Lloyd’s favorite service project was helping at a community farm that grew food for local meal programs and food pantries. During this project, Lloyd pulled weeds and dead plants, removed vegetables that had been destroyed by animals, and prepared an area for future planting. Lloyd explains, “They don’t have time to do certain things” because the farm is nonprofit and relies on community volunteers. The EPIC Service Warriors also learned about the cost of food and the resources needed to ship food to people. This is important because “people need food—we have families and group settings” who all need food. Lloyd also tasted his first fresh carrot that day, right out the ground. Working at the community farm helped Lloyd “reflect on what I do” and remember how much he enjoyed working outside. He had a summer job working for the city’s housing authority in landscaping and indoor remodeling. He found employment as a bus monitor, supervising a young boy during the long trip from his town to a specialized program several cities away. However, his experiences on the farm led Lloyd to seek assistance from EPIC staff and DDS caseworkers to seek a new job. Lloyd was offered a position in the Department of Public Works in the city where he now lived. Lloyd even met the mayor, who visited the city workers on the first day of training to thank them for their service to the community. Lloyd directly connected his experience with Service Warriors with this new job: “[It made me] realize that values of the community are very important. Being around with people and interacting—making sure our community is clean and safe and making it a better place so everyone can live and be happy. I want to see people be happy about their community, how it’s clean. My new job has that same value—it’s bunched up into one.”

Before coming to Service Warriors, Pat had been in other groups and activities. He was in 11th grade and working on passing standardized tests in English, math, and science required for a high school diploma. Pat shared: “I am one of those types of people that doesn’t pick something myself and look around. My mom picks it out and then I try it to see if I like it.” He had tried track, basketball, and music group. He also worked in the school store and had janitorial experience working with his uncle. He also was attending an after-school club, “a hangout, chill out club. But it wasn’t much, mostly set for kids with disabilities. I felt I didn’t have a place.”

Service Warriors was different. Pat explained, “We get a different task every time—it’s full of variety. And plus it’s never boring.... Plus a lot of the Service Warriors are supportive and sociable and they have a lot going for them, like

I have. It’s one laugh after another.” Pat enjoyed giving back to the community on issues that were important to him, like people who are homeless or can’t afford food. He enjoyed the day of service at a local agency providing services, supports, and housing to homeless individuals. They made salads and also packed up sandwiches in bags for the visitors. He also enjoyed painting a mural of a school motto during another school clean-up day. Pat described how this service activity was aligned with one of his talents: “I am an art freak. I find painting fascinating and I like to try my hand at it. So when I am given the privilege, it’s the most exciting thing that could happen art-wise. I am fond of painting inside the lines.”

Pat described how he accomplished all the different service activities throughout the year. “Sometimes when I am new to a position, I kind of do it with other group members to see how they do it, and see if we can help each other. Then when I get the hang of it, I do it by myself. I got help by asking, they demonstrated, and then I handled it pretty decently and independently.” However, Pat noted that some of the activities were difficult and didn’t always go well, such as when he tried to make a fleece blanket. The blanket took all day to make and required help from the Service Warriors, but by working as a team they were able to finish the blanket.

Programs like Service Warriors can expand the social networks of teenagers and young adults with disabilities. Lloyd explained how the group increased their bonds over time: “Around the middle of the year we started to interact with each other. By the time we hit toward the end of the year I was emotional. We made huge connections.... I am still in touch with some of them, and now that I am a Service Leader, I am with the new team.” Pat described how working with others toward common goals can help individuals achieve their personal goals. Pat shared that “being in EPIC extends back to one of my goals since I was younger—to be great to myself, to be great in this world. I was born to be great and I wanted to do something worthwhile for my family to make them proud. In EPIC, every one of us is supportive. I expected [EPIC staff] to support us, but it never ceases to amaze me.... we were all supporting each other.” See [Figure 12-10](#).

CASE STUDY 12-2 EPIC Service Warriors: “Discover Greatness Through Service”—cont’d

Programs that take a positive approach to disability and provide youth with the opportunity to challenge themselves in a supportive environment can *change how youth with disabilities think about themselves* and their abilities. Lloyd shared the following:

Being in Service Warriors helped me build up confidence and self-advocating for yourself, having strength in you. I need to overcome the situation.... We are living in a situation where it's very tough and there always need to be some resources.... Without us, other groups may not be able to provide help to other people.... You are setting a good example for a community. You are showing young people that you can do it, that you can tell them, "Hey listen, I did this. I want you to take this opportunity and show me." I want to guide them along and show them the steps. You have to accept that you have a disability and it's a natural thing ... back then when I was younger I didn't realize ... I always wanted to be better.... Basically, at the end, you have to share what your talents are.

Lloyd's statement also demonstrates how changes in his self-perception led him to reach out to other youth, further

expanding his own social networks as well as the social networks of others.

Pat shared a similar feeling about realizing his capacity through the support of the group:

You kind of use your talents that you never knew before, but then you can unleash. For example, when we were doing a school clean-up around a ball field, there was so much to pick up. I picked up a whole lot more than I could have forced myself to if I was doing it on a regular basis and not with EPIC. But with EPIC you can make it happen in a massive way.

Like Lloyd, Pat's personal experiences with EPIC led to a desire to reach out to others. He is a Service Leader for the next team of Service Warriors and tried to introduce the idea of doing community service to his after-school club: “At one point I was motivated [and] I asked other members if they considered doing so and they said no. But it's different in EPIC.... One purpose is not just making a difference, but to have each of our lives be great, each of our lives epic.”

disabilities.⁵⁷ Only about 27% of youth with autism or intellectual disability reported that they belonged to a religious youth group,¹¹⁰ but belonging to a community of faith and incorporating those values into everyday life is important for persons with disabilities.¹⁹ One study about faith participation was conducted with over 400 families that included U.S. youth and young adults with disabilities ages 0 to 30 years. Families reported the following affected the inclusion and participation of families with disabilities in congregations: (1) knowledge of disability and how best to support people with disabilities, (2) practices and supports available in the congregation, (3) attitudes and religious beliefs about disability, and (4) characteristics of the congregation, such as accessibility and size.⁶² Engagement in religious communities is not only important for the spiritual well-being and developing identity of young people with disabilities, but can also expand their social networks. For example, families reported that over 60% of youth with disabilities engage in congregational activities with same-age peers. Occupational therapists can provide population-based services by identifying physical and social religious environments that are more likely to facilitate the inclusion and social participation of youth with disabilities and their families.

Recreation and Leisure

As young people better identify their interests and hobbies, they devote more time to self-selected recreational and leisure activities that support their growing skills and identity.³² The ICF defines recreation and leisure as any form of play, recreation, or leisure activity that is informal or organized. “Hanging out” with friends at a local coffee shop, joining a community sports league, or playing in a band are all ways in which a young person engages in social participation. Often, these recreational activities are supported by youth's increasing economic independence and the money earned in part-time or informal employment.

Research suggests that there may be disparities in the social participation of youth with and without disabilities in recreation and leisure activities. In one study that included youth with autism and intellectual disabilities, 16% to 23% belonged to a sports team and 7% to 10% belonged to a performing group.¹¹⁰ [Research Note 12-1](#) summarizes the findings of a study comparing the participation of youth with and without disabilities in community activities, which included recreational and leisure activities and unstructured social interactions. Limited involvement in leisure and recreational activities can have a detrimental impact on the future development of young people with disabilities. Research with high school youth has shown that involvement in recreational and leisure activities provides young people with the opportunity to develop social skills, such as negotiation and compromise and emotional regulation ([Research Note 12-2](#)). Youth with disabilities may not experience these benefits if they do not participate in recreational and leisure activities.

Changes in Social Participation Over Time

Patterns of changes of social participation over time are less understood for young people with disabilities transitioning to adulthood. Some studies may provide insight about how social participation can change as youth transition to adulthood. For those with significant physical disabilities, such as cerebral palsy, spina bifida, and acquired brain injury, youth in early adolescence ages 12 to 14 years were found to participate significantly less in recreational activities than younger children with similar disabilities.⁷⁸ A recent cross-sectional study found that elementary and middle school children with disabilities have significantly greater odds of participating in organized activities in comparison to preschool or high school youth with disabilities.⁹¹ These studies could imply a pattern in which older youth with disabilities have fewer opportunities, supports, or less time or desire to participate in organized activities.

RESEARCH NOTE 12-2

Differing Profiles of Developmental Experiences across Types of Organized Youth Activities

Larson and colleagues⁷⁶ asked youth to reflect on the various skills or developmental opportunities that resulted from participation in different organized activities. The youth self-reported using the Youth Experiences Survey (YES) 2.0, which includes items that ask about specific skills and opportunities associated with positive development into adulthood, such as developing positive relationships, initiative, and exploring one's identity. Eleventh-grade students ($N = 2280$) from 19 high schools in Illinois participated in the study.

The authors calculated the mean response for each item on the YES for all 2280 responses. The authors then grouped the responses based on the type of activity youth referenced during their self-reports (e.g., sports, fine arts), and calculated the mean for each item. The means were then compared to determine whether different types of activities were more likely to support different opportunities and skills for youth transitioning to adulthood.

Sports. Youth reported significantly more opportunities to develop initiative and emotional regulation and engage in teamwork while participating in sports compared with other organized activities represented. They reported fewer opportunities to engage in identity work, develop positive relationships, and network with adults during organized sport activities.

Performance and Fine Arts. Youth who participated in fine arts programs reported significantly higher rates of initiative. Compared with other activities, performing arts supported fewer opportunities for teamwork, positive relationships, and adult networking experiences.

Academic Clubs and Organizations. Youth reported significantly fewer opportunities for all skills and developmental experiences during engagement in academic clubs and organizations compared with other activities.

Community-Oriented Activities. Compared with other activities, youth who participated in community-oriented activities reported significantly more opportunities to network with adults but significantly fewer opportunities to engage in teamwork and develop emotional regulation.

Service Activities. Youth in service activities reported significantly more opportunities for teamwork, building positive relationships, and networking with adult compared with other activities. They also reported significantly lower rates of developing emotional regulation through service activities.

Faith-Based Youth Groups. Youth who participated in faith-based youth groups reported significantly more opportunities for all skills and developmental experiences on the YES when compared with other activities.

Negative Developmental Experiences. Stress was reported to be higher than the average in sports and lower in academic, service, and faith-based activities. Regardless of gender, Socio-economic status and ethnicity, youth reported similar rates of both positive and negative experiences in various organized activities.

However, it is difficult to draw these conclusions from cross-sectional research that does not explore change in the same cohort of youth over time. One nationally representative, longitudinal database, the National Longitudinal Transition Study 2 (NLTS2; <http://www.nlts2.org>) followed students with disabilities over a period of 9 years. Findings from these NLTS2 data indicate significant social participation limitations in youth with disabilities. For example, many young adults with ASD age 17 to 21 years reported that in the previous year they had not gotten together with a friend (55%) or talked with a friend on the phone (64%).⁸⁰ Four years later, the same young adults reported more frequent contact with friends; only 38.6% had never seen friends and 47.2% had never received a call from friends.⁹⁷ Although social participation seemed to improve in this cohort as they became young adults, other factors, such as loss to follow-up, can affect the findings. Future research is needed in this area to understand how social participation may change during the transition to adulthood and identify how occupational therapists can best support the social participation of young adults with disabilities during this transition.

Evaluating Social Participation

Youth Self-Reports of Social Participation

Often, occupational therapists working with young people rely primarily on other professionals' or parents' perspectives.^{31,119,133} However, studies have shown that youth's needs and concerns are not always recognized or shared by parents or other adults.^{40,83,88,92,94} Also, parents have expressed difficulty providing proxy reports because they are not always aware of their child's feelings or familiar with what their son or daughter does at school or in the community.^{59,68} Use of a parent report may be more problematic for transition-age youth who may not share their feelings with parents or who may engage in many activities without the direct supervision of parents. Thus, it is imperative to use youth self-report to understand and evaluate social participation.^{106,125}

Child Occupational Self-Assessment

The Child Occupational Self-Assessment (COSA)⁷⁰ is a self-report of competence and value for daily activities based on the Model of Human Occupation.⁶⁵ COSA includes 25 items that represent daily activities that most youth encounter at home, school, and in their communities. Several items explicitly rate social participation, such as "doing things with classmates" and "doing things with friends." COSA also includes items that assess self-care, time management, and self-regulation. The primary purpose of COSA is to gather youth's perspectives about their participation and provide a mechanism for them to identify and create goals for occupational therapy.

Each COSA item is rated using two four-point scales: competence—I have a big problem doing this, I have a little problem doing this, I do this okay, I am really good at doing this—and importance—not really important to me, important to me, very important to me, most important of all to me. COSA can be completed in several ways. One form includes rating scale symbols to assist with comprehension; the importance scale uses an increasing number of stars, and the competence scale uses happy or sad faces. COSA also includes a card

sort completion option and a summary matrix that may be used for reporting purposes by young people who do not need the symbols to understand the rating scales.

COSA is interpreted by identifying gaps between youth's perceived competence for an activity and the reported level of competence. The Model of Human Occupation posits that youth are at risk for poor occupational adaptation when one's perceived competence for a valued activity is low. Thus, COSA is used to identify potential areas in which social participation may put a youth at risk for poor occupational adaptation at home, in school, and in the community.

Studies have found that COSA items address concerns that are meaningful to youth with disabilities.^{66,94} Therapists can use a variety of modifications during administration to ensure youth can access and understand the assessment.⁶⁹ COSA can be administered in several sessions, using different forms and simplified rating scales.⁶⁸ These types of accommodations are essential to ensuring that young people have a voice in the intervention planning process.

Youth Experience Survey

The Youth Experience Survey (YES) 2.0^{55,56} is a self-report instrument designed to capture high school students' developmental experiences in an organized youth activity, such as an extracurricular activity or community-based program. The survey is designed to ask about experiences that have been shown to promote positive development into adulthood.

Items in YES focus mainly on positive developmental experiences. Three domains are related to personal development: identity work, initiative, and basic skills. Three domains measure interpersonal development: teamwork and social skills, positive relationships, and adult networks and social capital. Items from each of these positive domains can be further grouped into subscales for a total of 17 scales. YES also has a negative experiences domain that measures negative experiences that young people may encounter. The domain has a total of five scales that address stress, inappropriate adult behavior, negative influence, social exclusion, and negative group dynamics.

Questions in each domain are worded in the first person and are statements about feelings or things that may have happened during participation in extracurricular activities. Some example questions that can be relevant to social participation are as follows:

- "Learned that my emotions affect how I perform" (emotional regulation scale)
- "Learned that working together requires compromise" (teamwork and social skills scale)
- "Got to know people in the community" (adult networks and social capital scale)

Youth rate each question on a four-point scale to indicate if they experienced the question during participation, from 1, not at all, to 4, yes, definitely. Each scale score is then computed as an average in which scores can range from 1 to 4. These scaled scores can then be aggregated to the domain level.

Other Youth Self-Report Measures

Other youth self-reports, discussed elsewhere in this text, may also be appropriate to assess social participation. One example is the Canadian Occupational Performance Measure (COPM), which is used in the case of Kara. Another example is the recently developed self-report participation measure, the

Questionnaire of Young People's Participation (QYPP). This is aligned with the ICF and includes items that capture information about interpersonal relationships; education; employment; and community, social, and civic life. QYPP has been validated with adolescent and young adults with cerebral palsy in England.¹²²

Other evidence-based measures that are not explicitly about social participation may provide therapists with information about young people's feelings or perceptions that could affect social participation choices, including the following:

- Measures of self-determination, such as the AIR Self-Determination Scale¹⁴⁰ and Arc Self-Determination Scale,¹³⁴ assess youth's perceived abilities to set and achieve goals of personal importance. Higher levels of self-determination in high school have been linked with more successful postsecondary transition outcomes relevant to social participation, including employment and independent living.^{135,136}
- The Self-Perception Profile for Adolescents⁵⁸ includes subscales of social competence and friendships.
- Assessments of leisure engagement or role participation, such as the Children's Assessment of Participation and Enjoyment (CAPE), Preferences for Activities of Children (PAC), and the Role Checklist, can be used to document areas of interest and identify new activities that may facilitate social participation.
- Goal attainment scaling⁶³ may be an effective approach to track progress toward individual social participation goals (see [Chapter 24](#)). Goal attainment levels can be developed by therapists in collaboration with youth and their families. For example, Project TEAM used goal attainment scaling to evaluate Emily's outcomes after completing the training.

Parent Assessments of Social Participation

Participation and Environment Measure—Children and Youth

The Participation and Environment Measure—Children and Youth (PEM-CY) is a parent report instrument that examines participation and environment across three settings: home, school, and community. Participation items for each setting represent types of activities typically performed in that environment about which the parent would likely have knowledge. There are ten items in the home section, five in the school section, and ten in the community section. Many of the items relate to social participation, for example, "socializing using technology" (home section), "getting together with peers outside of class" (school section), and "community events" (community section). For each activity type, the parent is asked to identify how frequently the youth participates (from daily [7] to never [0]) over the past 4 months; how involved the youth is while participating (five-point response scale ranging from very involved to minimally involved); and whether the parent would like to see the youth's participation in this type of activity change (no or yes; if yes, the parent can select whether he or she would like to see a change in frequency, level of involvement, or variety).

After answering the participation questions for each setting, the parent is then asked whether certain features of the environment help or make it harder for the youth to participate in

activities in that setting; response options include not an issue, usually helps, sometimes helps, sometimes makes harder, and usually makes harder. Additional questions are about perceived adequacy of resources such as information, money, or supplies; response options include not needed, usually yes, sometimes yes and sometimes no, and usually no.

Summary scores for the PEM-CY were constructed to provide the most useful information for the intended purpose of the instrument.³³ Most of the summary scores are computed as percentages of a particular response or the maximum percentage possible. The maximum percentage possible is particularly suited for calculation of summary scores in situations in which data are missing because not all items are applicable.

Pediatric Evaluation of Disability Inventory—Computer Adaptive Test: Responsibility Domain

The Pediatric Evaluation of Disability Inventory (PEDI), originally published in 1992, is currently available as the Pediatric Evaluation of Disability Inventory Computer Adaptive Test (PEDI-CAT).⁵² This is a clinical assessment for children and youth that can be used across all diagnoses, conditions, and settings.

PEDI-CAT is comprised of a comprehensive item bank of 276 functional activities acquired throughout infancy, childhood, and young adulthood. It can be completed by parent or caregiver report or professional judgment of clinicians or educators who are familiar with the child. PEDI-CAT is recommended for use with children approaching 1 year and up to 21 years of age. PEDI-CAT provides normative T-scores, age percentiles, and a criterion score.

PEDI-CAT includes four domains: daily activities, mobility, social/cognitive, and responsibility. The social/cognitive domain assesses the ability to interact with others in a community and participate in one's family and culture. The items address four content areas: communication, interaction, everyday cognition, and self-management. Some items on the social/cognitive domain assess skills that can facilitate social participation (e.g., "shows positive reactions to friends' success such as congratulating a peer for scoring a goal or doing well on a test"). The items in this domain are rated using four-point difficulty scale, from unable (1) to easy (4).

The responsibility domain is a unique measure of participation and management of higher level tasks essential for independent living and successful transition to adulthood. The responsibility rating scale measures the shift of responsibility from parents to the young person. The responsibility domain addresses overall independence in managing essential life tasks rather than requiring independent performance. Responsible management of essential life tasks may include seeking assistance or resources as needed or directing others to accomplish the task. Thus, the responsibility domain is aligned with the ICF's concept of participation.

The responsibility domain items address four content areas: staying safe, taking care of daily needs, organization and planning, and health management. Some items on the responsibility domain pertain specifically to social participation (e.g., "choosing and arranging all social interactions") and items that assess skills that can support social participation (e.g., "planning and following a weekly schedule" and "traveling safely within in the community"). All items on the responsibility domain are rated using a five-point rating scale that measures the shift of

responsibility from parents (1) to shared responsibility (3) to the young person taking all responsibility (5).

Child and Adolescent Scale of Participation

The Child and Adolescent Scale of Participation (CASP) measures the extent to which children participate in home, school, and community activities compared with children of the same age, as reported by family caregivers. It was originally designed to monitor outcomes and needs of children with traumatic and other acquired brain injuries (ABIs). The CASP subsequently has been used to assess children with other diagnoses.^{10,105,128,137} CASP has been recommended as an assessment that is aligned with the ICF to measure participation.¹

The CASP consists of 20 ordinal-scaled items and four subsections, some of which are aligned with social participation: (1) home participation (six items), (2) community participation (four items), (3) school participation (five items), and (4) home and community living activities (five items). The 20 items are rated on a four-point scale: "age expected (full participation)," "somewhat restricted," "very restricted," and "unable." A "not applicable" response is selected when the item reflects an activity in which the child would not be expected to participate because of age (e.g., work). Item, subsection, and total summary scores can be examined for use in research and practice. Higher scores reflect greater age-expected participation. CASP also includes open-ended questions that ask about effective strategies and supports and barriers that affect participation. Parent report and self-report versions are available. See [Tables 12-1, 12-2, and 12-3](#) for descriptions of assessments.

Interventions to Facilitate Social Participation

Following an assessment of social participation, occupational therapists can develop interventions to address social participation difficulties by the following:

- Helping youth with disabilities acquire communication and interaction skills
- Identifying ways to modify the environment to support social participation
- Using peers to encourage social interactions and social participation.

As illustrated by the cases in this chapter, interventions that use these approaches can facilitate the social participation of youth transitioning to adulthood. The interventions featured in these cases are informed by a variety of conceptual models and use a range of strategies. These cases demonstrate that a range of theories and strategies can be integrated into interventions to improve social participation. Occupational therapists should use clinical reasoning to select the principles and strategies most likely to support social participation based on the circumstances, needs, and specific goals of each young person.

