ball was not helpful for a child in this study who had poor postural stability. It may be that, for this child, sitting on a ball chair created stress and distraction owing to the extra challenge on postural control that this strategy imposes. These findings underscore the importance of conducting an assessment of sensory integration before selecting sensory strategies for a particular child. Research on use of therapy cushions (inflatable disks placed in the child's chair to sit upon) has not produced benefits that are as positive as therapy balls, but they may be a more practical alternative to therapy balls in some classrooms.^{218,236}

Less well known are sensory interventions that involve self-administration of deep touch pressure across the body

using special compression devices. A small RCT evaluated use of the Grandin hug machine for 6 weeks found some reduction in self-perceived anxiety and decreased arousal/reactivity, as measured by electrodermal responses, in children with ASD.⁸⁹ An experimental study of a similar device that provided self-administered deep pressure around the circumference of the body showed that it had a calming effect with decreased subjective anxiety and increase in perceived relaxation.¹³⁷

Many sensory strategies used by occupational therapists have not yet been studied systematically. Diana Henry has developed a series of guidebooks for different age groups that describe many of the sensory strategies that therapists have found to be useful and practical.^{110,113-115} She also has developed an electronic tool called *Quick Tips* for linking Sensory Processing Measure assessment results to a menu of sensory strategies to consider for the child being assessed.^{111,112}

Individual Training in Specific Skills

Although OT-SI intervention is focused on improving foundational neural functions that allow a wide range of capabilities and skills to emerge, therapists will provide interventions that immediately help a child develop specific skills and the family develop short-term coping strategies. For example, a child with poor proprioceptive feedback may need to keep up with handwriting exercises assigned in class. Application of individual OT-SI intervention would aim to help the child develop better body awareness that eventually will help not only with writing but also with catching, throwing, cutting, buttoning, and many other proprioception-dependent skills. However, because of everyday classroom stress from the demands of handwriting, the occupational therapist may provide specific handwriting interventions to help the child develop better handwriting skills. When working on specific skill development, the occupational therapist may find that success is easier to obtain when mindful of the basic assumptions underlying OT-SI intervention (see Box 9-2). For example, the occupational therapist could build on the child's inner drive by encouraging self-direction and active participation, for example, through having the child write words, sentences, or paragraphs related to individual interests and experiences.

Occupational therapists providing OT-SI intervention often reserve a segment of individual therapy sessions to devote to specific skill training, if indicated by the child's presenting problems and by the child and family's goals. Skills often targeted include fine motor skills, dressing skills, sensorimotor oral and eating skills, and games and activities that are popular with peers (e.g., jacks, bike riding). Expected outcomes are specific to the targeted skill. Other chapters in this textbook that address skill therapy programs provide detailed information about specific outcomes and how they are measured.

Group Interventions

Group activity programs may be provided in conjunction with individual OT-SI or after a period of time receiving individual OT-SI. These may include groups that focus on social skills, communication, visual-motor or fine motor skills, gross motor skills or activities, or self-regulation. Group programs are ideal arenas in which the increases in self-confidence made in

individual therapy can be tried out in the more challenging context of a social setting.

In some situations, external variables such as funding limitations, availability of staff, or organizational policies create the need for children to receive therapy in a group setting. If a group intervention is the only option, it is important that occupational therapists make recommendations for specific interventions based primarily on the needs of the children being served, rather than allowing the external factors to dictate the type of intervention that is provided in the group setting.

The occupational therapist working with a group of children cannot provide the same level of vigilance to individual responses that takes place during individual therapy. Therefore, some of the highly individualized applications of OT-SI intervention cannot be used within a group, nor can the therapist give the close guidance that is finely tuned to the individual child's needs at every moment of the treatment session. However, the principles of OT-SI outlined in [Box 9-3](#) are important concepts to incorporate into the group format as much as possible.

To apply sensory integration principles to a group program, an occupational therapist should be familiar enough with sensory integration theory to understand precautions and general effects of various sensory and motor activities. Experience and training in working with groups, including how to maintain the attention of children in a group, how to address varying skill and interest levels, and how to deal with behavioral issues, are also recommended for occupational therapists applying sensory integration principles in group programs.

Group programs, compared with individual therapy, tend to place greater demands on children for several reasons, including limited opportunity for individualization of activities, the presence of other children with their unpredictable behaviors, and reduced opportunity for direct assistance from the therapist. Thus, a limitation posed by group programs is that challenges imposed on the group may at times be too great for an individual child, leading to frustration and failure. The therapist who provides a group program needs to be alert to the potential for this undesirable effect and strive to avoid it as much as possible.

On the other hand, working with children in a group provides valuable opportunities to observe some of the ways in which sensory integrative problems disrupt participation in a social context ([Figure 9-13](#)). Some problems emerge only in group situations and may not be evident during individual therapy. For example, tactile defensiveness may not be apparent in the safe constraints of individual therapy but may become obvious as a child tries to participate within a group of people who are brushing by in an unpredictable manner. Observing how the group dynamic affects the child can help the therapist know which aspects of the classroom, playground, park, or after-school activities are likely to pose a threat or challenge ([Case Study 9-2](#)).

An especially innovative application of sensory integration concepts to groups is reflected in the work of Williams and Shellenberger.²⁴⁶ Through a group format, their Alert Program helps children learn to recognize how they feel when their levels of alertness and arousal change throughout the day. Using this awareness, participants then learn to monitor their arousal levels in a variety of settings and to identify the sensory experiences that they can use to change their level of alertness to

FIGURE 9-13 Group programs provide opportunities for children with sensory integrative disorders to develop coping skills that help them function in social context with peers.

function more optimally. This approach particularly seems to be useful in school settings and as an adjunct to individual OT-SI. In a survey of types of services provided by occupational therapists to children with emotional disturbances in public schools, Barnes and her colleagues found that the most commonly reported intervention was sensory integration, with nearly 47% using the Alert Program individually or in groups.³⁵ In another study, positive outcomes for children with emotional disturbance were documented following an 8-week long Alert Program delivered within the classroom setting.³⁶ An RCT showed that children with fetal alcohol spectrum disorders who received a caregiver-child adaptation of the Alert Program made significant gains in executive and emotional functioning compared with the control group.²⁴³

It is important to differentiate between what can be accomplished within a group versus an individual therapy session. Because group programs do not permit the same degree of intensive, individualized work, they generally are not expected to lead to the same outcomes. Goals for group interventions usually address the particular purpose of the group intervention, such as development of particular social or motor skills. Gains in social participation are among the most important and helpful of group intervention outcomes.

Consultation on Modification of Activities, Routines, and Environments

Sensory integrative problems are complex and are often misinterpreted as solely behavioral, psychological, or emotional. Helping family members, teachers, and other professionals to understand the sensory integrative nature of the problem can be a powerful means toward helping the child. When the child's behavior is reframed in sensory terms using everyday language, a new understanding of the child often ensues. Cermak aptly referred to this process as *demystification*.⁶² Parents commonly express relief at finally understanding puzzling and frustrating behaviors, and they may experience release from feeling that they have caused these problems through a maladaptive parenting style. This insight opens the door to discovering simple strategies that can be used throughout the day that help the

CASE STUDY 9-2 Drew

History

Drew was diagnosed with autism when he was 7 years of age. His cognitive functioning was within age expectations. His mother was a native Korean speaker, and his father was a native English speaker. Both Korean and English were spoken in the home. All of Drew's early developmental milestones were attained within normal limits, except for language acquisition. He did not speak any words until 2 years of age, and by age 3 his family was concerned about his delayed language skills. Drew attended an English-language preschool at 3 years of age and then a Korean-language preschool. He was asked to leave the second preschool because of aggressive behavior. When he was 4 years old, Drew attended a private special-education school where he received speech therapy and participated in a language-intensive playgroup. When Drew reached kindergarten age, he was enrolled in public special education programs.

Reason for Referral

Drew initially was referred by a counselor to an occupational therapy private practice for evaluation when he was nearly 8 years old. His counselor thought that Drew had signs of a sensory integrative disorder, and he believed that Drew might benefit from occupational therapy. Drew's mother reported that her main concerns for Drew were related to his poor socialization skills, his limited ability to play with games and toys, and his tendency to become easily frustrated.

Evaluation Procedures

Although the Sensory Integration and Praxis Tests (SIPT) were attempted during the initial occupational therapy assessment, Drew did not follow the directions or attend to the tests sufficiently to obtain reliable scores. Consequently, his occupational therapy evaluation was guided by the therapist's knowledge of sensory integration theory and comprehensive procedures for assessment of sensory integration. Evaluation procedures consisted of a parent interview, parent completion of a developmental history and sensory questionnaire, and structured as well as unstructured observations of Drew in a clinical therapy setting. At the time of assessment it was not possible to interview Drew's teacher. However, Drew's mother, who often observed him in the classroom, provided information about his performance at school.

Evaluation Results

Drew demonstrated inefficiencies in several areas related to sensory integration. During the assessment, signs of inconsistent responses to tactile input were evident. For example, Drew demonstrated a complete lack of response to some tactile stimuli such as a puff of air on the back of his neck or the light touch of a cotton ball applied to his feet when he was not visually attending. However, he withdrew in an agitated fashion when the therapist attempted to position him. His mother reported that he showed extreme avoidance of certain textures of food and clothing and that he disliked being touched. She also stated that he seemed to become irritated by being near other children at school and sometimes pinched or pushed peers who came close to him. Drew also

appeared easily overstimulated by extraneous visual and auditory stimuli. His mother stated that he often covered his ears at home when loud noises were present and that at school he sometimes seemed confused as to the direction of sounds. He was observed to pick up objects and look at them very closely, and he appeared to rely on his vision to complete tasks. In response to movement, he enjoyed swinging slowly but became fearful with an increase in velocity. His mother stated that he often seemed afraid when he was climbing on equipment at the park.

Drew's balance was observed to be poor, and his equilibrium reactions were inconsistent. He also had trouble positioning himself on various pieces of equipment, indicating poor body awareness. During the assessment he appeared to seek touch-pressure stimuli, including total body compression. He was reported to jump a great deal at home and at school. These types of proprioception-generating actions appeared to have a calming effect on Drew.

In the area of praxis, Drew imitated positions and followed verbal directions to complete motor actions, but he had difficulty initiating activities on his own or attempting something that was unfamiliar to him. He also had difficulty timing and sequencing his actions. His mother reported that he tended not to participate in sports or in park activities and that he had trouble throwing, catching, and kicking balls. Drew completed puzzles, strung beads, and wrote his name; however, bilateral activities such as cutting and pasting were difficult for him.

Socially, Drew demonstrated poor eye contact and tended to use repetitive phrases that he had heard in the past. His mother stated that he wanted to play with peers but found it hard to make friends. Drew was independent in all self-care skills, except for tying shoes and managing some fasteners.

Based on the interview and questionnaire with Drew's mother, as well as observation of Drew in the specialized therapy setting, the therapist's evaluation report concluded that his behaviors indicated irregularities in sensory responsiveness, including hyper-responsiveness to some aspects of tactile, vestibular, visual, and auditory stimuli. Perception of tactile and proprioceptive information was also thought to be affected because of signs of poor tactile awareness and inefficient use of position sense. He also demonstrated difficulty with balance, bilateral coordination, and the ideation, timing, and sequencing aspects of praxis. These difficulties were thought to interfere with Drew's ability to play purposefully with toys and to participate in age-appropriate games and sports. These sensory integrative problems, in combination with his language delays, very likely were interfering significantly with his social skills and his ability to make friends, and increasing his tendency to become frustrated, which were the major concerns of his parents.

Recommendation

Individual occupational therapy was recommended to improve Drew's sensory integrative functioning as well as fine and gross motor skills. Because socialization issues were such a major concern for Drew's family and were interfering with his performance at school, the evaluating therapist also

CASE STUDY 9-2 Drew—cont'd

recommended that Drew participate in an after-school group occupational therapy program to facilitate the acquisition of social skills.

Occupational Therapy Program

Drew received individual and group occupational therapy for 1 year in a therapeutic setting designed for the provision of OT-SI. The individual therapy involved OT-SI intervention as well as intervention strategies focused on specific skill development. Over the course of therapy, Drew demonstrated significant gains in sensory integrative functions. Specifically, he no longer exhibited signs of tactile defensiveness and fear of movement activities, and his performance in fine and gross motor activities suggested improved tactile perception and body position awareness. Motor planning of novel actions improved but continued to be of some concern for Drew. However, he made measurable gains in familiar motor tasks such as catching and throwing a ball, writing, and using scissors. Through the group occupational therapy program, Drew developed new social skills that enabled him to initiate and maintain interaction with peers, share objects, and play cooperatively with some assistance and structure from adults.

After this year of individual and group occupational therapy, a combination of consultation and individual therapy at school was recommended and provided. Teacher consultation addressed modification of classroom activities and routines to support Drew's success. The focus of this phase of Drew's occupational therapy program was to help him apply his improved sensory, motor, and social skills within the natural context of school. Because the initial year of therapy using an OT-SI approach had helped Drew tolerate and respond appropriately to sensory information, and because he

had developed many of the specific skills that he needed in the classroom during individual therapy, his focus on and mastery of the demands expected of him at school had greatly improved. By the end of the school year, Drew's occupational therapist recommended that occupational therapy be discontinued because she believed that his teacher would continue supports in the areas that had been addressed through the consultation program.

However, when the individualized educational program (IEP) team met to discuss Drew's transition to a new school, they had significant concerns that Drew might regress in a new setting with many new routines and expectations. The IEP team requested that occupational therapy continue to ensure a smooth transition for Drew and to put in place a plan that would continue to help him develop socially.

When school resumed in the fall, the occupational therapist had arranged a "big buddy" program with a local high school. Two high school seniors worked with Drew as part of a social service assignment during recess for the fall semester. The occupational therapist trained the high school students to carry out a socialization program aimed at helping Drew feel comfortable with a new set of peers. Drew seemed to look up to the high school students and responded well to the "big buddy" program.

By the end of the fall semester in the new school, Drew played cooperatively with peers, interacting independently and communicating appropriately. His occupational therapy program was formally discontinued at this time, although the occupational therapist continued to communicate informally with Drew's teacher on occasion. The option for further consultation or direct intervention was available should the need arise, but no further intervention was needed.

child to feel more comfortable and participate more fully in everyday occupations. Teachers also may appreciate having an alternative way to view child behaviors, especially when this new perspective is coupled with classroom strategies that promote responses from the child that are more productive. Children also stand to benefit greatly from understanding their own sensory characteristics. Because individual differences in sensory integration may be lifelong tendencies, it is critical that the child with sensory processing differences learn to construct daily routines and organize the sensory aspects of work and play activities and environments in order to live as comfortably and successfully as possible.⁸²

Through consultation and collaboration with those who are in ongoing contact with the child, the therapist can provide critical information and recommend implementation of specific strategies to influence the child's life positively across a variety of settings. Indirect intervention in the form of consultation is often critical for success and should be included in a comprehensive occupational therapy program for the child with sensory integration challenges. Whenever individual OT-SI intervention is provided, consultation with parents and/or teachers should also be provided.

Consultation using the concept of "sensory diet"²⁴⁴ involves collaboration with parents or teachers to embed individualized

sensory experiences at strategic time points throughout the day to support the child's alertness or calming at appropriate times. For example, a sensory diet for a child might include physical activity before school to boost arousal level, chewing gum while in class to support sustained attention, and a deep pressure massage to promote calming on returning home.

In many situations, the first step in the consultation process should be to help caregivers and teachers better understand sensory integration in general, as well as how sensory integration concepts apply to specific children. This can be achieved through individual meetings with parents or teachers, parent/teacher conferences, group experiential sessions, lecture and discussion groups, professional in-services, and ongoing education programs (Figure 9-14). Helping the adults in a child's life to understand their own sensory integrative processes is often an effective way to make new sensory integration concepts meaningful. Williams and Shellenberger use this tactic in their Alert Program.²⁴⁶ Before implementing the program with children, the adults who will administer the program participate in a training program designed to develop self-awareness and insight into their own sensory characteristics and preferences.

Perhaps the most important component of any consultation program is providing guidance for identifying, preventing, and coping with the specific challenges in everyday life that stem

FIGURE 9-14 Consultation in school involves joint problem solving between the occupational therapist and the teacher. (Photo © istock.com.)

from a child's sensory integrative problems. Sometimes specific activities can be suggested that help a child to prepare for a challenging task. For example, a child who has tactile defensiveness may more readily engage in activities such as finger painting or sand play if firm touch-pressure is applied to the skin before the activity. Modifying the activity might involve providing tools to use with the paint or sand to give the child a ready "break" from the unpleasant sensation. A home program that includes gradual introduction of tactile sensation in a safe place, such as the bathtub, can also help to reduce negative reactions. The therapist can also promote success in activities by suggesting individualized ways to help a child through difficult tasks. For example, some children with dyspraxia are likely to be more successful in completing a novel task when they receive verbal directions, whereas others respond optimally to visual demonstrations, and still others need physical assistance with the motions. Determining which method or combination of methods is most likely to help the individual child can assist adults in facilitating success.

Another important way that consultation can support a child's functioning is through recommendations for environmental modifications that aim to manage sound, lighting, contact with other people, environmental odors, and visual distractions in the classroom, playground, cafeteria, and assembly rooms. This is particularly important for children who are generally over-responsive, as they tend to be highly affected by sensory characteristics of their environments that others may not notice. Environmental modifications can make an important difference in a child's attention, behavior, and, ultimately, ability to participate in academic and social activities.

The same therapist qualifications needed to provide individual OT-SI intervention are desirable in providing consultation. The occupational therapist should be well versed in sensory integration concepts in order to explain them in simple yet accurate and meaningful terms. Furthermore, the therapist needs to fully understand the child's sensory integrative difficulties and use this understanding to predict what the child's likely responses will be to various activities and situations. Therefore, the occupational therapist needs to conduct a comprehensive assessment of the child before making any

suggestions, in order to identify the sensory strategies that are likely to be most helpful, and to consider any precautions that might apply. Procedures or techniques that require advanced training of an occupational therapist should not be recommended for parents and other professionals. For example, an appropriate consultation program never attempts to train a parent or teacher to provide individual therapeutic activities that require advanced training for monitoring the child's response, such as applying intense sensory stimulation. Also, it is imperative that the occupational therapist have excellent communication skills and respect for the various people and environments that are involved. Bundy provides a helpful description of the communication process involved in a good consultation program.⁵²

Expected outcomes of consultation programs depend on the individual child's presenting problems, the family or school team's goals, and the focus of the consultation. For instance, helping a teacher understand how best to seat a child in class (e.g., on a therapy ball chair versus a firm wooden chair, or in the front corner of the room near the teacher's desk versus the back of the room) may make it easier for the child to attend to instruction in the classroom. Desired outcomes might be measured as increased time on task, increased time in seat, decreased number of disruptive behaviors in class, or improved performance in academic tasks.

Limited research has been conducted on outcomes resulting from consultation involving changes to daily environments or routines, but the evidence that exists is consistently positive. In a study of the effectiveness of home-based consultation, Dunn et al.⁸⁷ evaluated a contextual intervention in which therapists made regular home visits to provide coaching to parents on issues related to activity settings, family routines, and sensory processing characteristics of their children with autism, all of whom demonstrated atypical sensory processing. Outcomes data from GAS and other instruments indicated that the parents felt more competent and the children demonstrated increased participation in everyday life following 10 intervention sessions. Hall and Case-Smith¹⁰⁶ conducted a pre- post-test study in which 10 young children with moderate to severe sensory modulation and visual-motor problems received a combined sensory diet and sound-based intervention that was individually tailored for each child and administered at home by parents with ongoing occupational therapy consultation. Results indicated improved sensory modulation and visual-motor skills. Kinnealey et al.¹³¹ conducted a single subject study of four adolescent males with sensory over-responsiveness, three of whom had autism, to examine whether modifications to classroom sound and lighting would improve their attention and perceptions of classroom experiences. The intervention consisted of replacing fluorescent with halogen lighting and installing sound-absorbing walls, which decreased the decibel levels within the room. Results indicated that all students demonstrated increased attention to academic tasks. In daily journals students expressed comfort and pleasure with the altered environment. An RCT that compared an 8-week course of school-based movement therapy to standard school routine showed behavioral improvements for the treatment group,¹⁰⁸ and a pre- post-test study of a 4-month manualized morning yoga program produced significant reductions in maladaptive behaviors of children compared with the standard morning routine

at school.¹³³ In all of these studies raters were not blinded to condition, which raises concern that outcome ratings may have been biased, but results are very encouraging and suggest that further evaluation of these interventions is warranted.

Often during consultation for individual children, occupational therapists become aware of sensory features within home, school, or community environments that can be modified in ways that benefit all of the children who live, work, and play there. In such situations, occupational therapists should consider using their knowledge of sensory integration to advocate for environmental changes that will benefit all children. For example, playgrounds or backyards may be modified to stimulate development of praxis and playfulness for all the children by providing equipment and materials that can present sensorimotor challenges at varying levels of complexity and can be played with in many different ways.⁵⁴ Adjustments to school environments may be especially important because children spend large amounts of time in this environment. These may include alterations in lighting, sound, or types and amount of sensory stimulation present in different areas. Additionally, daily routines with key sensory components may benefit all children in a classroom. For example, research indicates that children generally better attend to demanding academic tasks when they engage in physical activity breaks throughout the day, which boosts ability to sustain attention to cognitively challenging tasks.^{37,124} Initial morning routines involving sensorimotor activity may assist in preparing children for the cognitive work ahead in the school day, and regularly scheduled recess periods allow for physical activity to prepare children to return to the classroom refreshed and ready to work.¹²²

Sensory integration is a fascinating, dynamic, and complex area of pediatric occupational therapy practice. In addition to the interventions discussed in this chapter, new applications of sensory integration theory are emerging, for example, collaborations among occupational therapists, psychologists, and other professionals such as art therapists to merge sensory integration knowledge and techniques into psychotherapeutic interventions for children who have experienced trauma.¹³⁵ Other emerging applications of sensory integration knowledge aim to promote the well-being of communities as well as individual children, for example, through playground design and school-wide routines that support the emotional, physical, intellectual, and social development of all children. For these as well as established interventions for children with sensory integration difficulties, research will continue to be important in discerning the extent to which an intervention is helpful, how it is helpful, and for whom it is helpful.

Summary

Since the inception of this field 50 years ago, research has played an important role in shaping theory, assessment, and intervention practices that address sensory integration. The existence of different patterns of sensory integration challenges encountered by children has a strong evidence base with a long history. Although more research is needed to discern who are the best candidates for OT-SI, the existing research for this intervention is encouraging and suggests that it produces

outcomes related to children's everyday lives. Alternative interventions that build on sensory integration theory also influence today's landscape of occupational therapy practice for children.

Summary Points

- Sensory integration refers to a complex set of neural processes in the brain involving the integration of sensory information for active use in purposeful behavior.
- The term *sensory integration* is also used to refer to a specific practice approach in occupational therapy, that is, OT-SI.
- Sensory integration theory posits that the tactile, proprioceptive, and vestibular sensory systems are influential in early child development and that the child's active engagement to meet challenges by integrating and using sensory information leads to both neuroplastic and behavioral changes that influence further development and engagement in occupations.
- A long history of quantitative research provides evidence for the existence of several patterns of sensory integration problems that arise in childhood (i.e., sensory modulation, discrimination and perception, vestibular-bilateral, and praxis difficulties) that are associated with different effects on the occupational life of a child.
- Clinical assessment of sensory integration should be comprehensive and include history, interviews and questionnaires, naturalistic and structured observations, and standardized testing. Data from these different sources must be integrated to discern whether a recognizable pattern of sensory integration difficulty is present, and if so, what the appropriate course of action should be to help the child and family.
- Occupational therapy using a sensory integration approach (OT-SI) is provided in individual therapy sessions in which the occupational therapist encourages the child's active engagement, collaborates with the child on activity choices, and presents the child with sensory and motor challenges while ensuring success and safety, all within the context of play in a specially designed clinical environment.
- The Fidelity Measure for Ayres Sensory Integration Intervention can be used to ensure that when OT-SI intervention is provided, the process of intervention as well as occupational therapist qualifications and the therapeutic environment are appropriate.
- OT-SI may be appropriate when assessment results indicate a known pattern of sensory integration difficulty for children with learning and behavioral challenges, with autism, with other diagnoses, or with no medical diagnoses.
- Outcomes of OT-SI intervention include achievement of more sustained or complex adaptive responses, improved fine or gross motor skills, improved language or social skills, enhanced self-confidence and self-esteem, better participation in occupations at home and in school, and enhanced family life. These outcomes are evaluated using assessment of specific behaviors as well as standardized tests and methods such as goal attainment scaling.
- Evidence of effectiveness of OT-SI is mixed, but the best evidence uses rigorous research design, including fidelity

checks, and provides encouraging evidence of effectiveness, particularly when goal attainment scaling is used.

- Alternative interventions that are used in conjunction with or instead of OT-SI intervention include sensory stimulation protocols, sensory-based strategies incorporated into daily

routines, specific skill training, group interventions such as the Alert Program, and consultation models; outcomes vary for these diverse interventions, and studies of effectiveness are generally more limited.

KEY TERMS

Performance Based Approaches	Declarative and Procedural Knowledge
Cognitive Behavior Therapy	Metacognition Strategy
Cognitive Orientation to Occupational Performance (CO-OP)	Cognitive Strategy: Global and Domain Specific

GUIDING QUESTIONS

1. What theories provide the foundation for cognitive approaches?
2. What do the terms *cognition* and *metacognition* mean?
3. What concepts, principles, and key features define a cognitive intervention?
4. How are cognitive strategies applied in occupational therapy practice?
5. How is Cognitive Orientation to Occupational Performance (CO-OP) applied?

Cognitive interventions have their historical beginnings in the disciplines of education and psychology. Pediatric occupational therapists have begun to realize the effectiveness of cognitive approaches with children who experience various developmental disabilities. These intervention approaches are often referred to as *performance based approaches* and also have been called *top down* approaches in the occupational therapy literature. The focus of performance-based approaches is to assist the client in identifying, developing, and utilizing cognitive strategies to perform activities of daily living.^{41,44} Currently, in the pediatric occupational therapy practice, two main cognitive approaches are being used: cognitive approaches that attempt to change faulty or delayed cognitive processes, such as Cognitive Behavior Therapy, and cognitive approaches that enable occupational performance, such as the Cognitive Orientation to Occupational Performance (CO-OP) approach.

In this chapter we explain the role of cognition and cognitive strategies in supporting occupational performance. The following sections provide an understanding of the common terms used in cognitive interventions, a summary of the history of cognitive approaches, an overview of the theoretical perspectives that guide the use of cognitive interventions. A rationale

for using cognitive approaches will then be discussed highlighting the key features of cognitive interventions and the research evidenced supporting the use of these approaches.

Cognitive interventions focus on the development of strategies to accomplish the chosen task. The following table describes general terminology that is used in the cognitive literature and provides an overview of key concepts (Table 10-1).⁵⁰

Theoretical Foundations of Cognitive Approaches

The theoretical foundations of cognitive interventions are rooted in the fields of developmental and educational psychology. L. S. Vygotsky (1896-1932) was a Russian psychologist who made many important contributions to the fields of cognitive and educational psychology. Vygotsky believed that cognitive development occurred through the gradual internalization of concepts and relationships.⁶³ He noted that younger children used overt speech (talking out loud) when they were problem solving through a difficult task. In contrast, older children seemed to think about a solution internally before acting.³⁹ When comparing the problem solving dialogs (internal and overt) of the older and younger children he concluded they were similar, and deduced that as development occurs children gradually internalize their thought processes.⁶³ Vygotsky viewed learning as being embedded in social and cultural contexts. He underscored the necessity of cooperative dialogs between adults and children in the learning process, and saw these communicative opportunities as a way of developing children's internal dialogs.⁴ Children must be actively engaged in the learning and developmental process. Vygotsky viewed the learning process as a "circular reaction" in which action and motivation influence one another and contribute to the child's learning and development.⁶²

The zone of proximal development is the range of skills that a child can achieve through social interaction with a more competent individual. A child's developmental skills fall into a "zone, or range, of skills which differ contingent upon the social interactions accompanying the activity, rather than a specific skill level"²⁵ (p. 105). Therefore each stage of a child's development is characterized by different modes of social interaction. In therapeutic practice this concept is most commonly known as scaffolding.

Alexander Luria (1902-1977) was a developmental psychologist who worked closely with Vygotsky to create

TABLE 10-1 Common Definitions In Cognitive Interventions

	Definition	Application to Occupational Therapy
Cognition	Cognition is described as a child's ability to acquire and use information in order to adapt to environmental demands. ²⁷	Cognitive approaches that teach cognitive skills are focused on working collaboratively with children to enable them to identify and recognize cognitive processes and strategies utilized when completing meaningful daily activities. ⁵⁰
Declarative knowledge	Declarative knowledge is knowledge about things; it is the knowledge that is often explicitly known and can be consciously brought to the attention of the learner. ⁵⁴	Declarative knowledge includes rules and facts about a skill, and is often used during the initial stages of learning. ⁵⁴ It is kept within the individual's working memory and can be converted to procedural knowledge through rehearsal and verbalization.
Procedural knowledge	Procedural knowledge is the implicit knowledge about how to complete a task. ⁵⁴	Procedural knowledge is often acquired through the repetition of an activity and observed through enhanced task performance. ⁵⁴
Metacognition	Metacognition refers to an individual's knowledge concerning their own cognitive processes and products or anything related to them. Through metacognition, children generalize and transfer cognitive skills to meet changing contextual demands. ⁵⁰ Metacognition is made up of two components: metacognitive knowledge and self-regulation. ¹²	Metacognitive strategies are employed when a task becomes too difficult relative to the child's skill level and they are required to select appropriate cognitive strategies, monitor, and evaluate their application. ³⁹ During the implementation of cognitive approaches in occupational therapy, metacognition is the skill that is directly impacted and enhanced through the intervention process.
Metacognitive knowledge	Metacognitive knowledge consists of one's awareness of the cognitive processes that are employed to learn and perform a new task. ^{12,50}	This is the individual's ability to stop and reflect on how he or she is learning. Is it through the use of mnemonics, rehearsal, or imagery (or other various cognitive strategies that will be discussed later in the chapter) that they are able to retain new information? ⁶⁰
Self-regulation	Self-regulation is the individual's influence over their own thought processes, emotional states, motivation and patterns of behavior. ² It is the process of selecting, monitoring, and evaluating the effectiveness of cognitive strategies. ⁴⁴	To demonstrate self-regulation, an individual who encounters a problem pauses, selects a different strategy, applies it and evaluates the performance outcome. ⁵⁰ The ability to self-regulate allows for skill transfer and generalization to occur.
Cognitive strategies	Strategies are cognitive processes that are more advanced than the outcomes that are a natural consequence of carrying out a task. Strategies are both consciously employed and are controllable by the learner. ⁴⁸ Goal-directed strategies are used to help the individual achieve a task or fulfill a purpose. Cognitive strategies can be defined as a "mental plan of action that helps a person to learn, problem solve, and perform. The use of cognitive strategies can improve an individual's learning, problem solving, and task performance in terms of efficiency, speed, accuracy, and consistency" ⁶⁰ (p. 227).	Cognitive strategies support skill acquisition or reacquisition. They help individuals regulate and manage challenges in learning and performance, playing a key role in achieving a higher level of task performance. ⁶⁰ Strategies include the "how to" knowledge the individual uses when acquiring new skills and problem solving through a difficult situation or navigating contextual challenges. ⁶⁰ Coping with daily stresses, learning how to take the bus to a new location in the community, and deciding to cook a different meal for dinner all incorporate the use of strategies, and therefore strategies are a typical part of everyday learning and performance. ⁵⁰

cultural-historical psychology.²⁸ Luria believed that a child's development could not be simply explained through a natural inborn process, but that development is a complex and dynamic relationship between many factors including the child's social and cultural environment(s). Luria delineated how individuals explore problems and learn new concepts, identifying five stages in an individual's problem solving process. These included:

1. Discovery of the problem
2. Investigation of the problem
3. Selection of an alternative strategy

4. Attempt to solve the problem
5. Comparison of results of the solution^{28,29}

Children use overt verbalization of process steps when learning a new skill, which eventually fades into covert speech as the child rehearses the process steps of the new activity. Luria hypothesized that the speech system is formed in the process of the child's social intercourse with an adult and is a powerful means of systemic organization of human mental processes.^{28,29}

Meichenbaum^{34,36} further emphasized the importance of speech and adult guidance in driving the development of

cognitive strategies. Hypothesizing that internal speech can regulate one's behavior; he proposed that a child could follow self-instructional steps to assist in behavior regulation.³⁴ This problem-solving pathway included the child identifying a goal, developing a plan, enacting the plan, and then evaluating its success.³⁴ These steps are modeled by a more competent adult and then verbalized out loud by the child. Through adult guidance and functional practice and rehearsal, the steps of Goal, Plan, Do, Check are internalized and recalled covertly by the child when performing a task.³⁴ Meichenbaum also utilized scaffolding to help with the generalization of the newly formed cognitive strategies.

Scaffolding

Scaffolding emphasizes communication between adults and children in an effort to develop children's internal dialogs, which help to guide their own actions in the acquisition of new skills.⁴ In cognitive approaches the progression of moving skill acquisition from an overt to covert process demonstrates the increasing independence of the child in his or her understanding of task demands, in using problem-solving strategies, and in coping with failures.³⁵ Through scaffolding the occupational therapist modifies a cognitive intervention to create the just-right-fit between the child's ability level and the task demands. A clinical example of strategies moving from an overt to a covert process is when a child is learning how to hit a baseball. Initially the child may articulate aloud the steps required to successfully make contact with a baseball during practice. "Keep my eye on the ball," "swing through the ball," and "take my time" are examples of self-coaching, a domain-specific strategy that over time fades to an internalized (covert) strategy.^{44,45}

Discovery Learning

Discovery learning proposes that children construct their own knowledge by drawing on their past experiences and interacting directly with the task and the environment(s).⁸ Discovery learning, in a pure sense, is task exploration; however, through the addition of instructional scaffolding it can more accurately be defined as guided discovery.⁴⁹ In guided discovery learning, the therapist assumes the role as a facilitator. Rather than providing direct instruction, the occupational therapist allows the client to generate his or her own answers through tailoring the task and the environment to the individual.⁴⁹ Occupational therapists can pose questions to clients as they complete a task, offering them the opportunity to approach an activity differently. In doing so, they are also able to illuminate important components and concepts of the task. As a child engages in guided discovery learning, he/she takes control over his/her performance and the occupational therapist is able to reduce the amount of support/guidance provided.^{44,49} Through this increase in competence and the experience of success, guided discovery learning shifts the individual's reinforcement for learning from external to a more internal locus.⁸ "The child is now in a position to experience success and failures not as a reward or punishment, but as information"⁸ (p. 28). Guided discovery learning offers opportunities for the child to ask questions and generate ideas that can be further tested or researched.⁸ Through the shifting of the child's motivation for learning

from an external to internal locus of control, guided discovery aids in enhancing the learner's level of self-efficacy.

Metacognition

Bandura² believed that a child's experiences performing an activity contribute to his or her self-perceptions. Through the development of metacognitive abilities, children learn to evaluate their performance of a task and reflect on their areas of strength and weakness.^{2,39} When setting new goals based on their identified areas of difficulty, children begin to feel empowered. Similar to the foundational elements of guided discovery learning, empowerment fosters increased goal commitment, enhanced performance, and the intrinsic motivation to set new meaningful goals.^{2,39}

Like Vygotsky and Bruner, Bandura believed that the individual child was the main motivator for cognitive development and that these intrinsic capabilities emerge through interactions with others.^{2,14,61} Therefore engagement of the child in the learning process and to change interaction with social partners are key elements to successful learning.¹⁴ Learning occurs through the result of experience, and information is interpreted through the lens of the individual's values and beliefs. Contributions from the fields of cognitive and educational psychology have brought to light the foundational elements of discovery learning, and the understanding that children display optimal learning when they are allowed to reflect on their participation in their chosen occupations.⁶¹

Instrumental Enrichment

Feuerstein³ developed an Instrumental Enrichment program based on the notion that an individual's cognitive performance can be modified through intentional mediated interventions.²⁴ When an adult selects and organizes environmental stimuli so that it is congruent with the child's level of learning, the child's learning is optimized.^{3,39} Children learn when adults are mediators, assisting the child to derive generalized meaning from life experiences.¹¹ Feuerstein and Haywood¹⁷ developed mediation techniques for the adult to use to help children to make sense of their life experiences. These techniques include process questioning, bridging, comparison/describing, modeling, challenging, and elaborated feedback.^{11,39} These mediation techniques provide a method through which the child learns to bridge newly acquired cognitive strategies to daily living situations. Occupational therapists can use mediated learning to promote a child's ability to generalize new learning to his or her daily routine.

Rationale for Using Cognitive Approaches

Evidence is beginning to accumulate regarding the functional benefits of using a cognitive approach as an occupational therapy intervention.^{44,60} This section provides a rationale for using cognitive approaches.

Motivation

An individual engages in an occupation based on personal choice and motivation.^{39,44} The occupations that an individual

chooses to engage in define who he or she is, add to the individual's experiences and create new meaning.⁹ Participation in occupations directly influences identity and the development of one's self.⁹ Motivation also influences learning, persistence, and the willingness to participate in rehabilitation.¹⁰ Intervention goals need to reflect occupations that the child identifies as important and that he desires to improve.³⁷ These elements resonate with the values and beliefs in client-centered practice, and reflect the views of Meichenbaum who highlighted the importance of the child being an active collaborator in the therapeutic process.³⁷

Children who experience illness and/or a disability are often restricted in the occupations in which they can participate. Environmental, physical, and institutional barriers inhibit full engagement in many of the occupations.^{18,42} Participating in daily occupations brings meaning to lives, offers a sense of accomplishment, and is a determinant of health.⁴⁷ When an individual is unable to participate in a chosen occupation, lower self-esteem or self-efficacy, a decreased sense of independence, and an overall loss of motivation may result.^{1,13} Cognitive interventions and adult-guided discovery learning focus on child-generated ideas, maintain the child's internal locus of control, and can promote the child's self-efficacy.^{39,44,46} They offer individuals choice and control, which allow the child to derive a sense of self-determination and empowerment.⁴⁷

Generalization and Transfer

Generalization is defined as the ability of an individual to apply what they have learned in therapeutic rehabilitation to different environments and activities.^{56,58} Both internal and external factors affect the generalization of skills. External (to the learner) factors include the environmental context, the nature of the task, and the learning criteria of the activity. The internal factors that directly affect generalization are the learner's meta-cognition, his or her processing strategies, and the learner's characteristics.^{7,22,58} A multi-contextual approach can promote skill generalization.⁵⁸ Scaffolding through adult feedback can help a child generalize and transfer newly developed skills to different environments and tasks.³⁹ Cognitive approaches to therapeutic intervention focus on the generalization and transfer of skills through the following means:

- *Maintaining client motivation:* ensures that the child applies the strategies to different tasks. Children are collaborators in the therapeutic process, promoting motivation and aiding in the transfer of skills to the child's natural environments and daily activities.^{35,46}
- *Contextually relevant practice:* exposes children to a number of different transfer experiences that allows the child to understand the commonalities among situations/tasks.⁵⁸ Finding these commonalities among tasks, environments, and oneself can help the child their cognitive strategies in various environments and tasks.^{44,46}
- *Direct exposure to the task:* allows the child to engage directly in the task or occupation he desires to improve.^{5,42}

The occupational therapist uses dynamic performance analysis (DPA) to solve performance problems and identify possible solutions. Through DPA the child gains a deeper understanding of the task and environmental demands and explores solutions to performance problems.^{44,46} The process of analyzing performance eventually becomes internalized by the child

through scaffolding, which allows the child to "check" his or her occupational performance on an on-going basis. The child can then take the newly developed skills and transfer them to other tasks and environments while problem solving performance ongoing.⁴⁴

Lifelong Development

The occupations that individuals participate in over time can be defined as their occupational trajectories.²⁰ Individual's occupational trajectories are fluid in nature and can change owing to different life transitions.²⁰ Some examples of life transitions include moving to a different grade in school, leaving home for postsecondary education, or getting a job. As children grow, develop, and mature, they experience different tasks and activities that might become barriers to their occupational success.²⁰ Using a cognitive approach to guide therapeutic intervention recognizes the importance of children independently applying cognitive strategies to different environments and activities.^{44,59}

As children encounter transition points in their lives and as their occupations change, so do the cognitive strategies that they employ. Fluidity and flexibility in the attributes and uses of cognitive strategies enable them to be used over the life course.⁵⁹

Cognitive Interventions

A number of different cognitive approaches have been described in the broader literature. Bouffard and Wall (1990) proposed a five-step problem-solving framework to guide motor skill acquisition.⁶ The steps are Problem Identification, Problem Representation, Plan Construction, Plan Execution, and Evaluation of Progress. Henderson and Sugden¹⁸ also proposed an approach to motor skill acquisition, Cognitive Motor Approach, that centered on a three-step information-processing framework.⁶ The first step is Movement Planning and requires the child to understand the task and its demands and decide if the task is achievable. In order to do this, the child gains this information through sensory and perceptual processes, including vision and kinesthesia, and then translates this information into a plan.^{18,37} The next step is Movement Execution. During the final step, Movement Evaluation, the child monitors her or his progress. The Cognitive Motor Approach is effective in improving the functional skills of children with developmental coordination disorder (DCD).⁶⁵ Expanding on these principles, Cognitive Orientation to Daily Occupational Performance (CO-OP) uses a learning-based perspective on skill acquisition and occupational performance.^{37,44}

Cognitive Orientation to Daily Occupational Performance

"CO-OP is a client-centered, performance-based, problem solving approach that enables skill acquisition through a process of strategy use and guided discovery."⁴⁴ (p. 2).

CO-OP places emphasis on the interaction between individual and environmental factors to promote children's successful participation in daily activities.^{39,44} Developed within

CASE STUDY 10-1 Productivity

Matty is a 9-year-old boy who was referred for an Occupational Therapy assessment within the school setting to address difficulties with his printing skills. Matty displays challenges with baseline placement and spacing between words, which significantly affects the overall legibility of his written work and his overall academic performance. He was seen for eight occupational therapy sessions by his school-based occupational therapist. During this time the occupational therapist worked with him on his printing skills, using the CO-OP approach, and the Goal, Plan, Do, Check framework. Within this framework, Matty was able to identify his own concerns with his printing skills and generate his own solutions to resolve the problematic aspects of his handwriting. With verbal guidance from the occupational therapist, he was able to identify that sometimes all of his letters do not sit on the line and at times all of his words run together. The occupational therapist was then able to

guide Matty in identifying domain-specific strategies that can be used to assist with this including: using paper with a highlighted baseline to act as a visual cue for letter placement, using a finger space between words, and securing a “printing checklist” onto his desk to remind him of letter placement and spacing. Using these strategies, Matty improved these specific areas of his printing within the classroom environment.

Application of the CO-OP Approach: Goal and Points of Breakdown

Goal	Breakdown Points
Improve the quality of his handwriting	Poor letter formation Words are too close together Difficulty making sure his letters sit on the line correctly (baseline orientation)

Application of the CO-OP Approach: Strategy Use

Domain Specific Strategy	Specific Strategy/PLAN	Bridging for the Strategy
Task specification/modification	Finish the letter Make the letter larger	Having a writing checklist secured to his desk to prompt him of the important strategies that he had developed
Supplementing task knowledge	“There should always be a finger space between your words.”	Teach younger sister how to print: role-playing teacher Making scrapbook of summer vacation
Attention to doing	“Where do you need your letters to sit?”	Teaching student, teacher, and parent to highlight baseline of paper to help with attention to doing

an evidence-based framework, CO-OP draws on behavioral and cognitive psychology, health, human movement science, and occupational therapy to achieve its objectives.^{39,44} See [Case Study 10-1](#).

Primary Objectives of CO-OP

There are four objectives of CO-OP: (1) skill acquisition, (2) cognitive strategy use, (3) generalization, and (4) transfer of learning.^{44,46} CO-OP uses cognition as a performance support and does not attend to cognitive dysfunction. The primary objective of CO-OP is to enable occupational performance in children.^{37,44} In a typical CO-OP program, the child selects three occupations or activities to learn over 10 intervention sessions.^{44,46} The occupations are chosen by the child, in collaboration with his or her parents, and may include activities such as handwriting, rollerblading, tying shoe laces, or cutting paper. Through the intervention, cognitive strategies are used to solve the performance problems and enable skill development within the occupations.^{43,44,46} The second objective of CO-OP is to teach the child how to use these strategies to achieve his or her goals.^{44,46} Over the course of the intervention, children learn a global problem-solving strategy that enables them to discover and identify domain specific strategies that will support their performance.^{44,46} The third objective of CO-OP is to facilitate generalization of the occupation to other settings including home and school.^{44,46} Once the child has

obtained the skills required to perform the identified occupation, the focus of therapy shifts to facilitating generalization of the learning beyond the therapy situation.^{44,46} Thus the final objective of CO-OP is the transfer of the learning to other occupations. Because only three occupations are addressed in the course of a CO-OP intervention, it is important that the children learn to adapt their skills and strategies to other new occupations that they confront in daily life.^{44,46}

Who Benefits from CO-OP?