Skill-Focused Interventions

A range of interventions is used to improve communication skills of transition-age youth with autism and intellectual disabilities, including cognitive-behavioral approaches to teach self-monitoring, using prompting picture books and social

TABLE 12-1 Youth Self-Report Assessments Related to Social Participation

Instrument	Construct Assessed	Targeted Age	Respondent	Subscales and Domains Relevant to Social Participation	
				Example Item	Example Rating Scale
Child Occupational Self-Assessment (COSA)	Perceived competence and value for 25 everyday activities; responses can inform intervention planning.	7-18 yr	Youth self-report	Competence for everyday activities Value for everyday activities	Competence: "I have a big problem doing this, I have a little problem doing this, I do this okay, I am really good at doing this" (scale includes happy and sad faces). Value: Not really important to me, important to me, really important to me, most important of all to me Yes, definitely; quite a bit; a little; not at all
Youth Experience Survey (YES)	Assessing developmental experiences resulting from a range of activities or programs that promote positive development into adulthood	High school	Youth self-report	Positive relationships (diverse peer relationships, prosocial norms) Teamwork and social skills (group process skills) Adult network and social capital (integration with family, linkages to community, linkages to work and college)	"Learned I had a lot in common with people from different backgrounds." "Learned how my emotions and attitude affect others in the group." "Got to know people in my community."
ARC Self-Determination Scale	Identifying strengths and limitations in the area of self-determination	Adolescents to adults	Youth self-report	Autonomy Psychological empowerment	Autonomy: I do not even if I have the chance; I do sometimes when I have the chance; I do most of the time when I have the chance; I do every time I have the chance. Psychological empowerment: Choose between two statements. Never, almost never, sometimes, almost always, always
AIR Self-Determination Scale	Assessing the capacity and opportunity to act self-determined in the contexts of home and school	Adolescents to young adults	Youth self-report (parallel parent or professional self-report available)	Items can be grouped into knowledge, ability, and perception for each context. Items are aligned with think-do-adjust process across contexts.	"I make friends with other kids my age." "My friends and I choose activities we want to do." "I will have a hard time making new friends" or "I will be able to make friends in new situations." "People at school listen to me when I talk about what I want, what I need, or what I'm good at." "I have someone at home who can tell me if I am meeting my goals."
Self-Perception Profile for Adolescents	Perceived competence and self-worth	Adolescents	Youth self-report	Global self-worth, scholastics, social acceptance, job competence, behavior	Contrast two statements: Sort of true for me, really true for me

TABLE 12-2 Parent Report Assessments Related to Social Participation

Instrument	Construct Assessed	Targeted Ages (yr)	Respondent	Subscales and Domains Relevant to Social Participation		Example Item	Example Rating Scale (points)
PEDI-CAT	Performance of daily activities Management of daily life tasks	0-21	Parent self-report	Social-cognitive Responsibility		"Shows positive reactions to friend's success such as congratulating a peer for scoring a goal or doing well on a test" "Choosing and arranging all social interactions"	Social-cognitive: Unable, hard, a little hard, easy Responsibility five-point scale: Adult or caregiver has full responsibility; the child does not take any responsibility (1) Child takes full responsibility without any direction, supervision, or guidance from an adult or caregiver (5)
PEM-CY	Participation in daily activities (frequency, involvement, and desire for change) Impact of the environment on participation (barriers and supports, resources)	Children and youth ages 5-17 yr	Parent report	Home participation, home environment School participation, school environment Community participation, community environment		"School-sponsored teams, clubs, and events" "Neighborhood outings (e.g., shopping at the store or mall, going to a movie, eating out at a restaurant, visiting the local library or bookstore)." "The social demands of typical activities (e.g., communication, interacting with others)"	Frequency (eight-point scale): Daily to never Involvement (five-point scale): Very involved to minimally involved Environmental barriers or supports: Not an issue; usually helps; sometimes helps; sometimes makes harder; usually makes harder Environmental resources: Usually yes; sometimes yes, sometimes no; usually no
CASP	Level of participation compared with same-aged peers	Children and youth ages 5-17 yr	Parent report (parallel youth self-report available)	Home participation Community participation School participation		"Social, play or leisure activities with family members at home (e.g., games, hobbies, 'hanging out')" "Communicating with other children and adults in the neighborhood and community"	Age-expected (full participation), somewhat restricted, very restricted, unable

TABLE 12-3 Research Evidence and Psychometric Properties of Featured Assessments

Assessment Name	Assessment Validity	Assessment Reliability	Other Evidence
Child and Adolescent Scale of Participation (CASP)	Both parent and youth report have strong internal consistency ($\alpha = 0.95$ and 0.87 respectively). ⁸⁷	ICC analysis indicated moderate agreement between youth and parent reports (ICC = 0.63 ; 95% CI = 0.41 to 0.75), although youth reported their activity or participation to be significantly higher than their parents. ⁸⁷	During administration, therapists reported providing accommodations: scheduling, presentation, and response format.
Child Occupational Self-Assessment (COSA)	Assessment items on each scale (competence, importance) form a unidimensional construct, and good item fit indicates the items work well together to measure each construct. ^{71,73}	Youth who are younger or who have intellectual disabilities are more likely to use the four-point rating scale incorrectly. ⁷³ Parents and children disagreed 63.5% on competency and 61% on value responses. Substantial discrepancies (more than two rating categories) occurred on 20.5% of competency and 19% of value. Parents thought that their children saw themselves as less competent in occupations than the child reported to be. ⁹⁴	Therapists also reported therapeutic use of self during the administration of COSA by developing rapport and empowering the child. ⁶⁹
Participation and Environment Measure—Children and Youth (PEM-CY)	The PEM-CY items work well together to measure participation across contexts. Internal consistency coefficients were 0.59 (home), 0.61 (school), and 0.70 (community) for participation frequency and 0.83 (home), 0.72 (school), and 0.75 (community) for involvement. Cronbach's alpha was ≥ 0.80 for all scales except home-supportiveness (0.67) and school resources (0.73). The PEM-CY can discriminate among youth with varying levels of participation. Two-way analyses of variance found a significant effect of disability across all settings. Additional analyses showed that these differences were consistent within each age interval. For children without disabilities, there was a significant increase in the range of activities in which children participated as they got older, but this pattern was not seen consistently in the children with disabilities.	Test-retest reliability estimates (intraclass correlation estimates) of the total scores for participation frequency (maximum percentage possible) were moderate for the school setting (0.58) and good for home and community (0.84 and 0.79, respectively). Reliability of the percentage who ever participates score was highest for the home (0.92) and school (0.82) settings, and lower for the community (0.66). Test-retest reliability for mean participation involvement scores was moderate to good: 0.71 for home, 0.76 for school, and 0.69 for the community. Test-retest reliability for the desire for change total score was consistently good (>0.75). Test-retest reliability estimates for the environment section summary scores were all good; intraclass correlation coefficients for supportiveness totals were 0.76 for the home, 0.87 for school, and 0.96 for the community. All reliability estimates for the environmental resources scores were >0.80 , indicating good agreement across occasions in each setting.	The design of the instrument was based on results from focus groups and in-depth interviews with parents of children and youth with and without a variety of disabilities who helped define the relevant dimensions for measurement, activity types that were most applicable and important in each setting, and relevant features of the environment that affected their child's participation. ¹¹
Pediatric Evaluation of Disability Inventory—Computer Adaptive Test (PEDI-CAT)	Confirmatory factor analysis and item fit to a two-parameter item response theory model confirm that 60 items on the social-cognitive domain and 51 items making up the responsibility domain are unidimensional. ⁵²	Scores obtained on the social-cognitive and responsibility domain using the full item bank of 51 items and CAT of 15 items were highly correlated (both 0.99), indicating that CAT can produce an accurate measure in fewer items. ⁵² Test-retest reliability of the CAT was very high (ICC = 0.98 social cognitive; 0.96 responsibility). ³⁹	Parents reported satisfaction with the PEDI-CAT format. ³⁹
Youth Empowerment Survey (YES)	Items on each scale work well together to provide an acceptable measure of youth empowerment. Cronbach's alpha was ≥ 0.80 for all scales except negative group dynamics (0.75). The positive scales of the YES 2.0 (personal and interpersonal experiences) were moderately intercorrelated (15 of the 18 scales ranged from 0.50 to 0.60). The negative scales were also intercorrelated, ranging from 0.46 to 0.77. ^{55,56}	Significant and moderate correspondence was found between the students' and the leaders' responses on most of the YES scales. Emotional regulation and two subscales on the adult network domains were not significant. ^{55,56}	N/A

stories to facilitate interactions with others, and practicing specific communication skills in the context of games.^{22,26} These interventions target youth's ability to initiate social interactions, take turns during conversation, engage in an increased variety of conversation topics, and enhance interaction quality.^{22,26,103} Although these studies have found positive effects, the researchers examined specific social skills or measured communication skills on a second-by-second basis and did not consider social participation in the context of sustained social interactions.²⁶

Occupational therapy interventions extend beyond working on social skills and target other factors to support successful social participation. Such interventions may include the following:

- Transportation and mobility training to increase youth's ability to access social activities
- Gathering information through print, the Internet, and over the phone about available social activities and programs
- Developing time and money management skills that facilitate continued participation in social activities
- Identifying self-regulation strategies that can make social participation more enjoyable for young people with anxiety, poor attention, or repetitive behaviors

Kara's case ([Case Study 12-3](#)) illustrates how an adolescent uses goal setting and metacognitive strategies in combination with skills training (e.g., managing a bank account, community mobility) to achieve higher level social participation. Kara was empowered to set her own goals that were meaningful and motivating to her. The therapist used a metacognitive approach, which allowed Kara to set her own goals and become the change agent as she took on more responsibilities and gained more independence. With support and guidance, Kara replicated the approach and achieved subsequent goals. With time, she began to internalize the process so that she could replicate it without assistance. This shift allowed her to continue to set and achieve her own social participation goals as she made her way into the adult world.

Environment-Focused Interventions

Understanding social participation as a *social process* may help occupational therapists implement interventions that go beyond communication and social skill building. Models such as the ICF (see earlier) stress that the environment is a primary contributor to participation and disability. Modification of the environment is a central component of occupational therapy practice.⁴ During most occupational therapy interventions, parents or professionals adapt the environment on behalf of youth with disabilities, rather than teach youth with disabilities the skills needed to identify and advocate for environmental modifications. Thus, the young people remain dependent on the assistance of professionals. Environment-focused interventions need to involve youth themselves in actively generating and working to achieve solutions to challenges. As a result, modifications are more likely to be acceptable, and through the process of self-generating solutions, youth gain the knowledge and skills to be effective self-advocates.

Project TEAM (*Teens making Environment and Activity Modifications*) is an occupational therapy intervention that is research-based, theoretically grounded, and developed in

collaboration with youth with disabilities.⁶⁷ Project TEAM empowers youth with developmental disabilities to systematically identify environmental barriers and supports, generate modification strategies, and request reasonable accommodations. Skills that enable youth with disabilities to act as their own advocates include self-evaluation, problem solving, goal setting, and self-reinforcement skills. Project TEAM fosters the development of these skills using a self-monitoring process informed by a cognitive-behavioral approach called the Game Plan.⁹⁰ The Game Plan is a problem-solving and self-monitoring process that follows the steps of Goal-Plan-Do-Check. These new problem-solving skills facilitate youth's participation in postsecondary education and training, employment, and community living as they transition to adulthood.

Project TEAM is a manualized, group-based intervention designed to be cofacilitated by an experienced leader with a disability (disability advocate) and a licensed service provider (e.g., occupational therapist, social worker, educator). Project TEAM includes eight group sessions and two experiential learning field trips for each participant. Each trainee who begins Project TEAM identifies an activity or role (e.g., applying for a job or volunteer position, identifying a new role in an existing job, attending a leisure or social event (e.g., attending a rock concert, going out to dinner), or joining a community organization (e.g., sports team, theater group) that he or she strives to complete by the end of the 12-week self-advocacy intervention. The activity goal emphasizes participation, not independent performance, and is achieved by removing environmental barriers to participation. [Case Study 12-4](#) provides an example of how Project TEAM facilitated social participation in the area of employment.

Emily's case illustrates how a self-advocacy and problem-solving training such as Project TEAM can support the social participation of transition-age youth with disabilities. By attending to the aspects of the environment that posed a challenge, Emily realized she could advocate about her abilities and needs. For example, regarding the barrier of opening tight objects, Emily identified that co-workers could help her with this task. Despite having previously considered this to be a personal impairment, Emily now understood how the environment affects achievement of her goal. By identifying and addressing the environmental barriers, she realized that she could participate in infant childcare if the right supports and modification strategies were in place. Her use of the Game Plan helped her identify and resolve barriers to beginning a volunteer role and enabled her to work toward beginning this new role in her community ([Box 12-3](#)).

Peer Support Interventions

Although peer relationships are important aspects of comprehensive secondary schooling, the approaches used to support students with disabilities to participate in classrooms, clubs, and other school activities sometimes limit these important social connections. When youth with disabilities receive most or all of their support from adults (e.g., related service providers, paraprofessionals, special educators), they may have few opportunities to get to know their peers without disabilities. Peer support interventions offer an evidence-based alternative to reliance on adult-delivered support in school and community settings. This approach involves equipping one or more peers

CASE STUDY 12-3 Skill-Focused Interventions for Social Participation: Kara

Kara is a 21-year-old woman diagnosed with high-functioning autism and anxiety disorder. Until she was 19, she received a traditional education through a combination of integrated and substantially separate classrooms supported by an individualized education program (IEP) that included pull-out sessions for occupational therapy and speech language pathology services. Kara passed the required standardized exams in her state to obtain her diploma at age 18. However, her parents advocated to keep her in a specialized school through her 22nd birthday to focus on life skills, vocational skills, and social participation, all of which were severely affected by her autism and anxiety symptoms. When Kara turned 19, her anxiety increased and she became unable to attend school because of severe agoraphobia. Within a few months, her symptoms became so severe that she withdrew from school completely and received tutoring at home. Kara subsequently experienced significant feelings of depression, and her family grew increasingly hopeless as they faced her future.

Despite her often paralyzing anxiety, Kara was motivated to reach her long-term goals—make new friends, find a job she liked, and attend a college course. She also made a personal goal to travel to New York to see a show on Broadway, something she had done in years past but not since her anxiety had worsened. To do that, she needed to make some money, improve her ability to manage her anxiety, and gain some life skills to plan, organize, and execute her trip. Kara was evaluated using the Canadian Occupational Performance Measure (COPM)⁷⁷ and the Adult/Adolescent Sensory Profile¹⁸ (for more information, see Chapter 9). Kara identified the following goals after completing the COPM:

- Manage money (specifically to save and budget money for a trip to New York).
- Use a cell phone (especially to send and receive text messages).
- Diversify leisure (decrease time on Internet, increase social time).
- Take public transportation.
- Get a job.
- Take a college-level class.
- Prepare own meals.
- Do more chores around the house.

Kara gave the most disparate ratings for managing money: 3 for performance, 1 for satisfaction, and 9 for importance. Thus, Kara and the therapist decided that managing money would be the first goal they addressed. Kara's sensory sensitivity (more than most people) and sensory avoiding (more than most people) scores also indicated that she might have difficulty in social situations. She reported having trouble concentrating in a noisy environments, preferred to be alone, and avoided situations where unexpected things might happen. She specifically mentioned that despite her interest in plays, she has difficulty in many theaters because of the slope, stating that she feels "claustrophobic." She stated that she has a few coping strategies for dealing with her anxiety and sensory discomfort, namely, listening to familiar music, repeating familiar phrases to herself, and rocking in her chair. She expressed an interest to broaden her coping strategies to enable her to tolerate a wider variety of environments.

Kara was seen by an occupational therapist twice weekly for 45-minute sessions. Her IEP goals incorporated her

COPM goals, with an initial focus on money management and identifying sensory-based strategies to support her social participation in multiple contexts. The therapist worked with her in her classroom once a week during their banking and budgeting block and once per week outside the classroom.

Kara's therapy was primarily guided by the metacognitive strategy, *Goal-Plan-Do-Check*.⁹⁹ This particular metacognitive strategy requires the participant to set a goal, make a plan to achieve that goal, follow through with the plan, given support as needed, and then review her performance. Kara applied this framework to increasingly more complex tasks, beginning with the goal of opening a bank account and progressing over the year to her ultimate goal of using a budget to save enough money to fund her trip to see a Broadway performance. During the process, the occupational therapist provided Kara with guidance and support as she completed each step. For example, based on her COPM ratings, Kara's first goal was to open her own bank account, which would support her ultimate goal to go with family or a friend on a trip. Her plan was to do the following:

1. Identify a bank that had a branch close to her home and to her school. She planned to do this by searching online.
2. Contact the bank and find out the steps for opening an account. Included in this was identifying materials she might need to have prior to opening the account.
3. Gather the materials and information required
4. Travel to the bank and meet with a representative to open the account.

For the *do* portion of this intervention, Kara carried out each step during an occupational therapy session, and the therapist collaborated with Kara's family, her social worker, and her classroom teacher to ensure that she was following through with agreed-on tasks and was receiving the support she needed to be successful. After each step, Kara and the therapist reviewed her performance and the outcomes to make explicit the process, the strategies she was using, and the types of supports she felt were beneficial. This same approach, *Goal-Plan-Do-Check*, was applied to most of Kara's goals and was very effective at facilitating her success.

Kara's therapy sessions also gave her opportunities to explore different sensory strategies, such as a weighted blanket and deep pressure. The occupational therapist presented Kara with the strategies, and together they made a plan about when and where to use them and how to assess their effectiveness. With the involvement of Kara's family, she tested the strategies in different environments to determine when and where they were beneficial.

In a year, Kara earned enough to take her trip to New York with a cousin. In addition to attending a Broadway show, she visited the zoo, using the sensory strategies she identified. Using the *Goal-Plan-Do-Check* and sensory strategies, she achieved other social participation goals, including conversing with two friends via text message and Facebook, enrolling in a class at a local community college, and securing a job at a local museum orienting visitors when they arrived. During her annual assessment, Kara rated her performance of money management at a 7, her satisfaction at an 8, and importance as a 7.

CASE STUDY 12-4 Project TEAM Case: Emily

Emily, an 18-year-old Project TEAM trainee, has a mild intellectual disability and hypotonia. She is currently in her junior year of high school. This case will follow the steps of the Game Plan to illustrate how Emily identified and resolved physical and social environmental barriers to employment.

First Base Goal: What Activity Would I Like to Do?

When Emily spoke with the facilitator during their initial assessment, she was excited about creating her own activity goal. Taking on the formal position of a childcare volunteer became Emily's activity goal. Through this role, Emily would have greater interactions with members of her community. She would also gain experiences that would support her future vocational goals and help her become more familiar with the organizational structure and procedures of day-care centers, such as background checks and staff training requirements. Emily and the facilitator decided her goal would be to identify a center and shadow other staff members while helping to provide childcare to infants. She would also strive to babysit for longer than 1 hour, allowing her to become

more involved and engaged with the children. This information was used to create a series of goal attainment levels that would be used at the completion of Project TEAM to evaluate Emily's success (See Figure 12-12).

Second Base Plan Step 1: What Parts of the Environment Help Me or Make It Hard for Me?

As Emily began learning about environmental supports and barriers, she began to identify a range of factors that would help or make it harder for her to reach her goal to volunteer in infant childcare. She identified two parts of the environment as barriers using the Game Plan worksheet, services and organizations, and signs and information (Figure 12-11). These barriers made it challenging to find local community organizations that offered babysitting, accepted childcare volunteers, and readily described the application processes. Because of her hypotonia, Emily also noted that she was concerned about opening tightly closed objects, such as lids or bottles, which would likely be a responsibility of a childcare volunteer. Thus, she also identified *things* as a potential barrier while engaged in childcare.

Second base: Plan-Step 1		
What parts of the environment help me or make it hard for me?		
Parts of the environment	Supports	Barriers
Things	Helps	Harder
Inside places	Helps	Harder
Outside places	Helps	Harder
People	Helps	Harder
Services and organizations	Helps	Harder
Rules	Helps	Harder
Technology	Helps	Harder
Ground	Helps	Harder
Entrances and exits	Helps	Harder
Signs and information	Helps	Harder
Light, sound, and smell	Helps	Harder

FIGURE 12-11 Emily's completed Plan Step 1 of the Game Plan worksheet.

Continued

CASE STUDY 12-4 Project TEAM Case: Emily—cont'd

Rating	Level	Personal activity goal	Environment Factors goal	Strategy goal
+2	Much more than expected outcome, likely to occur 7% of the time	Providing assistance to younger children in a group setting for one hour with support on more than one occasion.	Can spontaneously and independently identify and explain barriers and supports involved in goal activity.	Using game plan worksheet, considers consequences of strategy use with support <u>IN</u> ADDITION TO activities in level +1.
+1	Somewhat more than expected outcome, likely to occur 21% of the time	Providing assistance to younger children in a group setting for one hour with support on one occasion.	Using the game plan worksheet/ cue cards can independently identify and explain barriers and supports for goal activity.	Spontaneously and independently names at least one appropriate strategy category and/or generates a specific strategy idea; <u>AND</u> uses the strategy during goal activity with support.
0	Expected outcome, likely to occur 43% of the time	Observing younger children in a group setting for at least one hour.	Using the game plan worksheet/cue cards [as needed] with orienting or guiding questions from facilitators, can identify and explain barriers and supports involved in goal activity.	Using the game plan worksheet independently names at least one appropriate strategy category and/or generates a specific strategy idea; <u>AND</u> uses the strategy during goal activity with support.
-1	Baseline/current, unless no worse is possible. Somewhat less than expected outcome, likely to occur 21% of the time.	Possesses knowledge of child-care provision to kindergartners in a group setting for a period of one hour with full support. At present time, is not involved in any type of child-care provision.	Using the game plan worksheet/cue cards can independently identify and explain one barrier <u>OR</u> support involved in goal activity.	When provided with a strategy category generates an appropriate strategy; <u>AND</u> uses a specific strategy during goal activity with support.
-2	Much less than expected outcome, likely to occur 7% of the time	Refusal to engage in provision of child-care.	Using the game plan worksheet/cue cards with orienting or guiding questions from facilitators can identify and explain one barrier <u>OR</u> support involved in goal activity.	Chooses one strategy during goal activity when provided with examples of specific strategy ideas, <u>AND</u> uses the strategy with support during goal activity.

FIGURE 12-12 Emily's goal attainment levels for Project TEAM.

Emily also noticed that several people, including the facilitator and her mother, acted as supportive listeners and provided suggestions.

Plan Step 2: What Strategy Can I Use to Change the Environment?

Through Project TEAM, Emily began to develop her ability to change the environment using the six modification strategies taught in the curriculum: plan ahead, change spaces, use technology or things, teach others about abilities and needs, change the rules, and ask someone for help. The first strategy she implemented was to use technology and things to search for information on the Internet, and she asked someone for help (her mother) to pinpoint an appropriate organization. She finally identified the local YMCA as a provider of infant childcare. However, Emily thought the website was not easy to navigate, and she made a phone call to contact the center. This approach provided her with specific information about

when babysitting is offered and how the overall childcare program works. Because the staff at the day-care site was helpful in offering this information, Emily also identified that staff people could be an additional support to help her achieve her goal.

After identifying the local YMCA as her targeted organization, Emily met with the facilitator to brainstorm how she would contact the YMCA by phone to share her interest in being a childcare volunteer. Creating a script in preparation of calling the director allowed Emily to use the plan-ahead strategy.

Plan Step 3: Would Using This Strategy Change the Activity for Other People?

Emily wanted to focus on the implications of using the two related strategies of teaching others about abilities and needs (to share information with her co-workers about her disability and why it is difficult for her to open bottles and lids) and

CASE STUDY 12-4 Project TEAM Case: Emily—cont'd

ask for help (by asking co-workers for help opening bottles and lids). Emily acknowledged that using these strategies would add to her co-workers' responsibilities because they would have to assist Emily in providing care to the other children. Additionally, Emily imagined that these strategies might make babysitting more difficult if she is working with only one staff member. However, with support from the facilitator, Emily identified that co-workers generally share responsibilities when they care for children. For example, if a co-worker is tying the shoelaces of a child who is upset, Emily may be able to help by making silly faces to help the child cheer up. Emily also considered the impact that using her strategies may have on the children. She wondered if children may become confused or have less fun if she could not provide all primary responsibilities. With support from the facilitator, Emily concluded that the children would have more fun if she volunteered with them because she knows how to be playful with children and encourage fun interactions.

Do: Who Do I Talk to About This Change?

With assistance, Emily logged onto the Internet on a computer and identified an e-mail and phone number for the

Director of Child Care at her local YMCA. Emily noted that the director was the correct person to speak to obtain an application because the director has authority. Therefore, Emily decided that the script she wrote with the facilitator would now be intended for the director and that she would follow the script when she called this person.

Check: Am I Able to Do This Activity Now?

During an end of the year meeting with her IEP team, Emily shared her interest in volunteering with the YMCA during the summertime. As a result, the team provided her with the opportunity to shadow childcare with a class at school and actively participate in providing care to children. This placed her final level of goal attainment at +2. In addition, her ability to identify environmental barriers and supports and generate strategies to resolve environmental barriers gave her a goal attainment level of +2 for learning goals related to environmental factors and modification strategies. Emily intends to continue to work toward her goal to volunteer with the YMCA with support from her parents and IEP team (Figure 12-12).

BOX 12-3 Supporting Social Participation for Teens and Young Adults with Significant Multiple Disabilities

- Modify positioning equipment so the young person can sit at the dinner table with family.
- Use picture schedules to structure a trip to the mall with friends that provides options for the beginning, middle, and end of the outing.
- Modify a line dance routine done at the prom so that all attendees can participate.
- Suggest that youth transport water and snacks for a team on his or her wheelchair tray or by pulling a cart.
- Partner with a local small business undergoing remodeling to include an accessible main entrance and/or accessible layout and signage.
- Provide education and training to the local Better Business Bureau about serving customers with disabilities.
- Create an adaptive digital camera that a young person can use to document events such as sports, school service projects, or arts programming.
- Implement a low-key lunch day in the office building's break room by lowering lights and limiting noise.
- Design a buddy system in a local arts production to pair actors with supporters who can help with lines, blocking, and staging.
- Program a student's speech-generating device to deliver the daily weather for the morning news program at a high school.
- Help a young person and their family complete applications for city paratransit services.

without disabilities to provide ongoing social and/or academic support to their classmate with a disability while accessing needed assistance from school staff.²¹ These interventions are undertaken through the following steps:

- A plan is developed for how peers will offer support in various school settings.
- Peers are invited to participate.
- An orientation meeting is held to equip peers for their new roles.
- School staff provide needed assistance and feedback as students work together.
- Adults gradually reduce their involvement and proximity as the student and peer gain confidence and experience together.

Research suggests peer support interventions can be effective and feasible to implement within secondary schools.^{23,27}

For students with disabilities, these interventions have been associated with higher rates of social interaction, increased access to social support, improved social skills, expanded friendship networks, and greater participation in the life of the school. However, it is the reciprocal benefits of these interventions that are particularly compelling. Peers without disabilities who have been involved in providing support report gaining a deeper appreciation of diversity, stronger commitment to the importance of inclusion and social justice, increased understanding of disability, enhanced self-esteem, stronger advocacy skills, and improved attitudes.²⁴ School staff also reported that these peer-mediated approaches are effective, easy to implement, and regularly used in their schools.²⁵ The flexibility of peer support interventions makes it possible to individualize them to for use within a wide variety of classrooms and with a diverse range of students. [Case Study 12-5](#) describes how a peer support

CASE STUDY 12-5 Peer Support Intervention: Dylan

Like many other seniors at his high school, Dylan is a fan of stock car racing and enjoys listening to country music. Dylan also has autism. He communicates using sign language or a program on his iPad through which he can select or spell out words. Although he spends most of his school day in a special education classroom, he attends a general education environmental science class every morning.

At first, Dylan had fairly limited participation in his environmental science class. He sat toward the back of the room next to Ms. Collins, an individually assigned paraprofessional. Ms. Collins worked to create activities for Dylan that were related to class content and could be completed successfully (e.g., word searches, matching worksheets). With help from Ms. Collins, Dylan completed these worksheets as his classmates participated in lectures, engaged in class discussions, and completed other individual and group assignments. Dylan's classmates were never unkind to him, but they hardly ever talked to him. Dylan did not complain about the class, but as soon as he finished a worksheet, he looked at Ms. Collins and pointed to his wrist—his way of asking her if he could return to the special education classroom.

Ms. Collins heard about an opportunity in her district to learn about peer support arrangements, an intervention strategy for fading adult support and empowering peers to provide academic and social support in inclusive classrooms. She was especially excited about learning strategies for engaging Dylan more fully in the class and building new social connections with his peers. Ms. Collins took steps to establish a peer support arrangement in Dylan's class. First, she identified peers who might be willing to participate. On a day when Dylan was absent, she spoke with the class about the purpose of peer supports and how this might be a fun opportunity to work with Dylan and get to know him better. She was pleasantly surprised by the number of students who expressed interest and she decided to initially involve three students—Chris, Alisha, and Sarah—as Dylan's peer supports.

Next, Ms. Collins held a brief orientation session with the peers to tell them more about Dylan and discuss how they might help support and interact with him during class. When she shared how Dylan liked stock car racing and listening to particular popular country music artists, Chris was surprised. He had no idea he and Dylan had so many shared interests. Ms. Collins explained that Dylan used his iPad and some sign language to communicate. She showed the peers the various signs Dylan uses most often and demonstrated how to program new words or phrases into Dylan's iPad. Ms. Collins then showed the peers a support plan she created for Dylan. She explained that the plan offered a starting point for the

peers to interact with Dylan and support him during various class activities, but she also encouraged the students to come up with their own ideas for how Dylan could become more actively involved in the class. Excited, Sarah asked if they could all begin working together with Dylan the next day.

The following day, Ms. Collins talked with the classroom teacher about rearranging the seating chart so Dylan could work next to Chris, Alisha, and Sarah in the midst of the rest of the class. Ms. Collins told Dylan he would be sitting in a new seat with some new friends who were excited to get to know him. At first Dylan seemed hesitant because he was not used to sitting with anyone other than Ms. Collins. But when Chris greeted him and started talking about a recent NASCAR race, Dylan excitedly followed Chris to his new seat.

Over the next few months, Chris, Alisha, and Sarah found creative ways to interact with Dylan. They introduced Dylan to other students, and soon many others were greeting Dylan in the hallways and in class. Alisha noticed Dylan's iPad did not include the vocabulary used in class discussions during environmental science class, so she asked Ms. Collins if it would be okay to help Dylan program in new words. Ms. Collins worked with the teacher to get a list of key words each week so Alisha could help Dylan program in these words on a regular basis. Knowing Dylan has access to content-related words on his device, Dylan's teacher began to call on him to answer questions for the very first time. Sarah helped Dylan find a correct response on his iPad and Chris started prompting Dylan to raise his hand in class to share answers. Before long, Dylan volunteered to answer questions on his own, and was noticeably excited when he knew the right answer.

Dylan was not the only person to benefit from being part of the peer support arrangement. At the end of the semester, the peers shared what a positive experience it had been to get to know Dylan, help him meet others, and participate more fully in the class. Alisha said, "I now understand Dylan's disability in a different way than before, and I have developed a friendship with him." Sarah noted the experience had changed "how I view people with disabilities. I learned that they do understand what is going on a lot of the time and can be great friends." Chris was very glad he had an opportunity to "get to know Dylan as a person" and emphasized that Dylan "opened up a ton after we began getting to know one another." Ms. Collins was especially excited about how well things had gone. She reflected on her experience by saying, "Coming to class is more enjoyable. Dylan comes on his own now and looks for his peers." She says that implementing peer support has "benefited everyone—even me."

intervention helped one young man, Dylan, develop social relationships with other high school students.

In the case of Dylan, a paraprofessional identified and created peer support opportunities. However, an occupational therapist could play a vital role in working at the school level to structure a peer support system, identify and train paraprofessionals to facilitate peer support, and create opportunities for peer interactions through special activities. This intervention

approach is a type of tier I intervention that can enhance the social participation of all students (see [Chapter 23](#)).

Summary

This chapter reviews conceptualizations of participation from a variety of fields, including rehabilitation, education, and

sociology, to illustrate the complexity of social participation during adolescence and transition to adulthood.

- A framework based on the ICF grounded our discussion of social participation in interpersonal interactions and relationships and identified four participation contexts that are particularly relevant for adolescents in which social interactions can occur: work; education; community life, religion, and citizenship; and recreation and leisure.
- This chapter also described how the physical, social, cultural, and political environment can affect social participation by shaping the opportunities available to young people with disabilities.
- The research review demonstrated the developmental benefits of participation in these contexts for future success as

adults. However, we also highlighted the social participation disparities experienced by adolescents with disabilities and potentially negative developmental implications.

- Occupational therapy can play an important role in facilitating the social participation of transition-age youth with disabilities and their successful transition to adulthood.
- Occupational therapists have at their disposal a range of youth self-report and parent report assessments that can be used to identify needs related to social participation.
- Interventions that target youth skills, the physical and social environment, or that use peers may be used to increase social networks and enhance the social participation experiences of young people with disabilities transitioning to adulthood.

Interventions and Strategies for Challenging Behaviors

Renee Watling

KEY TERMS

Challenging behaviors
Contingency methods
Functional behavioral analysis

Positive behavioral support
Prevention

GUIDING QUESTIONS

1. What are the four functions of challenging behaviors?
2. How can a therapist *prevent* challenging behaviors from occurring?
3. What are strategies for *supporting* positive behaviors in children?
4. What are principles and strategies to reduce challenging behaviors?
5. How are positive behavior support and functional behavioral analysis used to support student behaviors in school contexts?

Strategies for Managing Difficult Behavior

All children display inappropriate or challenging behaviors as they grow through the various ages and stages of childhood. Special attention must be given when such behaviors interfere with the child's ability to engage and participate in daily life activities, when they are disruptive to the engagement and participation of others, or when the behaviors place the child or others at risk for injury (*Case Study 13-1*). It is important for occupational therapists to be familiar with and skilled at using therapeutic strategies designed to prevent and reduce challenging behaviors to diminish the negative impact of such behaviors on the child's occupational performance. This chapter introduces behavior management concepts and presents evidence-based strategies for preventing and reducing challenging or unacceptable behavior in children.

Much of what is known about challenging behavior and the strategies to facilitate behavior change has emerged from the fields of education and psychology. In recent years, behavioral intervention methods have gained increasing popularity as their effectiveness has been demonstrated in programs for children with autism spectrum disorders and other conditions. Robust research investigating these methods provides a wealth of

knowledge that occupational therapists can apply to help understand why challenging behavior occurs, how to prevent challenging behavior, and how to intervene when a child exhibits challenging behavior.

Behavior Happens

Behavior is an expressive act by an individual that can have many different forms and meanings (*Figure 13-1*). Whether a certain behavior is appropriate and acceptable is dependent on the context and contextual norms for the given situation. For example, in a public school building, it would be inappropriate and unacceptable for a student to leave the classroom and go to the playground when the teacher passes out a work assignment; however, the same behavior would be appropriate and desirable in response to the recess bell or a clanging fire alarm. Similarly, it is considered inappropriate and unacceptable for a child to scream and withdraw when his or her dinner plate loaded with green beans is placed on the table, but screaming and withdrawal are acceptable and possibly even anticipated when a child receives an immunization shot. Humans are dynamic organisms with constantly active neurologic, physiologic, and physical systems who interact with environments, materials, and other dynamic organisms. With so many variables at play, the possibility of a mismatch between two or more variables is likely. When such a mismatch occurs between person and contextual variables, the likelihood of undesired or inappropriate behavior increases.³⁵

Inappropriate behavior can take many forms. Passive behaviors such as noncompliance, withdrawal, avoidance, inattention, and lack of response are not overtly disruptive but still interfere with occupational performance and participation. Active behaviors such as direct refusal to engage, opposition, aggression toward people or property, or self-injurious behavior not only interfere with occupational performance and participation, but can also be disruptive or harmful to self or others. Passive and active forms of inappropriate behavior can be difficult to manage and require attention and intention by caregivers and service providers.

Behavior Always has a Purpose

In many, if not most, daily situations, inappropriate or challenging behavior is seen as an inconvenience and an irritant to others in the surrounding environment. Have you ever been seated in a restaurant at a table next to a screaming toddler? Or in the movie theater behind a person using a cell phone?

CASE STUDY 13-1 Sam and Eli

Sam is a 2½-year-old boy who lives with his mother, father, and 6-year-old brother. Sam enjoys staying at home to play with his toys or watch movies. He plays by himself for unlimited periods of time. He spends many hours a day driving his cars and trucks back and forth while lying prone and watching the wheels turn. If his brother plays with the cars, Sam screams uncontrollably until the car is returned to him. Another of Sam's favorite activities is playing with balls. He pulls the basket of balls to the top of the stairs, where he bounces them off the wall and down the stairs into the family room over and over. If someone else retrieves one of the balls or tries to engage Sam in a ball game, an ear-piercing scream is heard before Sam deteriorates into a kicking, screaming tantrum.

Sam's brother, Eli, is 6 years old. He attends kindergarten 5 days each week, where he follows the classroom routine, engages with teacher-directed activities, and plays side by side with his peers. At home, Eli plays by himself for up to 30 minutes at a time. He prefers activities such as coloring and playing with dinosaur figurines. His favorite color is blue and his coloring pictures show all shades of the hue. His favorite dinosaur is a *Tyrannosaurus rex*, and Eli can recite a number of known facts about this creature. When a visitor comes to the family home, Eli inundates the person with incessant talk

about the *T. rex*. His eye contact is spontaneous but fleeting. He is easily distracted, looking away from a task to investigate all noise or movement around him. When approached by others, Eli gives a quick "Hi" and then directs his gaze to the person's shoulder and begins reciting facts about the *T. rex*.

Sam eats approximately 10 different foods. His diet is restricted by his own preferences for certain tastes and textures and also by intolerance for gluten. His mother is careful to prepare foods that are gluten-free and that she knows Sam will eat. He is able to use a spoon and fork moderately well but prefers to use his fingers for self-feeding. He refuses all fruits, vegetables, and dairy products. His mother has expressed concern about Sam's nutrition. His behavioral rigidity considerably affects the family's daily life. He does well on weekdays during the school year while his brother is at school. On school days, Sam accompanies his mother on errands to one familiar place at a time if his mother brings favorite toys and a snack. If his mother tries to combine two errands into one trip, Sam has tantrum and refuses to exit the car. Sam's behavior is much more erratic on weekends and holidays when the schedule is inconsistent and more people are at home.

Both Sam and Eli are diagnosed with developmental disabilities.

FIGURE 13-1 All behavior serves a purpose. A child ready to strike out could be acting aggressively, seeking attention, or protecting himself from a source of harm. Determining the purpose the behavior serves for the child is the first step in managing challenging behavior.

How about needing to get a child dressed to leave the house for a doctor's appointment, but when you try to help, the child repeatedly hits his or her ears?

To manage difficult behavior effectively, it is critical to remember that all behavior serves a purpose. The purpose of a given episode of challenging behavior can be most accurately identified only by the person executing the behavior. However, while engaged in challenging behavior, a child is unlikely to be in a state in which he or she can verbalize the purpose

FIGURE 13-2 The child in this figure is demonstrating two behaviors: crying and pointing. Crying often allows a person to avoid an undesired event, while pointing is a method of obtaining a desired item or event. (Photo © istock.com)

of the behavior. Decades of research has identified four primary purposes of challenging behavior: (1) obtaining a desired object or event; (2) avoiding a situation; (3) escaping from an undesired object, event, or demand¹⁴; and (4) sensory functions³⁰ (Figure 13-2).

These four functions may be influenced by a range of factors. Some of these are internal and emerge from a lack of skill or ability to perform in a desired manner. Others are external factors that are outside a child's control. Box 13-1 identifies

BOX 13-1 Factors That Influence Behavior**Internal Factors**

Desire for control
 Fatigue
 Illness
 Ineffective communication
 Pain
 Poor emotional regulation
 Poor self-regulation
 Poor sensory processing

External Factors

Task demands greater than skill level
 Change in schedule
 Unfamiliar person
 Unfamiliar place

some of the internal and external factors that can influence behavior.

Functional behavioral analysis (FBA) is a formal process for evaluating the factors influencing behavior to understand why a challenging behavior is occurring. It is widely used in school systems; the process is usually directed by professionals with specialized training in behavioral analysis methods. The FBA process aims systematically to identify a behavior's antecedents (events occurring before and triggering the behavior) and consequences (events after the behavior that reinforce the behavior). An FBA can be resource-intensive and often is reserved for situations in which extreme or dangerous behaviors are occurring. The formal FBA process is described later in the chapter. For less severe situations, a modified FBA can be conducted informally by determining mismatches between the person's skills and abilities and the contextual factors that are in effect when the challenging behavior occurs.

Being Prepared for Problem Behavior

To be best prepared to manage the range of behaviors likely to be experienced in a pediatric setting, the occupational therapist should give special attention to developing knowledge and skills specific to behavior management. This includes becoming familiar with a variety of general strategies that can be implemented to help create a context in which challenging behaviors are less likely to occur and more readily managed if they do occur. The following methods are suggested as general approaches to being prepared for problem behavior. These strategies are recommended as first steps in reducing the likelihood that problem behavior will occur. As a child grows and develops greater knowledge and skills, it is appropriate to adjust the type, structure, frequency, and intensity of supports provided.

Ruling Out Pain or Illness

Children experiencing pain or illness can act out in a variety of ways.³ Pain-based behaviors can be especially difficult to identify in children who are nonverbal. Behaviors associated with pain or illness may have a sudden onset, be associated with a certain body position, be cyclic, or occur frequently for no apparent external reason. If behaviors appear to be

associated with pain, the occupational therapist should work with the child's family and other service providers to determine whether the behavior is driven by pain and, if appropriate, should follow through with recommendations to remediate the source of pain.

Establishing Predictability and Consistency

Maintaining a consistent context in relation to schedule, environment, people, and demeanor helps allay a child's anxiety about what is going to happen next.¹³ When anxiety is diminished, the child has more resources available to direct toward self-management and productivity. Children are more successful when expectations, environments, people, and situations are familiar. As much as possible, the occupational therapist should work to increase the known and decrease the unknown. Strategies include scheduling activities in a similar order and location from day to day, keeping the physical arrangement and furnishings in the environment consistent, offering the same type of activities, establishing consistent social expectations, and arranging to have the same people interact with the child during the same activities.

Creating a Calm Atmosphere

Keeping the physical environment clean and organized creates a sense of order and predictability. Children know where to find desired items and which areas to avoid if certain items are off limits. In addition, maintaining a calm demeanor when mishaps occur can help minimize chaos and preserve a sense of order. Children often react to the stress and anxiety displayed by others with a disorganization of their own behavior. When adults remain calm, a sense of order is maintained, and the child is at ease.

Praise for Appropriate Behaviors

It is recommended that for every negative comment, a child should hear at least eight positive comments.¹⁶ Adults should consistently reward and reinforce appropriate behaviors by attending to them, complimenting the child on his or her behavior, and identifying specifically what the child did that was appreciated. Specific feedback can increase the child's awareness of the desired behaviors. Although general feedback can help a child build confidence in his or her ability to produce desired behaviors, specific feedback helps the child know exactly what to do the next time and increases the likelihood that the desired behaviors will occur again.

Using "Do" Statements

Similar to providing specific feedback, using "do" statements tells a child exactly what is desired. Rather than telling a child "Don't pull Susie's hair," the occupational therapist rephrases the statement to direct the child to do a behavior that is desired, for example, "Use your hands for nice touching." In contrast with the "don't" statement, the "do" statement appeals to the child's desire to please and helps keep a positive atmosphere. Modeling the instructed behavior while saying the instruction helps reinforce what is being communicated.

Keeping Perspective

Challenging behavior happens despite preventive measures. As children learn and grow through new stages of development and independence, they continually seek to discover where

CASE STUDY 13-2 Dominic

Dominic has an extensive collection of train engines that he keeps arranged in a row on his bedroom floor. A new train engine is a treasure to Dominic. He carries it with him for days after receiving it and carefully determines its placement in his collection at bedtime. His satisfaction with determining each train's placement is celebrated with laughter, clapping, and jumping. If the trains are disrupted, as when the floor is vacuumed, Dominic becomes upset, making guttural vocalizations of increasing intensity while rocking back and forth. When he recovers from being upset, Dominic meticulously works to ensure that each train engine is in the correct order and placement.

The challenging behaviors that Dominic displays when his trains are disrupted can be avoided by giving careful attention

to the situation. First, Dominic should be prepared in advance for the need to move the trains. For example, his mother should inform him that she needs to vacuum the floor and allow Dominic time to move his trains carefully on his own. Second, support and assistance should be offered when the trains are disrupted. For example, Dominic should be informed when the trains become disrupted, and the person responsible should offer to assist Dominic in replacing the trains. The assistance should be provided in a manner meaningful and acceptable to Dominic, whether it is handing the trains to him one at a time, pointing to the place in line where each train should be placed, or simply being near Dominic as he works on replacing each train.

limits exist, where their capabilities lie, and what they are allowed to do. It is important for the occupational therapist to be prepared to respond whenever the challenging behavior occurs so that expectations for appropriate behavior are quickly and effectively reestablished.

Behavior Management Approaches

Management of challenging behavior can take various forms, and the specific approach chosen will depend on the context, knowledge, skill, and available resources. Behavior management may occur at the individual level in the home, community, or clinic environment. School programs typically use a system-wide positive behavior support (PBS) approach to addressing challenging behaviors in children and youth. PBS combines a range of prevention and intervention methods to reduce challenging behaviors and increase appropriate behaviors.²⁷ The overarching goal of PBS is to improve quality of life for children. Many of the methods used in PBS are described below. Research support for PBS has demonstrated its effectiveness at reducing behaviors for children and youth who demonstrate disruptive or negative behaviors, those at risk of being identified as having a behavior disorder, and those with a variety of disabilities.^{4,5,9,21,26,34}

The PBS approach is described in more detail in the section on intervening when challenging behaviors already exist.

Three primary approaches to managing challenging behavior are presented in this chapter: (1) preventing challenging behavior from occurring, (2) supporting desired behaviors, and (3) intervening when challenging behaviors already exist. Strategies associated with each of these approaches are discussed in this section.

Preventing Challenging Behavior

Strategies for preventing challenging behavior are similar to the general strategies for supporting appropriate behavior described earlier. However, these strategies become extremely useful when a child is known to have a repertoire of challenging behaviors, and the goal is to prevent those behaviors from emerging.

Minimizing Aversive Events

Children often demonstrate inappropriate behaviors in response to events that they find aversive ([Case Study 13-2](#)).¹⁴ To minimize aversive events, situations and scenarios must be perceived through the child's eyes. In other words, the occupational therapist should think about what it is that the child finds aversive. Often, these are things that adults or other children do not consider problematic. Careful consideration of a particular child's temperament, personality, likes, dislikes, skills, abilities, and sensory processing tendencies can be helpful in identifying which conditions and events the child finds aversive. When an aversive condition is identified, minimizing the frequency, intensity, or duration of the condition can help reduce the child's reactive behaviors. For example, if a child is known to act out when he or she enters a classroom full of children, an adjustment can be made so that the child arrives earlier and enters a relatively empty classroom. Other examples include decreasing the amount of time that the child accompanies the parent on errands and reducing the volume at which the radio is played if these situations are known to result in displays of challenging behavior. If the correct events or conditions are not identified and addressed, no change in the behavior should be expected.

Sharing Control

Children often have very little control over their environments and the situations that surround them throughout the day. By allowing the child to choose activities, determine the order of events, or contribute ideas about what should happen, the occupational therapist can instill a sense of value and build self-esteem. The experiences of making acceptable choices, contributing to a collaborative effort, and giving valued input not only help the child feel important but can foster a sense of commitment to the therapeutic relationship. In turn, this can create the desire to preserve the relationship through effective and appropriate behaviors. See [Research Note 13-1](#).

Providing an Environment That Promotes Successful Engagement

Challenging behaviors often occur when a child is bored or unoccupied. Providing an environment that promotes

RESEARCH NOTE 13-1

Benefits of Providing Activity Choices

Rispoli, M., Lang, R., Neely, L., Camargo, S., Hutchins, N., Davenport, K., & Goodwyn, F. (2013). A comparison of within- and across-activity choices for reducing challenging behavior in children with autism spectrum disorders. Journal of Behavior Education, 22, 66–83.