Traditionally, the CO-OP approach was developed for use with children with DCD.^{37,44,46} and CO-OP has been shown to be effective with this population.^{5,64} More recently, CO-OP has been used with children with high-functioning autism spectrum disorders (ASD), traumatic brain injuries), attention deficit hyperactivity disorder and motor skill delays.^{16,40,51,66} See [Research Notes 10-1](#) and [10-2](#).

Cognitive interventions have been used to address a variety of client goals including: fine motor skill development such as printing or cutting; gross motor skills such as shooting a basketball or riding a bike; organizational activities; and a variety of ADLs such as getting dressed and meal preparation.^{40,65} In order for the CO-OP approach to be successful, research highlights the importance of parent support and inclusion within the therapeutic process as well as the ability for the child to understand the cognitive framework and application of

RESEARCH NOTE 10-1

The Use of Cognitive Interventions for Children with Autism Spectrum Disorders (ASD)

Phelan, S., Steinke, L., & Mandich, A. (2009). *Exploring a cognitive intervention for children with pervasive developmental disorder*. Canadian Journal of Occupational Therapy, 76(1), 23–28.

Abstract

Purpose. This study investigated use of CO-OP with children who have PDD (more current term: ASD). CO-OP emphasizes problem-solving strategies and guided discovery of child- and task-specific strategies.

Method. Three goals were established in collaboration with the parents and the child. Pre- and post-measures of parents' perceptions of child performance were identified using the Canadian Occupational Performance Measure (COPM). Repeated measures were taken using clinical observations, video analysis, and the Performance Quality Rating Scale (PQRS).

Findings. Improved COPM ratings of performance and satisfaction were observed, and these results were paralleled by improved PQRS scores.

Self-report and PQRS results provide preliminary evidence of the effectiveness of the CO-OP approach with children who have ASD, supporting the use of CO-OP and suggesting further investigation.

Implications for Practice

- When working with children with ASD, it is essential to incorporate their special interests into therapy sessions whenever possible in order to increase motivation and enhance learning opportunities.
- Parent's observations and interaction with their children during the intervention sessions influenced engagement and performance levels.
- The use of additional strategies, which increased structure to the intervention sessions, seemed to benefit the children in the present study. These included verbally and visually outlining the session schedule.

cognitive strategies.^{37,44} Although a certain level of cognitive functioning is required for the CO-OP approach to be successful, cognitive interventions can often be modified based on the client and the specific population.

Key Features of the CO-OP Approach

Essential to the effectiveness of CO-OP is that the child and occupational therapists are fully engaged in the approach as it has been specified in the intervention protocol.^{44,46} CO-OP is comprised of seven key elements, referred to as key features (Figure 10-1).

The first key feature is goal identification.^{44,46} The client goals are established in collaboration with child and family, and focus on occupations the child wants, needs, or is expected to perform. The child is actively engaged in the goal-setting

RESEARCH NOTE 10-2

The Use of Cognitive Intervention for Children with Acquired Brain Injury

Missiuna, C., DeMatteo, C., Hanna, S., Mandich, A., Law, M., Mahoney, W., & Scott, L. (2010). *Exploring the use of cognitive intervention for children with acquired brain injury*. Physical & Occupational Therapy in Pediatrics, 30(3), 205–219.

Abstract

Introduction. Children with acquired brain injury (ABI) often experience cognitive, motor, and psychosocial deficits that affect participation in everyday activities.

Objective. This study explored the use of CO-OP with children with ABI.

Method. Children with ABI, experiencing school and self-care difficulties, were identified from a previous study. Six children, aged 6 to 15 years, completed 10 weekly intervention sessions with an occupational therapist. Children and parents rated the child's performance of challenging everyday tasks and their satisfaction with this performance. Task performance was also evaluated objectively through videotape analysis.

Results. Participants showed significant improvement in their ability to perform child-chosen tasks and maintained this performance 4 months later. However, they had difficulty applying extensive problem-solving strategy and discovering cognitive strategies on their own.

Implications for Practice

- Children with ABI were able to identify and sustain motivation to work on child-chosen goals using the CO-OP approach.
- Cognitive strategy use and retention appeared to differ with children with ABI. Children with ABI did use more task-specific cognitive strategies and had more challenges transferring the “Goal, Plan, Do, Check” strategy to other tasks.
- Overall, CO-OP was effective with children who have had an ABI to facilitate skills development of child-chosen goals. Some adaption of the CO-OP approach may be required when working with his population, including increased parent/caregiver involvement.

process to ensure motivation.^{1,44} In the CO-OP approach, the child's perspective is integral to the therapy process. As such, the child is actively engaged in choosing the goals.^{44,46}

The second key feature of CO-OP is Dynamic Performance Analysis (DPA),⁴⁵ which acknowledges that performance is the result of the interaction between the person, environment, and occupation. The occupational therapist analyzes the child performing the task and documents the performance problems or performance breakdowns. In doing so, the occupational therapist focuses on the fit between client abilities, skills, and actions and the task and environmental demands and supports.^{44,45} The focus of CO-OP is on performance and correcting performance problems or breakdown, not on underlying component skills.⁴⁴ Once the occupational therapist has identified

FIGURE 10-1 Key features of the CO-OP approach.⁴⁴

the initial performance breakdown points, the therapist uses cognitive strategies to bridge the gap between ability and skill proficiency.^{44,45}

The third key feature is cognitive strategies that are used to support skill acquisition, generalization and transfer.^{44,46} As discussed in the previous section, cognitive strategies are cognitive operations beyond those that are inherent to the task itself. In the CO-OP approach, the child uses cognitive strategies to problem solve a performance issue and monitor the outcome.^{44,46} In other words, the strategies promote metacognition and thinking about one's thinking.^{12,23} Two types of strategies are used in the CO-OP approach: global and domain specific. Global strategies are intended to be used over long periods of time, in a variety of different contexts.⁴⁴ The global or executive strategy Goal-Plan-Do-Check used in CO-OP was developed by Camp, Blom, Herbert, and VanDoorwick (1976) and used by Meichenbaum.^{35,36}

Goal: What do I want to do?

Plan: How am I going to do it?

Do: Do it!

Check: How well did my plan work? Do I need to revise my plan?

In CO-OP, the child is taught to use the mnemonic Goal-Plan-Do-Check, to support the solving of occupational performance problems.⁴⁴ During the first therapy session, the child is introduced to the Goal-Plan-Do-Check strategy and is directly taught how to use it. To ensure that the child understands the global strategy, the child is asked to teach the occupational therapist an activity using this new framework.^{44,46} The global strategy frames each intervention session. Initially the occupational therapist takes the lead in using the Goal-Plan-Do-Check strategy. As the child learns the strategy, the child gradually begins to initiate strategy use.^{44,46} Through the process of overtly talking oneself through an occupation, the steps become

internalized and eventually covert, therefore speech guides behavior (Figure 10-2).^{37,44}

The second type of strategies used in CO-OP is domain specific. Domain-specific strategies (DSS) are specific to a particular task or part of a task.^{30,37,43,44} See Table 10-2 for a comprehensive list of domain-specific cognitive strategies that can be used within the CO-OP approach. All DSSs are nested in verbal guidance. The goal is to lead the child from early reliance on the occupational therapist's verbal guidance to the independent use of cognitive problem solving strategies through self-talk.^{44,46} Therefore, as the intervention progresses, the occupational therapist encourages the child to talk himself through a sequence. Verbalization ensures that the cognitive mechanisms that distinguish it from other approaches are used; that the strategies are brought to the attention of the child; that the child understands the role of the strategies; and that the child can use the strategies independently, in the absence of the occupational therapist.⁴⁴ Once the child and occupational therapist have identified the strategies, the therapist reinforces their use during the intervention sessions (Figures 10-3 and 10-4).

The next key feature of CO-OP is guided discovery.⁴⁴ In the guided discovery process the learner is helped to identify a problem to solve; she is not given the solution but is provided with hints, coaching, feedback, or modeling to identify a solution.^{44,46} In CO-OP the process of guided discovery is closely linked with the process of strategy use. It is used in conjunction with the DPA process primarily to identify when the child becomes "stuck" and elucidate the plan within the Goal-Plan-Do-Check problem-solving process.^{44,45} Guiding the child to discover the plans and the DSSs increases the likelihood that he/she will attribute the success of the plans to himself/herself, supporting self-efficacy.^{1,45}

Guided discovery supports both skill acquisition and strategy use. Guided discovery has four main elements: (1) One

FIGURE 10-2 Concept Map: Goal, Plan, Do, Check.

FIGURE 10-3 Productivity: Highlight margins.

FIGURE 10-4 Productivity: Finger space.

thing at a time; (2) Ask, don't tell; (3) Coach, don't adjust; and (4) Make it obvious!^{44,46}

- *One thing at a time.* When a child is having difficulty performing an occupation, often several performance problems exist. Because CO-OP is embedded in a learning paradigm and skills are considered to be learned, not developed, it is important to keep the intervention and the client focused on only "one thing at a time."^{44,46}

- *Ask, don't tell.* When a child discovers the solution to a performance problem, the child is likely to remember that solution and use more often than when he or she is told the solution. Through Socratic questioning, the child is taught to critically think, analyze, and evaluate solutions. Asking questions helps the child focus on the relevant aspects of the performance and strategy identification is facilitated.⁴⁴

TABLE 10-2 Defining and Describing Domain Specific Cognitive Strategies

External Sensory & Environmental Strategies		
Domain Specific Strategy	Defining & Describing	Clinical Examples
Sensory cues or prompts from the environment that the individual provides to him/herself to help guide skill acquisition	Tactile, visual, auditory, and/or kinesthetic cues.	Pictures, vibrations (from buzzer or other external device), alarms—any other modality that attracts the learner's attention and guides them through the steps of a task, or prompts their memory or previously learned motor patterns. ⁶⁰
Mental or Self-Verbalization Strategies		
Domain Specific Strategy	Defining & Describing	Clinical Examples
Self-coaching	Encouragement, positive self-talk, strength-based thinking to help increase persistence and/or to control and regulate the learner's emotions	"I can do this!" "Stay calm and focused. ..." "Only a few more times and I will have it!"
Self-guidance	Providing instruction to himself/herself to assist in completing a new/difficult task, cueing oneself and reminders to prepare for or complete an activity	Talking oneself through the steps of an activity, talking aloud through the problem-solving process, self-talk
Self-questioning	Identifying and asking himself/herself or visualizing key questions relating to the activity or task performance	Picturing in the "mind's eye" key transition points of an activity, identifying and asking himself/herself specific areas of difficulty experienced in each task
Imagery	Mental images that are created to represent physical objects, actions, experiences, or events	Creation of images, symbols, or representations that have direct meaning to the client. Can also include imaging textures, sounds, smells, and kinesthetic feelings of movement.
Association	Relating previous knowledge to relevant information about task	Associations can arise from previous experiences, recognition of physical similarities, and knowledge of categories.
Rote-script	A rote pattern of words or phrases that are meaningful to the client and can help to guide a sequence of actions or improve the recall of information	Some motor pattern rote scripts might include: "dribble, dribble, shoot" (basketball), or "slide down, climb up, slide down" (making an "x" in printing)
Elaboration	Increase and add new information and relate it back to previous knowledge.	Can include the expansion and addition of images, symbols, actions, words, or sentences. It also includes verbal and mental processes.
Mnemonic techniques	Associating pictures, words, phrases, or images to cue an action or enhance memory recall	"Bunny ears"—when tying shoes "Helper hand"—when printing and completing bilateral cutting activities
Rehearsal	Repeating information visually or mentally to aid in retention of important information related to the given task/occupation	Repeating key words/actions out loud, creating internalized visual images of the task procedure and visually carrying out the task in a repeated manner
Reconstruction	Involves mental and verbal processes and involves the learner thinking back to a previous task, experience, or context to guide their performance in a new situation	The learner reconstructs experiences, activities, or contexts through imaging, replaying, and/or verbalizing.
Anticipation	Preparing for a new activity through imagining or verbalizing possible outcomes, areas of difficulty, or scenarios the learner might encounter	Before a client goes to school she anticipates loud noises, crowds, visual distractions, and possible "safe spots" to collect her thoughts when feeling overwhelmed.
Knowledge	Identifying, acknowledging, and reflecting on what the individual knows about a given task	Observing the individual completing the task, conducting assessment/interview in an attempt to discover how much the learner knows and understands regarding task sequence and demands

TABLE 10-2 Defining and Describing Domain Specific Cognitive Strategies—cont'd

Mental or Self-Verbalization Strategies—cont'd		
Domain Specific Strategy	Defining & Describing	Clinical Examples
Translation	Converting written instructions and directions into different mediums in order to meet the individual's unique learning needs	Creating visual images/schedules explaining written information, chunking directions together into smaller steps
Task Modification and Specification Strategies		
Domain Specific Strategy	Defining & Describing	Clinical Examples
Finger pointing	Similar to attention to doing; however, limited to pointing with one's finger directly at relevant task stimuli to enhancing timing within a task or refocus the learner's attention	As the individual is reading (book, task directions, etc.) have the learner point at each word to slow down the pace at which he or she is acquiring new information and to ensure not to skip ahead.
Task simplification	Simplifying or breaking apart the parts of a task into more manageable pieces	When printing, the learner writes his name, date, and title at the top of the page and then the teacher scribes the rest of the assignment.
Lists	Creating and/or using a list of steps to help guide task performance and/or cue actions	The list can be comprised of audio, visual, or written steps. For example a written list/script that is left by the phone that walks the learner through the socially appropriate steps to carry out when answering the phone
Task specification	Discussion regarding the specifics of a task, its components, or relevant features prior to engaging in the activity	These specifications should highlight those areas that require special attention, planning, or consideration. For example, placing an "x" where the child hangs his book bag or places his lunch bag.
Attention to doing	Identifying the specific and relevant cues or features that need to be attended to when completing the task	An example might be: "Where do you need to start your letters?" (printing)
Pacing strategies	Activities that assist with the timing of tasks	Some examples might include: humming a song, taking breaks, counting out-loud or to oneself, or tapping one's foot.
Stimuli reduction	Removing or decreasing the amount and number of stimuli present at a given time	Covering or removing a part of task stimuli: for example, when reading a page of information, placing a blank sheet over-top of the rest of the lines of text (hiding it) so that the reader can focus on one line at a time
Organization	Restructuring and reorganizing task materials or steps so that they are grouped together in a more logical or meaningful way	Commonly referred to as categorization or association. Reorganizing a list of chores so that all of the ones that need to be completed in the morning are together, and all the ones that need to be completed in the evening are together.

Adapted and Referenced from.^{44,59,60}

- *Coach, Don't Adjust.* One of the most important components of the CO-OP approach involves adjusting the task or the environment to support occupational performance and skill acquisition.^{44,46} Many occupational therapists intuitively adjust a variety of factors including body positions, chair position, or equipment to ensure success. Often this leads to success within therapy sessions and in the presence of the occupational therapist, but the child may not be aware of these enabling strategies and may find it difficult to achieve success in the absence of the therapist.^{44,58} Within the CO-OP intervention, the occupational therapist is required to bring these adjustments to the child's attention by guiding the child to discover the personal, task, or environmental adjustments that will improve occupational performance.^{44,46}
 - *Make it Obvious.* Often children do not readily learn from observation and may have difficulty identifying the important components of a task.⁴⁴ Therefore when working with a child using the CO-OP approach, the part of the occupation the child needs to attend to is "made obvious" by the occupational therapist. As well, the relationship between strategy use and outcome are also "made obvious."^{44,46}
- The fifth key feature of CO-OP is the four enabling principles that are used throughout the intervention.⁴⁴ These four enabling principles include: (1) Make it fun; (2) promote learning; (3) work toward independence; and (4) promote

generalization and transfer. These enabling principles are important in engaging the child in therapy.

Parent or caregiver involvement is essential throughout the CO-OP therapeutic process.^{15,44,46} The primary role of parents or caregivers is to support the child in learning the occupations and the strategies and to facilitate the generalization and transfer of these to the home, school, and other environments.^{21,44,57}

The CO-OP program involves ten intervention sessions.^{44,46} In the first phase of the CO-OP process the child identifies three goals to address during intervention and then the occupational therapist assesses the child's baseline performance in each one of the chosen skills.^{44,46} Subsequently, the occupational therapist teaches the child the Goal-Plan-Do-Check strategy and then it is applied to the child's three goals. The Goal-Plan-Do-Check strategy is then used to identify the DSSs.^{44,46} Once therapy is complete the occupational therapist re-evaluates the child's performance. See [Case Study 10-2](#).

Evaluations Used in CO-OP

Within the CO-OP intervention, a variety of evaluation tools can be used by the occupational therapist to ensure meaningful goal selection, monitor skill acquisition, and demonstrate improvements in occupational performance ([Figure 10-5](#)). These include but are not limited to the following.

- *The Daily Activity Log* is a tool used to record the activities a child identifies as important over the course of a day. In CO-OP, the client is asked to complete the Daily Activity Log, with the assistance of parents/significant others if necessary, thinking about a typical day. The completed Daily Activity Log is used to provide the occupational therapist

with information on the client's typical day and is used to initiate the process of goal setting.^{44,46}

- *Pediatric Activity Card Sort (PACS)*³¹ are picture-based assessments used to determine level of occupational engagement. Organized in four categories, hobbies, chores, sports, and personal care, clients are asked to sort the pictures into those he or she does and those he or she does not do. The PACS may be used to complement the Daily Activity Log in the process of goal setting.
- The *Canadian Occupational Performance Measure (COPM)*²⁶ is a client-centered, self-report measure designed to identify treatment goals in the areas of self-care, productivity and leisure. Within the CO-OP approach, the COPM is used to identify the three client-chosen goals that are the focal point of the intervention. The occupational therapist uses the information obtained from the Daily Activity Log to initiate the COPM interview and to help guide the questions asked so as to ensure that the best goals are identified. The COPM is administered again at the end of intervention to measure outcome.
- The *Performance Quality Rating Scale (PQRS)*^{19,33,37} is an observation-based rating scale used to measure performance and change in performance.
See [Case Study 10-3](#).

Evidence for Using Cognitive Approaches

This chapter describes interventions focused on the role of cognition and cognitive strategies in supporting occupational performance. [Research Note 10-3](#) describes the use of CO-OP with children under 7 years old.

CASE STUDY 10-2 Self-Care

Sarah is a 10-year-old girl who was referred for an occupational therapy assessment of her fine motor skills. Sarah demonstrates difficulties completing a variety of self-care activities such as tying her shoes, buttoning buttons, and zipping zippers. An assessment of Sarah's fine motor skills was conducted, revealing some challenges with in-hand manipulation skills and bilateral motor coordination skills. Sarah's challenges in these areas were impacting her ability to be independent in a variety of areas. Sarah was seen by a private occupational therapist for 12 sessions, in which the CO-OP approach was used to support skill acquisition. Throughout the first sessions, the occupational therapist introduced the Goal, Plan, Do, Check framework and applied it to activities that Sarah was already

successful in completing. In doing so, Sarah then understood how the Goal, Plan, Do, Check strategy could be applied. Working with Sarah's parents, the occupational therapist explained this strategy and discussed how to incorporate it into Sarah's daily activities. The occupational therapist then used dynamic performance analysis (DPA) to better understand client motivation, task knowledge, and current occupational performance. The occupational therapist, Sarah, and her parents identified a variety of domain-specific strategies to assist in skill acquisition. Through identifying proper body/hand positioning, feeling the movements, and using verbal instruction and self-guidance, Sarah mastered the three selected skills within the 12 therapy sessions.

Application of the CO-OP Approach: Goal and Point of Breakdown

Goal	Breakdown Points
Tying her shoes	She does not know how to form the loops. She struggles with manipulating the laces in her hands (holding the one still and looping the other around, or holding two loops at the same time). She does not know how to tie the final knot.
Buttoning buttons	Grasping the button while holding the fabric steady with her other hand Aligning the button with the correct hole Pulling the button through the hole

CASE STUDY 10-2 Self-Care—cont'd

Goal	Breakdown Points	
Doing up and undoing her zippers	Holding the zipper stable with one hand and manipulating the other side of the zipper with her other hand Pushing the end of the zipper all the way into the pull tab (having it grab so that the zipper does not split)	
Application of the CO-OP Approach: Goal and Strategy Use		
Domain Specific Strategy	Specific Strategy/PLAN	Bridging for the Strategy
Attention to doing	Making an X Glue my loop to the shoe	Tying soccer cleats and figure skates
Motor mnemonic	Make a bunny ear	Tying her doll’s shoes and indoor gym shoes at school
Feeling the movement	“Feel the edge of the button and grip that as you pull it through the hole.” “Feel the end of the zipper fit snugly into the pull tab before pulling up.”	Buttoning her doll clothing and helping her younger brother with dressing in the morning Putting her sleeping bag back together when camping
Verbal rote script	“Hole one—button one, hole two—button two, hole three—button three”	Buttoning doll clothing and helping her younger brother with dressing in the morning
Body position	“Pinch the pull tab between your index and thumb.”	Buttoning (pinching the button to manipulate more effectively)

FIGURE 10-5 A-G, Brushing teeth.

FIGURE 10-5, cont'd

CASE STUDY 10-3 Leisure and Play

Sam is a 7 year old boy who has a diagnosis of Developmental Coordination Disorder. He was referred for private occupational therapy services with one goal in mind: learning to ride his new bike. Through completion of the COPM, the occupational therapist working with Sam and his family realized that Sam was highly motivated to acquire the skills to complete the activity successfully. The occupational therapist used the CO-OP approach as the framework for Sam's 12 therapy sessions. They focused on task components of bike riding as the "just right challenge for him." The occupational therapist modeled the activity of bike riding while using verbal guidance to ensure that Sam had all the information (verbal, visual, and physical) necessary to attempt to complete the task accurately. The occupational therapist used domain-specific cognitive strategies like body position and feeling the movement to help Sam navigate through the motor learning process. Ensuring Sam was an active collaborator in the therapeutic process guaranteed his motivation and improved his skill acquisition and retention. Sam was provided "homework" to practice the skill of bike riding at home, using the

cognitive strategies that he learned during his treatment sessions. The home program encouraged the involvement of Sam's family in the learning process, and helped with skill retention, generalization, and transfer. After succeeding at each "step" of bike riding (determined through task analysis), Sam was able to perform the task of bike riding in a controlled environment. The next step for Sam's success was to practice his newly developed skills in an open environment (on his street at home) to learn how to manage environmental obstacles (e.g., street signs, curbs, traffic) using his cognitive strategies.