Four children with autism whose challenging behaviors served the purpose of escaping from the task demands placed on them. Participants ranged in age from 5 to 11 years old. Two children were in self-contained classrooms, one in an inclusive classroom and one in a resource room setting. Data collection included in vivo recording for two students and video recording for the other two. Between one and five challenging behaviors were targeted per student. These included screaming, aggression, elopement, verbal protesting, delayed echolalia, and property destruction. During the baseline phases of the study, each child received adult-selected schoolwork to complete at a table. The work was removed for a brief period if the child demonstrated one of the target behaviors. During the intervention phases, the children experienced two different choice conditions. Each child was given the opportunity to choose (1) the type of schoolwork he or she would do while seated at the table or (2) the manner in which he or she would complete schoolwork selected by the adult. Available choices were location, materials, and vocal quality of spoken responses. The interventionist used prompting to encourage task engagement (baseline) or choice making (intervention) and positive reinforcement to acknowledge engagement or choice making. Data analysis revealed that all children displayed lower levels of challenging behavior when given choices for activities and methods of engagement.

Clinical Application

- Challenging behaviors often can be reduced by offering activity choices. Types of choices include the following:
 - Selecting between preferred and nonpreferred activities
 - Selecting the method of engagement, such as using crayons, markers, or chalk for writing or drawing
 - Selecting where to engage in the task—for example, completing puzzles on a swing or doing oral-motor activities while seated on a therapy ball
- Choices can be offered at the beginning of a session, allowing the child to help establish the sequence of activities to occur, or offered throughout a session, providing the child with multiple choice-making opportunities.

engagement can reduce boredom and thereby reduce occurrences of challenging behavior.¹⁵ Environments that promote engagement offer structured and unstructured activities that are appropriate to the child's level of development, are enjoyed by the child, and allow the child to experience success. Supplies and materials should be readily available to the child in locations that allow independent access (Figure 13-3). Strict rules about how and where materials are used should be relaxed to allow creativity and ingenuity. A child who is dynamically

FIGURE 13-3 Labeled bins that are positioned within easy reach for the child allow him to access materials without hindrance. This supports positive behaviors by increasing his independence.

engaged in productive activity is less likely to engage in inappropriate or challenging behaviors.

Increasing Communication Effectiveness

Children who do not have an effective means of communication often use behavior to deliver a message. Messages about pleasant experiences or enjoyable activities may be communicated through a smile, hug, or clapping. However, messages about pain, an undesired activity or location, frustration, or an unpleasant situation may be communicated through a variety of inappropriate methods such as screaming, hitting, throwing, or destroying property. Being attentive to a child's efforts to communicate is a first step in preventing situations that lead to frustration with communication barriers. Providing a means for the child to express positive and negative messages effectively and efficiently can reduce inappropriate behaviors associated with lack of functional communication.¹¹ Working with a speech-language pathologist to identify and implement the most effective and appropriate communication system is highly recommended. Strategies that can be helpful include using physical gestures or sign language and exchanging written symbols or icons. Strategies should be appropriate for the child's ability level and should be portable for easy accessibility in all environments and situations.

In addition to providing an effective means for the child to communicate, it is equally important that the child receive and comprehend messages directed to him or her. This responsibility often falls to the speaker because many children are not able to express that they do not understand a message. Awareness by the receiver that a message has been communicated but not understood can be very frustrating. When the message is not acted on, the sender becomes frustrated at the lack of response. The receiver is not only at a loss to decipher the message, but may also receive verbal and/or nonverbal communication about the sender's growing frustration. This scenario can result in increased anxiety, which may lead to behavioral outbursts. Using simple language to convey messages, allowing additional time for processing of information, and supplementing verbal information with gestures or visual information can increase the

FIGURE 13-4 By positioning himself on the child's level, the adult is better able to speak directly to the child. Simple language, allowing additional time for processing, and inclusion of gestural or physical cues can also promote effective communication and help to decrease challenging behaviors.

possibility that messages are received and understood by the child, reducing the likelihood of frustration and resulting behavioral reactions¹⁹ (Figure 13-4).

Clarifying Expectations

When activities or schedules are similar from day to day, assumptions may be made that expectations are known. Children, while sensing the comfort of a familiar environment, schedule, and social structure, do not necessarily attach performance expectations to environments or situations. Uncertainty about what is expected may lead the child unknowingly to act in inappropriate ways or to act out to test the limits. Many children respond best when rules are clearly established and limits are defined. Explicitly communicating expectations about what the child is supposed to do and how he or she is expected to act can alleviate any misconceptions or misunderstandings and help ensure that the child and therapist have the same expectations.³⁵

Supporting Self-Regulation

Many children who demonstrate challenging behaviors also have difficulty managing responses to environmental stimuli (see Chapter 9 on sensory integration). Ambient noise, flickering lighting, constant movement of others, inadvertently being bumped, and other unpredictable or intense environmental stimuli can be anxiety-producing for persons who are sensitive to these stimuli. The result can be physiologic overarousal such that the individual's sympathetic fight-or-flight response occurs. This response can manifest as behaviors such as aggression toward others, hyperactivity, violence, self-injurious behaviors,

BOX 13-2 Environmental Modifications to Support Child's Self-Regulation

- Minimize ambient noise by adding carpeting, closing the classroom door, turning off appliances, and/or removing fluorescent lighting.
- Reduce visual stimulation by removing decorations from walls, closing curtains on windows, closing the classroom door, and providing a study carrel.
- Reduce situations that may result in accidental bumping or brushing against the child. Pay attention to stationary activities as well as activities requiring movement.
- Create zones for specific types of activities (e.g., quiet work, messy work, moving bodies).
- Install dimmer switches for lighting.
- Provide a hideout so the child can withdraw from overstimulating conditions.
- Arrange seating to minimize the possibility of the child being bumped or jostled.
- Rearrange the schedule to allow moving through the school building or visiting a community location at a time when it is not crowded.

and immediate and intense withdrawal from the situation. For these children, disorganized behavior may be a precursor to problem behavior.

The occupational therapist should watch for disorganized behavior and help the child identify when behavior is becoming dysregulated. This may include informing the child of the disorganized behavior by specifically describing the behavior that was observed, identifying the context in which the behavior occurred, and describing what behavior would have been more appropriate to the context. In addition, the therapist should help the child develop a repertoire of more appropriate responses. Careful attention to and management of stimuli present in the environment can prevent the "fight, flight, or fright" response from occurring, allowing the individual to participate in the environment successfully. Box 13-2 identifies some suggested environmental modifications.

Matching Demands to Abilities

When performance demands exceed an individual's abilities, that person can become frustrated, angry, avoidant, or aggressive. Conversely, when performance demands are too low and do not match or challenge an individual's abilities, the person can become bored or uninterested in a task or activity. Either of these situations can result in challenging behavior as the individual expresses frustration with the mismatch between demands and abilities.¹ Creating individualized expectations and adjusting activities so that the child experiences an appropriate level of challenge can help alleviate frustration and create a just-right match between each child's performance demands and performance abilities (Figure 13-5).

Supporting Positive Behavior

Strategies for supporting positive behaviors can be powerful tools in preventing situations that elicit problem behaviors. Some of the strategies are global and can be particularly useful for group situations in which more than one child requires

assistance in managing appropriate behavior.²⁹ Other strategies are individualized to a particular child. All the strategies should be implemented consistently and predictably to create a context that supports the child's ability to be successful.

General Strategies

Meeting Sensory Needs

Sensory input is an inherent part of life. Every experience and situation is saturated with sensation. Sensory information is received, interpreted, and managed by the central nervous system through a variety of chemical and electrical mechanisms. The central nervous system produces behavioral and emotional responses to this input. When an individual's processing of sensory information is ineffective or inaccurate, erratic behaviors that are inappropriate to the context or situation can be displayed.² These behaviors can take many forms. Often, the

FIGURE 13-5 Therapists can easily adapt puzzles so that all children experience success by altering the complexity of the puzzle. This allows all children to participate.

behaviors can be identified as sensation-seeking or sensation-avoiding.¹⁰ Sensation-seeking behaviors result in an increased quantity or intensity of sensory input to the nervous system. In contrast, sensation-avoiding behaviors result in a decreased quantity or intensity of sensory input to the nervous system. In and of themselves, sensation-seeking and sensation-avoiding behaviors are not inappropriate, but they may occur with inappropriate intensity, at inappropriate times, and without regard for the safety of others or the environment. For example, a child who is seeking sensory input may frequently touch other objects or people, press so firmly with a pencil that it breaks, or hug others so tightly that they feel discomfort. In contrast, a child who avoids sensory input may attempt to leave the classroom if the overall sensory stimulation level of noise, lights, and activity becomes too high and may strike out at others if he or she is not allowed to withdraw from an overly stimulating environment. By being aware of and taking efforts to meet an individual's sensory needs, such situations can be avoided, allowing individuals to have greater success in interacting with the people, objects, and situations around them. This can be accomplished through a variety of strategies ranging from intense, one-on-one intervention to a range of sensory-based strategies that are embedded in the daily routine. An example of addressing challenging behavior by meeting sensory needs is presented in [Case Study 13-3](#). In addition, see [Chapter 9](#) for a discussion of sensory integration disorders and strategies to meet sensory needs.

Building New Skills

Children who have deficits in performance areas can become frustrated with the frequent experience of poor performance or lack of success. As noted, frustration can lead to a demonstration of undesired behaviors as a way of expressing or dealing with the frustration.¹⁷ Thus, it is important that occupational therapists incorporate efforts to build new skills into their intervention plans. When developing the intervention plan, those skills that appear to pose the greatest barriers to independence

CASE STUDY 13-3 Stephen

Stephen is a 10-year-old boy enrolled in the third grade. His teacher states that Stephen often has difficulty with attention to tasks, following directions, and completing his work. He constantly fidgets with his clothing and does not sit still in his chair. He is frequently sent to the principal's office for disrespecting a teacher's authority and having an uncooperative attitude. He often has a scowl on his face and does not greet others or participate in social interactions. His comments are negative and demeaning toward others. He does not receive compliments or praise but deflects these comments by highlighting a rule that was broken or promise not kept. A recent psychological evaluation resulted in a diagnosis of oppositional defiant disorder.

The classroom teacher requested an occupational therapy evaluation to address Stephen's difficulty in performing the handwriting required to complete his schoolwork. In addition to poor development of intrinsic hand musculature, the occupational therapy evaluation identified difficulties in processing visual, auditory, and tactile sensation such that behavior and

fine motor performance were affected. The occupational therapist recommended modifications to Stephen's classroom to address his sensitivity to bright lights, ambient noise, and unexpected touch. The placement of his desk was moved from the center of the classroom to the side, near the teacher's desk, a study carrel was brought into the classroom, and Stephen was allowed to wear sunglasses in class during work time. The occupational therapist collaborated with the classroom teacher to develop an activity plan incorporating regular opportunities for movement and physical effort to help meet Stephen's need for increased proprioceptive input. In addition, she conducted an in-service for the school staff, instructing them on the relationship between poor sensory processing and ineffective behavioral regulation, the importance of addressing sensory needs as a first step in helping children regulate behavioral responses to others more effectively, and the need to teach and reinforce those behavioral skills intentionally that the child needs to develop.

BOX 13-3 Skills That Promote Social Participation

Communicating wants, desires, dislikes
 Compliance with requests
 Cooperation with adults and peers
 Flexibility
 Giving an object on request
 Independent play
 Ability to initiate
 Ability to sustain
 Ability to conclude
 Making choices
 Parallel play
 Social play
 Variety in play
 Sharing
 Turn-taking
 Waiting

in self-care, physical mobility, play, or education are often prioritized. However, it also is important to include the development of skills that enable the child to experience success in the regular daily occupations of social interaction and participation. [Box 13-3](#) identifies skills that are easily overlooked but are important to social participation. These should be incorporated into the occupational therapy intervention plan in an effort to build new skills and reduce frustration and the resulting problem behaviors.³⁵

Specific Strategies**Increasing Compliance Through Contingency Methods**

Many children resist engaging in tasks that they do not enjoy. Resistance can take many forms, including, but not limited to, withdrawal, refusal, avoidance, and aggression. Contingency methods such as offering rewards or using a token economy can help elicit participation in nonpreferred activities. Contingency methods are based on the principle of allowing access to a desired event contingent on performance of or compliance with a directive, instruction, or rule. For example, during intervention, a child who enjoys blowing bubbles would be allowed to play with bubbles only after he or she has completed a therapist-directed task, such as pencil and paper work. Contingency approaches are commonly used in everyday life for children; for example, access to outdoor play is not granted until the child puts on a coat, or dessert is not served unless the child finishes dinner ([Figure 13-6](#)). By withholding the desired item or activity until after the child completes the mandatory task, motivation is increased and compliance is gained.

Use of contingencies can be complicated when a child unfamiliar with contingencies tries to negotiate the demands or displays undesired behaviors in an effort to avoid the contingency. It is important that the therapist avoid engaging the child in power struggles during these times. Instead, the adult should, in a matter-of-fact manner, adhere to the contingency in place and ensure that the child does not gain access to the desired event or activity unless the required task is completed.

FIGURE 13-6 The child in this figure is resistant to using tools, including paintbrushes. Her typical approach is to fingerpaint. The adult is positioned close enough to the child to facilitate the required behavior of paintbrush use, after which the child is allowed to fingerpaint.

Token Economies

Token economies are similar to withholding strategies but are more complex. A system in which the child earns tokens for desired behaviors is established and taught. Examples of behaviors that are reinforced are compliance with a rule, completion of a certain task or part of a task, and keeping hands out of the mouth. The tokens can be exchanged for privileges such as 2 minutes of play with a preferred toy, a piece of candy, or the opportunity to play a game on the computer. In essence, certain privileges are withheld from the child until he or she has sufficient tokens to buy them. The tokens are earned through performance of desired tasks, engagement in prescribed activities, or demonstration of an appropriate behavior. In establishing the token economy, the specific behavior for which tokens can be earned should be specified, as should the number of tokens each behavior is worth. For example, a child might earn one token for engaging in seat work for 3 minutes without needing redirection, or earn two tokens for spontaneously sharing art supplies with another child ([Figure 13-7](#)). In addition, the privileges or items that the child can purchase with the tokens and the cost of each should be established at the outset of establishing the token economy.

The complexity of token economies can be adjusted depending on the child's developmental and cognitive age. A very simple system may involve merely the earning of tokens and purchasing of rewards, whereas a complex system may incorporate having the child relinquish tokens for episodes of undesired behaviors ([Case Study 13-4](#)). In one type of system, the child earns one color of token (often green or white) for desired behaviors and another color (often red) for undesired behaviors. The tokens for desired behavior have purchasing value, and those for undesired behavior decrease purchasing value. For example, a child might earn one green token for each 2 minutes that he or she remains seated during independent work time and one red token each time he or she moves out of the chair. At the end of a 10-minute work period, the child has four green tokens and two red tokens. Each red token cancels out one green token, leaving the child with two tokens for that period of time.

CASE STUDY 13-4 Stephen

In addition to addressing Stephen's sensory needs, the occupational therapist worked with Stephen and his teacher to develop a behavior contract outlining expectations for appropriate interactions with the teacher, school staff, and other children. The contract includes a token economy and specifies the positive behaviors that Stephen is expected to display. He earns a green token for each desired behavior, a red token for undesired behavior, and specific graduated consequences for not abiding with the contract. Green tokens are earned for specific occurrences of appropriate interactions with others

and for maintaining an appropriate on-task classroom behavior for a specified duration of time. Red tokens are given to Stephen for occurrences of inappropriate social interactions, off-task behavior, swearing, and noncompliance with the teacher's instructions. Tokens are counted and exchanged at the end of each school day for a choice from the school prize box, 5 minutes of free choice from a specified set of activities, or opportunities for special activities, such as ice cream with the principal.

FIGURE 13-7 A token board is a variation on the token system. The child earns one token for a specified amount of work such as putting one piece in a puzzle. Once the token board is full, the child earns the opportunity to engage with the activity represented in the picture.

Positive Reinforcement

Positive reinforcement is a specific strategy that has been established as a powerful behavior change technique. Positive reinforcement is the contingent presentation of a type of consequence that when presented immediately after a behavior, increases the probability of that behavior occurring again.²⁴ In other words, a consequence that strengthens a behavior functions as a positive reinforcer for that behavior. Consider the mother who gives in and hands her child a cookie to stop the crying that began when the mother first denied the child's request for the cookie. Although the mother's purpose in giving the cookie was to stop the crying, the crying resulted in the child obtaining a desired object. In other words, from the child's perspective, the crying worked. The likelihood that the child will behave in the same manner in the future (crying) has been increased by the positive reinforcer (obtaining the cookie). The power of positive reinforcement to effect behavior change has more than 40 years of empirical support^{22,23,37-39}; however, occupational therapists typically are not trained in these techniques.³⁶ Strategic and effective use of positive reinforcement can increase desired behaviors and reduce challenging

behaviors, thereby supporting client engagement in therapeutic activities.

Alternate Preferred and Nonpreferred Activities

At times, all children need to participate in or complete tasks or activities that they do not enjoy. Attempts to gain the child's compliance in a nonpreferred task can lead to opposition, withdrawal, or outright refusal. If the adult keeps pressing the child to comply, challenging behaviors can escalate. One strategy for gaining compliance is to alternate the nonpreferred activity with one or more preferred activities. This strategy is similar to the contingency approaches in which a desired activity or event is withheld until the child performs a therapist-directed task. To implement this strategy successfully, the nonpreferred activity should seamlessly follow the preferred activity and should be presented in a matter-of-fact manner that does not highlight the child's lack of preference for the activity. By strategically and seamlessly sequencing the nonpreferred activity to come immediately after a preferred activity, the child is more likely to comply because the activity seems to flow from the one that was just completed ([Case Study 13-5](#)).

Addressing Transitions

Transition between activities or environments can be a particularly problematic time during which challenging behaviors emerge. In school situations, the classroom schedule often dictates when children transition between activities. Adults have strategies such as watching the clock and having an awareness of how much time has passed, which helps them anticipate a pending transition. Children do not have the same strategies, and transitions can appear to be arbitrarily imposed. Some practical strategies can support children to anticipate and make transitions; these help minimize noncompliance, refusals, or behavioral outbursts.

A *transition routine* can help set the stage for a positive transition. Transition routines consist of using the same set of events each time a transition needs to occur. Singing a particular song and using a hand-clapping pattern are simple, distinct events that can be used to signal transitions. Using the same strategies for each transition provides familiarity, establishes context, and communicates expectations, all of which can help children transition successfully ([Figure 13-8](#)).

Visual schedules are a commonly used and effective method for supporting successful transitions.^{8,33} These are particularly useful in situations in which the schedule remains relatively similar from day to day or week to week or to represent changes

CASE STUDY 13-5 Anastasia

Anastasia is a 5-year-old girl with a diagnosis of developmental delay. She demonstrates many signs of sensory processing disorder, including sensory-seeking behaviors, distractibility, and high frequency of movement. These behaviors result in poor engagement in tabletop activities. Anastasia's mother has brought her to occupational therapy with concerns about readiness for school, specifically her unwillingness to engage in pencil and paper activities. During the evaluation, Anastasia refused to complete the writing activities on standardized testing of fine motor and visual-motor skills. During observations, Anastasia used a static tripod grasp while drawing on a chalkboard. She approximated continuous circles, but no other shapes. Her attention was fleeting and she did not return to the chalkboard spontaneously or on request.

Evaluation results identified significant deficits in fine motor and visual motor skills as well as poor processing of vestibular, tactile, and proprioceptive input. The occupational therapist began intervention using a sensory integration approach. As part of therapy sessions, Anastasia participated

in obstacle courses in which she was challenged to push, pull, climb, swing, jump, ride a scooter board around obstacles, and crawl. As Anastasia's distractibility decreased and her willingness to engage in therapist-directed activities increased, the occupational therapist began to incorporate pencil and paper tasks into the obstacle courses. After using a hand-over-hand motion to pull herself up a ramp while riding prone on a scooter board, and then jumping off the ramp platform into a mountain of pillows and crawling through a tunnel, Anastasia sat on a therapy ball and drew straight lines on paper mounted on a slant board. Anastasia was not allowed to continue the obstacle course until she completed the pencil and paper task. Over time, the occupational therapist gradually increased the complexity of drawing, duration of the drawing task, and quality of work expected. As she alternated between the sensory-based activities she needed to become prepared and organized for table work with the table work activities, Anastasia's willingness to engage and her duration of engagement increased, allowing her to develop new skills.

FIGURE 13-8 This class of students is engaged in a song accompanied by clapping, which indicates that it is time to transition from circle time to the next activity.

in the schedule for a child who has difficulty tolerating change. Picture icons or word cards can be arranged on a schedule board to represent the sequence of activities or events that is going to occur. Children can follow the visual representation of the sequence. Depending on a given child's abilities, he or she can learn to use the visual schedule independently, consulting it when one activity is completed or when a transition is indicated. Some visual schedules merely represent activity sequences, with no time allotted. Other schedules are time-based and indicate the day of the week, time of day, and activity that will be occurring. Many visual schedules use removable cards so that the schedule can be modified easily if the schedule changes. Some schedules are written on poster

board mounted to the wall; others are secured in a binder or notebook that is easily transported from one setting to another. The form of the schedule and amount of support given to the child in using the schedule are individualized to the child's capabilities.

Timers provide an objective signal that something is about to occur.¹² Once it is set, a timer operates independently of an adult, so the implication that changes are arbitrarily imposed by the adult is reduced. To implement the use of a timer, the occupational therapist shows it to the child and informs him or her about what will happen (e.g., "The timer will make a beeping sound. When you hear the beeping sound, it will be time to clean up the blocks and come to the table for snack"). The occupational therapist trains the child on how to turn the timer off. When the timer signals, the occupational therapist cues the child that the timer is beeping, helps the child turn off the timer, and reminds the child what the sound meant (Case Study 13-6).

Once an occupational therapist establishes use of the timer, it can be applied in a variety of contexts and situations. Children can learn to operate the timer themselves as a way to self-monitor use of time and compliance with time limits. Alarm clocks can be used in a similar manner as timers to indicate events that occur at a specific time of day, such as time to go to the bus stop, time to get ready for bed, and time to leave for an appointment.

Another strategy for supporting transitions is the use of *representational objects*. In this method, concrete objects that clearly represent the various activities or events that make up the child's day are assembled. When the child needs to transition to a new activity, he or she is shown or given the relevant representational object and a simple verbal instruction. For example, the occupational therapist may hand the child a crayon and say, "It is time for art." The child may take the object and carry it to the location where the next activity will occur. The use of representational objects is flexible and can be paired with the other strategies of transition routines, visual

CASE STUDY 13-6 Meg

Meg is a 4-year-old girl with autism. She enjoys playing with alphabet blocks and her toy piano. Meg has extreme difficulty concluding her play to transition to a different activity. When a transition is imposed on her, Meg demonstrates one of two predictable responses: a complete lack of response, as if she did not hear the instruction, or extreme refusal to transition, expressed by screaming and stamping her feet. At times, the behavior can escalate into a full-blown tantrum including hitting, kicking, dropping to the floor, and throwing toys.

Meg is enrolled in a preschool classroom for children with developmental disabilities. Transition between activities occurs multiple times each day as the children engage in different play centers, circle time, snack time, and outdoor play.