Application of the CO-OP Approach: Goal and Points of Breakdown

Goal	Breakdown Points
Riding his bike	Taking off from a stopped position (balancing bike and starting to pedal) Turning the bike while pedaling at the same time Remember to pedal backward to stop his bike

CASE STUDY 10-3 Leisure and Play—cont'd

Application of the CO-OP Approach: Strategy Use

Domain-Specific Strategy	Specific Strategy/Plan	Bridging for the Strategy
Body position	Keep my feet moving.	Running, playing volleyball or badminton
Feeling the movement	"Feel your body lean to the side as you turn the corner." "Feel the forward power (motion) as you start pedaling"	Enhancing body awareness and positioning to improve task performance in all sport skills (Figure 10-6)
Attention to doing	"Look ahead to where you are going to turn ... where you are going."	Roller blading and skateboarding
Verbal motor mnemonic	"Step back."	Stopping the bike, stopping when using roller blades
Task-specification modification	Use training wheels until confident with balance and control of the bike.	Understanding that when learning new skills, support from equipment or a person is useful for gaining confidence in task performance.

RESEARCH NOTE 10-3

Using Cognitive Interventions for Children Under 7

Taylor, S., Fayed, N. & Mandich, A. (2007). *CO-OP Intervention for Young Children with Developmental Coordination Disorder*. OTJR: Occupation, Participation and Health, 27 (4), 124–130.

Abstract

Children with developmental coordination disorder experience difficulties with fine and gross motor tasks that affect their occupational performance. Research has found Cognitive Orientation to daily Occupational Performance (CO-OP) to be an effective approach for improving skills in daily occupational with children between 7 and 12 years old who have developmental coordination disorder. The purpose of this single-case design was to determine the effectiveness of using the CO-OP approach with children ages 5 to 7 years. Four children chose three different goals to work on during therapy. Child and parent Canadian Occupational Performance Measure (COPM) ratings at follow-up demonstrated

the effectiveness of the CO-OP approach, supporting the use of CO-OP with younger children and suggesting further research on the CO-OP with younger children is warranted.

Implications for Practice

- CO-OP was shown to be an effective treatment method to be used with children as young as 5 years.
- Slight modifications to the administration of the CO-OP were necessary with younger children. The younger the child, the more varied each session was required to be to maintain their attention span, and repetition between sessions was important. Reducing the session length with young children and increasing the number of sessions may be beneficial for children in this age group.
- All children reported improvements in their perceived performance of their chosen tasks, with improved ratings of performance by occupational therapists and parents.
- Children ages 5 to 7 with DCD appear to demonstrate the ability to draw on metacognitive strategies to improve on tasks that are meaningful to them. Furthermore, young children may be able to modify their own cognitive processes through training in skills such as planning, checking, and monitoring.

Summary

Cognitive interventions are frequently used by occupational therapists.⁵⁵ Research evidence is accumulating that suggests they are effective in enabling occupational performance in children.^{43,49,50,55} As well, cognitive strategies can be used to guide the acquisition of new skills and to promote generalize and transfer of these skills.^{43,53}

- Cognitive and educational psychology theories have directly informed the development of cognitive approaches in occupational therapy. The key theorists include Vygotsky, Luria, Meichenbaum, Bruner, Bandura, and Feuerstein.^{1,4,10,13,29,34-36,38,43,57,58} Each theorist contributes to the foundational concepts, principals, and key features of cognitive interventions in occupational therapy.
- Cognitive strategies are the implicit mental processes that guide learning.^{43,55} When the task becomes difficult, relative to the child's skill level, then metacognitive strategies are required to select appropriate cognitive strategies, monitor and evaluate their application.^{23,44,60} Once a strategy use becomes automatic and can be efficiently used, then thinking about and monitoring the strategies consciously becomes unnecessary.^{39,44}
- Cognitive interventions focus on working on the goals identified by the child and the family, therefore enhancing motivation, skill retention, generalization, and transfer.^{21,44,53}
- Scaffolding is intentional and graded adult feedback to promote the skill development of the child. It is a global problem-solving structure that enables learning through everyday activities and helps children to bridge their newly developed skills to different environments and activities.^{39,44,62,63}
- Guided discovery is task exploration with purposeful scaffolding. The occupational therapist assumes the role of a facilitator and allows the child to generate her or his own answers (strategies) through tailoring the task and the environment to the individual.^{44,46}
- Using DPA, the occupational therapist analyzes the child's performance of the task on an ongoing basis, documenting performance problems and/or areas of skill breakdown. Focus is placed on the fit between client abilities, skills, and actions, paired with the task and environmental demands and supports.^{44,46}
- CO-OP's four enabling principles include: (1) Make it fun; (2) promote learning; (3) work toward independence; and (4) promote generalization and transfer. These enabling principles are important in engaging the child in therapy, and prompting cognitive strategy development.^{44,46}
- CO-OP is applied through a family- and client-centered framework that focuses on a performance-based problem-solving approach that enables skill acquisition through a process of strategy use and guided discovery.^{39,44}
- The CO-OP approach uses the global cognitive strategy Goal-Plan-Do-Check coupled with individually relevant domain-specific cognitive strategies. Emphasis is placed on the child using cognitive strategies developed through guided discovery and the implementation of the enabling principals, to problem solve a performance issue and monitor the outcome.⁴⁴
- Research has shown that children who participate in cognitive interventions demonstrate a higher level of self-efficacy, skill retention, generalization, and transfer.^{37,43,44}

CHAPTER

11

Interventions to Promote Social Participation for Children with Mental Health and Behavioral Disorders

Claudia List Hilton

KEY TERMS

Anxiety disorders	Sensory integration
Mood disorders	Applied behavior analysis
Autism spectrum disorders	Relationship development intervention
Fetal alcohol spectrum disorders	Social stories
Attention-deficit/hyperactivity disorder	Mind reading
Social cognitive	Video detective
Executive function	Emotions charades
Theory of mind	Power cards
Weak central coherence	Stress thermometer
Joint attention	Incredible five-point scale
Social cognitive	SOCCSS
Behavior modification	Video modeling
Self-determination	Social autopsies
Peer-mediated intervention	Comic strip conversations
	Privacy circles

GUIDING QUESTIONS

1. What are the diagnostic categories and potential problems of children who may have social participation deficits?
2. What are the major theories that explain social skill deficits in children?
3. What are the roles of occupational therapists and other team members who provide services to children and youth with social skill impairments?
4. What specific types of skills can be addressed with social skills interventions?
5. How do theories and approaches inform social skills intervention?
6. What are the principles and strategies that occupational therapists use to improve social skills in children?
7. What evidence supports interventions that can be used with children who have social skill impairments?

This chapter discusses the role of occupational therapy in supporting children's social participation. It examines diagnostic categories of children for whom social participation can be problematic and describes various theories explaining the basis for these impairments. It describes types of social

goals, approaches, and strategies to help practitioners design intervention.

International Classification of Functioning, Disability, and Health, Occupational Therapy Practice Framework, and Social Participation

The International Classification of Functioning, Disability, and Health: Children and Youth Version (ICF-CY) identifies interpersonal interactions and relationships as one of the domains of activities and participation necessary for children's health.¹⁷⁰ The Occupational Therapy Practice Framework (OTPF) identifies social participation as one of the occupations whereby occupational therapy promotes children's health.⁴ Social participation is defined as "organized patterns of behavior that are characteristic and expected of an individual or a given position within a social system."¹⁰⁶ Social participation includes engagement with community, family, and peers or friends in interpersonal interactions and relationships. Promoting social participation for children in natural contexts supports social well-being and is a focus of occupational therapy intervention.

Establishing and maintaining satisfying interpersonal relationships are essential elements of social well-being.¹⁶⁶ Close, confiding, and supportive relationships enhance health by preserving the immune system and encouraging good health habits.⁶ Socially sanctioned, approved, and valued occupations are most supportive of a person's health. The qualities of a person's social relationships have been consistently associated with physical health, life satisfaction, and mortality.^{7,13,24,75} Therefore, occupational therapy interventions to promote a child's social participation and social well-being can contribute to multiple aspects of health, functional performance, and quality of life.

Importance of Social Skills and Social Participation

Children achieve developmental milestones and occupational goals through social interactions.^{38,53} Social skills can be defined as "socially acceptable learned behaviors that enable a person to interact with others in ways that elicit positive responses and assist the person in avoiding negative responses."⁵⁴ Social skills

BOX 11-1 Examples of Social Goals**Demonstrate Specific Social Behaviors**

- Appropriately greet others.
- Introduce self (to peer and adult).
- Ask someone to play.
- Start a conversation.
- Appropriately give compliments.
- Ask for help.
- Appropriately respond to irritating behaviors of others.
- Participate in conversations.
- Talk about areas outside of special interests.
- Demonstrate cooperative interaction during activities with peers.
- Look at others while engaged in conversation.
- Increase social initiations.
- Participate in conversations.
- Take turns in conversations.
- Start conversations

Awareness of Social Rules

- Demonstrate awareness of unwritten social rules.
- Maintain appropriate physical distance from others.
- Use respectful words when disagreeing with others.
- Stand up for self in an appropriate manner.
- Improve appropriate social responding.
- Use good manners.
- Participate and cooperate in a group project.
- Deal appropriately with irritating behavior by peers.
- Exhibit good manners and good friend behaviors.

Awareness of Others

- Assist others when needed.
- Demonstrate how and when to interrupt.

- Demonstrate how to share a friend with others without becoming jealous or angry.
- When talking, pause appropriately to allow others to talk.
- Differentiate between types and topics of conversation appropriate for different people and situations (e.g., peers, teachers, girls, boys).
- Verbalize understanding of intentions of others.
- Demonstrate increased social motivation.
- Correctly read nonverbal cues.

Executive Function Skills**Self-Management**

- Recognize and verbalize uncomfortable sensory feelings.
- Demonstrate strategies to deal with uncomfortable sensory feelings.
- Apply strategies that help to calm self.
- Keep hands and feet to self.
- Participate in activities when rules are made by others.
- Reduce interfering behaviors.
- Use appropriate voice volume.
- Take turns.
- Follow directions given by adults after first time.
- Stay with group while participating in an activity.
- Think before acting.

Problem Solving

- Ask for help when needed.
- Negotiate with friends.
- Deal with bullies appropriately.
- Compromise when you disagree.

are necessary for effective social participation. Participation in educational and social activities is the context in which children and youth make friends, learn social skills and competencies, and develop their sense of purpose.^{63,85,108} As a child gains social skills, he or she can participate in the meaningful occupations of childhood with greater competence and satisfaction. Development of these skills facilitates the formation of relationships with others that are comfortable and non-threatening. Children develop moral and social values consistent with those of their cultures through social networks. Social skills have a great impact on improving a child's self-esteem. The importance of social interactions in boosting coping skills and resiliency has been established in studies of children with disabilities.^{62,133}

In addition to the direct benefits of social participation for the child and his or her development, parents and children place great importance on socialization.^{45,114} Cohn et al.⁴⁶ found that one of the parents' main hopes for intervention outcomes was the development of behaviors and skills needed for their child to fit in and be included at school and in the community. Parents identified the need for their children to learn appropriate behaviors so that they can conform to the norms of their environments and can interact fully and form meaningful relationships with siblings, same-aged peers, and other children in general. Therefore, developing a child's social competence benefits the child, satisfies parental goals, and enhances the quality of family life. For occupational therapy to be most effective in providing family- and client-centered

services, addressing social participation is an essential part of intervention.

Occupational Therapy Goals for Social Participation and Social Skills

Social participation goals addressed by occupational therapy fall into several categories: those in which the child needs to learn specific behaviors, those that involve becoming aware of social rules, those that involve being more aware of the perspectives of others (theory of mind), and those that involve improvements in executive function, such as self-management and problem solving. Box 11-1 provides examples of social goals.

Social Participation Impairments in Specific Childhood Conditions

Children with mental health or behavioral disorders often exhibit limited social participation. The following sections describe evidence about the types of social impairment seen in children and youth with these conditions.

Autism Spectrum Disorders

Social and communication deficits comprise one of the two core components of autism spectrum disorder (ASD).⁵ Problem

areas include social awareness, social motivation, social communication, theory of mind (see later section, “[Theoretical Basis of Social Deficits](#)”), and executive function. Children with ASD experience profound difficulties in interpersonal communication and social relationships, with relatively poor insight into their own difficulties.⁶⁸ Social difficulties contribute to a lack of close, reciprocal relationships with other children. Church et al.⁴⁴ reported social problems of being too quiet and unassuming, lacking the social skill of assertion, or being too exuberant and active to the point that the child would violate social boundaries. These behaviors frequently alienate classmates and create patterns of negative interactions that are hard to overcome.

Studies investigating the social skills of individuals with ASD cite lack of friends as a problem.^{18,68,86} Children with ASD are usually aware of and interested in others, but often approach them in inappropriate ways.¹⁵⁶ They may express an interest in having friends, but usually become frustrated because of frequent failures. Very few adolescents and adults with autism in one study had friendships with same-aged peers, which included participation in a variety of activities, were reciprocal in nature, and occurred outside prearranged settings.¹¹⁵ Typically, the greater the demands on spontaneous use of social skills, the greater the level of social disability experienced in individuals with ASD.

Social dysfunction, one of the primary features of ASD, may be its most defining characteristic.¹²⁷ Improving social functioning is one of the most important and daunting challenges to professionals working with children who have ASD.^{127,159} Social skills and social skill interventions are probably more frequently studied in children with ASD than any other diagnostic group.

Fetal Alcohol Spectrum Disorder

When gestationally exposed to alcohol with a diagnosis of fetal alcohol spectrum disorder (FASD), individuals experience a multitude of sociobehavioral impairments that tend to persist across the life span and may even worsen with age.⁹⁰ These include impairments in social competence,^{28,34,98} social relationships,^{26,151} social problem solving,¹⁴⁴ inappropriate friendliness,¹¹¹ and difficulty with peer relationships and socially appropriate interactions.²⁶ Children with FASD may also experience social withdrawal, teasing or bullying, poor social judgment, difficulties with perceiving or responding to social cues, difficulty exhibiting consideration for others, and difficulty forming reciprocal friendships.^{34,147} Children with FASD may benefit from interventions to improve executive function, theory of mind, and social problem solving.

Attention-Deficit/Hyperactivity Disorder

The core symptoms in ADHD are problems with attention, impulsiveness, and hyperactivity.^{14,65} Other problem areas include difficulties in the domains of attentional and cognitive functions, such as problem solving, planning, orienting, flexibility, sustained attention, response inhibition, and working memory.^{119,134} Additional problems are often seen in affective components, such as emotional regulation,^{39,113,136} that are fundamental to children’s problems with social skills.^{92,160} Children with emotional regulation problems become easily irritated

when things do not go their way or they cannot get what they want immediately, which often results in unpleasant social interactions. Intervention goals for these children include improving behaviors that reflect executive function.

Anxiety Disorders

Problems in social skills and social interactions are often seen in children diagnosed with anxiety disorders. In their study of 154 children ages 6 to 11 years, Ginsburg et al.⁶⁴ found that highly socially anxious children reported lower levels of social acceptance and global self-esteem and more negative peer interactions. The girls with high levels of social anxiety were also rated by parents as having poor social skills, particularly in the areas of assertive and responsible social behavior. Anxiety disorders can develop into social anxiety disorder (SAD) in the teen years and, without treatment, tend to follow a chronic, unremitting course.^{42,84} SAD is characterized by a marked fear or anxiety about one or more social situations in which the individual is exposed to possible scrutiny by others.⁵ Cognitive-behavioral therapy (CBT) has been shown to be effective in reducing symptoms and functional impairment and in improving social skills in individuals with SAD.^{73,157} CBT is a psychotherapeutic approach that uses a combination of behavioral and cognitive principles to address dysfunctional emotions, maladaptive behaviors, cognitive processes, and contents through a number of goal-oriented, explicit, systematic procedures.⁴⁴ Learning specific social behaviors, awareness of others, self-management, and problem solving are areas of intervention to address social problems seen in children with anxiety disorders.

Learning Disabilities

Social impairment is often a barrier to participation in social occupations for children with a learning disability (LD). Many children with an LD have difficulty with interpersonal understanding and social interaction,^{3,88} which is often exhibited by misconduct in the classroom,⁴⁹ inability to cooperate and establish positive relationships with peers,¹¹⁶ and marked difficulties in working through rough spots in peer relationships in comparison to typically developing peers.¹⁶² Agaliotis and Goudiras³ have found that children with LD experience more difficulty than typically developing children in appreciating the components that make up the context of interpersonal conflict, devising alternative solutions to resolve a conflict, and appreciating the consequences of the solutions that they propose. Furthermore, typically developing children select assertive strategies such as compromise, whereas children with LD select unilateral, less acceptable, nonassertive, and powerless strategies, such as avoidance of negotiation, to resolve an interpersonal conflict situation.³⁵

Mood Disorders

Problems in self-regulation (see [Chapter 13](#) for more information about self-regulation), coping,⁴⁷ and interpersonal difficulties^{66,79} are among the factors associated with increased risk for depression. These vulnerabilities increase individuals’ chances of encountering stress, another risk factor for depression, and decrease their ability to deal with the stress once it occurs. Therefore, many depression prevention strategies include

TABLE 11-1 Developmental Disorders and Common Social Problems

Diagnosis	Common Social Problems
Autism spectrum disorders	Interpersonal communication, social relationships, relatively poor insight into their own difficulties, being teased or bullied, executive function, theory of mind, social awareness, social motivation, social problem solving
Fetal alcohol spectrum disorder	Social competence, social relationships, social problem solving, inappropriate friendliness, difficulty with peer relationships and socially appropriate interactions, social withdrawal, being teased or bullied, poor social judgment, difficulties with perceiving or responding to social cues, exhibiting consideration for others, forming reciprocal friendships, executive function, theory of mind, social problem solving
Attention-deficit/hyperactivity disorder	Attentional and cognitive functions, such as problem solving, planning, orienting, flexibility, sustained attention, response inhibition, working memory, emotional regulation, executive function
Anxiety disorders	Social skills, social interactions, awareness of others, self-management, problem solving, executive function
Learning disabilities	Social awareness, social interaction, inability to cooperate and establish positive relationships with peers, social problem solving, executive function
Mood disorders	Self-regulation, coping, communication skills, social skills

training in coping, social problem solving, and social and communication skills.⁶¹

Table 11-1 provides an overview of developmental disorders and associated social problems.

Theoretical Basis of Social Deficits

Several theoretical models have emerged to describe the alterations in thought processes that explain social skills deficits and participation limitations in children. Most of these theories originate from research examining children with ASD. The dominant models include the constructs of *theory of mind*, *weak central coherence*, *joint attention*, and *reduced competence* in a cluster of neuropsychological skills called *executive functions*.^{109,155}

The theory of mind hypothesis defines the social dysfunction in ASD as the result of disruptions in processes leading to the acquisition of the capacity to conceive of other people's and one's own mind.¹⁶ In other words, the person is blind to the existence of thoughts, beliefs, knowledge, desires, and intentions that contribute to why people do what they do. This may lead to problems such as misunderstandings about the intentions of others, misreading their facial expressions and body language, getting too close while interacting with them, being perceived as insensitive or inconsiderate, and having difficulty understanding how to take turns in conversation and how to talk about the interests of others.

For example, Sasha is a 10-year-old with FASD. She has impaired theory of mind. When her classmate, Mary, who is frequently very clumsy, accidentally knocks a few books off Sasha's desk, Sasha becomes very upset and yells at Mary to stop being mean to her. In another incident, Ben, a classmate, was very upset one time because his grandmother had just died. Instead of offering words of comfort, Sasha said, "She was old. Old people die," which made Ben feel even worse.

A second explanation is the weak central coherence hypothesis.⁷³ It describes the problem as a tendency to process all stimuli in a fragmented fashion, focusing on details rather than integrated and meaningful wholes, which results in a piecemeal

and disjointed internal social world. This might account for a preoccupation with parts of things rather than the whole, such as spinning the wheels of a toy car instead of play that demonstrates a functional understanding of how a car is used, or with preoccupations with letters or numbers instead of using them for reading words or understanding quantities.

A third explanation for social deficits in children is limitation in joint attention.²⁹ Joint attention is the process of sharing one's experience of observing an object or event by following gaze or pointing gestures. It is critical for social development, language acquisition, and cognitive development. A child with limited joint attention may not share a toy with his or her sibling, point to pictures of a book, or verbalize to his or her parent who is reading the book. Children with joint attention problems do not usually assimilate others' facial expressions when engaged in a joint activity; therefore, they lack awareness of others' nonverbal communications.

The fourth explanation for deficits in social skills is the executive dysfunction hypothesis, which focuses on the lack of self-organizing elements required in general learning. Executive functions guide attention, inhibit irrelevant responses, abstract rules, and generate goals used for task execution.¹²² A child with executive dysfunction has problems with general learning because of perseveration and poor self-regulation, difficulties with change, reduced forward planning, and ineffective problem-solving skills. He or she can usually do well with familiar tasks in familiar contexts with familiar people, but struggles with understanding and dealing with new tasks in unfamiliar contexts with unfamiliar people. Issues with adherence to strict routines and avoidance of new situations can be explained by this hypothesis.

Occupational Therapy Evaluation of Social Participation

Occupational therapists are well qualified to play a primary role in working with children who have mental health and behavioral disorders that limit social participation. With a solid

knowledge of social, cognitive, behavioral, and sensory development, occupational therapists use client-centered practice and therapeutic use of self to motivate and empower clients to achieve higher levels of social competence and social participation. Other professionals and paraprofessionals are often involved in social interventions, including clinical psychologists, speech-language pathologists, social workers, and teachers. Each has specific knowledge and skills that contribute to the potential effectiveness of the intervention.