Meg's difficulties with transitions often disrupt the class. The occupational therapist works with Meg on a weekly basis and introduces a timer to help her learn how to conclude an activity. Within 3 days, Meg consistently responds when the timer signals. She alerts to the sound, discontinues her activity, and turns the timer off. Sometimes she returns to her activity and reengages, but when cued by the teacher or occupational therapist, she is able to transition to the next activity. By the end of nine school days, Meg reliably alerts to the sound of the timer, discontinues her activity, and consults a visual schedule to determine what she is to do next. She then activates the timer for a preset duration of time and transitions to the activity indicated on her schedule.

schedules, and timers in the manner that best supports the child's success.³³

General Support Strategies

Many challenging or inappropriate behaviors can be ameliorated through the use of general positive strategies. These strategies are examples of the therapeutic use of self.

- Providing extra time for a child to process a verbal instruction or organize an appropriate response to a stimulus can alleviate anxiety and stress and the resulting behavioral reaction.
- Providing encouragement that communicates belief in the child's ability to succeed can improve self-esteem and a sense of self-worth.²⁵
- Giving explicit instructions on how to approach or complete a task can alleviate fears of failure that may cause a child to withdraw or disengage from an activity.
- Providing specific feedback about the child's efforts and what could be done differently next time can also build confidence and motivate a child to try again, rather than walk away from a task with a feeling of despair.

The occupational therapist uses the therapist-client interactions strategically to support the child in whatever challenge he or she is experiencing and to communicate belief in the child's ability to achieve his or her desires. Effective therapeutic use of self leads to a partnership between the occupational therapist and client that is empowering and encouraging.³² The power of these experiences can help prevent misbehaviors that are associated with feelings of despair and low self-esteem.

Intervening When Children are Known to Have Challenging Behaviors

When challenging behaviors are known to exist, the occupational therapist should collaborate with the child's caregivers and other service providers to understand the frequency, intensity, and purpose of the behaviors before intervening. It is important that the team of service providers have a unified approach across environments and providers to address the behavior most effectively and efficiently. Because all behavior serves a purpose, it is critical that the intervention be preceded

by a systematic evaluation of the behavior. This systematic process identifies the function of the behavior and contextual factors that support and maintain the behavior, both of which are crucial for selecting relevant interventions. Systematic evaluation of the behavior is best accomplished through an FBA. An FBA is one component of a comprehensive approach to behavior management (PBS).

Positive Behavioral Support

Positive behavioral support encompasses a range of positive behavioral interventions that aim to reduce challenging behaviors while promoting development of socially important behaviors. The overarching goal of PBS is to improve the quality of life for children by increasing desired behaviors and reducing challenging behaviors.^{6,31} The primary strategies of PBS emerged through decades of educational research and involve environmental adjustments of those factors that may trigger, reinforce or maintain the challenging behaviors.²⁸ Sugai and colleagues³¹ identified four foundations of PBS that govern its use. PBS is based on *behavioral science* and emphasizes the relationships between behavior and environmental factors and the belief that human behavior can be changed through manipulation of those factors. The PBS approach uses *practical interventions*, such as redesign of environment or curriculum, to address the goodness of fit between contextual factors, problem behaviors, and the interventions implemented.¹ For PBS to be considered effective, the *outcomes* must be socially significant, and behavior must change to a degree that enhances the quality of life of the individual. In addition, PBS adheres to a *systems perspective* that addresses the multiple contexts and social partners of the individual, as well as the policies that govern each context. See [Research Note 13-2](#).

PBS can have a highly significant and positive effect on reducing the behavioral challenges of students with disabilities in schools.⁵ The Individuals with Disabilities Education Act (IDEA) amendments of 1997, which were reaffirmed in 2004,²⁰ specifically identify PBS as an effective preventive program for children whose behaviors impede their own learning or the learning of others (20 U.S.C. § 1414(d)(3)(B)(i)). The use of behavioral interventions within a PBS model is always based on an FBA, a systematic process that analyzes problem behavior to define the behavior operationally, identifies the events that

RESEARCH NOTE 13-2

Effects of Positive Behavioral Support

Chitiyo, M., Makweche-Chitiyo, P., Park, M., Ametepee, L. K. & Chitiyo, J. (2010). *Examining the effect of positive behavior support on academic achievement of students with disabilities*. *Journal of Research on Special Educational Needs*, 11, 171–177.

In a meta-analysis of studies published from 1996 to 2006, Chitiyo et al.⁷ found support for a relationship among problem behavior, positive behavior support, and academic performance. Five published studies met the inclusion criteria and were included in the analysis. The resulting population was 25 participants between 5 and 14 years of age with diagnoses of attention-deficit/hyperactivity disorder (ADHD), autism, developmental disorder, emotional and behavior disorders, and students at risk of delay. Inclusion criteria required that the studies addressed problem behavior in school settings, used positive behavior support at an individual or classroom-wide level, and measured behavior and academic performance. Results identified a positive correlation ($r = .40$) between behavioral outcomes and academic achievement, suggesting that as problem behaviors improved, so did academic performance. Outcomes were more favorable for participants with emotional or behavior disorders and those with ADHD.

Application to Practice

- Positive behavior supports can support positive outcomes in academic performance. In addition to measuring change in students' challenging behaviors, occupational therapists should include cognitive outcomes when measuring the effectiveness of these strategies within classroom and school-wide intervention programs.
- Positive behavior supports produced stronger effects in behavior change and academic performance for students with emotional and behavioral disorders and those with ADHD. Careful consideration of client characteristics is warranted when considering PBS as an intervention and developing goal statements for measuring progress.
- Students with autism demonstrated milder changes in response to positive behavior support strategies, so it may be important to include PBS as only one component of a comprehensive program of intervention to support students with autism.
- Individual outcomes should be closely monitored and the intervention program modified if desired outcomes are not achieved.

reliably predict the occurrence and nonoccurrence of those behaviors, and those factors that maintain the behaviors across time.³¹ FBA is mandated by IDEA in the following situations:

- A child who does not have a behavior intervention plan is removed from their current placement for more than 10 school days (e.g., suspension) for behavior that turns out to be a manifestation of the child's disability (20 U.S.C. § 1415(k)(1)(F)(i)).
- (It is) appropriate to address any behavior that results in a long-term removal (20 U.S.C. § 1415(k)(1)(D)).

As a systems-wide approach, PBS includes three levels of strategies.²⁸ The first level aims to *prevent* challenging behaviors from occurring. Strategies may include creating an organized environment to support learning, arranging the physical environment to promote engagement and positive behavior, and providing instruction in communication and social skills to support social interaction and participation. If challenging behaviors emerge or continue after the first wave of supportive strategies are in place, more targeted methods are used. This second level of intervention may include group instruction in school success strategies or skill development, establishment of a support network throughout the school, or implementation of corrective teaching. A third level of intervention is implemented on a student-by-student basis for challenging behaviors that are resistant to the first two levels of intervention. This level of intervention provides intensive individualized strategies, including the following: (1) an FBA resulting in a comprehensive behavior plan, (2) implementation of targeted methods during daily routines and activities to decrease challenging or interfering behaviors, and (3) further development of communication and social skills to support participation. The Evolve site lists resources for positive behavior support.

Functional Behavioral Analysis

FBA is a five-step process consisting of the following: (1) team building and goal setting, (2) functional assessment of the behavior, (3) hypothesis development, (4) development of the comprehensive support plan, and (5) implementation and outcome monitoring of the plan, including refining the plan as needed.⁴ Occupational therapists may be part of the FBA process because they often have personal knowledge of the client and direct experience with the targeted behavior. Each of the five steps of the FBA process is described briefly here.

The first step of the FBA process is to gather a team of individuals who collaborate to work together for the child's best interest. Ideally, the team includes the child's parents or caregivers as recognized experts on the child and as partners in the intervention process. Together with the caregivers, the team works first to identify desired outcomes for the child.⁴ Team planning considers the child as a "whole" person, including the child's capacities and areas needing further development. This process creates a foundation on which the intervention and support plans are built.

The second step involves the comprehensive functional assessment of the specific behavior. Efforts focus on clearly describing the challenging behavior, the context(s) in which it occurs, antecedents and consequences that maintain the behavior, and functions of the behavior. The goal of this step is to understand the purpose of the behavior and determine when the behavior is most or least likely to occur. Data collection is the best method for understanding the purpose of the behavior and the events that maintain the behavior. Data can be gathered by interviewing people who have direct knowledge of the child and experience with the behavior, observing the child where and when the behavior is most likely to occur, reviewing records in which the behavior has been documented, and gathering information about contextual variables such as health or changes in other environments or activity schedules.

The third step in the FBA process is to develop hypotheses about the behavior, including the antecedents (factors that

trigger the behavior), consequences (responses to the behavior), and function of the behavior (e.g., requesting something, avoiding or escaping from something, meeting a sensory need). Hypotheses statements are generated based on the information gathered in the second step.

In the fourth step, a comprehensive behavior support plan is developed. The plan itself has four elements: (1) functional assessment of behavior, including hypothesized functions of the behavior; (2) specific individualized intervention strategies to be used; (3) strategies to be applied throughout the day; and (4) evidence that the plan is consistent with the values and resources of the child receiving support and of those providing support.¹⁸

The collaborative effort of the team to gather data about the behavior and develop hypotheses about the function and reinforcing events surrounding the behavior is used to understand the behavior and functional purpose that it serves for the child. This understanding is used to develop the intervention component of the plan, which includes positive behavioral strategies aimed at preventing the challenging behavior from occurring and strategies aimed at helping the child develop new skills that effectively and efficiently achieve the same function as the challenging behavior. The new skills are taught to the child as replacement strategies for the

challenging and undesired behavior. The PBS plan may incorporate the strategies identified earlier in this chapter if they are appropriate for the factors that are influencing the target behavior(s). The plan also includes contingencies for the challenging and replacement behaviors. The contingencies for demonstration of the replacement behavior are designed to reinforce and strengthen use of the new behavior, whereas the contingencies for the challenging behavior are designed to discourage its use.

The final step of the PBS process is implementation of the plan and measurement of outcomes. Once the plan is developed, it is tested for goodness of fit with the personal, physical, and social contexts of the child, family, and other service providers to ensure that all persons involved in implementing the plan are equally comfortable using the plan in their respective situations. Ensuring goodness of fit is a critical step in increasing the likelihood that the plan is used.

As the plan is implemented, the team evaluates the effectiveness of the plan in producing the desired results: reduction of the challenging behavior and demonstration of the replacement behaviors. The team meets periodically to review the plan's effectiveness and the child's progress. Modifications and adjustments are made as needed, followed by implementation and monitoring of the revised plan ([Case Study 13-7](#)).

CASE STUDY 13-7 Jessie

Seven-year-old Jessie was suspended from his second-grade classroom because of uncontrollable aggressive outbursts that included yelling at the teacher, refusing to complete schoolwork, overturning desks, and throwing school supplies. The behaviors had been building throughout the fall and culminated with punching the teacher in early December. An FBA was initiated in November and revealed that Jessie's behaviors escalated when work demands involved extended writing and during collaborative group work activities. The occupational therapist had observed Jessie's handwriting abilities in October at the request of the classroom teacher. Jessie used a mature tripod grasp, formed letters correctly, and exhibited good upper extremity positioning and postural support for handwriting tasks. Jessie performed handwriting activities without difficulty when copying from a sample or when writing personal information, such as his name. The occupational therapist observed signs of anxiety when Jessie was asked to write creatively, documenting that he "seemed unable to generate ideas or topics to write about and he became flushed, fidgeted with his pencil, and stated that the assignment was 'stupid.'"

During the FBA, it was discovered that signs of anxiety often preceded Jessie's behavioral outbursts and that the outbursts were worse later in the day, during the creative writing lessons. Jessie also showed signs of anxiety during collaborative work activities. When group work was assigned, Jessie fidgeted with materials in his desk and did not join his group until specifically instructed by the teacher. He did not join in the group discussions or participate in work activities. Rather, he remained at the fringe of the group. If his participation was requested by a peer or instructed by the teacher, Jessie shifted his weight and looked around anxiously, often giving

excuses for not working. If pushed to participate, he verbally refused with increased vocal intensity and volume, and sometimes shoved a desk or chair. The FBA team hypothesized that the behaviors were a result of poor ability to cope with anxiety and that writing and social situations were anxiety-producing for Jessie.

The FBA team worked together to develop a plan to match writing and social demands to Jessie's abilities better, provide support during writing assignments, and provide intervention to develop social skills that would support his ability to participate in group learning activities.

In addition to modifications the teacher made to assignments, the occupational therapist provided recommendations for modifying the classroom environment to decrease anxiety-producing situations and add coping supports. She also designed a program aimed to help Jessie develop improved self-regulation of behavior, body scheme, fine motor coordination, and social skills. Some classroom-wide strategies included seated isometric exercises for the entire class at key times during the school day, regularly scheduled dimmed lighting and whispered voice times, and a "cozy corner" for independent use by students. The occupational therapist also worked with Jessie, his teacher, and the school counselor to identify two peers with whom Jessie could work to build his social skills. She provided training sessions with the students, teacher, and counselor, including instruction on teamwork, complimenting, turn-taking, and collaboration. Data collection forms were used to track Jessie's behavior. A change in the frequency and intensity of Jessie's behavior was seen almost immediately, and within 3 weeks of implementing the program, Jessie's inappropriate behavior had diminished to occasional verbal outbursts, with no physical aggression.

Summary

- Challenging and inappropriate behaviors are demonstrated by children with a wide range of developmental disabilities and can interfere with engagement in occupation, prevent participation in context, and create situations that are potentially harmful.
- Intervention includes prevention of challenging behaviors, support of positive behaviors, and system-wide and individualized interventions for existing problem behaviors.
- Challenging behaviors always have a function, and understanding that function is the first step of planning intervention. When problem behaviors exist, reducing the problem behavior should be a primary focus of occupational therapy intervention.
- Using familiar activities in a predictable sequence can be an effective strategy for reducing the anxiety that often precedes inappropriate withdrawal, refusal, or aggressive behaviors.
- Effective management of challenging behavior includes not only improving an individual's behavioral competence, but also creating contexts that support positive behaviors and intentionally managing consequences.
- A child with poor sensory processing and integration may have considerable difficulty regulating behavior in highly stimulating environments. Addressing a child's sensory needs can be a key part of a program to prevent challenging behaviors.
- Contingency methods in which a child gains access to a preferred activity, object, person, or event only after engaging in or completing a specified activity can be useful in helping the child build or develop new skills. Use of contingency methods must be individualized and customized to the child and to the behavior being addressed.
- The therapeutic use of self, which is an inherent part of occupational therapy service delivery, is an essential aspect of building therapeutic relationships that support positive behaviors. Occupational therapists working with children with challenging behaviors should be intentional about building the therapeutic relationship and using it as an intervention strategy.
- Because all behavior is purposeful, it is important to analyze and identify the function of each challenging or undesired behavior systematically using a functional behavior analysis. Occupational therapists can participate in this process by contributing their observations of behavior and its relationship to occupational performance and contextual factors for the individual child.
- Occupational therapists have knowledge and skills in task analysis, human behavior, and occupational engagement and participation, enabling them to collaborate with caregivers and other service providers effectively to analyze problem behavior, develop behavioral intervention plans, and implement behavior management strategies. These attributes make occupational therapists key contributors to designing and implementing positive behavioral support programs in home, school, and community environments.

CHAPTER

14

Feeding Intervention

Kimberly Korth • Lauren Rendell

KEY TERMS

Aspiration	Gastroesophageal reflux
Cleft lip and palate	Gastrointestinal endoscopy
Differential attention for behavioral intervention	Gastrostomy tube
Dysphagia	Laryngeal penetration
Esophageal motility	Modified barium swallow study
Esophageal pH probe	Nasogastric tube
Food or liquid bolus	Phases of swallowing (oral preparatory, oral, pharyngeal, esophageal)
Fiberoptic endoscopic evaluation of swallowing (FEES)	Rooting reflex
Gastric emptying or gastric motility	Tracheoesophageal fistula
	Upper GI series

GUIDING QUESTIONS

1. Which medical conditions are commonly associated with feeding and swallowing disorders?
2. Which cranial nerves influence oral motor control and swallowing?
3. What are the typical developmental sequences for oral feeding and self-feeding skills?
4. How do occupational therapists evaluate feeding, eating, and swallowing?
5. What are the supplemental diagnostic tests used to evaluate underlying causes for feeding disorders?
6. What are the major components of a comprehensive intervention plan for pediatric feeding, eating, and swallowing problems?
7. How does positioning influence self-feeding and swallowing skills?
8. Why do occupational therapists modify foods and liquids in the feeding intervention plan?
9. What are the theoretical principles and strategies associated with behavioral interventions for selective eating or food refusal?
10. What are the safety considerations for occupational therapists working with children with feeding and swallowing disorders?

The process of feeding, eating, and swallowing is critical for health and wellness and plays an integral part in a child's social, emotional, and cultural maturation. At the most basic level, the process of taking in adequate nutrition is essential for normal growth and development. Feeding, eating, swallowing, and

participation in mealtimes are all important occupations for infants and children.

Feeding, eating, and swallowing are complex processes, with multiple underlying medical, sensory, motor, behavioral, positioning, and environmental influences. A holistic approach is required during evaluation and intervention planning, often accompanied by collaboration with other professionals. This chapter will assist the occupational therapist in recognizing and understanding these complex processes and underlying influences to help develop safe and effective intervention plans.

Feeding: Definition and Overview

Throughout childhood, from infancy through adolescence, dietary requirements are constantly changing. At the same time, a child's feeding development gradually moves from complete dependence toward independent self-feeding. This dynamic process is integrally dependent on the acquisition of a multitude of skills, including overall muscle tone and stability, gross motor and upper extremity development, fine motor skills, and complex oral motor and swallowing skills. Mealtimes allow a child to explore new tastes and textures while concurrently encouraging the development of motor skills through finger feeding and the use of utensils.

Of equal importance, the feeding process is marked by social contact with other children, parents, and family members, and it is essential for the development of social interaction skills in the child. Children learn to communicate needs and desires through verbal and nonverbal cues. Feeding is one of the earliest instances in a child's life in which he or she learns to signal needs and desires, such as hunger, satiety, and thirst. Finally, because this complex process is shaped by cultural and social norms, it often lays the foundation for the acquisition of certain customs and rules of sociocultural behavior.

Feeding—sometimes called *self-feeding*—is defined as the process of setting up, arranging, and bringing food from the table, plate, or cup to the mouth. *Eating* is the ability to keep and manipulate food or fluid in the mouth and swallow it. *Swallowing* is a complex act in which food, fluid, medication, or saliva is moved from the mouth through the pharynx and the esophagus and into the stomach.⁴

Incidence of Feeding Disorders

Feeding and swallowing disorders are relatively common among children. Feeding and swallowing problems are reported in 10% to 25% of all children, 40% to 70% in premature infants, and

70% to 80% in children with developmental delays or cerebral palsy.^{43,44,48,52} Feeding and swallowing disorders can have significant health implications, including adverse effects on nutrition, overall development, and general well-being.

Common Medical Diagnoses Associated with Feeding Disorders

Children develop difficulties with feeding, eating, and/or swallowing as a result of medical, oral, sensorimotor, and behavioral factors, either alone or in combination.⁴⁴ A variety of medical conditions can influence a child's ability and willingness to participate in oral feeding. Some of the most common medical diagnoses associated with feeding dysfunction include prematurity, neuromuscular abnormalities, structural malformations (such as cleft lip and/or palate), gastrointestinal conditions, visual impairments, and tracheostomies. The diagnosis of autism spectrum disorder (ASD) has a high prevalence of feeding difficulties due to sensory, motor, or behavioral challenges influencing the child's food preferences and willingness to eat.

Children with developmental disabilities may fail to meet basic nutritional needs because of delayed or deficient oral motor and self-feeding skills. Oral motor dysfunction causing poor nutrition is strongly associated with poor growth and adverse health outcomes.^{24,51} These children may exhibit food refusal or selectivity behaviors, vomiting, swallowing difficulty, prolonged mealtimes, poor weight gain, and failure to thrive.

Behavioral problems are very common in children with feeding disorders. Food refusal and/or food selectivity can relate to multiple factors, including anxiety, hypersensitivities, behavioral rigidity or need for routine, or behavior dysregulation. Selective eating may also relate to underlying medical causes, such as gastroesophageal reflux disease (GERD) and food allergies.

A child who has frequent or chronic vomiting after feeding may be diagnosed with GERD. It is important to note that reflux is not uncommon, and most babies spit up on an occasional basis as their gastrointestinal system matures. This occasional spitting up or vomiting is not harmful to the baby, and, generally, no adverse effects on feeding or growth should be identified. The infant likely will outgrow these symptoms as he or she gains postural control and stability and maturation of the gastrointestinal system. GERD becomes problematic, however, when chronic spitting up and vomiting leads to

problems with the infant's or child's health, ability to eat successfully, and poor growth or inadequate weight gain.³⁸

Food allergies are also a common medical condition that can influence a child's success with feeding. Food allergies may create significant discomfort, resulting in a negative experience associated with eating. Some of the most common food allergies include milk, eggs, soy, wheat, and peanuts. The presence of food allergies may cause esophagitis, vomiting, skin rash, itchiness, pain, breathing difficulties, and/or discomfort during eating, contributing to the child's unwillingness to eat and subsequent negative behavior.

Depending on the severity of a child's feeding dysfunction, children with medical, oral, sensorimotor, and/or behavioral factors may ultimately require supplemental enteral feeding support to meet his or her nutritional needs for adequate growth and development. This enteral feeding support can be delivered via nasogastric, gastrostomy, or orogastric tubes. For children needing sustained enteral nutrition support (longer than a few weeks), health care providers often recommend a gastrostomy tube, which is considered optimal for long-term use. The decision to provide enteral nutritional support for a child is often not easy and should be determined in coordination with the child's primary caregivers and medical team.

Feeding Development and Sequence of Mealtime Participation

Anatomy and Development of Oral Structures

Intact oral structures and cranial nerves are prerequisites for eating and drinking. Various aspects of oral motor development emerge as the child begins to control movements of the tongue, cheeks, and lips. The anatomic structures of the mouth and throat change significantly during the first 12 months of life. The growth and development of the oral structures allow for increasingly mature feeding patterns.

The oral cavity houses the structures that enable successful management of foods and liquids during oral feeding. These structures consist of the mandible, maxilla, upper and lower lips, cheeks, tongue, teeth, floor of the mouth, hard palate, soft palate, uvula, and anterior and posterior faucial arches and aid in sucking, biting, chewing, and food bolus formation in preparation for swallowing. Table 14-1 outlines the functions of oral structures in feeding.

TABLE 14-1 Functions of Oral Structures in Feeding

Structure	Parts	Function During Feeding
Oral cavity	Hard and soft palates, tongue, fat pads of cheeks, upper and lower jaws, and teeth	Contains the food during drinking and chewing and provides for initial mastication before swallowing
Pharynx	Base of tongue, buccinator, oropharynx, tendons, and hyoid bone	Funnel food into the esophagus and allows food and air to share space; the pharynx is a space common to both functions.
Larynx	Epiglottis and false and true vocal folds	Valve to the trachea that closes during swallowing
Trachea	Tube below the larynx supported by cartilaginous rings	Allows air to flow into bronchi and lungs
Esophagus	Thin and muscular esophagus	Carries food from the pharynx, through the diaphragm, and into the stomach; collapses at rest and distends as food passes through it

Adapted from Wolf, L. S., & Glass, R. P. (1992). *Feeding and swallowing disorders in infancy: Assessment and management*. Tucson, AZ: Therapy Skill Builders.

The newborn has a small oral cavity filled with fat pads inside the cheeks and tongue. The small and tight oral cavity allows the child to grasp and easily compress the nipple during breastfeeding and achieve automatic suction. The negative pressure caused by the sucking movements of the jaw extracts liquid from the nipple.³⁸ Thus, a full-term, healthy newborn can suck easily and successfully from a breast or bottle nipple. Between 4 and 6 months of age, the infant's oral structures begin to change, influenced by growth and maturation of postural control and overall motor systems. The oral cavity becomes larger and more open, the tongue becomes thinner and more muscular, and the cheeks lose much of their fatty padding. With the increase in oral cavity space, the tongue, lips, and cheeks provide greater control of liquid and food within the mouth. New sucking patterns develop, enabling the infant to handle liquid without the structural advantages of early infancy. These include up and down movements of the tongue to extract liquid from the nipple.

During this time, sucking patterns become more voluntary, and oral motor control begins to support lumpy foods and spoon feeding. This maturation continues as the child grows and acquires teeth to allow effective mastication and improved management of food textures.

Multiple cranial nerves support sensory and motor functions during oral feeding. Cranial nerves (CNs) V, VII, and XII innervate the sensory-motor pathways required to suck and extract liquid from a nipple. The trigeminal nerve (CN V) influences the oral motor function of mastication, as well as the lower jaw and palatal elevators. It also enables sensory function of the face, teeth, tongue, palate, nose, and nasal sinuses. The facial nerve (CN VII) provides motor function to specific muscles of the face and sensory innervations to the tongue. Lastly, the hypoglossal nerve (CN XII) enables motor function of the tongue.^{38,58} Table 14-2 lists the cranial nerves associated with eating and swallowing.

Pharyngeal Structures and Function

The pharynx consists of distinct structures important to management of air flow for respiration and control of food or liquid during swallowing. The pharynx, comprised of the

nasopharynx, oropharynx, and laryngopharynx, plays an integral role in the proper timing of breathing and swallowing during oral feeding.

The structures in the infant's throat are also in close proximity to one another. The epiglottis and soft palate are in direct approximation. As a result, the liquid from the nipple safely passes from the base of the tongue to the esophagus. During swallowing, the larynx elevates and the epiglottis falls over the opening to the upper airway. Therefore, aspiration is less likely before 4 months of age, and the infant can safely feed in a reclined position.

As the infant grows, the hyoid, epiglottis, and larynx descend, creating space between these structures and base of the tongue. The hyoid and larynx become more mobile during swallowing, elevating with each swallow. The greater complexity of the suck-swallow-breathe sequence leads to greater coordination among these structures. The elongated pharynx increases the risk of aspiration during feeding in a reclined position, as the pull of gravity accelerates the flow of liquid into the entrance of the esophagus. During this time, most children are fed in a more upright position as they generally transition away from bottle feeding to cup drinking, and more advanced food textures are introduced. Figure 14-1 depicts the anatomic structures of the mouth and throat.

Phases of Swallowing

There are four defined phases of swallowing. The oral preparatory phase is often reflexive in young infants and under voluntary control in older children. During this phase, oral manipulation of food occurs, using the jaw, lips, tongue, teeth, cheeks, and palate. This results in the formation of a food bolus. The amount of time spent in this phase varies, depending on the texture of the food or liquid.

The second phase is the oral phase, which is also generally reflexive in young infants and under voluntary control in older children. This phase begins when the tongue elevates against the alveolar ridge of the hard palate, moving the bolus posteriorly, and ends with the onset of the pharyngeal swallow.

The third phase, the pharyngeal phase, is primarily reflexive. During this phase, the swallow is triggered at the anterior

TABLE 14-2 Cranial Nerves Associated with Eating and Swallowing

Cranial Nerve	Type	Function
I (olfactory)	Sensory	Sensory fibers for smell
V (trigeminal)	Mixed	Sensory fibers from cheek, nose, upper lip, and teeth Sensory fibers from skin over mandible, lower lip, and teeth Motor fibers to the muscles of mastication
VII (facial)	Mixed	Sensory fibers from taste receptors to the anterior two thirds of the tongue Motor fibers to the muscles of facial expression and salivary glands
IX (glossopharyngeal)	Mixed	Sensory fibers from taste receptors on the posterior third of the tongue Motor fibers to the muscles used in swallowing and to the salivary glands
X (vagus)	Mixed	Sensory fibers from the pharynx, larynx, esophagus, and stomach Motor fibers to the muscles of the pharynx and larynx Autonomic fibers to the smooth muscles and glands to alter gastric motility, heart rate, respiration, and blood pressure
XII (hypoglossal)	Motor	Motor fibers to the muscles of the tongue

Adapted from Morris, S. E., & Klein, M. D. (2000). *Pre-feeding skills* (2nd ed., p. 49, Table 4.2). Tucson, AZ: Therapy Skill Builders.

FIGURE 14-1 Anatomic structures of the mouth and throat.

faucial arches. The hyoid and larynx move upward and anteriorly, and the epiglottis retroflexes to protect the opening of the airway. It ends with the opening of the upper esophageal sphincter.

The final phase is the esophageal phase, which, along with the pharyngeal phase, is not under voluntary control. It starts with relaxation of the cricopharyngeus muscle to open the upper esophageal sphincter and ends with relaxation of the lower esophageal sphincter at the distal end of the esophagus, allowing foods to enter the stomach.

The glossopharyngeal nerve (CN IX) and vagus nerve (CN X) are the primary cranial nerves providing innervation for reflexive swallow functions. The glossopharyngeal nerve provides motor and sensory function to the pharynx. The vagus nerve enables motor function of the pharynx, larynx, and esophagus and innervates sensory function of the pharynx, larynx, trachea, and lungs.^{38,58}

Stages and Ages of Feeding Development

Before a child is even born, the fetus develops necessary feeding skills that will support functional and successful oral feeding after birth. Initial early feeding reflexes such as the swallowing reflex have been known to develop between 10 and 14 weeks of gestational age. This reflex helps regulate amniotic fluid and aids in the maturation of the fetus' gastrointestinal tract. Around 16 to 20 weeks gestational age, the fetus mouths his or her thumb in early, non-nutritive oral stimulation. As early as 15 to 18 weeks, sucking is observed; however, not until after birth does the infant learn to coordinate suck, swallow, and breathing patterns for successful oral feeding.

Infants born preterm may lack the oral motor development required for effective oral feeding. Because technologic advances have been made in the medical field in the past several decades, infants are able to survive outside the womb at a very young

gestational age, often as early as 22.5 or 23 weeks postconception. Depending on the infant's age, many factors must be taken into consideration when determining if a premature infant is ready to begin the process of oral feeding. As a result, it is imperative to understand the development of feeding skills in utero, as well as feeding readiness cues, when assessing an infant's ability to engage in oral feeding experiences. Cues such as skin color, state, breathing, and motor changes, as well as coordination of swallowing and breathing, are all factors to take into consideration when determining the premature infant's readiness to feed. Working with the fragile neonatal population requires advanced learning activities and mentored clinical experiences.

An infant born healthy and full term is typically ready to take on oral feeding, whether by breast or bottle. Infants are born with significant physiologic flexion, which enables them to continue to coordinate a successful sucking pattern outside the womb. Early reflexes such as the rooting reflex, sucking reflex, and synchronized suck-swallow-breathe patterns typically aid in the infant's success with initial oral feeding. During the first 3 months of life, infants feed using symmetric oral motor sucking movements. When fed, they are typically held by their caregiver and cradled in a flexed position, which allows them to bring the hands to midline and eventually to the mouth. During this period, infants experience a variety of sensory stimulation that prepares them for further sensory experiences. They feel input from the caregiver's hands, clothing, and other surfaces. They hear their parents' voices, experience eye contact, feel rhythmic heartbeats against the caregiver's chest, and experience a variety of smells during early feeding experiences. These early sensory and social activities during feeding may become a foundation for parent-infant bonding and later social development.

Between 3 and 6 months of age, the infant has developed improved head and neck control and is now able to lift and turn

the head to maintain head position in supported sitting. As a result of this improved motor control, infants at this age are often positioned more upright for feeding. During this period, infants are becoming more interested in their surroundings and reach and grasp for toys and items of interest. The 3- to 6-month-old infant is still breast- or bottle-fed, but now brings hands to midline to help hold the bottle or embrace the caregiver. During this stage, oral reflexes (see earlier) are fading, and the infant develops voluntary control over sucking and swallowing patterns. The infant continues to use symmetric oral motor movements to suck and extract liquids; however, increased mobility of the tongue is often seen as the infant begins to explore toys and other items orally. This oral exploration plays a critical role in preparing the infant's oral sensory and oral motor development for further food texture introductions. During this stage, some infants demonstrate readiness for puréed food; however, this is not consistent across all infants.

The healthy 6- to 12-month-old infant should now be ready for the introduction of more advanced food textures. At this stage, motor skill development has significantly progressed. Typically developing infants should be sitting up independently and ready to sit in a high chair for feedings. Further refinement of fine motor skills has also occurred and the infant is beginning to use radial digital and then pincer grasps to pick up small items, such as a piece of solid food. The 6- to 12-month-old infant is continually engaging in a greater variety of sensory experiences. During this time, with the aid of tooth eruption, an explosion in oral sensory mouthing behavior is often observed, further aiding in readiness and developmental skills for more advanced feeding and eating activities.

The 6-month-old infant continues to be fed by breast or bottle. However, at this stage, the infant is now ready for the introduction of spoon feeding with purées and should be ready for meltable finger foods at around 8 months of age. Throughout this age range, the infant opens his or her mouth in response to presentation of the spoon and, with practice and experience, learns to close the mouth around the spoon to clear the purée into the mouth. A continued suckle transit pattern is used to swallow.

Chewing patterns also develop at this stage, first with munching, using symmetric up and down movements characterized by the jaw and tongue moving together in unison. Later, between 8 and 12 months, the infant begins to develop vertical chewing movements, characterized by disassociation between the jaw and tongue. Tongue lateralization is emerging at this stage, contributing to greater control of food within the oral cavity. Cup drinking is often introduced during this stage as well. Significant anterior fluid loss can be expected as the infant first begins to explore a cup, straw, or sippy cup.

By 12 to 24 months of age, the young toddler is now able to feed himself or herself independently because of further development and refinement of gross, fine, and oral motor skills. The toddler uses a mature pincer grasp and release pattern to pick up small finger foods and successfully place them in the mouth. Although a 12-month-old can bring a loaded spoon to the mouth, mastery of spoon feeding develops between 18 and 24 months as the child learns to scoop with the spoon successfully and orient the spoon correctly to feed with minimal spilling. Throughout this year, cup drinking has also progressed because bottle feeding and breastfeeding are typically fading. Further development of postural stability

enables the toddler to transition from the high chair to a less supportive booster seat. By 12 months of age, the toddler is able to bite through a soft food with the front teeth and has developed more rotary chewing skills, characterized by diagonal jaw movements and the presence of lateral tongue movements. These more advanced oral motor skills enable the toddler to manage more challenging food textures, such as soft and coarsely chopped table foods, with more difficult chewable foods being managed by 24 months.

Some foods present a high choking risk in toddlers, such as some raw fruits and vegetables, seeds, nuts, and small round foods. These foods should be avoided or cut into small pieces during this stage of development. At this age, the toddler is engaging in sensory exploration with a variety of foods and textures, enabling him or her to learn about foods (through taste, smell, temperature, and texture).

At 24 months through 5 years of age, children develop significantly improved core stability and postural control. Because of this skill development, they are able to sit at the table without further adaptations or assistance. They are independently self-feeding with fingers, utensils, and cups. As a result of further refined rotary jaw movements, the 2- to 3-year-old child is now successfully eating a wide variety of table foods. At this age, highly chokeable foods should still be avoided but can be introduced with caution at 3 years. By 5 years, fully functional adult patterns have developed, and intake is generally based on personal preference, exposure, and experience. [Tables 14-3](#) and [14-4](#) summarize the developmental sequences for oral feeding and self-feeding skills in infants and young children.

Mealtime: An Overview

Often, mealtime is a family time that provides physical, cognitive, and emotional nourishment to all members. Meals arrange the day temporally, organize it into periods, and signal that certain activities end and new ones begin. Mealtimes provide routine and structure and offer a time for relaxation, communication, and socialization. At mealtimes, parents and children communicate symbolically and emotionally while at the same time satisfying very basic nourishment needs.¹⁹ Many believe that “to nourish a child is to nurture a child.” Thus, mealtimes are cultural rituals and, as such, an integral part of a family's life and a time for bonding and sharing.

Caregivers and children engage in shared and individual roles during mealtime. Usually, the child is expected to remain seated, attend to the caregiver, feed himself or herself (when age appropriate), communicate with others at the table, and follow family rules for table manners and routines. The caregiver is expected to provide food in quantities sufficient to satisfy hunger, assist in feeding younger children, communicate and interact with other family members, and establish mealtime norms and routines.

A child's mealtime participation changes as he or she goes through the different stages of growth and development, from infancy to adulthood. During infancy, parents are responsible for feeding or assisting the child. During preschool and school-age years, the parents' role shifts toward oversight, communication, and discipline. Almost all parents try to create a pleasant and relaxing family atmosphere during meals. Families frequently have ever-changing dynamics that create busy

TABLE 14-3 Developmental Sequence of Eating Skills

Age (mo)*	Type of Food	Sucking and Drinking Skills	Swallowing	Biting and Chewing
1-4	Liquids only	Uses a suckling or sucking pattern	Tongue moves in anterior-posterior movement to swallow	Does not bite or chew
5	Liquids and beginning puréed foods; formula or breast milk remains primary source of nutrition	Uses a sucking or suckling pattern; tongue moves up and down	Choking on breast or bottle is rare; sequences 20 or more sucks from bottle or breast	Uses a primitive phasic bite and release pattern; biting not yet controlled or sustained; jaw moves up and down in munching and biting
6	Liquids and puréed foods	No longer loses liquids during sucking; introduction of sippy cup or small sips from open cup or straw; tongue moves in anterior-posterior pattern with cup drinking; may have anterior liquid loss when drinking from cup or straw	Swallows thin puréed foods; uses long sequences of coordinated sucking, swallowing, and breathing with breast or bottle; may cough or choke when using a cup	Up and down jaw movements more variable and less automatic; some tongue lateralization when food is placed to the side
8-9	Soft foods, mashed table foods, meltable solids.	Strong sucking pattern, no liquid loss with bottle; continuing introduction of sippy cup or straw	Uses long sequences of sucking during cup drinking; takes one to three sucks before stopping to swallow or breathe; swallows thin or thick purées	Uses lateral movements to transfer food from the center to the sides of the mouth; munches with diagonal movement; voluntary biting on food and objects; lips active with jaw during chewing
12	Easily chewed foods including soft meats, coarsely chopped table foods	Most of liquid now from a cup; uses a sucking pattern (up and down tongue movement); may lose liquid when using an open cup	Swallows liquids and semisolid foods with tongue tip elevation; at times exhibits tongue protrusion while swallowing; lips often closed during swallowing	Controlled sustained bite with soft cookie; easily transfers food from the center to both sides; begins rotary chewing movements; lips active during chewing
18	Coarsely chopped table foods, some raw fruits, most cooked meats	Mature sucking patterns; jaw is stable when drinking from cup	Uses tongue tip elevation with swallowing; swallows solid foods with easy lip closure; no loss of food	Uses controlled sustained bite on hard cookie; chews with lips closed; demonstrates rotary chewing
24	Most table food; use caution with raw vegetables, foods with skins, tough meats, or small round foods that increase risk of choking	Adult-like drinking pattern	No liquid loss; swallows solid foods with easy lip closure; tongue tip elevation used for swallowing	During chewing, can transfer food from both sides of the mouth; uses circular rotary movements when transferring food; lips closed during chewing

*Ages are approximate and may vary among infants.

environments, often not allowing time to create these important mealtimes, with consistent structure and routine. Creating a pleasant family atmosphere during mealtime can be challenging if a child has a disability that affects eating performance. The child's temperament, health, and disposition and the parents' health and moods are all important factors contributing to mealtime social interactions.

Contextual Influences on Mealtime: Cultural, Social, Environmental, and Personal

Contextual (environmental) factors must be taken into consideration when working with children who have feeding disorders and with their families. In some cases, feeding problems are based primarily on contextual issues, including physical, social,

TABLE 14-4 Developmental Continuum in Self-Feeding

Age (mo)	Eating and Feeding Performance	Concurrent Changes in Performance Components		
		Sensorimotor	Cognition	Psychosocial
5-7	Takes cereal or puréed baby food from spoon	Has good head stability and emerging sitting abilities; reaches and grasps toys; explores and tolerates various textures (e.g., fingers, rattles); puts objects in mouth	Attends to effect produced by actions, such as hitting or shaking	Plays with caregiver during meals and engages in interactive routines
6-8	Attempts to hold bottle but may not retrieve it if it falls; needs to be monitored for safety reasons		Object permanence is emerging and infant anticipates spoon or bottle	Is easily distracted by stimuli (especially siblings) in the environment
6-9	Holds and tries to eat cracker but sucks on it more than bites it; consumes soft foods that dissolve in the mouth; grabs at spoon but bangs it or sucks on either end of it	Good sitting stability emerges; able to use hands to manipulate smaller parts of rattle; guided reach and palmar grasp applied to hand-to-mouth actions with objects	Uses familiar actions initially with haphazard variations; seeks novelty and is anxious to explore objects (may grab at food on adult's plate)	Recognizes people once regarded as strangers; emerging sense of self
9-13	Finger feeds self a portion of meals consisting of soft table foods (e.g., macaroni, peas, dry cereal) and objects if fed by an adult	Uses various grasps on objects of different sizes; able to isolate radial fingers on smaller objects	Has increased organization and sequencing of schemas to do desired activity; may have difficulty attending to events outside visual space (e.g., position of spoon close to mouth)	Prefers to act on objects than to be passive observer
12-14	Dips spoon in food, brings spoonful of food to mouth, but spills food by inverting spoon before it goes into mouth	Begins to place and release objects; likely to use pronated grasp on objects like crayon or spoon	Recognizes that objects have function and uses tools appropriately; relates objects together, shifting attention among them	Has interest in watching family routines
15-18	Scoops food with spoon and brings it to mouth	Shoulder and wrist stability demonstrate precise movements	Experiments to learn rules of how objects work; actively solves problems by creating new action solutions	Internalizes standards imposed by others for how to play with objects
24-30	Demonstrates interest in using fork; may stab at food such as pieces of canned fruit; proficient at spoon use and eats cereal with milk or rice with gravy with utensil	Tolerates various food textures in mouth; adjusts movements to be efficient (e.g., forearm supinated to scoop and lift spoon)	Expresses wants verbally; demonstrates imitation of short sequence of occupation (e.g., putting food on plate and eating it)	Has increasing desire to copy peers; looks to adults to see if they appreciate success in an occupation; interested in household routines

temporal, and cultural factors. Understanding the contextual factors that influence mealtimes and feeding performance helps determine the basis for problems and possible solutions.

A family's culture can be described as a set of beliefs, values, and traditions that guides their actions, often including what types of foods a family eats and specific mealtime routines and roles. In some cultures, children are fed by a caregiver throughout the preschool years, whereas in others, infants are encouraged to self-feed, despite the ensuing mess. Cultural beliefs also

determine the amount and type of food that parents believe that their children should eat and where and when mealtime occurs. As occupational therapists, it is imperative to respect a family's cultural beliefs and social norms to provide the best support of their mealtime routines and the values they hold around eating.

A family's socioeconomic status also has an impact on mealtime and feeding patterns. Families in poverty may be unable to provide sufficient food or may eat less nutritious foods,

which often tend to be high in carbohydrates and fat. A parent's educational level, which can be related to socioeconomic status, can affect a child's diet because an undereducated parent may lack knowledge of basic nutrition. In these situations, it is important to help families not only with knowledge of feeding and development, but also to involve other resources and providers who may assist with these challenging situations. Occupational therapists can refer families to resources such as social workers and the Women, Infants, and Children (WIC) program (also called the Special Supplemental Nutrition Program).

A caregiver's personality traits and other individual factors can also shape mealtime and affect a child's ability to feed. When the caregiver does not enjoy feeding a child or approaches it as a chore, the task can lose much of its meaning, changing the mealtime experience for the adult and child. For example, some caregivers are anxious about feeding and tend to be controlling when the child is a poor eater. The caregiver may have preconceived ideas about how much the child should eat and may engage in force feeding or maladaptive feeding routines to compensate for the child's disinterest in eating. A controlling parent may find that the child desires control of what he or she eats, and a battle of wills may result. Controlling parents may also have difficulty with allowing the child freedom to explore and interact with foods as they learn to participate in self-feeding. They may have difficulty allowing their children to become messy, limiting their overall sensory experiences with foods.

Comprehensive Evaluation of Feeding and Swallowing Skills

The process of analyzing and identifying feeding and swallowing challenges in children is complex. Comprehensive evaluation requires clinicians to question, observe, and analyze multiple factors within the child's abilities and family's routines that influence the mealtime structure and limit or enhance success with oral feeding.

Initial Interview and Chart Review

When initiating a feeding and swallowing evaluation, it is important to begin this complex process by gathering as much background information as possible. The team reviews the child's medical chart and may request that the caregiver complete a feeding, developmental, and/or nutritional intake questionnaire prior to the appointment. The child's developmental status and health history are also important in identifying feeding problems and guiding decisions about subsequent evaluation and intervention needs. The written reports from physicians, occupational and physical therapists, speech-language pathologists, early childhood specialists, and teachers provide fundamental information about the child. For example, a child with a past history of prolonged hospitalization may not have had typical feeding, motor, or sensory opportunities. A child with a history of motor delays may have had restricted upper extremity movements, resulting in limited oral exploration and influencing sensory systems and delayed self-feeding skills. Understanding the child's developmental course and rate

of change in other occupational performance areas such as object play and social interactions is important for the occupational therapist to set realistic goals, prioritize objectives, and choose appropriate intervention strategies.

The occupational therapist then gathers general information about the family's concerns with oral feeding and mealtimes. The occupational therapist obtains information about current feeding practices, cultural norms, social rules, and mealtime routines by asking the parents to describe the child's feeding over the course of a typical day. This open-ended inquiry, as opposed to multiple-choice questions, allows the occupational therapist to identify potential areas of concerns that were not reported during the initial description of the child's feeding problems.

A discussion of the feeding problem from the parents' perspective is critical because it helps identify the primary concerns. For example, are the parents most concerned about weight gain, or is it the length of time required for feeding that poses a problem? Does the child seem to lose most of the food consumed during feeding (e.g., through vomiting or reflux)? Is the child's behavior during feeding causing distress for the entire family during mealtimes? Although the parents' expressed concerns become the focus of the subsequent intervention, the occupational therapist should always consider other concerns expressed by health care professionals (e.g., physicians or other health care providers) when developing a feeding plan, especially when these concerns differ from those expressed by the parents.

The parents also provide information about the child's development and feeding history, including feeding milestones. Obtaining this information may help the occupational therapist identify the root of the feeding problem (e.g., long-standing sensory or behavioral issues may have affected feeding). Inquiring about remediation strategies used with the child in the past may be helpful in identifying appropriate next intervention strategies. Parents whose child has been seen by other medical or therapy providers may have important information to share regarding interventions that worked and those that did not.