Assessment of Social Participation in Children

Assessment of social skills is included in several comprehensive child development assessments and can also be ascertained by using assessment tools that are specific to social skills and social development. Social skills assessment includes information such as eye contact with others during interaction, understanding of nonverbal communication, social awkwardness, sense of humor, turn-taking or sharing, appropriate voice volume when talking with others, interest in others, and understanding of rules and appropriate proximity when interacting with others.

Occupational therapists can choose from general assessments that include social information and specific assessments of social behaviors (Table 11-2). Examples of comprehensive assessments that include social performance are the Hawaii Early Learning Profile and Pediatric Evaluation of Disabilities Inventory—Computer-Adapted Test for young children and the School Function Assessment for school-age children. Chapter 6 identifies other examples.

Goal Attainment Scaling

Assessment tools for measuring social skills and social participation can be used to measure progress. However, these assessments may not be specific and sensitive enough to capture the stages of improvement in intervention goals. Another option that can be more individualized is Goal Attainment Scaling (GAS).⁸⁶ GAS can be a useful tool for measuring social skills progress because of its ability to identify and measure progress toward very individualized goals, which may not be included in standard assessments. It can establish expected levels of improvement to measure progress. See Chapters 12 and 23 for more details.

GAS was introduced in the mental health field to evaluate program effectiveness. It has since been applied in various settings, including rehabilitation and education, and has become a common method of measuring progress in some areas of occupational therapy. GAS can provide an outcome measure that is broad enough to detect meaningful improvements while sensitive enough to the specific goals of the individual child and family.¹⁰⁷ Goals are typically set for each client and are then weighted by clients and their caregivers, depending on importance. The goals are scaled from -2 to +2, in which zero is the expected outcome and +2 greatly exceeds the expected level of performance following intervention.¹⁴⁶ The score of -2 has been defined as an outcome that is “much less than expected” and -1 as “less than expected.”⁹⁶ The five possible outcomes allow therapists to give credit for partially achieving a goal or exceeding it. The score can be standardized, despite the individual nature of the goals, because each possible outcome is

theoretically equally as difficult to achieve.⁵⁸ In one study, GAS was found to be more sensitive to intervention-related client change (the change brought about by participation in a specific intervention program) than norm-referenced standardized measures.¹³²

Use of the GAS promotes cohesion among the intervention team members, family, and child because they can all be involved in developing and prioritizing the goals.⁹⁹ GAS provides focus on intervention outcomes and does not compare the child’s performance with that of a typically developing child⁸⁶ (Figure 11-1).

Theoretical Models and Approaches for Social Skills Interventions

Elliot and Gresham⁵⁴ have identified five factors that contribute to social skills deficits: (1) lack of knowledge, (2) lack of practice or feedback, (3) lack of cues or opportunities, (4) lack of reinforcement, and (5) the presence of interfering problem behaviors. These factors help identify potential strategies for interventions and explain the potential value of social interventions. Five theoretical approaches and models are frequently used by occupational therapists to develop occupational therapy social skills group.¹⁵⁶ The five approaches to facilitate social participation include social cognitive, sensory modulation, behavioral modification, self-determination, and peer-mediated intervention. Each theoretic approach or model guides interventions and aligns with principles widely used in occupational therapy practice (Table 11-3).

Peer-Mediated Intervention

This educational intervention model includes typically developing children who are partnered with children with disabilities to effect some type of behavioral changes in the children with disabilities.^{117,128} The use of peer-mediated intervention is based on the belief that peers can be as good as or even more effective than adults at intervention. For many skill domains, the contexts created by peers are closer to the typical environments in which children must be able to function. The abundance of peers in most settings creates natural opportunities for clients to learn from multiple examples, and the natural variability of peers’ methods creates many opportunities for clients to learn under variable training conditions. Peer-mediated interventions are believed to facilitate generalized outcomes.¹⁴⁹ Children with autism become more responsive to social interactions and engage in increased peer interactions when increased peer support is present.^{17,84}

To capitalize on the benefits of peer mediation, the social skills program includes at least one typically developing child who is the same age or slightly older than the other participants. Occasionally, a younger sibling of one of the participants can also be effective, especially if the two have mostly positive interactions and if the younger sibling is relatively mature in his interactions. Peers can be taught to remind the child with social skills impairments what he or she needs to do in a certain situation. A trial period may sometimes be necessary to determine the appropriateness of using siblings as peers.

TABLE 11-2 Specific Assessments for Social Impairment

Name of Measure	Brief Description of Content
Caregiver-Teacher Report Form (CTRF) ¹	For children ages 1½ to 5 years old, this questionnaire is designed to obtain caregivers' or teachers' reports of children's academic performance, adaptive functioning, and behavioral-emotional problems. Teachers rate the child's academic performance in each subject on a five-point scale ranging from 1 (far below grade level) to 5 (far above grade level). For adaptive functioning, teachers use a seven-point scale to compare the child to typical pupils for how hard he or she is working, how appropriately he or she is behaving, how much he or she is learning, and how happy he or she is.
Teacher Report Form (TRF) ¹	Questionnaire for children ages 6 to 18 years old. See Caregiver-Teacher Report Form for description.
Child Behavior Checklist (CBCL) ¹	Designed to assess the behavioral problems and social competencies of children per parent report for ages 1½ to 5 years and ages 6 to 18 years. Subscales include Social Withdrawal, Somatic, Anxious/Depressed, Social Problems, Uncommunicative, Hyperactive, Delinquent, and Aggressive. The CBCL also includes 20 social competence items covering the child's activities, social relations, and school performance. Questions are easy to understand; items address behaviors found across a wide range of functioning; and probes regarding social behaviors are useful with investigations of children with ASD.
Friendship Qualities Scale ³¹	Theoretically grounded, multidimensional measurement instrument to assess the quality of children's and early adolescents' relationships with their best friends according to five conceptually meaningful aspects of the friendship relationship: companionship, conflict, help-aid, security, and closeness.
PKBS-2: Preschool and Kindergarten Behavior Scales ¹⁰³	Separate score conversion tables are available for home-based and school-based raters. Completion of the rating form takes about 12 minutes. The Social Skills scale includes 34 items on three subscales: Social Cooperation, Social Interaction, and Social Independence. The Problem Behavior scale includes 42 items on two subscales, Externalizing Problems and Internalizing Problems. In addition, five supplementary problem behavior subscales are available for optional use. The PKBS-2 was standardized with a nationwide sample of ratings of 3317 children ages 3 through 6 years. Ethnicity, socioeconomic status, and special education classification of the standardization sample are very similar to those characteristics of the U.S. population, based on the 2000 census.
School Social Behavior Scales, 2nd edition (SSBS-2) ¹⁰²	64-item questionnaire designed to assist school personnel in identifying student deficits in school-related social competence and antisocial behaviors. It can be completed in 5 to 10 minutes by teachers to help identify social skills goals for children 5 to 18 years of age. It provides an inventory of a student's ability to apply the skills necessary to meet with success in school settings and for eventual success in employment settings. It was standardized with a national sample of 2280 students, in grades K-12. Raw scores are converted to T-scores, percentile ranks, and descriptive Social Function Levels.
Social Communication Questionnaire (SCQ) ¹³⁴	Brief questionnaire used to evaluate communication skills and social functioning in children older than 4 years who may have autism or autism spectrum disorder (ASD). It is completed by a parent or other primary caregiver in less than 10 minutes. Current and lifetime versions are available.
Social Responsiveness Scale, 2nd edition (SRS-2) ⁴⁸	65-item questionnaire that inquires about a child's ability to engage in emotionally appropriate reciprocal social interactions through interpersonal skills and communication. It can be used as a screener or as an aid to diagnose ASD. It uses a quantitative scale to determine where a child falls within the range of social behaviors that are addressed and occur in the population as a whole. The SRS divides these behaviors into five subscales to be used for treatment planning and evaluation of program effectiveness; these include social awareness, social cognition, social communication, social motivation, and autistic mannerisms. A singular T-score is then generated and determines the severity of social deficits.
Social Skills Improvement System (SSIS) ⁶⁹	The SSIS provides a broad, multirater standardized assessment of social skills and problem behaviors of students from preschool through high school. Students are rated in areas of how often behaviors occur and how important each behavior is to the respondent. Forms consist of three-point, Likert-type scales reported by the teacher, student, and/or parent. Separate forms are used for preschool, elementary, and secondary levels of school.
Triad Social Skills Assessment, 2nd edition ¹⁴⁸	Designed for children ages 6 to 12 years who have basic reading skills at the first-grade level. It is criterion-based and assesses knowledge and skills in three areas: cognitive, behavioral, and affective. Sources of information are (1) parent report, (2) teacher report, (3) observation, and (4) direct child interaction.

Goal: Take turns in conversation. Baseline: Rachel will answer questions that are asked to her with very short answers but no explanations, and will not ask a question or make a statement to continue a conversation with peers.				
Much less than expected outcome	Less than expected outcome	Expected outcome	More than expected outcome	Much more than expected outcome
−2	−1	0	+1	+2
Rachel will answer one question asked during an exchange with a peer with an explanation that is more than a few words long.	Rachel will answer two or more questions asked during an exchange with a peer with an explanation that is more than a few words long.	Rachel will ask one question to continue a conversation after being asked a question by a peer.	Rachel will ask two or more questions to continue a conversation after being asked a question by a peer.	Rachel will ask a question to start a conversation with a peer.
Goal: Stress modulation/calm self. Baseline: Seth frequently (more than once per day) becomes overwhelmed with situations that occur in school that cause him to have a behavioral meltdown, which is very disruptive and interferes with his social interactions with peers.				
−2	−1	0	+1	+2
Seth will identify his stress level appropriately and apply a modulating tool that has been suggested to him on one occasion during therapy when he is already calm.	Seth will identify his stress level appropriately and apply a modulating tool that has been suggested to him during therapy which calms him on one occasion when he is beginning to feel stressed.	Seth will identify his stress level appropriately and apply one modulating tool during therapy which calms him without being told on one occasion when he is beginning to feel stressed.	Seth will identify his stress level appropriately and apply one modulating tool outside therapy which calms him without being told on one occasion when he is beginning to feel stressed.	Seth will identify his stress level appropriately and apply one modulating tool outside therapy which calms him without being told on two occasions in one day when he is beginning to feel stressed.

TABLE 11-3 Theoretical Approaches and Models Supporting Social Skills Groups

Intervention Approach or Model	Principles	Strategies
Peer-mediated	Typically developing children are partnered with children who have disabilities to affect behavioral changes in the children with disabilities.	During therapy sessions or social skills groups, a same-age or slightly older peer is included in the session to provide role modeling and help facilitate socially appropriate behaviors in the child who has social impairment.
Sensory integration	Children may need to learn more effective habits for modulating their sensory processing needs in a safe, acceptable manner in social situations through sensory integration.	Activities might include hanging on a trapeze bar upside down and swinging back and forth, jumping into a ball pit, or pulling themselves up a ramp on a scooter board.
Self-determination	This involves satisfaction of the needs for autonomy, competence and relatedness promote well-being.	Children make choices, indicate preferences, problem solve, plan, and initiate activities included in therapy and social skills group sessions.
Social-cognitive	Children learn by observing the behavior of others. Groups based on this theory include two phases, acquisition and performance.	Participant goals are addressed and worked on by the entire group during the didactic social skills segments of the groups. The leaders or other participants describe and demonstrate the social skills, followed by others performing the skill.
Behavioral interventions	Behavior is a response to an environmental stimulus and behavior is reinforced by environmental consequences that follow.	A reward system is used, such as a goal chart, to recognize and reward attempts to work on goals. Rewards are provided at the end of the session if the number of attempts to work on goals meets previously identified quotas.

Sensory Integration Intervention

The use of sensory integration in a social skills group adds an important aspect that is usually only included when groups are developed by occupational therapists (see [Chapter 9](#)). Ayres, an occupational therapist, has defined sensory integration as “the neurological process that organizes sensation from one’s own body and from the environment and makes it possible to use the body effectively within the environment” (p. 11).⁸ Children who have difficulty integrating the continuous stream of sensory input and responding appropriately may also have difficulty with self-esteem, self-actualization, socialization, and play.³² Many children with ASD have atypical sensory processing that appears to contribute to their social impairment⁷⁶ and that can be misinterpreted as a social or behavioral problem.¹⁰⁵ These children may need to learn more effective habits for modulating their sensory processing needs in a safe, acceptable manner in social situations. They may also need to learn to integrate the needs of others with their own needs. For these reasons, principles of sensory modulation can be included in each session to enhance participants’ ability to filter sensations, attend to those sensations that are relevant to the activity, and maintain and personally recognize optimal level of arousal throughout sessions.

In a small randomized controlled trial (RCT), children with sensory processing disorders who received sensory integration intervention made significant gains in goal attainment, attention, and cognitive-social skills.¹⁰⁴ In a more recent RCT of sensory integration intervention, Pfeiffer et al.¹²³ found improvements in autistic mannerisms and self-regulatory behaviors in children with ASD who received the intervention. This reduction was believed to be an indication of improved ability to process sensory stimuli in the environment without needing to resort to self-stimulatory behaviors. Fazlioglu and Baron⁵⁶ found a significant reduction in atypical sensory responses in a group of children with ASD after participating in a sensory integration intervention program in which many of the test items referenced social behaviors (e.g., can answer when his or her name is uttered, cannot give answers to simple questions asked, cannot use “yes” or “no” for a specific purpose). Schaaf et al.¹³⁷ examined changes in a child with ASD following sensory integration intervention. They found improved regulation and organization in responses to sensory input and improved communication. The parent report described a happier child with less rigid behaviors and increased tolerance of unexpected changes in routine, a decrease in his activity level, distractibility, and impulsivity, with better safety during play, improved play skills, and so much improvement in his attention in the classroom that he did not need an aide for his school work.

Therapists can implement the core elements of sensory integration intervention^{120,121} to promote self-regulation at the start of each social skills session by providing participant-initiated sensory modulation activities (see [Chapter 9](#)).¹²³ Examples include hanging on a trapeze bar upside down and swinging back and forth, jumping into a ball pit, or pulling themselves up a ramp on a scooter board. Under the therapist’s guidance, the children can build their own obstacle course that incorporates proprioceptive, tactile, and vestibular input. Following the activities to promote self-regulation, the children identify their levels of arousal before and after their chosen activities to help them better recognize their levels of arousal, better understand

FIGURE 11-2 Principles of sensory integration theory can be included in each session to enhance participants’ ability to filter sensations, attend to those sensations that are relevant to the activity, and maintain and personally recognize their optimal levels of arousal throughout sessions. (Photo by Washington University Program in Occupational Therapy.)

how to measure the impact of modulation, and determine the best modulating activities for them.¹⁵ Additional discussion regarding identifying and meeting individual needs in a socially appropriate way, without external supports, can be discussed in subsequent groups ([Figure 11-2](#)). See [Chapter 9](#) for more information on sensory integration.

Self-Determination

The self-determination theory, from the field of psychology, states that satisfaction of the needs for autonomy, competence, and relatedness promotes well-being.¹³⁵ Autonomy refers to having a sense of choice, initiative, and endorsement of one’s activities. Competency represents a sense of mastery over one’s capacity to act in the environment. Relatedness denotes feelings of closeness and connectedness to significant others. “As young children make choices, indicate preferences, problem solve, plan and initiate, they are making sense of the world around them in a way that can ultimately produce feelings of competence, confidence, and empowerment.”⁵⁵

By encouraging children to make their own choices in social skills sessions, therapists support self-determination. As children progress along the continuum, activities become increasingly meaningful, intrinsically motivating, and more satisfying. Participants are involved in the initial selection of social skills goals and identification of focus goal(s) for each session. They take part in brainstorming a name for the group, identifying rules of behavior for the group, making choices about the content of group activities, choosing snacks, and choosing rewards for goal attainment. This model also supports competency in social situations by providing “just-right” challenges. Children apply newly developed social skills in small, less intimidating, peer context, with gradually decreasing external support from therapists. Individual growth and acquisition of skills during sessions is possible because of the connections and

FIGURE 11-3 By encouraging the children to make their own choices in social skills sessions, activities become increasingly meaningful, intrinsically motivating, and more satisfying. (Photo by Claudia Hilton.)

friendships made while relating to other group members (Figure 11-3).

Social Cognitive

This psychological theory, proposed by Bandura,⁹⁻¹¹ is a typical model for social skills groups. This theory supports the idea that children learn by observing the behavior of others. Groups based on this theory include two phases, acquisition and performance. During acquisition, a child observes the behavior of others and its consequences. The child remembers this observation for later use. During the performance phase, the child performs the behavior based on his or her perception of the situation and its consequences.

Participants' goals are addressed and worked on by the entire group during the didactic social skills segments of the groups. The leaders describe and demonstrate the proper social skills, followed by the group members performing the skills. Social interactions can provide opportunities for a child to serve as a role model for others while simultaneously acquiring new behaviors or attitudes through the imitation of others (Figure 11-4).^{43,72}

Behavioral Interventions

Founded by psychologist B. F. Skinner,^{143,144} behaviorism builds on the theory that all behavior is a response to an environmental stimulus and that behavior is reinforced by environmental consequences that follow. Behavioral interventions use techniques of altering an individual's reaction to stimuli through positive reinforcement and the extinction of maladaptive behavior. A measurable system of reinforcement is established to focus specifically on behavior. The system encourages using positive reinforcement only, thus lessening the emphasis on negative behavior, and is another model commonly used to promote the development of many skills of children with disabilities.

Once social skills goals are established for participants in the group, a chart may be used as a visual reminder. This chart also

FIGURE 11-4 Children can learn by observing the behavior of others. (Photo by Cheryl Klohr.)

serves as a record to reward daily efforts toward goal attainment (Figure 11-5). One goal is identified as the most important goal for that session and is indicated on the chart with an arrow. The most important goal changes as one is achieved or if another becomes more important. Each time the child works on any goal, he or she receives a star in the box for that goal. Participants can be encouraged to note or comment on each other's positive behaviors to further facilitate socialization. At the end of each session, each child who earns a specified number of stars for his or her most important goal and at least one star for each of the other goals can then be allowed to choose a small prize (usually a small toy or treat) from the prize bowl, which has already been identified as a good prize by the child so that the reward is readily sought by the child.

Interventions for Social Skills

The ultimate goal for social skills interventions is to participate in group and social situations appropriately. Some children with ASD do not have adequate interest or behavior to interact with others successfully. In this case, social skills can be introduced individually with the therapist. The following activities are appropriate for children who are at least 4 years old, are higher functioning, and who demonstrate some interest in social interaction. According to the child's progress, the child can be introduced to dyads (groups of two children) and then later to social skills groups (Figure 11-6).

Social Interventions

Although the purpose of social interventions is to improve social skills, these interventions can be part of individual or group interventions. The following activities can be introduced to children on an individual basis to prepare or participate in social skills groups.

Promoting Specific Social Behaviors and Adherence to Social Rules

Practitioners can provide social skills training in groups or individually. Most strategies to promote social skills can be used

Name	Goals	Session #1	Session #2	Session #3	Session #4	Session #5
Joshua	1. Identify stress thermometer level and choose tool to adjust	☆☆	☆☆	☆☆	☆☆☆	☆☆
	2. Use appropriate voice volume	☆	☆☆☆	☆☆	☆☆☆	☆☆

	5. Deal well with bullying.	☆☆☆	☆☆☆☆	☆☆☆☆	☆☆	☆

FIGURE 11-5 Goal chart.

one-on-one or in groups. The strategies in this section, however, were designed for individual use. These interventions were developed for children with ASD; however, they can be effectively used to promote social participation in children with a range of mental health and behavioral disorders.

Video Modeling

The original concept of teaching children to model the behavior of their peers was termed *observational learning* or *modeling*.⁹ Video modeling and video self-modeling evolved as technology became more available. Video modeling involves an individual watching a video demonstration of a certain behavior and then imitating the behavior of the model.²¹ Video self-modeling is used to allow children to observe and model from their own behavior.⁷⁷ The use of these interventions for children with ASD has been extensively examined and found to be

effective for improving social communication skills, functional skills, and behavioral functioning.²⁰ Video modeling promotes skill acquisition; skills are maintained over time and transferred across persons and settings.

The therapist and child identify social or behavioral areas that are difficult for the child to perform (e.g., greetings, introductions, offering help, asking for help, transitions, play skills) and then prepare a script in which the child successfully performs that particular social interaction. The child is videotaped while acting out the script with another individual. The child and therapist view the video and identify how the child acted and the effect of the behavior on the other person. The videotape can be sent home with the child for repeat viewing, if possible. The amount of script preparation completed by the child can be graded, depending on how much the child can

FIGURE 11-6 Some children who may not be ready for social skills groups can benefit from the less threatening structure of a dyad. (Photo by Cheryl Klohr.)

do. This strategy can be used for other social and behavioral areas in which the child has difficulty.

Video self-modeling has been used effectively for treating many conditions, including depression,⁸¹ stuttering,²⁷ elective mutism,¹²⁴ attention disorders,^{53,169} behavior disorders,⁹⁴ and aggressive behaviors.¹⁰¹ It is effective for children diagnosed with ASD for improving communication skills,^{40,41,141} behavior during transition,¹³⁹ and play skills.^{30,52,115,154}

Social Scripts

Many human social events have expected sequences of interactions that involve specific verbal routines, termed *social scripts*.⁵⁷ Persons with ASD often struggle with these scripts because of their lack of social awareness.¹⁵⁸ Social scripts or scripting can be used in an intervention so that children can practice what to do in those social situations that they find awkward.⁶⁰ The therapist helps the child think of an awkward or challenging social situation, such as introducing self, giving help, asking for help, and giving or receiving a compliment. The therapist works with the child to identify a script appropriate for that type of situation. The script is written so that the child can practice it. The child can be paired up with another child to practice the script, simulating a situation in which the script can be used. Then the child practices the script in a real situation. As the child remembers and uses the script consistently, the therapist fades out use of the visual prompt. The child can keep a notebook to record useful scripts to refer to as needed. During intervention, various situations can be presented to the child, who is encouraged to develop a new and appropriate script for each situation. Social scripts can be used for video self-modeling.

Studies examining the effectiveness of social scripts have shown decreased perseverative speech in children with ASD,⁶¹ improved initiation of conversations in children with ASD and Down syndrome,^{89,97} and increased length of time spent in conversation in children with ASD.⁸³ A major limitation of this intervention approach is that the child may become dependent on the script and be unable to engage in spontaneous, unscripted interactions. Script fading has been developed to address this problem.⁸⁹

Power Cards

Power cards recognize a child's special interests or heroes and are used to help facilitate appropriate behaviors in social situations and routines.⁵⁹ To implement this strategy, the therapist identifies a social situation or behavior that the child needs to handle better. He or she finds a picture of a favorite hero of the child and adheres to a card. The therapist writes a scenario of the hero advocating the correct behavior (e.g., SpongeBob talking about the appropriate way to act during circle time in the classroom). The desired behavior is divided into steps and written on the card with the picture of the hero (e.g., walk quietly to your carpet square, sit down without touching your classmates, listen to the teacher, sit quietly while the teacher is talking, sing the good morning song with the class). The therapist and child practice acting out the scene, using the information on the card as prompts for appropriate behavior. The therapist can laminate the card so that the child can keep it with him or her to help as a reminder on how to handle the situation. The card can be posted at the location where the behavior is most appropriate, such as posting a hand washing card near the sink.

Because many children with ASD have special interests or heroes and are strong rule followers¹⁵⁹ and because they process visual information better than auditory information,¹²⁶ this strategy is effective for many children with ASD. It can also be used for a larger group (e.g., classroom, entire school) to support preferred behaviors, such as walking quietly in the hall, washing hands after using the bathroom, antibullying behaviors, and increasing attendance by using popular characters from movies or television shows. Power cards have been used successfully to increase good sportsmanship behavior in a child with autism⁸⁵ and improve disruptive and noncompliant behaviors of children with autism in the classroom setting.¹¹¹

Social Stories

Social stories were developed to teach social skills to children with ASD.⁶⁸ One social skill or issue is addressed in each story. This method helps children who take things literally to understand concepts, overcome fears or preoccupations, establish healthy routines, and develop new social skills. The stories consist of four types of sentences¹⁰⁹ that prepare the children for what they can expect to feel and what they should do in certain situations that are difficult for them. The types of sentences are as follows:

1. *Descriptive sentences* explain what occurs and why, who is involved, and provide background for the story. Example: "Kids often need to go to the bathroom at school or public places and so do I."
2. *Directive sentences* provide direction to the child and instruct on how to do something or how to respond. They frequently use the words "I can" or "I will" and never use negative words, such as "I will not." Example: "I can go to the bathroom without flushing all the toilets."
3. *Perspective sentences* describe the reactions of other people and their feelings. Example: "It bothers other people when someone flushes all the toilets in the bathroom."
4. *Control or affirmative sentences* are sometimes written by the student to help him or her recall information. Example: "I will only flush my toilet one time when I go to the bathroom in the school or in a public place."

The story should be kept brief and written in the first person, and visual aids, such as photos and diagrams, can be

helpful. Stories can be bound in a small binder so that the child can carry them.

Social stories have been shown to be effective for decreasing inappropriate behaviors and increasing appropriate behaviors in children with various diagnoses. Examples of social stories outcomes for children and youth with ASD include improving mealtime skill,²⁵ decreasing disruptive behaviors,¹¹⁸ increasing prosocial behavior,⁵¹ teaching sex education,¹⁵³ and increasing game play skills.¹²⁷ Other positive effects for social stories include increasing physical activity of developmentally disabled students when used in combination with visual schedules¹⁷² and improving appropriate interpersonal conflict resolution strategies in children with learning disabilities.⁸² Box 11-2 on the Evolve website lists websites for social stories.

Applied Behavior Analysis

Applied behavior analysis (ABA) is a didactic approach to help children perform socially significant behaviors through a reinforcement training technique.¹⁵⁵ ABA supervisors are usually licensed clinical psychologists, with training and certification in applied behavior analysis. They often supervise others, including paraprofessionals, who require specialized training. Occupational therapy students are often among those who are ABA providers. Occupational therapists may work in collaboration with the ABA providers.

ABA intervention for children with ASD is often intensive—that is, up to 40 hours per week. ABA is considered a successful behavioral intervention, yielding substantial gains in intelligence quotient, language, academic performance, and adaptive behavior, with significantly better social behavior.¹⁵⁵ ABA currently has many different forms.

Discrete trial training (DTT), from Lovaas' Young Autism Project,⁹⁶ is now the most widely recognized form of ABA. DTT works on developing learning readiness by teaching fundamental skills such as attention, compliance, imitation, and discrimination learning as small, individually acquired tasks.¹¹⁰ It consists of one-on-one instruction to teach skills in a planned, controlled, and systematic manner in small repeated steps. Each trial or teaching session is discrete, having a definite beginning and end. Within DTT, the use of antecedents (prompts) and consequences is carefully planned and implemented. Praise and/or rewards are used to reinforce desired skills or behaviors. Data are collected about beginning skill level, progress and challenges, skill acquisition and maintenance, and generalization of learned skills or behaviors used to support decision making.

ABA, in its various forms, is conducted entirely in a structured teaching environment and has been questioned for its applicability in natural situations. To address these concerns, traditional ABA techniques have been modified in recent years for use in more natural situations.¹³⁸ Traditional ABA has long been recognized as the educational treatment of choice for young children with autism, but it is less clear whether this treatment paradigm is the optimal approach for less severely affected, higher functioning individuals.¹⁵⁵

Privacy Circles

Privacy circles are used to help children identify which topics or activities are appropriate to discuss or to do with different people and in various settings.¹³⁰ Privacy circles address the lack of social awareness,¹⁵⁸ mindblindness,¹⁶ and poor knowledge regarding privacy issues.¹⁴⁷ The therapist gives the child a template with eight to ten concentric circles (like a target). The child or therapist puts the child's name in the middle. The child lists people that he or she might interact with regularly, such as mom, dad, brothers, sisters, teacher, friends, neighbors, and people at the grocery store. The therapist helps the child categorize the people in intimacy levels from most intimate to least intimate. These people are then placed in the circles, with the most intimate toward the middle and the least intimate toward the outside. The therapist then gives the child examples of conversation topics or activities that range in levels of intimacy (a concern about a private part of his or her body, new shoes that light up when she or he walks). The therapist then has the child identify in which circle the conversation or activity fits. Redirection may be necessary, and discussion is part of the process. As situations come up, new topics and activities can be added to the privacy circles to help the child understand the contexts of their appropriateness (Case Study 11-1).

Enhancing Social Awareness and Relationships with Others

Mind Reading

Theory of mind explains the social dysfunction in children with ASD, in which the person is blind to the existence of thoughts, beliefs, knowledge, desires, and intentions that contribute to why people do what they do.¹⁶ Mind reading helps children with ASD improve in and increase their theory of mind.

The first level of this strategy uses drawings and photos of faces to determine what a person might be feeling.⁷⁸ Drawings and photographs of facial expressions can be used to help

CASE STUDY 11-1 Cedric

Cedric is a 7-year-old with FASD. He has noticed recently that offering details about his father's anatomy brings much attention from other children in his class, which he is constantly seeking. His teacher knows that his parents would be mortified to learn that he was sharing such intimate information about his father and would like to help Cedric be better able to judge what is appropriate to share with whom. The occupational therapist suggested that they might try using privacy circles to help Cedric understand what is appropriate and what is not appropriate. They also discussed

the issue with his mother, who was very supportive of the plan. Cedric worked on his privacy circles, kept a copy at his desk, and took a copy home with him. The teacher told him that if he could follow his privacy circle rules each day, he could help her pass out homework papers to the class at the end of each day. He liked the attention that he got from the class and how important he felt for passing out the homework papers. After a few reminders, he was able to follow his privacy circles without needing more reminders.

children identify the emotions expressed in them. Children can make charts of emotions by cutting out photographs of people expressing different emotions and placing them on the chart for each emotion. To make the activity easier, participants can choose from a small list of emotions. Beyond recognizing facial expression of emotions, mind reading can include understanding expectations of emotional responses based on intent (e.g., statement about what Jimmy wanted, statement about what his mother gave him, and question of how he feels about it) and understanding why someone might have a different perspective from the child (e.g., removing the candy from a candy box, replacing it with crayons, and asking a child who did not witness the switch what is in the box).

Measurement tools have been identified for mind-reading competence,¹⁵⁷ and encouraging results were seen in a study of three boys with ASD.¹⁹ Various adaptations of this strategy have also been developed. Interactive computer software has been developed for mind reading to teach individuals to recognize emotions through the use of video clips, photographs, voice recordings, lessons, and games involving individuals displaying a range of emotions.^{65,93,142} One study found marked improvement in recognizing emotions in pictures and voices presented similarly in the computer program but showed little improvement when subjects were presented with photographs of the individual's eyes or with film clips.⁹³ Other studies found improvement beyond the specific areas addressed by the program, including the use of emotion recognition cartoons, understanding strange stories,¹⁴² and face and voice emotion recognition.⁹³

Emotions Charades

Emotions charades adds a real-life and present aspect to mind reading. It uses role-playing situations that involve expressions of emotions. Other people guess which emotion is being expressed.¹⁰⁰ The activity can be structured in several ways, depending on the ability levels of the children. The therapist may act out a short situation in which he or she uses facial expressions and body language to express an emotion and then have the children guess the emotion. Students can pair up and select a short scenario in which one person must express one emotion and the other expresses another emotion. The pair then acts out the scene, and others guess which emotions they are expressing. This activity can be graded by changing the complexity, adding or subtracting the number of emotions included, and posting a list of emotions to which the participants can refer as they try to decipher the charade. See Figure 11-7 for a list of emotions that can be acted out through this strategy.

Video Detective

This strategy adds another dimension to mind reading. It consists of watching video clips to help children increase their skills of interpreting nonverbal communication.^{100,112} The therapist first explains concepts of body language and verbal and nonverbal communication. Then a video segment is played, with the volume muted. Children are asked which emotions certain actors appeared to be expressing through their nonverbal behaviors in the video. Each child has a turn to respond and provide explanations for his or her answers. The scene is played again with the volume on, and the children examine their previous answers to see if they still agree. The group discusses the nonverbal behaviors that were helpful, those that they found confusing, and which actors seemed to do the best at nonverbal

Afraid	Bored
Anxious/Worried	Disgusted
Cautious	Embarrassed
Frightened	Guilty
Terrified	Hopeful
Uncertain	Indifferent

FIGURE 11-7 Suggested emotions for emotions charades.

communication. To make this activity easier, the therapist can give the children choices of which emotions are being expressed, choose clips that have very expressive nonverbal actions (such as silent movies), or choose clips with only a few actors.

Social Autopsies

Social autopsies were originally developed for children with an LD.⁹⁵ They can also be effective for children with ASD and FASD because they can address incidents related to theory of mind¹⁶ and provide a nonthreatening way to examine retroactively how the child handled a difficult situation. They also use problem-solving strategies that are useful for children with ADHD, LD, anxiety, and mood disorders. After the situation occurs, the child is asked to describe the event and the possible motivations of others who were involved. The therapist engages the child in a discussion of alternative responses that could have been used. The therapist and child discuss good and poor responses to situations. Using videotapes that demonstrate the behavior and resulting consequences can increase understanding and motivation for the child.

Enhancing Executive Function

Self-Management

Self-management strategies have demonstrated considerable effectiveness for changing behavior in children with behavior disorders,³⁶ developing academic skills in children with learning disabilities,⁷⁴ increasing social interactions in children with ASD,^{87,140,150} and decreasing off-task behaviors in children with ASD.⁵⁰ Learners are taught to discriminate between appropriate and inappropriate behaviors, monitor and record their own behaviors accurately, and reward themselves for behaving

appropriately.¹¹⁴ Teaching a child to monitor and manage his or her own behavior gradually increases independence and supports generalization of the skills. Self-management can be directed at skills prerequisite to social skills, such as self-regulation. Several types of interventions could be included under the umbrella of self-management. Examples include use of video modeling, checklists, goal charts, stress thermometers, five-point scales, wrist counting devices, and role playing. They might be used by occupational therapists for intervention with children with ASD, FASD, ADHD, anxiety, LD, and mood disorders.

Comic Strip Conversations

Comic strip conversations are similar to social autopsies, but use comic strip drawings to illustrate a social interaction.⁶⁷ They are designed to promote theory of mind and improve social interactions in children by facilitating joint attention and understanding intention. The situation is drawn as a comic strip at a calm time, after a difficult situation occurs (Case Study 11-2). The drawing includes the thought bubbles of the various participants' perspectives and intentions. This gives the child practice in attempting to understand the perspectives and intentions of others. For situations that did not go well, the comic strip can be redrawn to show a more ideal interaction and outcome, which instructs and models better social behavior choices for the child.

A limited number of small studies have examined the effectiveness of comic strip conversations. This strategy was found to be effective in increasing social satisfaction and decreasing loneliness in three children with ASD and, when used in combination with social stories, was effective in reducing inappropriate social behaviors of two individuals with ASD.⁸⁰

Stress Thermometer

Scales and thermometers can help children recognize, quantify, and describe different levels of their emotions and behaviors. The scales or thermometers can be introduced to a group of children or an individual child. They can address group behaviors, such as voice volume or stress level, or individual behaviors, such as obsessions or compulsions.

For the anger or stress thermometer, the therapist gives the child a template for a thermometer with graded levels of anger or stress²³ (Figure 11-9). It may include four to ten levels, depending on the understanding of the child. The therapist can list the emotions for the child (e.g., calm, irritated, furious, enraged), and the child can look for pictures of faces in a magazine to match those emotions. The child may code the thermometer with colors, according to the emotion. The child may also use special interests as themes for the thermometer, such as weather (with *hurricanes* at the top level and *calm and breezy* at the bottom) or dinosaurs (with *Tyrannosaurus rex* at the top and *pterodactyl* at the bottom). Children who are not yet proficient at writing can use pictures for the levels. The therapist and child can then determine where the child's level of anger fits on the anger thermometer during a specific situation.

Initial teaching of this technique should be done at a quiet time after an angry event. The therapist asks the child to recall a time when he or she felt like a *tornado* or felt *calm and breezy* and the levels in between (see Figure 11-9 for an example). The therapist and child can also role play and re-enact original words, tone of voice, and actual level of anger to understand the system better. The thermometer can be used to help the

child become better aware of his or her responses, regulate responses, and keep track of responses to various situations or interventions (see Figure 11-9).

Incredible Five-Point Scale

The Incredible Five-Point Scale³³ organizes behaviors, such as voice volume, friendly behaviors, and feeling angry or afraid, along a five-point continuum (Figure 11-10). The scales can be used to help children better understand the social impact of their behaviors, regulate their responses, and calm themselves when they overrespond. Like the thermometers, the scales should be introduced at a quiet and calm time after an event in which the child had difficulty with regulation. The scale can be used to quantify the behavior and give the child a way to communicate about the behavior in a quantifiable way. For example, if a child has difficulty with being too loud, a voice volume scale can be used to help the child understand the need to modulate the volume of his or her voice. The therapist can have the child demonstrate the different levels on the scale. Then the scale is shared with others who interact with the child, including parent and teacher. They can then give feedback about the volume level when it is not appropriate for the situation. See Case Study 11-3.

Relationship Development Intervention

Relationship Development Intervention (RDI) is a parent-based, cognitive-developmental approach in which primary caregivers of children, adolescents, and young adults with ASDs and similar developmental disorders are trained to function as facilitators for their children's mental development to provide daily opportunities for successful functioning in increasingly challenging dynamic systems.⁷⁰ RDI is designed to teach parents to play an important role in improving critical emotional, social, and metacognitive abilities through carefully graduated, guided interaction. The therapist works with the child and teaches and guides the parent to provide effective social cues to facilitate the child's attention and responsiveness.

One study that examined the progress of 16 children with ASD who participated in RDI over a 5-year period found important changes in the Autism Diagnostic Observation Schedule (ADOS) and Autism Diagnostic Interview-Revised (ADI-R) scores, along with measures of flexibility and school placement.⁷¹ At baseline, all of the children met ADOS and ADI-R criteria for autism prior to treatment, but no child met these criteria at follow-up. Similar positive results were found in relation to flexibility and educational placement. Studies examining the effectiveness of this intensive parent-based intervention are limited but indicate its potential value in addressing social skill deficits in children. Occupational therapists may find that using this approach in collaboration with parents may enhance their ability to support development of social skills in their young clients.

Alert Program: How Does Your Engine Run?

Children often experience stress in response to events that occur in their lives. For certain children, stress may be related to sensory responsiveness. Sensory over-responsiveness and under-responsiveness are common problems for many children with ASD, which can interfere in social participation when not well managed.^{2,12,22,76,160}

The Alert Program¹⁶⁷ is a systematic intervention designed to help children who have difficulty staying on task or who become upset because of certain types of sensory input. The aims of the program are to help children with the following:

**CASE STUDY 11-2 Stephanie**

Stephanie, an 11-year-old girl with ASD, has difficulty understanding slang and expressions that are not meant to be taken literally, a common problem in children with ASD. Wendell, a boy in her class, greeted her with “Hey, Baby!” and she became upset because she thought that he thought she was a baby. She told her occupational therapist about the incident and they made a comic strip conversation of the event. After

discussion with the therapist, she realized that the slang term “Baby” was actually meant to be a friendly and endearing expression. They rewrote the comic strip to show how she could handle the situation next time. See Figure 11-8 for this example of using comic strip conversations to improve social interactions.

FIGURE 11-8 Comic strip conversation.

Level of Stress Condition	Level Number	When I Feel That Way
Hurricane	10	Missing recess because I argued with the teacher
Tornado	9	
Lightning	8	
Hail	7	When another student said I was weird
Thunderstorm	6	
Very Windy	5	Finding out that I was the only kid in my class not invited to a birthday party of another kid in the class
Rainy	4	
Cloudy	3	Going to gym class
Hot and sunny	2	
Calm and breezy	1	Playing one of my favorite computer games

FIGURE 11-9 Labeling thermometer.

1	No Talking

FIGURE 11-10 Voice volume scale.

(1) To learn to recognize their arousal states within the environment as related to behavior, such as their sensitivity and reactions to sounds, touch, and movement in their surroundings; and (2) to expand their use of self-regulation strategies during participation in various school occupations. The Alert Program uses cognitive learning and sensory activities to help children become aware of, maintain, or change their levels of alertness to match the demands of a situation or task.¹⁶⁷ Results of one study of children with emotional disturbance¹⁵ showed some improvement, suggesting that the Alert Program was effective in helping improve children's abilities to self-regulate, change tasks, organize themselves, cope with sensory challenges, and focus on tasks in the classroom as perceived by their teachers. Significant improvements were seen in another group of children with FASD in executive function and interpersonal problem-solving skills.¹⁶³

For example, Aubrey, a 6-year-old with ASD, became stressed and overaroused when he went to school assemblies that were held in the gymnasium at his school. The high noise level and the proximity of all the children often caused him to feel overstimulated, resulting in disruptive behaviors. His occupational therapist worked with him using the Alert Program¹⁶⁷ to identify his arousal level and find activities that would help

CASE STUDY 11-3 Darrius

Darrius is an 8-year-old boy with FASD. He has been having difficulty with touching and being affectionate to others in inappropriate ways, such as kissing and hugging his classmates, and people he does not know very well, such as store clerks or friends of his parents whom he has just met. His teacher was very concerned about this, so she collaborated with the occupational therapist and his mother to come up with a five-point scale addressing this behavior (Figure 11-11). They explained to Darrius that each number on the scale referred to touching others, and each number had a special type of person whom it was okay to touch in that way. They also added a reward system to help encourage him to follow the scale, in which he would have 15 minutes of computer time at the end of the day if he could follow the scale or if he would quickly respond when reminded that he was not following the scale. After 2 weeks using the scale, Darrius was able to follow it without reminders and, after a month, no longer needed to use the scale.

5	Kiss	Family
4	Hug	Family and close friends when you say hello or goodbye after a long time
3	Patting back, Touching arm	Classmates, family, and close friends
2	Shake hands	Anyone when you first meet them or say hello or goodbye after a long time
1	No touching	Anyone

FIGURE 11-11 Who can I touch scale.

to reduce it. He began doing the calming activities before the large school assemblies. He also learned how to detect when his arousal level was getting high and he needed a calming strategy. Aubrey learned how to calm himself enough to be able to tolerate attending the assemblies for longer and longer periods. He was also able to give his teacher a sign that he was becoming overstimulated so that she could remove him from the assembly to a quiet area to calm himself.

Problem Solving

Coaching

Coaching is defined as an interactive process that promotes the care provider's ability to support a child's participation in everyday experiences and interactions across settings by developing new skills, refining existing abilities, and gaining a deeper understanding of their actions.¹³¹ It can also be used directly with children to empower them to organize and execute their responsibilities in an academic setting and in everyday life. Coaching uses questions that elicit reflective thinking and prompt students' ability to plan and carry out their goals. Coaches view the students as creative and resourceful; their role is to help students learn how to take action to accomplish goals that are important to them.¹⁶⁵ Coaching has been used successfully with college-age individuals with ADHD to create structure and execute change by identifying strategies that circumvent their deficits in executive functioning.¹⁵² In another study of coaching college students with ADHD, improvements were seen in motivation, time management, anxiety, test preparation, and self-efficacy.¹⁷³

For example, Jasmine, a 14-year-old with LD, was having difficulty keeping friendships. Jasmine discussed with her occupational therapist the problem of her most recent best friend, Amanda, becoming less responsive to her invitations to participate in social activities. The therapist asked her questions about what happened just before she saw the change in Amanda, and

Jasmine reported that she had become very upset and started screaming at Amanda and calling her names because Amanda was going with another friend to the mall when Jasmine invited her to go swimming at the public swimming pool. The therapist asked Jasmine how she might have felt if Amanda had responded the same way to her, and Jasmine stated that it would have made her angry. The therapist asked how she could better handle the situation that would not upset Amanda. Jasmine identified a plan to apologize to Amanda and, for the next time that Amanda has other plans, she will suggest another, later option rather than screaming at Amanda and calling her names.

SOCSSS

Another strategy addresses children's theory of mind limitations and social problem solving by assisting them in identifying problem situations, possible solutions, and possible consequences for each solution. It is known as SOCSSS (situation, options, consequences, choices, strategies, simulation).¹²⁹ This strategy sequentially organizes social and behavioral concerns for students with social interaction challenges.^{112,113} The procedure involves six steps; it is used after a difficult situation has occurred as a way of examining the options for the next time a similar situation comes up or, if possible, to interrupt and examine a current situation before the choice step is made.

1. **Situation:** The therapist and student identify a problem that has arisen. The problem is defined, and a goal is stated through discussion, writing, and drawing (e.g., "Tommy cuts in line in front of me at the drinking fountain. I don't want him to cut in front of me").
2. **Options:** The therapist and student brainstorm to identify possible solutions. The therapist does not evaluate the student's responses. Multiple solutions are encouraged.
3. **Consequences:** The therapist and student evaluate each of the student's responses by answering: "Will the solution get me what I want? Will I be able to do it?"