Although these issues are discussed separately, feeding problems are seldom attributable to a single cause and usually are the result of delays, impairments, medical concerns, or behavioral challenges in multiple areas. For example, children with severe sensory problems may have subsequent oral motor skill delays, and children with neuromotor impairments may also experience swallowing disorders. Often, because of past feeding challenges, families will modify routines, mealtime structure, and behavioral expectations, thus creating maladaptive contextual challenges, which must be addressed. [Box 14-1](#) provides an example of guiding questions that may be used to evaluate the contexts of feeding.

After the therapist has completed a comprehensive interview, initial impressions are often formed about the child's feeding difficulties, the family's routines and structure around eating and mealtimes, and any additional areas that may help determine the cause of the feeding problem. The next step is to complete a hands-on evaluation of generalized muscle tone, neuromuscular status, sensory processing development, and general developmental level. Observations of movement initiation, play, and transition patterns allow the occupational

BOX 14-1 Guiding Questions to Evaluate the Contexts for Feeding**Physical**

- Is seating and positioning adequate? Supportive? Does it provide stability?
- Are head, neck, shoulders, and pelvis well aligned?
- Is space adequate for eating activities?
- Are noise and activity levels conducive to eating?

Social

- Who feeds the child?
- Who is present during the meal?
- What is the nature of the social interaction among family members during the meal?
- What communication or interaction occurs between the caregiver and child during feeding?

Temporal

- Is sufficient time allotted and available for a relaxing meal?
- How often is the child fed?
- How long does it take?

Cultural

- How do cultural beliefs and values influence mealtime?
- What foods does the family eat?

therapist to observe muscle tone, sensory processing, and postural control. Low postural muscle tone can interfere with the ability to maintain upright posture and head and neck alignment. Hypotonicity or hypertonicity can lead to difficulty grading or sustaining oral motor patterns, uncoordinated breathing, drooling, decreased oral exploration, and limited self-feeding. Sensory processing difficulties may influence the child's ability to sit successfully for meals, progress with food textures, or tolerate other typical mealtime experiences.

Structured Observation

Once an evaluation of the child's motor systems, sensory development, and muscle tone has been completed, the next step in the evaluation process is to complete structured observations of the child's oral structures and oral motor patterns. Initial observations should include assessments of symmetry, size, tone, and range of motion of the outer oral structures, including the jaw, and then proceeding intraorally to the lips, gums, dentition, hard and soft palates, and tongue.

Once observations of oral structures are complete, the evaluator should then progress with observations of the child eating a snack or a meal with the parent or caregiver. This observation enables the occupational therapist to get a sense of mealtime routines, feeding practices, and social or behavioral interactions typically occurring at home. Observing the parent-child interaction provides insight into the everyday context of feeding. For example, does the parent talk to the child? Does the child send clear cues regarding readiness to eat, satiation, or food preferences? Does the parent respond to the child's verbal and nonverbal cues?

Objective observations of the parent-directed mealtime enable further assessment of the child's motor, sensory, cognitive, and communication skills. It is often recommended that parents bring foods that the child typically accepts at home, as well as foods that are more challenging for the child. This allows the occupational therapist to observe the child in an optimal and less optimal performance. The occupational therapist also encourages the caregiver, when possible, to use the seating system, plates, and utensils that are typically used at home.

After all interviews, observations, and assessments have been completed, the occupational therapist interprets all assessment findings, prioritizes concerns, and develops initial recommendations to assist the family. It is important to mention that evaluation of a child's feeding and eating, for most children, relies on structured interview and observations. To date, few standardized assessments and reliable outcome measures to evaluate the complex process of oral feeding are available.

Additional Diagnostic Evaluations

When a child exhibits feeding difficulties, a variety of medical procedures may be recommended to evaluate feeding and swallowing skills further. The upright modified barium swallow study (MBSS), also called a videofluoroscopic swallow study, is the radiographic procedure of choice for assessing the oral, pharyngeal, and upper esophageal anatomy and function during feeding and swallowing. It is most useful in identifying aspiration or the risk of aspiration and in tailoring treatment for infants and children with feeding disorders. This evaluation can also be helpful for detecting problems related to head and neck positioning, bolus characteristics, rate and sequence of feeding, and safe food or liquid consistencies. The results of the test can be helpful in identifying compensatory techniques to minimize the risk of aspiration and maximize eating efficiency.⁸ The occupational therapist selects the types of food and liquid textures based on the child's current diet and level of feeding performance and mixes them with liquid, powder, or barium paste.⁴⁷ It is important to remember that the MBSS only captures a brief sample of swallowing, and positioning, food or liquid amount, and order of presentation are up to the therapy team conducting the study.⁷ Typically, during this evaluation, radiation exposure is limited to 5 minutes or less, thus requiring occupational therapists to determine clinically the most important food and liquid textures to examine during this brief period.

The MBSS is used to analyze the swallow mechanism and is particularly important for children who aspirate or are at a high risk for aspiration because of severe motor, neurologic, developmental, or structural abnormalities. Clinical observations that may suggest swallowing problems include gagging, coughing, choking, nasopharyngeal reflux, increased congestion, wet vocal quality, and frequent occurrence of respiratory infections and/or pneumonias. Aspiration may be silent, so a thorough history and feeding observation are critical.

During the MBSS, the occupational therapist should distinguish aspiration from laryngeal penetration. Aspiration refers to food or liquid entering the airway before, during, or after a swallow. The presence of aspiration is an abnormal finding and may lead to chronic lung disease, pneumonia, and other medical

problems. Laryngeal penetration describes the flow of food or liquid underneath the epiglottis into the laryngeal vestibule, but not into the airway. It does not pass through the vocal folds. The frequency and severity of laryngeal penetration may vary and may not always correlate to an increased risk of aspiration. Infants and children may have intermittent episodes of mild laryngeal penetration (also called epiglottic undercoating) during swallowing, which do not increase the risk for aspiration.²³ The presence of deep laryngeal penetration, characterized by food or liquid entering the laryngeal vestibule to the level of the vocal cords, is correlated to an increased risk factor for aspiration episodes.²³

Because the MBSS recording shows food traveling through the mouth and pharynx, the occupational therapist receives real-time, detailed information about the child's oral motor and pharyngeal function. The results of the MBSS indicate the safety and appropriateness of oral feeding and guide the occupational therapist's recommendations.⁵⁹ These may include modified feeding positions and/or food and liquid textures for the parents to use during feeding that appear to result in optimal swallowing patterns, without aspiration. Although the MBSS gives the occupational therapist important information and insight about the swallowing problem, it may not always be representative of the child's typical feeding in a more natural environment.

Similar to the MBSS, a fiberoptic endoscopic evaluation of swallowing (FEES) also evaluates a child's swallow function. In contrast to the MBSS, the FEES uses a flexible endoscope with a light and camera that is inserted into a nostril and down the throat. With this evaluation, the camera then records the pharyngeal swallow function from the inside as the child eats or drinks. This allows for direct visualization of the larynx and pharynx to observe for penetration, aspiration, and residual material. It is important to note that the child must be awake and willing to cooperate with eating while the endoscope is in place.

An upper gastrointestinal (GI) series is a common evaluation used to screen for anatomic differences, such as GI malrotation, stricture, vascular ring, and/or fistulas or pouches, which may cause vomiting and other feeding problems. An upper GI series is helpful in evaluating for the presence of gastroesophageal reflux (GER). It is important to note that the upper GI series evaluates one moment in time and, according to expert clinical guidelines, is not usually helpful in diagnosing the presence or severity of GER.⁵⁶ The upper GI series typically does not assess swallow function or the presence of aspiration.

Medical providers often recommend an esophageal or pH probe to discover the presence and severity of GER. With this evaluation, a probe is inserted into the esophagus though the nose to monitor abnormal acid levels, typically over a 24-hour period. However, a pH probe test may be difficult to complete because it often requires an overnight stay in the hospital, and the probe may be poorly tolerated by young infants and children.

An endoscopy may be used to evaluate the esophagus, stomach, and duodenum, referred to as an esophagogastroduodenoscopy (EGD). This test involves passing a flexible endoscope through the nose and visualizing the structures for the presence of esophagitis or other abnormalities. Tissue biopsies may be taken from the esophagus, stomach, or duodenum to evaluate for the presence of eosinophils. Eosinophils are present

in abnormally large numbers when a child is experiencing food allergies. They contribute to esophagitis and discomfort during eating. It is important to note that a child needs to be sedated to participate in an EGD.

Table 14-5 provides a comparison of the most commonly used diagnostic procedures for children with feeding disorders.

Intervention: General Considerations

Problems with feeding, eating, and swallowing are often caused by multiple underlying factors. If feeding problems persist as the child grows older, new problems or skill impairments may appear that further complicate the intervention needs. For example, children with dysphagia who require nonoral feeding for an extended period may experience subsequent developmental delays in self-feeding skills because of limited experience. Occupational therapists can provide direct intervention for children with feeding, eating, and swallowing disorders to improve functional participation in mealtimes. Throughout the intervention process, occupational therapists must consider medical and nutritional problems that often coexist with the child's feeding disorder, prioritize areas of focus, and collaborate with physicians, nutritionists, and other health care professionals to create an optimal intervention plan.

Feeding activities occur multiple times throughout the day in a variety of natural environments, and occupational therapists must work closely with families and other caregivers to ensure carryover within the daily routine. Children with oral feeding difficulties often require one-on-one attention or increased caregiver time and effort throughout each day. Mealtimes may be quite stressful for parents or caregivers, especially when the child's oral feeding difficulties create ongoing problems with nutrition and growth. Whenever possible, typical family mealtime routines should be preserved within the intervention program. Occupational therapists should consider the caregivers' time investment and provide realistic recommendations that do not significantly increase the burden of care within the family system. Parents of children with feeding, eating, and swallowing disorders may benefit from peer support groups, which have been shown to strengthen caregivers' abilities to cope with stressful problems on a daily basis.¹⁵

Occupational therapists use a holistic approach when developing an intervention plan for children with feeding, eating, and swallowing disorders. Consideration is given to many different overlapping areas, including child factors, performance skills, activity demands, environmental contexts, and family patterns.⁵ A comprehensive occupational therapy intervention plan may include environmental adaptations, positioning recommendations, adaptive equipment, food texture or liquid modifications, sensory development activities, behavioral strategies, neuromuscular handling techniques, and/or suggestions to improve independence in self-feeding. When implementing new recommendations or interventions, occupational therapists may encourage parents to try a technique a number of times before determining that it is successful or unsuccessful. Occupational therapists may also recommend that parents implement only one or two key changes at a time to determine which interventions are more successful than others.

A variety of intervention models are used to treat children with feeding problems, including specialized inpatient

TABLE 14-5 Comparison of Most Commonly Used Diagnostic Procedures for Children with Feeding Disorders

Test	Indications	Advantages	Limitations
Upright modified barium swallow study (MBSS); videofluoroscopic swallow study	- Analyze the swallow mechanism - Rule out aspiration - Determine point of aspiration - Identify safe food and liquid consistencies	- Fluoroscopy, not a single-picture x-ray videotaped - Upright position simulates feeding - Primary feeder often presents food - Familiar feeding utensils (bottle, cup, spoon) - Use of liquid, purée, and/or solid - Lateral and anterior/posterior view - Can determine when aspiration occurs - Investigation of treatment options - Clear contrast image of upper GI anatomy - Documents gastroesophageal reflux (GER) events if they occur during study - Observes esophageal motility and mechanism for stomach emptying	- May be difficult to simulate normal feeding in radiology examination room - Child must be able to swallow appropriate amount of barium - Results reflect that particular date and time - Study environment may increase child stress, resulting in aspiration - Radiation exposure from fluoroscopy
Upper GI series	Diagnose structural abnormalities of the esophagus, stomach, or intestines, such as malrotation or stricture	- Clear contrast image of upper GI anatomy - Documents gastroesophageal reflux (GER) events if they occur during study - Observes esophageal motility and mechanism for stomach emptying	- X-ray radiation exposure - Supine positioning - Barium flow rate may not simulate bottle feeding - Primary feeder often not present - Limited accuracy in capturing or diagnosing GER - Invasive procedure, often requiring overnight stay in a hospital
Esophageal pH probe	Quantifies frequency, acidity, and duration of GER	- Prolonged evaluation of GER over 24 hours - Documents effect of movement, sleep, and meals on GER - Documents frequency and severity of GER events - Can be combined with other assessments, such as pulse oximetry, or documentation of choking episodes - Established guidelines for normal and abnormal results	May not correlate with clinical symptoms (e.g., coughing, vomiting, wheezing)
GI endoscopy, esophagogastroduodenoscopy (EGD)	Provides a direct view of GI tract to diagnose inflammation or structural abnormalities	- Direct observation of esophageal and stomach tissues for changes that may have occurred with chronic GER - Tissue biopsies often studied for presence of eosinophils, which may indicate food allergies	- Invasive procedure, requiring anesthesia - Presence of inflammation or abnormalities may not correlate with clinical symptoms (e.g., vomiting, other feeding problems) - Cannot determine frequency of GER
Fiberoptic endoscopic evaluation of swallowing (FEES)	- Analyze the swallow mechanism - Rule out aspiration - Identify safe food and liquid consistencies - Visualize anatomic structures during swallowing	- Allows variability in positioning the child during eating or drinking - No x-ray radiation exposure - Can be combined with traditional laryngoscopy	- Requires child to be awake and cooperative while having small tube inserted in the nose and pharynx while swallowing - Often requires coordination between swallowing therapist and otorhinolaryngologist or ear, nose, and throat physician - Visualization while swallow is occurring can be difficult because structures close and contract.

Adapted from Morris, S. E., & Klein, M. (2000). *Pre-feeding skills* (2nd ed.). San Antonio, TX: Therapy Skill Builders.

programs, intensive outpatient programs, direct weekly therapy, and periodic consultative services. Many pediatric hospitals and outpatient centers have multidisciplinary feeding clinics for additional support, allowing access to a number of health care professionals from different medical backgrounds. In general, children with mild feeding difficulties often do well with weekly therapy or consultative therapy. Children with more severe feeding problems may require more intensive models of therapy.

Safety and Health

Basic safety guidelines should be followed when providing occupational therapy intervention. Children who demonstrate clinical signs of aspiration may require additional assessment with an upright MBSS to determine appropriate feeding goals. Occupational therapists must also consider the child's nutritional status and prioritize treatment goals to maximize a child's ability to meet basic nutritional needs. Some interventions may require implementation outside regular meal sessions so as not to disrupt the child's ability to meet oral intake requirements.

Universal precautions are followed during therapy activities when the occupational therapist will potentially contact food, mucous, or structures within the child's mouth. These precautions include the use of gloves to prevent the spread of infection.³⁹ Another critical factor when working with different food textures is the understanding that certain foods carry a high choking risk and require modifications or close supervision with young children. Occupational therapists must also understand and follow any dietary restrictions for children with food allergies, metabolic disorders, diabetes, or religious or cultural beliefs.

Intervention Strategies

Environmental Adaptations

Occupational therapists often recommend changes to the mealtime structure or environment to promote success with oral feeding. Environmental adaptations may be recommended to modify the child's daily mealtime routines. Specifically, occupational therapists may provide intervention recommendations for scheduling and location of meals, length of meal periods, sensory stimulation within the environment, and/or changes to the order of mealtime activities (e.g., solid foods before liquids, nonpreferred foods before preferred foods).

Children often benefit from regularly scheduled meals at consistent times or locations from day to day. Consistently scheduled meals and snacks allow the child to experience periods of time without eating, which may promote hunger cues and more interest in eating.³⁸ When parents allow children to snack or consume liquids throughout the day, children may have little opportunity to become hungry at mealtimes, when more nutritious foods are presented. Children should also have a consistent location for meals, such as sitting in a high chair or at a specific table. Wandering around while eating or having meals in different locations every day may be distracting for young children and does not help establish positive mealtime behaviors.³³

Some children may require modifications to the length of their meal periods. Children with neuromuscular impairments

may eat slowly and have a long meal period because of oral motor or self-feeding difficulties. Parents of children with poor growth may prolong mealtimes to try to encourage more food intake. When mealtimes are longer than 30 to 40 minutes on a regular basis, the demands on the child and caregiver become extremely high. Children who become fatigued during prolonged meals may expend increased energy to sustain the feeding, outweighing any benefits from additional oral intake.²⁶ Children with delayed gastric emptying or GER may benefit from smaller, shorter, more frequent meals throughout the day.³⁸ Larger meals may create more discomfort or episodes of vomiting in children with GI disorders. In typical children without feeding problems, meal periods of 15 to 30 minutes are usually ideal, depending on the age of the child and complexity of the food being offered.

The amount of sensory stimulation and number of distractions within the environment may also affect a child's oral feeding skills. Many children show improved oral feeding when environmental distractions are limited. Limiting the sensory stimuli in the environment may be beneficial for children who are concentrating on independent self-feeding, children who are hypersensitive to environmental stimuli, and infants with disorganized suck-swallow-breathe coordination. A calming sensory environment can be created with dim lights, reduced noise, soft or rhythmic music, and limited interruptions. Alternatively, some children may eat better when environmental distractions are present during mealtimes. Active toddlers may consume more food or have improved ability to remain seated at a meal when they are allowed access to a favorite toy or television show. When distractions are present, toddlers may not focus on the actual eating activity and may need more assistance from caregivers. The use of distraction may also help some children with sensory defensive behaviors to reduce the child's focus on the discomfort of the oral feeding activity.⁴⁰

Occupational therapists may also consider the order of presenting foods and liquids during meal sessions. Some children have more success when challenging oral feeding activities are presented at the beginning of the meal, when the child is feeling hungry. Alternatively, when the challenging feeding task creates disruption or distress and impacts the child's oral intake for the remainder of the meal, occupational therapists can recommend a new intervention outside meals or during a smaller snack session.

When considering a variety of environmental modifications, occupational therapists can often use information obtained during the initial feeding assessment to assist with clinical reasoning for these interventions. Often, a period of trial and error may occur to determine ultimately the best environmental modifications for each individual child.

Positioning Adaptations

Oral motor and feeding activities require skilled movement and coordination of many small muscle groups, which are supported by overall gross motor control and stability. Children with postural instability and neuromuscular impairments have difficulty with oral motor control if they do not have adequate positioning support. Positioning changes may have an immediate impact on some difficult oral motor problems, such as tonic bite and tongue thrust movement patterns. When an

occupational therapist is making positioning adaptations, proximal support (support at the trunk and neck) influences distal movement and control. Thus, occupational therapists consider positioning throughout the child's whole body. Positioning of the feet, legs, and pelvis influences the child's trunk stability. Stability, muscle tone, and postural control in the trunk muscles will affect the child's head and neck position. The position and graded muscle control of the child's head and neck influence jaw movements. Finally, good jaw stability and freedom of movement influence the child's tongue and lip control.³⁸ Providing external support, stability, and alignment through the use of positioning adaptations will often improve comfort and optimize oral motor skills and oral intake during mealtimes.

Infants may be supported in a variety of positions during oral feeding. Side-lying in the caregiver's arms is a common position during breastfeeding. This position may also be recommended for children who have difficulty coordinating sucking, swallowing, and breathing, because the impact of gravity does not immediately draw the liquid into the pharyngeal space. It may be difficult for the caregiver to hold a child comfortably in a side-lying position for prolonged periods, especially with older children or infants with hypotonia. Infants may also be supported in an elevated supine or sitting position in the caregiver's arms or on a caregiver's thighs, facing the caregiver. This elevated supine position (Figure 14-2) provides excellent alignment and midline orientation for infants who take formula from a bottle. An infant seat, car seat, or Tumble Forms Feeder Chair (Figure 14-3) may be adapted with small rolls to provide head and trunk support or slight shoulder protraction to help an infant hold his or her own bottle. Both these positioning options allow the feeder to have two hands free, creating opportunities to provide oral motor support or implement handling techniques. Occupational therapists should monitor whether these positions contribute to a slouched or compressed posture in the trunk and make adjustments if excessive slouching is present.

Allowing infants or young toddlers to drink a bottle while lying in a flat supine position (e.g., in a crib, on the floor) is generally not recommended. Positioning that includes propping the bottle on the young infant's chest should also be discouraged.

FIGURE 14-2 Face-to-face positioning for feeding.

For older infants and toddlers who are engaging in spoon-feeding activities, additional positioning options are available (Figure 14-4). A regular high chair may provide adequate trunk support for some children and can be easily adapted with small towel rolls for additional foot support or lateral support. The height of a standard high chair also allows caregivers to sit comfortably at the table, promoting social interaction between the child and family.

Older children with neuromuscular impairments may require a wheelchair or an adaptive stroller, such as a Kid Kart or Rifton chair, to provide optimal support during oral feeding. A variety of options and accessories are available for customization of these positioning devices. Within a seated position, the child should have supported feet and neutral pelvic alignment. Lateral trunk or arm supports, pelvic strap or seat belt, head

FIGURE 14-3 Tumble Forms Feeder Chair offers support and an adjustable feeding angle.

FIGURE 14-4 Adaptive positioning provides a firm base of support to the trunk and feet during self-feeding.

rests, specialized chest straps, or a tray may help provide more stability for the pelvis, trunk, and head. Children with neuromuscular impairments demonstrate improved head control, reaching, grasping, sitting posture, and visual tracking when using positioning devices during activities of daily living.³¹ Optimal positioning includes vertical head and trunk position, hip flexion greater than 90 degrees, knee flexion at 90 degrees, and feet supported on a flat surface.³¹

Occupational therapists may need to work with families to determine whether positioning equipment will fit comfortably in the home and evaluate caregiver perceptions about adaptive equipment. Reilly and Skuse studied positioning during mealtimes in the home for children with cerebral palsy.⁴² They found that positioning problems were common among children with cerebral palsy; however, only 50% of parents who received adaptive positioning devices routinely used the equipment.

In general, positioning adaptations aim to provide stability in the trunk and support the child in a midline orientation, with the head and neck aligned in neutral or slight flexion during oral feeding. The child's age, size, neuromuscular status, and self-feeding skills must be considered, as well as the caregiver's position and comfort. Finally, positioning adaptations should promote social interaction and communication during mealtimes. Occupational therapists must evaluate each child and caregiver individually to determine the best options for positioning during oral feeding, provide education about the benefits of proper positioning, and suggest alternatives to positioning equipment when necessary.

Adaptive Equipment

A variety of adaptive equipment is available for feeding activities, including adaptive spoons, forks, cups, and straws. Adaptive equipment may promote improvement in oral motor control, increase independence in self-feeding, and/or compensate for a motor or sensory impairment.

Occupational therapists should consider the properties of the spoon or fork used in feeding activities. A spoon with a shallow bowl may help a child with decreased lip closure. A spoon with bumps or ridges on the bottom of the bowl or a chilled metal spoon may provide additional sensory input for a child with decreased sensory registration. A rubber-coated or dense plastic spoon may be used as an alternative to a metal spoon for a child who bites down on the utensil. Utensils with shorter handles, curved handles, or larger grip diameters may help a child self-feed more independently.³³

A child first learning to drink from a straw may do well with a shorter or smaller straw, such as one that typically comes with a juice box. These straws require less oral suction and may deliver a smaller liquid bolus that is easier to control in the mouth. Children who require thickened liquids or those with decreased lip closure may benefit from the use of a relatively short straw with a standard diameter. Therapists may also consider using a straw with a specialized one-way valve. When liquid is pulled into a straw with a valve, it does not fall back into the cup if the child loses suction, thus allowing the child with weakness to put forth less effort and achieve more success. A cup with a handle may help a child with poor fine motor skills to drink more independently. U-shaped cut-out cups help maintain a neutral head position when drinking liquid. Clear cut-out cups also allow the therapist or caregiver to see liquid

entering the child's mouth easily when physical assistance is provided for drinking activities.