4. **Choices:** The student prioritizes the options and consequences and selects a solution. The solution selected is the one with the most advantageous consequences.
5. **Strategies:** The student originates a plan of action with guidance from the therapist.
6. **Simulation:** The strategy is practiced through role playing, writing it out, imagery, or talking with a peer.

This strategy can be simplified by offering a range of options for the child to choose from during each step of the process. Studies of the SOCCSS approach have revealed varying degrees of success when used to decrease tantrums, rage, and meltdowns related to misunderstanding social situations by two elementary age boys with Asperger syndrome.¹¹³ See [Case Study 11-4](#).

Description and Evidence for Specific Interventions in Social Skills Groups

Social skills groups have been used to improve social skills and participation in children. Studies have shown that social skills groups can be effective for improving peer relations,¹⁶⁸ improving theory of mind,¹¹⁹ improving social skills,^{91,125} improving greeting and play skills,¹⁷¹ improving knowledge of social skills,¹⁶¹ increasing empathy,⁷⁵ increasing social interaction,³⁷ and improving facial recognition.¹⁴⁵

Most of the studies examining the effectiveness of social skills groups have been small and methodologically weak¹⁶⁴; criticisms of these studies include inadequate measurement of

CASE STUDY 11-4 Sam

Sam is a 7-year-old with LD. He is not quite as tall as most of the other boys in his class. Sometimes Jeremy, a taller boy in his class, does things that are inconsiderate toward Sam, such as pushing in line in front of him. Sam's social skills group was talking about SOCCSS, and Sam told them of the incident with Jeremy butting in line in front of him at the drinking fountain. He said that he usually tried to hit

Jeremy and then either got hurt or got in trouble. The group helped him to think of options, consequences, and his choice ([Figure 11-12](#)). They role played the situation with him so that he could practice his response. The next time that Jeremy pushed in front of him, he tried out his choice, and it worked. Jeremy listened to him and let him have his turn first.

SOCCSS Situations, Options, Consequences, Choices, Strategies, Simulation		
Situation Who: Jeremy and Sam What: Jeremy butted in line for the drinking fountain in front of Sam When: After recess Why: Sam was watching another classmate when it was his turn		
Options	Consequences	Choice
Shove or punch Jeremy	I could get in trouble	
	Jeremy could hit back harder	
Tell Jeremy that it is my turn and if he doesn't listen, tell the teacher	Jeremy might listen or the teacher could tell him not to butt in line	X (Sam's choice)
Don't do anything	Jeremy will probably butt again	
Call Jeremy a bad name	Jeremy could hit me or call me a name	
	I could get in trouble	
Strategy The next time Jeremy butts in line, Sam will tell him that it is his turn, not Jeremy's. If Jeremy does not listen, Sam will tell the teacher.		
Simulation Sam will role play this situation with a friend or classmate until he has the confidence to carry it out with Jeremy.		

FIGURE 11-12 Example of SOCCSS—Jeremy and Sam.

FIGURE 11-13 Social skills group activities allow children opportunities to practice their new skills in a structured environment, with immediate feedback. (Photo by Cheryl Klohr.)

social skills and deficits, small and poorly characterized samples, minimal examination of the degree to which learned skills generalize, inadequate dosage, lack of intervention fidelity, and lack of client-centeredness in matching a strategy to the individual needs of a child.²¹ Occupational therapists often conduct social skills groups in collaboration with psychologists, social workers, speech language pathologists, and other professionals (Figure 11-13).

Process of Developing the Social Skills Group

Social skills groups can be developed to be included in a school-based program, outpatient clinic, or after-school program. School-based programs are usually more convenient for families and encourage friendships and continued support for the practice of social skills. The number of children who could potentially participate, availability of space and equipment, and willingness by the school administration to dedicate personnel and time to social skills programming are important considerations. It may be useful to conduct a focus group or discussion group with interested parents to determine the location, frequency, and schedule for potential participants.

When selecting children who could benefit from participating in the groups, the occupational therapist chooses participants who do not have aggressive behaviors that might be dangerous to others, have adequate language to interact with others, and have adequate motivation to interact with others. Children who do not fit these criteria can begin in individual sessions or dyads (with only one other child) until they meet the criteria for participation in a group. It is helpful to publicize the groups through parent communication networks, such as parent support groups, other autism service providers, and Internet parent discussion groups. Fees can be covered directly by families, insurance carriers, special autism funds in certain states, and grants. Funding may be available through the school district or Medicaid.

Social skills groups can be administered in school, after school, or during the summer. For optimal impact, the groups should be scheduled at least twice a week for 60 to 90 minutes over a 14-week session or daily for at least a 2-week session

BOX 11-2 Key Elements of Social Skills Groups

- Parents, participants, and therapists should be involved in establishing goals.
- Consistent and predictable format—a visual schedule should be posted at each session.
- Rules for behavior for the group should be determined by the group and then posted.
- Parents should receive intensive training and home programming.
- Clients and parents should be provided with immediate feedback and “homework.”

over the summer. Age groups can include children across a 3-year span, but longer age spans may be less effective because social issues change more significantly across a wider age span.

Key Characteristics

Certain important qualities are necessary for a successful social skills group. These include parent involvement, use of schedules, and use of activity themes (Box 11-2).

Parent Involvement

For maximum effectiveness, it is important that parents be very involved in the social skills group.²³ Parents should initially be oriented to the theoretical models, format of the sessions, and what they will be expected to do to support their child. Pretests can be completed using assessments that will be used to measure the effectiveness of the groups. Parents select the goals that they think are important to address by the social skills group. Each participant should also identify goals that he or she thinks are important. These goals are used to guide the therapist in finalizing a list of goals that are developmentally appropriate for the child. The parents are apprised of the activities and goals for each session. When the child returns to the next session, he or she can receive credit on the goal chart for attempts to address the goal at home or at school. Parents may document attempts. Some activity themes can culminate in a presentation that parents can observe, which is another way to include them in the groups.

Schedule

Because of the need for sameness and predictability in children with ASD¹²² and because they process visual information better than auditory information,¹²⁶ each session should provide similar structural components, which are posted on a daily visual schedule. The schedule may include a sensory modulation segment to promote optimal arousal levels, didactic social skills segment, social skills application activity, and snack (Figure 11-14). Topics to promote development of social skills include the areas of social deficit, which include such items as friendship skills, self-control, conversation skills, understanding the feelings of others, taking turns, and dealing with bullies. Activities are graded to meet each child’s needs and ensure success. The therapist tailors discussion topics to address individualized goals.

Social Group Themes and Activities

Activity themes add a playful aspect to the groups and can be helpful to guide the selection of activities. Themes can be identified ahead of time by the leaders or at the beginning of each month by the participants (for the longer groups). Depending on the age and gender mix of children in the group, themes might include grossology, let’s build it, aviation, creepy

bugs, the wild world, show time, chef school, transporters, make it grow, rock star, and shopping. See Table 11-4 for more details about what could be included for these themes.

The activity theme gives the participants good and enjoyable opportunities in which to practice their developing social skills. Attending a group that uses a child's special interest as a theme can be a strong motivator for participation (Figure 11-15).

Schedule of Activities	
15-20 minutes	Sensory modulation
20-30 minutes	Didactic social theme
20-30 minutes	Activity theme
15-20 minutes	Snack
15-20 minutes	Game
10-15 minutes	Review goals

FIGURE 11-14 Schedule of activities.

FIGURE 11-15 A shopping theme can give children an opportunity to role play social situations in the community. (Photo by Claudia Hilton.)

TABLE 11-4 Social Skills Group Themes

Theme	Topics That Might Be Covered
Grossology	Making goop, flubber, slime, silly putty, instant worms, or other sticky, gooey, gross materials (recipes can be found on the Internet). Making earthworms, pudding "cake" with chocolate cream-filled cookies (recipe can be found on the Internet) Identifying "body parts" by touch without being able to see them (spaghetti noodles = worms, dried apricot or pear = ear, candy corn = tooth, peeled grape = eyeball, cooked cauliflower = brains, extra dense jello = liver)
Let's build it Aviation	Select items that can be built; can start with individual projects and later construct a large group project This could include any aviation project, such as paper helicopters (patterns can be found on the Internet), parachutes made from plastic bags cut into squares and connected to small army men by strings from the corners, paper airplanes. The group can find a balcony or parking lot from which to drop them toward a target placed on the ground.
Creepy bugs	Activities that involve insects, such as making a collage of favorite insects cut from magazines, drawing insects, construction of insects, making no-bake cookies that look like insects, collecting insects
The wild world Showtime	This can include activities that involve animals, similar to the insect theme (above). This usually culminates in some type of show that can be presented to parents at the end of the theme segment and may involve acting out a short book or a singing or musical instrument presentation.
Chef school	This can involve any type of food preparation. Caution should be given to safety when using a stove or oven and to prepare items that will be ready by the end of the session. In addition, diet restrictions of the participants need to be considered, so using gluten-free flour or preparing items that do not include milk products, peanuts, or soy may be incorporated into the planning. Some creative and easy recipes are available on the Internet, such as candy sushi, Missouri mud, snack mix, fruit smoothies, pretzels, and tortilla snowflakes.
Transporters	Transportation theme that includes trucks, trains, or other favorite vehicles. It can involve drawing or constructing individual vehicles or making a group train or wall mural.
Make it grow	Any activity involving learning about or growing plants, such as growing sprouts, starting bean plants in pots, and planting plants in an outdoor space.
Rock star	Activities can include making easy percussion instruments, such as rain sticks, tambourines, drums, or chimes (patterns available on the Internet); identifying and making a collage of favorite musicians, performing a musical performance for parents at the end of the segment
Shopping	Activities revolve around various shopping experiences. Participants can make items to sell to each other, parents, and staff; set up a store to sell the items; or set up a simulated store to work on money exchange.

Summary

This chapter examines aspects of social skill impairment in children across several diagnostic categories. It examines theoretical bases of social impairment and theoretical models for intervention. It provides occupational therapists with several specific strategies and methods to use in intervention to address this important area of occupation in children. Evidence for various social participation interventions is included. It suggests that a combination of social, cognitive, behavioral, and sensory strategies can effectively increase social participation in children with mental health or behavioral disorders.

- Social participation problems are often seen in children who have ASD, FASD, ADHD, anxiety disorders, LDs, and mood disorders.
- Theories that explain social skill deficits in children include limited theory of mind, weak central coherence, delayed

acquisition of joint attention, and limitations in executive function.

- Occupational therapists play primary roles in working with children who have social impairment and limited social participation. Social skills interventions can be conducted in collaboration with psychologists, social workers, speech language pathologists, and other professionals.
- Social skills interventions can improve specific social behaviors, understanding of social rules, awareness of others, and executive function.
- Theories and approaches used to inform social skills interventions in this chapter include peer-mediated intervention, sensory integration, self-determination, social cognitive, and behaviorism.
- Many principles and strategies that occupational therapists can use to improve social skills in children are addressed in this chapter.
- Evidence for the interventions ranges from no specific evidence to strong evidence.

Social Participation for Youth Ages 12 to 21

Jessica Kramer • Kendra Liljenquist • Matthew E. Brock •
Zachary Rosetti • Brooke Howard • Melissa Demir • Erik W. Carter

KEY TERMS

Social participation	Environment
Transition to adulthood	ICF

GUIDING QUESTIONS

1. How is social participation of adolescents and young adults conceptualized?
2. How is social participation influenced by the environment?
3. How does social participation in adolescence affect future development and the capacity to perform adult responsibilities and roles?
4. How do occupational therapists evaluate social participation in youth and young adults?
5. Which intervention approaches and strategies improve social participation in youth and young adults?

What is Social Participation?

Social participation has broad and varied meanings; examples include connecting with friends electronically via text or virtual chat, volunteering in the community, interacting with co-workers, and completing a school assignment with friends. Occupational therapists may use the term *social participation* to describe all these interactions. Leaders in the fields of rehabilitation, sociology, psychology, and education have proposed different ways of understanding engagement in social contexts. Integrating these varying approaches can provide occupational therapists with a robust understanding of the various ways in which youth involvement in social life situations can enhance development and successful transition to adulthood.

Identity Development and Social Participation

Adolescence is an important time for the development of identity—that is, defining who one is, what to value, and which directions to pursue in life.⁴² Identity development was originally conceptualized as a series of linear stages. However,

research has suggested that identity development is a dynamic process that occurs throughout adolescence.⁸⁹ The development of an identity is important to youth as they transition to adulthood because youth may select career trajectories, social networks, and leisure choices that reflect their developing identity.

Social participation can facilitate the development of identity of all young people, including youth with disabilities. Qualitative work done by Hansen et al.⁵⁶ highlighted two important themes about the development of identity that relate to engagement in occupations: *trying new things* and *learning your limits*. Trying new things allows adolescents to discover how these new activities fit or do not fit into their developing identity. New activities may also require youth to use or develop a different set of skills. Thus, participation in activities offers young people a chance to explore their unique abilities and furthers the development of their identity. Occupational therapists can play an important role in the identity development of youth with disabilities by facilitating social participation through skill development and environmental and task modifications.

Social relationships also play an important role in identity development, especially in the development of a positive disability identity. The literature on youth transition to adulthood continually cites peer mentorship, support, and modeling as best practices for youth with disabilities.^{13,16,28,43} Youth with disabilities appreciate the opportunity to talk with others who face similar barriers in their daily lives and acquire new skills and insights when exposed to other youth who have resolved similar problems.^{60,65,102,124} Connecting with other people with disabilities can also help youth identify and appreciate valuable aspects of their disability, a key step to integrating a disability identity into a positive sense of self.⁴⁶ For example, a study of youth attending a disability-only summer camp found that camp participation facilitated personal and group identity formation.⁴⁹ Camp provided youth with the opportunity to spend time with other youth with disabilities, manage their time and schedules without assistance from their parents, and explore a range of new activities in a safe and accepting environment. After these experiences, they expressed a positive change in feelings about their disability, identity, and what might be possible in the future. Although inclusion with peers without disabilities and equal access is an important right that must be ensured for young people with disabilities, additional experiences within the disability community may play an essential role in the development of a positive disability identity.

Participation and International Classification of Functioning, Disability, and Health

The World Health Organization's International Classification of Functioning, Disability, and Health (ICF) has defined participation as "involvement in a life situation."¹³⁹ This broad definition provides an opportunity and a challenge for the field of rehabilitation. The general conceptualization of participation provides the profession with the opportunity to address areas of involvement that are determined most relevant and important to individuals in rehabilitation. However, the lack of a clear delineation between participation and other related concepts, such as the ICF concept of activity, has made it difficult for researchers and clinicians to measure and intervene at the level of participation.

Rehabilitation scholars have attempted to define participation better as it relates to social interactions with others. The American Occupational Therapy Association (AOTA) Practice Framework has defined social participation as "organized patterns of behavior that are characteristic and expected of an individual or a given position within a social system" that occur in the community, family, and with peers.⁴ Khetani and Coster have noted that the ICF terms *participation* and *social participation* have been used interchangeably in rehabilitation, and that "any life situation can be social."⁶¹ Whiteneck and Dijkers¹³⁸ suggested that participation requires role performance at the societal level, rather than activities that an individual may perform on his or her own. This chapter will structure the discussion of social participation around the following ICF concepts (Figure 12-1):

- *Interpersonal interactions and relationships.* This concept provides an understanding of social relationships and how they may be enacted across the major life areas and contexts discussed below.

FIGURE 12-1 Conceptualizing social participation based on the International Classification of Functioning, Disability, and Health (ICF).

- *Major life areas of education, work, and economic life.* For adolescents, these areas of occupation are often a primary focus of education and other interventions during their transition to adulthood. For our discussion of social participation, we will examine education and postsecondary training, as well as work and prevocational experiences.
- *Community, social, and civic life.* These are participation contexts outside the family in which social interactions are a key component of meaningful participation for adolescents transitioning to adulthood and developing more autonomy. This includes community life, religion, and citizenship, as well as recreation and leisure. For our discussion of social participation, recreation and leisure (a primary concern of occupational therapists) will be discussed separately from community life, religion, and citizenship.

Role of the Environment and Culture on Social Participation

Social participation, by its very definition, involves an interaction between a person and an individual or group of individuals. These interactions are further influenced by other structural and cultural expectations. Therefore, social engagement is not only an action that occurs between individuals, but also a result of specific environmental opportunities and constraints.⁶² For youth with disabilities, limited social participation is as related to environmental barriers as it is to impairments or limited social skills. Research with younger children with disabilities has suggested that after controlling for the effect of impairment on participation, differences in the levels of participation of children with disabilities are explained by the community in which they live.^{44,53} Although similar work has not yet been conducted with transition-age youth, these findings point to the potential impact of the environment on the participation of all youth with disabilities.

The field of positive youth development considers the various environmental and personal factors and experiences that can influence the successful development of youth into adulthood. In this field of study, the ongoing interactions, or transactions, between two or more people or groups are conceptualized as *social processes*.¹²³ These social processes occur in specific settings, such as classrooms, after-school programs, or community centers. Resources in these settings and the organization of those resources dictate how social processes occur in a specific setting and may determine a positive or negative social participation outcome.

One example of the impact of transactions on social participation can be found in the case study about Project TEAM (see later, [Case Study 12-4](#)). In this case study, when Emily sought information about a volunteer opportunity, the positive attitude and responsiveness of the staff person at the daycare center facilitated a positive social interaction. This social interaction helped Emily obtain the information she needed to become a volunteer. Emily built on this positive interaction and identified staff at the day-care center as a potential source of support to help her meet future job responsibilities. The outcomes may have been different for Emily if the day-care center had different resources available or chose to organize and use those resources in a different way—for example, if the staff person did not have enough time to answer questions because

of his or her job responsibilities or held a negative attitude about disability, or the organization made information available only on their website.

Another way to conceptualize the impact of the environment on participation comes from the field of disability studies.^{2,54,96} The social model of disability posits that disability is not the result of impairment but a consequence of inaccessible environments. Instead of viewing disability as a natural consequence of bodily differences (or impairments), the social model of disability suggests that disability is a result of cultural and social beliefs and expectations about individuals who are different.⁹⁵ Cultural and social assumptions about impairment that can lead to the segregation and isolation of youth with disabilities include the following:

- Individuals with different minds, such as those who experience positive psychiatric symptoms (e.g., hallucinations), are labeled as intellectually disabled or unsafe or dangerous without supervision and intervention.^{48,104}
- Bodily differences and the resulting functional differences, such as not being able to walk, are tragic or unbearable and lead to a poor quality of life.⁸¹
- Bodily or mental differences are a manifestation of spiritual differences or have occurred in retribution for spiritual transgressions.⁹³

The social model of disability challenges the origin of these types of assumptions. Examples of subcultures in which these assumptions do not exist demonstrate how individuals with disabilities can be fully included in society and are not seen as different or labeled as “disabled.” For example, at the beginning of the twentieth century, a small and isolated island off the coast of New England, Martha’s Vineyard, had a high proportion of deaf citizens.⁵¹ This was a result of a genetic trait found in many of the families who had settled there. Because so many individuals in this close-knit community were deaf, most individuals on the island were fluent in sign language, leading to a culture in which hearing and deaf individuals attended school, conducted business, and socialized together. This was a stark contrast to life off the island, where individuals who were deaf were treated with suspicion or isolated in special settings, such as institutions or training schools for the deaf. This story illustrates how social inclusion and participation can be facilitated or restricted by cultural structures and beliefs.

Environment and the International Classification of Functioning, Disability, and Health

Occupational therapists can use the ICF framework to identify key resources in the environment systematically.¹³⁹ Box 12-1 provides examples of how different environmental factors, as defined by the ICF, can influence social participation. Numerous studies illustrate the impact of these environmental factors on the social participation of youth and young adults with disabilities.^{5,72}

The impact of the physical environment on participation of youth with disabilities has been widely documented. Frequently mentioned barriers to participation include the physical layout of spaces, such as the presence of stairs and other structural features that limit mobility, thus affecting youth’s ability to participate in the full range of activities.^{17,98} In addition, lack of adequate space to provide individualized attention and

assistance to youth with disabilities can be a barrier to social participation and lead to misperceptions among peers. One young person explained, “A few teachers took me aside and went through things with me. But we had to work in the canteen, there was nowhere else. Classmates were astonished at me—spending time with a teacher! If they knew what [we] were talking about, they’d know I needed the extra help” (p. 164).¹¹¹

Further logistical issues, such as lack of transportation, often in school-related endeavors outside the typical school day, such as field trips, have also been shown to influence participation.^{38,84} Inadequate transportation is a major barrier to social and community participation¹²⁷; 34% of persons with disabilities report a lack of appropriate transportation options compared with 16% of those without disabilities.⁵⁷

Social aspects of the environment also affect how youth with disabilities experience participation in a range of settings. Issues such as close proximity of adults and negative attitudes of others can reduce engagement with peers.^{37,25,127} Attitudes, especially misunderstandings regarding the abilities and needs of young people with disabilities, can also be detrimental to successful social participation.⁷² For example, when adults overestimate the needs of an individual youth with a disability, they may restrict choices and opportunities for participation. For example, a youth shared how a substitute teacher singled her out as “the only person who could not participate in an activity that she had previously played” (p. 65).¹⁵ However, underestimating the needs of youth with disabilities can be equally dangerous. In another study, a young woman explained how a gym teacher believed that she was not working hard enough. She explained, “He had me walking, jogging, running and I said ‘Sir, I can’t do this, I’m going to be sick.’ I was in such a state, I was blue.... But they still made me do it” (p. 274).⁷⁹

Policies have also been shown, positively and negatively, to affect the participation of youth with disabilities in school, extracurricular activities, and community activities. The lack of needed services and services that are not tailored to the youth’s needs and interests are reported as barriers to participation.⁷² Service and support systems that provide opportunities for young people to make choices and that involve youth in organizational decision making may support higher levels of social participation.¹²⁷ For example, in one study, a youth explained how not integrating his input in decision making led to poor outcomes at school: “He [the teacher] promised to ask and take into consideration what I could and could not do, but actually he did not accept any changes and nothing was done” (p. 159).⁶

Finally, federal and international policies may help create structures that facilitate the inclusion and participation of youth with disabilities. The United Nations Convention on the Rights of the Child stated that all children, including children with disabilities, are entitled to be involved in matters and decisions concerning them.^{9,28,45,75,115,121}

These policies can influence federal and state governments, international nonprofit organizations, and other groups to develop practices that systematically include youth with disabilities in society. Legislation such as the Individuals with Disabilities Education Act (IDEA; see Chapter 23) guarantees youth with disabilities the right to be educated next to their general education peers in the least restrictive environment.

BOX 12-1 International Classification of Functioning, Disability, and Health: Environmental Factors and Social Participation**Products and Technology**

These are natural or synthetic products or systems of products, equipment, and technology in an individual's immediate environment that are gathered, created, produced, or manufactured.

- Augmentative communication devices can be used to share ideas with other students in a class activity.
- Smartphone apps can be used to help individuals remember the steps of a game or organize their social time.

Natural and Human-Made Changes to the Environment

These are animate and inanimate elements of the natural or physical environment and components of that environment that have been modified by people.

- Weather, such as extreme temperatures, may affect the ability of individuals with chronic medical conditions to move about their community.
- Universal design, such as curb cuts and well-lit signage, can provide access for a broad range of individuals in a community—for example, parents who push strollers, persons who use a wheelchair, or an older adult who may have an unsteady gait.

Support and Relationships

These are the amount of physical or emotional support, nurturing, protection, assistance, and relationships provided by people or animals to other persons in their homes, places of work, schools, at play, or in other aspects of their daily activities.

- A service dog may help a teenager with autism spectrum disorder (ASD) feel more comfortable in a new social setting, such as a community dance.
- An encouraging teacher assists a student with a disability with his college application, providing additional post-secondary opportunities for the student.

Attitudes

These are observable consequences of customs, practices, ideologies, values, norms, factual beliefs, and religious beliefs.

- A coach may think that it is not safe for a youth with a disability to play sports. The coach requires a teenager to obtain extensive medical documentation before allowing him or her to join the team.
- An occupational therapist works under the assumption that skills are best developed during engagement in meaningful occupations, rather than in contrived situations. Instead of pretending to plan a route using the bus, the occupational therapist rides the bus with a young adult to practice going to a new job site.

Services, Systems, and Policies

These include the following: services that provide benefits; structured programs and operations in various sectors of society designed to meet the needs of individuals; systems that exert administrative control and organizational mechanisms and are established by governments at the local, regional, national, and international levels or by other recognized authorities; and policies constituted by rules, regulations, conventions, and standards established by governments at the local, regional, national, and international levels or by other recognized authorities.

- A local center for independent living provides access to personal care attendants. Having assistance to get ready in the morning allows a young adult to move out of his or her parents' house into an apartment with a roommate.
- The Americans with Disabilities Act ensures that persons with disabilities can access businesses in their community such as movie theaters, recreational centers and pools, and restaurants.

Although this policy does not guarantee social participation, it can encourage practices that may lead to increased social participation. This includes regulations such as inclusion in the standard curriculum next to students without disabilities. Similarly, in 2013, the U.S. Department of Education called for educational systems to provide equal opportunities for youth with disabilities to participate in sports. Participating in school sports opens opportunities for youth with disabilities to interact with other students and adults and may also facilitate skills associated with positive development into adulthood (see later, [Research Note 12-2](#)).

Another environmental and contextual factor that may have a significant influence on the social participation of youth with disabilities is socioeconomic status. Shattuck and colleagues¹¹⁰ found that youth with autism spectrum disorders (ASDs), ages 13 to 17 years, with family incomes higher than \$75,000, were more likely to be involved in extracurricular activities, have friends, and be invited to activities compared with youth with ASDs with family incomes lower than \$50,000. Youths with ASD ages 18 to 21 years were four times more likely to be employed or enrolled in postsecondary education if their families were above the poverty level during early adolescence (ages 13-16 years).⁸⁰ For early adolescents with cerebral palsy, lower

levels of parent education (which may be associated with lower income) were associated with lower scores of social function.¹²⁹

Social Participation in Adolescence and Young Adulthood**Interpersonal Relationships**

The ICF defines interpersonal interactions as carrying out the actions and tasks required for basic and complex interactions with people (from strangers to family members) in a contextually and socially appropriate manner. Thus, these interpersonal interactions are the foundation of social participation. The ICF includes a range of *relationships* in which a youth may engage on a daily basis, including friendships, relating to persons in authority such as teachers and employers, family relationships such as siblings and parents, and brief interactions with strangers within the community. Thus, while completing an individual task such as shopping, the opportunity for social participation may emerge if a young person is shopping with a friend, bumps into a former sports coach, or seeks assistance from a store clerk.

Adolescent relationships are marked by increasing autonomy.¹⁴¹ Youth social networks expand beyond the family and friendships arranged by parents. Adolescents begin to initiate friendships of their own choosing and begin to form intimate relationships. They also begin to form relationships with adults outside the family and increasingly see teachers, coaches, or other community members as mentors. Thus, transition is a time when adolescents begin to build a larger social network beyond the family.

Friendships and Youth with Disabilities

Many students with disabilities, especially those with intellectual and developmental disabilities, experience far fewer social interactions and social invitations than their peers without disabilities.^{114,126,130} A study of youth ages 5 to 17 years found that those without disabilities participated in significantly more social activities with peers compared with those with ASD and intellectual disabilities. Social activities included playing games, sleepovers, and going out to places in the community.¹¹⁷ Youth with different disabilities also experience a varying amount of social contact and social participation experiences. Of adolescents ages 13 to 17 years with ASD, 43% reported never seeing friends, compared with 15.7% of youth with intellectual disabilities. A common method of communication among teenagers is the phone,⁵⁰ yet 47.7% of youth with intellectual

disabilities report getting calls from friends once a week, but only 9.6% of youth with ASD report getting calls from friends more than once a week.¹¹⁰

High school students with disabilities receiving special education services in public schools often remain socially isolated because of the possibility of disability-related stigma⁴⁷ and other barriers to friendship opportunities, such as the presence of adult paraprofessionals and limited inclusion in nonacademic school activities.⁷² Central to the concept of friendship for students with disabilities is the distinction that when students without disabilities receive some form of incentive (e.g., money, class credit, volunteer experience) to spend time with a classmate labeled with a developmental disability, it is not friendship.^{82,85,109} However, often programs that foster relationships through matching or mentoring are the only opportunities for youth with and without disabilities to interact. Such programs may be an avenue for those without disabilities to begin to understand better that youth with disabilities have interests, feelings, and experiences similar to those of all teenagers.^{20,22} Sometimes these programs can lead to meaningful and long-lasting friendships, as in the story of Joshua and Stephanie (Case Study 12-1).

The element of choice is the essential component of friendship between all youth, with and without disabilities.^{107,120} Meaningful friendships between high school students with

CASE STUDY 12-1 The Friendship of Stephanie and Joshua: Defining Friendship on Their Own Terms

Stephanie and Joshua were sophomores at East High School, a suburban public high school in the northeastern United States with an approximate population of 1100 students. Stephanie is an outgoing young woman with an easygoing nature who does not have a disability. Joshua is an outgoing young man with a playful nature who has Menkes syndrome. He is very expressive with his facial features and watches everything going on around him, constantly looking to interact with people who are close by. He uses a wheelchair, does not speak words, and needs support with most daily tasks because his one consistent movement is to reach out with his left hand. The two have been friends since they met as reading partners in an inclusive fifth grade classroom. From then, Stephanie followed the general education curriculum in classes with her peers while Joshua received special education services in a separate, self-contained class.

One day, Stephanie knelt to the right of Joshua's wheelchair and he reached across his body with his left hand toward her head. He flashed a wry grin, looking as if he knew exactly what he was doing when he tugged at her hair. She said, "Hey! Josh!" She pulled her hair out of his hand and stood back up. He laughed and she shook her head with a friendly and feigned look of exasperation. She smiled at him, and he straightened up with excitement in his wheelchair. They held hands for a moment before leaving.

Joshua displayed intentionality using one of the few movements that he can control to interact playfully with Stephanie. He demonstrated a type of slapstick humor that represents a complex form of nonspoken communication and helped form their connection. Whenever either one of them entered a

room, they immediately scanned it to find the other and share a smile. They consistently expressed enjoyment to be together.

However, Stephanie struggled to describe her friendship with Joshua in any way other than with the immediate connection she felt with him:

We just kind of clicked and I felt comfortable with him from the start. Being with him is a lot of fun. He's always smiling and we just really get along. I can't imagine not seeing him.... We just click and it doesn't matter what either of us can do. We just have a close relationship. It shouldn't be compared to others. It's just our relationship.

Later, in an attempt to define friendship generally, she returned to the metaphor of clicking:

Oh, wow. Just having a bond. You can't explain it. You can't explain why you click, but you just do. You just mesh together with someone.

Joshua does not have a way to communicate by speaking words or selecting or typing words and letters. Stephanie stated that she knows what Joshua likes from spending so much time together and reading his facial expressions and reactions:

I know Joshua and I are such good friends because of all the time we spend together. Both of us know a lot about the other. Joshua is really good at sensing what kind of mood I'm in. I know he enjoys seeing me from his expression when I get there, happy, and when I leave, sad. I'd say for any friendship to become a great one you need to spend a lot of time with the friend. I'd say that any good friendship evolves from spending as much time together as possible.

and without developmental disabilities are chosen individually, occur outside friendship programs, and are based on shared interests.^{3,11,14,30,35,82,100,107,116,113,118,120}

These relationships are defined by the value of human reciprocity.⁶⁴ In a self-report study, almost all adolescents ages 12 to 18 years with ASD (96%) reported having at least one friend, whereas 86% of their parents reported that the same youth had at least one friend.⁷⁴ When comparing the names of friends listed by adolescents themselves and their parents, adolescents and parents agreed 60% on the adolescent's best friend; however, 21% of the adolescents and parents listed completely different names of friends.⁷⁴ These findings may indicate that youth may define or understand friendship in a way different from adults. For example, one study of friendships between high school students with and without disabilities found that young people did not want friendships to be defined by outside expectations (see [Case Study 12-1](#)).

Education and Postsecondary Training

The societal role of student is commonly associated with the time period of adolescence. Our modern conceptualization of education includes a formalized setting in which adults with expertise provide youth with the knowledge and skills needed to be successful in society.⁸⁶ Secondary school, vocational training, and higher education are formal education contexts named in the ICF. These educational contexts require youth to engage with others to achieve learning outcomes.

Research on children's participation in school-related settings often varies, making it difficult to draw decisive conclusions in regard to the participation patterns of children with disabilities in school. A national survey of teachers ($N = 1180$)¹¹² found that 50% to 60% of students with disabilities were rated as "fully participating" in learning-related activities such as science labs, library use, or art classes, and 69% fully participated in field trips. How do we know if this reported rate of academic participation is problematic or lower than in students without disabilities?

Using the Participation and Environment Measure—Children and Youth, Coster et al.³⁴ reported on the differences in participation patterns for youth with and without disabilities living in the United States and Canada ([Research Note 12-1](#)). Youth with disabilities were less likely to get together with peers outside class and less likely to participate in school-sponsored team activities, clubs, or organizations ([Figure 12-5](#)). In addition, in the school context, youth with and without disabilities reported differences in the environmental barriers encountered and environmental supports available to them. Overall, students with disabilities are more likely to encounter features in the environment that make it difficult to engage in school activities ([Figure 12-6](#)). These barriers do not appear to be ameliorated by other resources; up to 20% of parents have reported that the school resources are inadequate ([Figure 12-7](#)).

Overall, this study paints a picture of school participation disparities for youth with disabilities who are ages 12 to 17 years and highlights the need for supports and services that support optimal social participation and inclusion at school. Such participation disparities could explain why some research finds that youth with disabilities in the United States have a higher dropout or incompletion rate (17%) than students without disabilities (11%).⁵⁷

RESEARCH NOTE 12-1

Community Participation of Children and Youth with and without Disabilities

Using the Participation and Environment Measure—Children and Youth, Bedell and colleagues explored the community participation patterns of children and youth with disabilities compared with their typically developing peers.¹² The study included over 500 children and youth ages 5 to 17 years from the United States and Canada. Half of the sample included youth with disabilities; disability categories ranged from mobility limitations to intellectual and development disabilities. Parents used the PEM-CY to report frequency of participation in a range of activities in the community. The scale ranged from never (0) to daily (7). Parents also reported on the absence or presence of environmental barriers, as well as the adequacy of resources.

The study found that young people identified as having a disability participated in community activities at significantly decreased rates when compared with youth without disabilities ([Figure 12-2](#)). In addition, environmental supports and barriers were shown to vary drastically between youth with and without disabilities. Youth with disabilities experience a higher rate of barriers in the community environment ([Figure 12-3](#)). Furthermore, parents of youth with disabilities reported inadequate resources to address these barriers. At least 50% or more parents reported that public transportation, programs and services, equipment and supplies, and money were not adequate to support consistent community participation ([Figure 12-4](#)).

FIGURE 12-2 Mean frequency of participation in Community Participation Involvement of Youth.

Work and Prevocational Experiences

Acquiring and keeping a part-time, full-time, or volunteer job is an important societal role. Many first employment experiences occur during adolescence in informal positions such as

FIGURE 12-3 Percentage of parents indicating that a feature of the environment makes it harder for their child with a disability to be involved in community activities.

FIGURE 12-4 Percentage of parents indicating that an environmental resource is inadequate to support community participation.

babysitting or landscaping or part-time work in community stores. These experiences provide youth with the opportunity to develop the skills they need to be successful employees after transition to adulthood. Employment also provides youth with an identity and is a mechanism to increase their autonomy from their parents and families.¹⁴¹ Paid employment also provides them with the opportunity to engage as an economic participant in society, which includes purchasing goods, owning a checking account, and increasing economic self-sufficiency by saving and acquiring resources such as a car.

For adolescents and young adults with disabilities, employment experiences during their transition years may not lead to long-term employment. Recent national surveys have shown that only 21% of working-age adults with disabilities in the United States (ages 18-64 years) are employed, compared with 59% of working-age adults without disabilities.⁵⁷ A myriad of

FIGURE 12-5 Mean frequency of participation involvement of school participation of youth with and without disabilities, ages 12-17 years.

FIGURE 12-6 Percentage of parents of youth ages 12-17 years indicating that a feature of the school environment makes it harder to participate in an activity.

factors affect the employment of persons with disabilities, including lack of adequate vocational training, discrimination from others, and provision of essential medical benefits that are dependent on income level.⁵⁷ A recent study found that for youth with significant disabilities, such as ASD and intellectual disabilities, one predictor of employment in early adulthood after controlling for disability severity was summer vocational experiences during high school and parent expectations of future employment during high school.⁴¹ Occupational therapists can play an important role in helping adolescents and young adults with disabilities identify, secure, and participate in employment. The Project TEAM case study gives an example of one manualized intervention that supported the career goals of Emily, a young lady with an intellectual disability.

FIGURE 12-7 Percentage of parents of youth ages 12-17 years indicating that an environmental resource was inadequate to support school participation.

Community Life, Religion, and Citizenship

Community organizations such as charities, clubs, and professional organizations provide youth with opportunities to engage in contexts outside their families and schools. Involvement in cultural organizations may also contribute to an adolescent's identity development. Although youth may belong to the same religious community as their family, adolescence may be a time in which young people engage in more independent exploration of their spiritual beliefs, with a deepening or withdrawal from the family's selected spiritual community. They may also become more involved in local civic life as they become increasingly aware of problems in their communities and as they approach voting age. They may become involved in advocating for local or national legislation and policies that reflect their expanding belief systems. A national survey of adults in the United States found that persons with and without disabilities are equally likely to vote in national elections.⁵⁷ For an example of the positive impact of group political advocacy on the social participation of young adults with disabilities, see [Box 12-2](#).

BOX 12-2 Group Political Disability Advocacy in Young Adulthood *Desiree Forte, MS.Ed., and Ryan Levita, Disability Advocate*

Act Today, Influence Tomorrow (ATIT)* is a youth advocacy group formed to give youth with disabilities an outlet to help promote change and bring attention to issues surrounding disability rights. The group comes together one Saturday a month to focus on issues chosen by the youth, such as state graduation requirements, community issues, disability history, and disability awareness. For many of the young people, this is their first time being fully exposed to the disability community and a way to be out independently. This group also gives them a chance to gain the tools they need to help improve their quality of life by spending one Saturday a month not feeling different or isolated. Disabled youth[†] who do not have access to a group like this can become uncomfortable and lack the proper etiquette of being around other people with disabilities. This can lead to having poor self-esteem and being uncomfortable about their own situations. By being part of a group such as this, youth have been able to learn how to work with others and deal with some of the issues they face surrounding disability. We are two young adults, Ryan and Desi, who benefited tremendously from being a part of this group in our late teens and early 20s, and we collaborated to write this article.

ATIT was originally created in collaboration between multiple disability agencies (Boston Center for Independent Living and Easter Seals Massachusetts).^{*} This collaboration allowed us to network and connect with other youth programs, giving us the avenues to expand personally and as a group. For example, Ryan later gained employment from a program he learned about by being part of ATIT. The mentor and supporters with and without disabilities who also attended the meetings provided additional networking opportunities. For example, a supporter from the group provided Desi with work experience, helping greatly improve her skills and resume. Both of us gained a wealth of knowledge about how advocacy and working with others can help increase disability awareness and promote positive change.

In 2009, the group decided that a major issue in Massachusetts was lack of a month recognizing disability. The group was also concerned about the lack of disability history and awareness being taught in public schools. The group felt strongly that by teaching students about disability, it would lower the negative stigma and decrease bullying. With the help of the group's mentors, a bill was drafted to establish the month of October as Disability History and Awareness Month in Massachusetts. As a group, everyone worked to promote the bill through word of mouth and social media to build support for the cause. When it came time for the group's voice to be heard at the State House, members of the group testified before the Senate Oversight Committee. The group also held a rally at the State House to make one final push. In less than 1 year of filing, the bill was passed. This means that every year, the governor issues a proclamation declaring October Disability History and Awareness Month in Massachusetts. For everyone, individually and as a group, this proclamation was a huge accomplishment.

Creating and passing a bill was an eye-opening and educational experience for all involved. By working as a group, members of ATIT learned the importance of advocating for what they believe in, along with the effort it takes to have our voices heard. Everyone also learned more about the process of government and that government officials were not as hard to face as initially thought. Although this process became overwhelming at times, the group learned that by working together, the process was more enjoyable and that as a group our voice becomes much louder. The group continues to work today to help spread awareness about Disability History Month and is trying to find a way to mandate that disability history and awareness be taught in public schools and universities. As time goes on, the group dynamics are constantly changing as members become older and new ones join. Still, the positive effects of being part of a group such as this will never change, and youth will continue to learn and grow by working with great peers and mentors.

*ATIT is now the Massachusetts Easter Seals Youth Leadership Network.

[†]Person first language, such as youth with disabilities, is a respectful way to write about people with disabilities. However, some members of the disability community choose to use the term *disabled* to describe a person to highlight the centrality of disability to their identity. This reflects a positive and empowered disability identity.

The benefits to participating in community service are clear; for example, youth who participate in volunteer service are more likely to have higher grades and graduate from college.^{36,108} Providing service learning opportunities in middle school and high school also appears to be associated with reduced disciplinary referrals.¹⁰¹ Providing youth with disabilities with the opportunities to engage in community service may be one way to increase their social networks and support successful transition to adulthood. However, they may not be as involved in community, civic, and religious organizations as those without disabilities. Only one in six adults with disabilities has participated in a group or organized activity that advocates for the

rights of people with disabilities, and those with at least some college education are more likely to participate in advocacy.⁵⁷ Youth with disabilities also report low levels of civic engagement; only 35% of youth with autism and 33% of youth with intellectual disabilities ages 13 to 17 years completed volunteer or community service.¹¹⁰ Innovative programs such as EPIC Service Warriors (Case Study 12-2) can provide unique opportunities for youth with disabilities to build social networks and serve their community.

Persons with and without disabilities also differ in religious participation; 50% of adults with disabilities attend religious services regularly compared with 57% of adults without

CASE STUDY 12-2 EPIC Service Warriors: “Discover Greatness Through Service”

EPIC Service Warriors is a community service and education program for youth with disabilities between the ages of 16 and 23 (Figure 12-8). By creating the change they want to see in the world, the Service Warriors learn more about local communities and develop practical skills that will help them develop as leaders and pursue future goals. This program also flips the switch on assumptions of many community members by changing the position of power; instead of being served, youth with disabilities serve others.

The EPIC Service Warriors Program runs from April to March. During the year, a team of Service Warriors participates in an Opening Day and Orientation in April, completes a minimum of 11 community service and skill-building projects in the greater Boston Area, and attends a graduation celebration at the end of its service year. Graduates of the program have the opportunity to become Service Leaders for future teams of Service Warriors. The Service Warriors are also supported by a staff of persons with and without disabilities.

Each month, the Service Warriors engage in a day of service such as a clean-up of a local park or school, making food at homeless shelters and food kitchens, and wrapping toys for a toy drive. Often, the Service Warriors partner with other service and community organizations for the day of service. Partnering not only increases manpower for the service day, but also increases the other organizations’ awareness of the capacity of youth with disabilities and demonstrates how service organizations can become more inclusive (Figure 12-9).

Each service day begins with a team-building activity, such as sharing something “epic” that each warrior has accomplished since the previous service day. The team then begins completing the service task. Although the EPIC Executive Director, Jeff Lafata, ensures that each site is physically accessible so all members can “get in the door,” he does not provide

any preliminary training or task modification. Instead, the philosophy “if you need us, tell us” guides the day. Together, the Service Warriors figure out how to accomplish their service task. At the end of the service day, the group engages in a critical discussion about the assumptions that others may have toward specific areas of the community or members of the community. Questions such as “What did you expect?” and “What did you see?” help young people reflect. For example, after a park clean-up service day in a neighborhood with a reputation for violence and poverty, the group reflected that many members of the community were spending time at the park, and the neighborhood was vibrant and active.

The stories of two recent graduates of the EPIC Service Warriors program, Lloyd and Pat, illustrate how engagement in community service builds skills, increases self-determination, and enhances social participation.

CASE STUDY 12-2 EPIC Service Warriors: “Discover Greatness Through Service”—cont’d

When Lloyd began Service Warriors, he was 20 and experiencing “huge struggle(s).” He had been homeless and received “personal” help through the state Department of Developmental Services (DDS). After securing an emergency placement at a short-term residential facility, Lloyd still had to deal with drama and difficulty with schoolwork and paperwork related to his learning disability. Through a teacher, and after completing a disability awareness training, Lloyd found out about EPIC Service Warriors and signed up because he wanted to “find something to do.”