Typically, most young children use sippy cups as a transition between the bottle and an open cup or straw. Sippy cups are perceived as being easy to use and comforting to children. A variety of sippy cups are commercially available for children. They may have hard plastic spouts or soft spouts and permanent or removable nonspill valves. They may be fast-flowing, with little suction required, or slower flowing, requiring more oral suction. Occupational therapists working with children with feeding and swallowing disorders must carefully consider how different sippy cup properties affect the child's oral motor control and swallowing function.

Interventions to Improve Self-Feeding

Children experience delays in self-feeding skills because of physical weakness, abnormal muscle tone, cognitive delays, visual impairments, sensory processing difficulties, behavioral refusal, or poor motivation to eat. Each of these underlying causes creates different challenges for the intervention plan. Children will have the most success when they have begun to demonstrate an interest in self-feeding and an interest in exploring food more independently. Within each intervention plan, the occupational therapist's goal is to facilitate the child's success and gradually decrease the amount of caregiver assistance required during mealtime.

For children with physical or neuromuscular deficits, it is particularly important to create a balance between the effort of self-feeding and the impact on oral motor skills, swallowing safety, overall length of the meal, and child's nutritional needs. Therapists may implement self-feeding activities for only a portion of the meal, or during a smaller snack session, to allow practice and skill development opportunities without creating lengthy meal periods or causing reduced food intake for the child.

Adaptive positioning can be used to facilitate grasp patterns or hand to mouth movements. Adaptive positioning to support self-feeding activities may include a chair that provides good postural support and allows access to a stable tray or table for increased arm stability. A raised tray or table surface may provide more trunk and shoulder stability while decreasing the distance the child needs to move the spoon or fork from the bowl to the mouth. Stabilizing the elbow on the table or tray can also help reduce the physical demands of self-feeding, extending the child's endurance.

A Dycem mat or a nonskid placemat may help prevent movement of the dish or bowl to compensate for uncoordinated arm movements. Children may have improved independence when self-feeding with foods that stick to the spoon or with a scoop dish that has raised edges. Some dishes also have a suction cup on the bottom to help secure them to the table.

Children with upper extremity weakness or poor grasping skills may benefit from simple adaptations, such as a utensil with a lightweight, built-up handle or universal cuff (a palm strap that secures the utensil to the hand in a stable position). More complex options for severe weakness include a deltoid aid, mobile arm support, and electronic feeding systems activated by a simple push button switch.

A variety of adaptations can be made to help children drink liquids more independently. Cups with a wide base or cups with

lids may help reduce spillage when the child is placing the cup on a table. Some children may benefit from a long straw placed into a cup that is secured in a cup holder, reducing the need to lift or move the cup with the hands.

Children with cognitive or behavioral problems may benefit from backward chaining of self-feeding, with gradually decreasing levels of assistance provided. During the first step of this backward chain, a child may be required only to move the spoon with the hand for the last few inches before it reaches the mouth. The child then advances to lifting a spoon from the plate to the mouth after the occupational therapist has provided assistance to scoop the food. The last step encourages total independence with both scooping and bringing the food to the mouth. The occupational therapist praises and encourages the child for each step of his or her progress toward independent self-feeding.

When encouraging self-feeding in children with a visual impairment, occupational therapists may recommend consistent orientation of food and drink on the placemat. For example, placing the cup in the 2 o'clock position next to the plate or placing different foods in consistent locations in the dish may improve the child's awareness of the mealtime environment for improved independence. Occupational therapists may also use contrasting colors with plates, cups, and placemats to improve visual discrimination.

Children with tactile hypersensitivity may be less willing to explore food with their hands to finger-feed independently or they may become upset with food that spills during initial attempts at spoon feeding. Therapy activities to reduce generalized hypersensitivity outside mealtimes are indicated to prepare the child for self-feeding. During mealtimes, occupational therapists may try a variety of spoons, such as those with a small diameter or smooth handle, to improve a child's success and tolerance. Some hypersensitive children may be more willing to try self-feeding when they are simply provided with a napkin or moist cloth to reduce their discomfort if the feeding activity becomes messy.

Modifications to Food Consistencies

Different textures and sensory properties of foods may be considered in an intervention plan. Foods with a smooth, even, cohesive consistency, such as yogurt and strained fruits or vegetables, are easier to manage when a child has oral sensory and oral motor impairments. Thick, lumpy, or pasty foods such as oatmeal require more oral motor strength and sensory tolerance when compared with smoother and thinner puréed foods. Foods that are dense, crunchy, sticky, or uneven in consistency are more difficult to manage and require more advanced chewing skills. Table 14-6 provides examples of food progressions based on texture and consistency.

The National Dysphagia Diet, published in 2003, was an effort to provide standardized terminology when describing food texture modifications in dysphagia management.³ Although pediatric therapists often use additional descriptors for food textures, such as “stage 3,” “junior,” or “ground,” some institutions have begun using the terminology from the National Dysphagia Diet (Box 14-2).

When presenting foods and liquids, therapists may alter the size of the bite or sip of liquid. When first beginning to advance with a new skill for the child, occupational therapists may

BOX 14-2 Levels of Food Texture for Dysphagia Management

Level 1: Puréed—puréed foods that are homogeneous, cohesive, or pudding-like.

Level 2: Mechanically altered—cohesive, moist, semi-solid foods that may require some chewing; ground or minced meats and fork-mashed soft fruits and vegetables included in this diet level; most bread products, crackers, dry foods excluded

Level 3: Advanced—soft-solid foods that require more chewing ability, such as crackers, breads, cooked vegetables, soft fruits, and meats; excludes some fruits with skins, hard or crunchy vegetables, tough meats such as beef or pork steak, and foods that are very sticky or dry

Level 4: Regular—no food restrictions

present a food or liquid in a small, consistent bolus size. For example, offering one teaspoon of liquid (5 mL) from a small cut-out cup may help the occupational therapist to evaluate the child's oral motor and swallowing skills clearly when compared with unmeasured, free access sips. Similarly, offering a smaller food bolus when trying a new taste or texture may result in greater success for the child.

Consideration should be given to other sensory properties of foods, such as taste and temperature. Cold foods or foods with strong flavors, including tangy, salty, or sour foods, may be beneficial for children with decreased oral sensory awareness. Bland, room temperature, or slightly warm foods may be more tolerable for children with oral hypersensitivity.

Modifications to Liquids

Different consistencies of liquid require different oral motor and oral sensory demands. Thin liquids presented from an open cup are the most difficult to control in the mouth and pharynx during swallowing. Occupational therapists may recommend modifications to the thickness of liquid to compensate for a variety of swallowing, oral motor, and oral sensory deficits.

Thickened liquid is easier to control with the lips and tongue, moves more slowly in the mouth, and allows the child more time to organize a bolus for effective swallowing, without early spillage into the pharyngeal cavity. Children with dysphagia may not be able to coordinate swallowing with thin liquids, and aspiration and penetration events are more common with thin liquids when evaluated with MBSS.^{13,23,37} Thickened liquids may also be used to compensate for oral motor skill deficits when a child is first learning to drink from an open cup, even when the child has pharyngeal competence with thin liquids from a bottle or sippy cup. See Box 14-3 for descriptions of the three most commonly used liquid consistencies.

A variety of foods and supplements can be used to thicken liquids. SimplyThick is one type of commercial gel thickener, made with xanthan gum, that may be recommended for older children. Other commercial powder thickeners typically contain modified food starch and/or cornstarch. Note that important new precautions and warnings have been issued by the U.S. Food and Drug Administration (FDA) for the use of xanthan

TABLE 14-6 Food Progression Based on Texture and Consistency

	Puréed	Junior, Coarse Puréed	Wet-Ground, Mashed	Soft, Dissolved	Chopped, Soft Solid	Full Diet
Meat and meat substitutes	Strained meats or proteins; foods are blenderized to a smooth, even consistency	Commercial junior foods; soft meats finely ground in a food grinder with added liquids; scrambled eggs are mashed; hummus	Ground meats with gravy; scrambled soft eggs; mashed tofu	Ground meats; regular scrambled eggs; tofu	Small pieces of soft meats; hard-cooked eggs, deli-sliced turkey or ham	Cut-up meats; stew; almonds or nuts
Dairy products	Thinned pudding; plain yogurt; strained cottage cheese	Fork-mashed cottage cheese; tapioca pudding; thickened cream soups	Cottage cheese	Yogurt with soft fruits; American cheese slices	Cheddar or Swiss cheese	All dairy products
Bread and cereals	Infant cereals thinned with milk	Thicker infant cereals; Cream of Wheat	Cooked cereals such as oatmeal	Breads, muffins, crackers, cereal (without milk), pancakes; well-cooked pasta or rice	Dry cereals with milk; sandwiches with smooth filling cut into small pieces; firmer pasta or rice	Sandwiches with various fillings
Fruits and vegetables	Strained fruits and vegetables	Junior fruits; junior vegetables; regular unstrained applesauce; mashed potatoes or yams	Fork-mashed, soft canned fruits without skins; soft ripe mashed fresh fruits; fork-mashed, well-cooked vegetables	Canned fruits (peaches, pears) or soft ripe fruits cut into small pieces (peeled); well-cooked vegetables	Canned fruits or increased texture (fruit cocktail); regular bite-sized pieces of cooked vegetables cut into small pieces	Raw fruits; dried fruits; raw vegetables with fibers or skins (corn, celery, peppers); vegetable soups, mixed salads

BOX 14-3 Liquid Consistencies (from Thinnest to Thickest)

- Thin—consistency of water or juice
Many formulas and milk products have a slightly higher viscosity than that of clear liquids; however, they are still considered thin liquids. Soup broth and foods that melt are also considered thin liquids.
- Nectar—consistency of tomato juice, including many natural fruit nectars (e.g., apricot nectar, pear nectar) and some store-bought yogurt smoothies
- Honey—consistency of honey, which slowly drips off a spoon

gum thickeners with young infants, premature infants, and older children who have a history of necrotizing enterocolitis.^{10,54,55} Necrotizing enterocolitis (NEC) is a serious medical condition related to necrosis of tissue in the intestines or bowel. Current xanthan gum precautions have a significant impact on

treatment options for young infants with swallowing disorders. Occupational therapists are urged to become knowledgeable about these FDA warnings and provide education to other medical providers.

Regular fruits and vegetables, baby foods, yogurt, and pudding may be blenderized to make thickened smoothies or shakes for older children. Dried infant cereals or mashed potato flakes may be added to thicken pediatric formula or nonhuman milk. Infant cereals are not effective to thicken expressed human breast milk because the starches contained in the cereal are broken down by the amylase in breast milk, quickly returning the milk to a thin liquid. Each thickener has different sensory, nutrition, and thickening properties, all of which should be considered in an occupational therapist's recommendations.

Interventions for Dysphagia

When aspiration or pharyngeal dysphagia affects a child's ability to eat safely, the availability of well-researched intervention

RESEARCH NOTE 14-1

Bulow, M., Olsson, O., & Ekberg, O. (2003). *Videoradiographic analysis of how carbonated thin liquids and thickened liquids affect the physiology of swallowing in subjects with aspiration on thin liquids*. *Acta Radiologica*, 44, 366–372.

Abstract

The purpose of this study was to evaluate how carbonated thin liquids affected swallowing physiology during videofluoroscopic assessments. Participants were evaluated with a variety of liquid consistencies during a videofluoroscopic swallow study. Forty adults who demonstrated aspiration with thin liquids were then included in this study and received additional assessment with carbonated thin liquids. Of the 40 participants, 36 had a diagnosed neurologic impairment. Data were analyzed to compare carbonated liquids with thin and thickened liquids regarding the frequency of aspiration or penetration, pharyngeal transit time, and pharyngeal retention during swallowing. The results indicated that carbonated liquids significantly reduced aspiration and penetration events and demonstrated faster pharyngeal transit time when compared with thin and thickened liquids. Carbonated liquids also demonstrated significantly decreased pharyngeal retention when compared with thickened liquids. When thickened liquids were compared with thin liquids, significantly fewer penetration and aspiration events were noted with the thickened liquids.

Implications for Practice

The use of thickened liquids and carbonated thin liquids by those who demonstrate aspiration or penetration with thin liquids is supported by this descriptive study. Although this study has not yet been duplicated with a pediatric population, the results suggest that carbonated liquids may reduce aspiration in children known to aspirate thin liquids. Carbonated liquids may be an alternative to thickened liquids.

options is limited. Historically, occupational therapists recommended food or liquid consistency adaptations, such as thickened liquids for children who aspirate with thin liquids. Although this continues to be a popular recommendation, it may not be suitable for young infants.

When thickened liquids are recommended for children of any age, the child's liquid intake and hydration status must be closely monitored to ensure that the child is meeting daily fluid requirements. Some children who are prescribed thickened liquids have poor acceptance of the new liquid and reduce their oral intake. Studies have suggested alternatives to thickeners, such as carbonated liquids, to reduce aspiration or penetration (Research Note 14-1). Comprehensive caregiver training is needed to ensure understanding of aspiration, methods for modifying food or liquids, and safety precautions during oral feeding.

As noted earlier, supportive positioning can have a major impact on the child's oral motor and swallowing skills. A chin tuck position may be recommended when the child has delayed swallow initiation. During an MBSS, a delay is typically seen as

pooling of food or liquid in the pharyngeal space located close to the opening of the larynx. When the child is positioned with a slight chin tuck, the laryngeal opening may become smaller, reducing the risk of aspiration or penetration. Occasionally, a chin tuck position may be contraindicated for young infants who have laryngomalacia or tracheomalacia (softening of the cartilage in the larynx or trachea) because their soft tissues may be more prone to collapse.⁴⁶ Garon also reported problems associated with the chin tuck position in dysphagic adults with abnormal epiglottic movement patterns after a neurologic insult.²⁵ Occupational therapists need to make individualized positioning recommendations based on a comprehensive assessment and, when available, information obtained from an MBSS.

Adaptations to the mealtime structure may be made to compensate for dysphagia. Occupational therapists may recommend reducing the meal length to compensate for weakness or muscle fatigue. Some children with poor oral control require multiple swallows to clear one bite of food. If a child is unable to complete a subsequent swallow in response to a verbal prompt, an empty spoon offered in the same way as a bite of food may stimulate oral movements to prompt a second swallow. Therapists may also provide recommendations for the pace of oral feeding to allow the child sufficient time to swallow all the food between each bite. More difficult foods, liquids, or self-feeding activities may need to be limited or presented within the first few minutes of a meal session, when the child is less fatigued. Children may also benefit from smaller bites of food or sips of liquid. This can be achieved through the use of a controlled-flow cup, smaller diameter straw, single discrete sips, slow-flow bottle system, or smaller spoon.

Research studies have been completed with adult and pediatric clients evaluating the use of neuromuscular electrical stimulation (NMES) in the treatment of dysphagia. Although the overall evidence is still considered inconclusive, especially in pediatric populations, some studies have shown that NMES produces significant improvements in swallow function when other traditional interventions have failed.^{17,22} NMES is provided to strengthen or reeducate muscles on the face and anterior neck. The use of NMES has precautions and contraindications, and this type of therapy should be administered only by occupational therapists who have obtained additional specialty training and/or certification.

In many cases, aspiration is silent and cannot be detected during clinical observations. Because of the potential medical complications resulting from chronic aspiration and the limited number of effective treatment options, alternative, nonoral feeding methods may be required for some children. Occupational therapists are urged to work collaboratively with physicians, nutritionists, and other professionals to individualize each intervention plan for children with dysphagia.

Interventions for Sensory Processing Disorders

In most young children, oral exploration and gradual adaptation to new sensations are natural processes. Abnormal sensory processing, such as hypersensitivity to food tastes, textures, or smells, can create significant problems with oral feeding. Children with oral hypersensitivity often react negatively to touch near or within the mouth. They may turn away from feeding or toothbrushing activities, restrict food variety, gag

frequently, or have difficulty transitioning to age-appropriate food textures. Children diagnosed with generalized tactile defensiveness have a significantly higher incidence of oral hypersensitivity and oral feeding difficulties compared with their typical peers.⁵⁰ Oral hypersensitivity is also common in children who have received extensive medical interventions. Medical interventions such as endotracheal intubation, orogastric or nasogastric tube feeding, tracheostomy, or frequent oral suctioning may have caused ongoing distress, gagging, or pain, affecting the development of the sensory systems. Early feeding problems experienced in infancy, such as GER or swallowing difficulties, can create negative associations between food consumption and sensory discomfort.⁴⁹ The child's sensory system becomes overprotective, and hypersensitivities may continue long after the noxious stimuli has been eliminated. Children with developmental and neurologic conditions, including autism, pervasive developmental disorders, cerebral palsy, traumatic brain injury, genetic conditions, and sensory processing disorders, commonly exhibit oral hypersensitivity.

During intervention, occupational therapists create opportunities for gradual oral sensory exploration through play and positive experiences to reduce oral hypersensitivity. Children may tolerate greater sensory input if the activity is under the child's control and provided in the context of a motivating, developmentally appropriate play activity.¹⁴ Occupational therapists provide access to textured objects, teethingers, or vibrating toys and playfully encourage the child to explore them with his or her hands, face, and mouth. Occupational therapists may also engage the child in songs or games to encourage self-directed touch to the face or play dress-up with hats, scarves, or sunglasses. Children with oral hypersensitivity may benefit from generalized deep pressure or calming strategies such as slow linear rocking before oral stimulation. Infants may be encouraged to soothe themselves with hand-to-mouth activities or a pacifier. Occupational therapists often aim to create a balance of stimulating and calming sensory input to elicit an adaptive, more normalized response from the child.

Children may gradually improve acceptance of occupational therapist-directed touch with firm pressure that is first applied distally on the body, such as on the arms or shoulders, before moving to touch near the face. A variety of tools can be used to provide stimulation within the mouth, including a gloved finger, vibrating toy, warm washcloth, Nuk brush, infant or child toothbrush, or teething ring. Applying firm pressure to the child's gums or palate may help reduce oral hypersensitivity. Older children with more mature oral motor skills may enjoy whistles, oral sound-making games, bubbles, and blow toys to improve oral sensory processing.

During feeding activities, the occupational therapist introduces new flavors and textures gradually. A lollipop or teething ring can be dipped into a new flavor of food. Children may advance their oral feeding skills when slight changes are made to their current preferred foods. The occupational therapist can gradually thicken a food, combine strained baby foods with puréed table foods for stronger flavors, or change food temperatures to expand the child's sensory experiences. The occupational therapist or parent should provide consistent praise and encouragement for the child's oral exploration and feeding attempts.

Some children with sensory processing disorders have low sensory registration and may demonstrate poor oral sensory

awareness. These children may frequently seek oral sensory stimulation by mouthing their hands, toys, or clothing. They may have decreased awareness of drooling or try to overstuff their mouths when eating. Occupational therapists may establish a treatment program to provide enhanced oral sensory input intermittently throughout the day. Oral activities with a rubber massage brush, cold washcloth, or vibrating device can be used to provide oral sensory stimulation.³³ During mealtimes, foods with strong flavors and cold temperatures may help the child take appropriately sized bites of food. Children who consistently overstuff their mouths when eating may require foods that are cut into pieces and close supervision for safety.

Behavioral Interventions

Food refusal often begins with the presence of underlying medical or skill problems. Children with GER, constipation, or food allergies may feel uncomfortable when eating and develop food refusal behaviors as a result.⁴⁹ Children who gag with textured foods or refuse cup drinking may not have adequate sensory or motor skills to manage these feeding activities. However, a child's refusal behaviors and oral aversion may persist long after the initial medical, sensory, or skill problems have been adequately managed. Children with ASD may exhibit selective eating or refuse to try new foods, given their propensity for rigid and repetitive behaviors and olfactory, gustatory, or tactile sensitivities (see later). When children exhibit food refusal or selective eating, behavioral power struggles may develop during mealtimes. Behavioral inconsistencies may be seen in which the child accepts cup drinking in the preschool setting but refuses to drink from a cup at home. In many cases, occupational therapists may need to include behavioral intervention strategies to promote successful advancement of oral feeding.

A child's refusal to eat may contribute to caregiver stress, and mealtimes may become a battleground, with increasing levels of negative or stressful interactions.²⁸ Occupational therapists try to create new positive interactions and child associations around feeding activities and mealtimes. Occupational therapists and caregivers should have a relaxed, confident, and caring demeanor when implementing behavioral interventions during oral feeding and therapy activities. Offering choices and turn taking during an activity may help a child feel a sense of control and increase his or her willingness to participate during mealtimes. For example, a caregiver may offer a choice of two different foods, or the occupational therapist may allow the child to choose which activity is performed first.

Behavior management interventions include the use of positive reinforcement to increase desired behaviors and ignoring or redirecting negative behaviors. Multiple research studies have supported the use of differential attention during mealtimes, during which positive reinforcement is combined with ignoring or redirection of inappropriate behaviors to improve oral intake.^{9,32,41} Positive reinforcement and regular exposure to nonpreferred foods can significantly improve oral consumption and self-feeding skills.⁵⁷ The use of punishment or negative reinforcement is not recommended. When possible, occupational therapists are encouraged to consult with psychologists and other professionals with knowledge and experience treating behavioral problems in children.

When implementing behavior management strategies, the occupational therapist carefully determines an appropriate form of praise or reinforcement for each individual child. Examples of positive reinforcement include social attention, verbal praise, music, favorite toy, stickers, access to a small prize box, video games, or television. If the child is not motivated to earn the reinforcement item or activity, the intervention will have limited success. Furthermore, toys or activities that are used to praise a child for positive eating behaviors should not be readily available outside feeding sessions. If the child is allowed free access to the reinforcement outside feeding activities, the child will not be motivated to earn the item during the mealtime.

During behavioral interventions, the occupational therapist should break the activity down into small achievable steps and provide clear expectations. When the expectations are small and achievable, the child has the opportunity to experience praise and positive reinforcement for participation and success. Consistent success with an activity should be attained before the expectation is increased.²¹ If the performance expectation increases too rapidly, or the activity is continued indefinitely, until the child's refusal behaviors intensify, the child may quickly learn to refuse more strongly to escape the activity the next time it is presented. When behavioral strategies are implemented with gradual progression of new skills, positive reinforcement, and clear expectations, the child learns to trust the occupational therapist or caregiver, and the negative behaviors may quickly decrease in frequency and intensity.

It is not unusual for children with feeding disorders to experience negative behaviors when trying new oral feeding activities. Negative behaviors may include crying, pushing the spoon or cup away, and spitting out food. Occupational therapists can intentionally ignore these behaviors, calmly persist with the meal, and redirect the child without focusing too much attention on the disruptive behavior. When parents or occupational therapists react strongly to negative or disruptive behaviors and immediately end the activity, the child's behaviors tend to increase in response to the attention and removal of the nonpreferred feeding activity. Occupational therapists may suggest the use of a visual schedule or timer set in advance to help the child clearly understand when the activity is finished, rather than having the parent end the meal when the child's behavior has escalated. This clear end to the activity may also help the child transition from the difficult or new task back to the usual routine of feeding or postmealtime activity.

Interventions for Food Refusal or Selectivity

Many typical children refuse new foods when they are first introduced as toddlers. Evidence has been reported that it takes multiple presentations of a food before a child feels comfortable with it and before a true food preference can be determined.³⁴ Some caregivers will encourage their child to try a new food once or twice and then give up. Occupational therapists should educate parents to continue offering small amounts of a new food across multiple meal sessions to allow the child sufficient time to adapt to the new taste or texture. As noted, some children referred to occupational therapists are highly selective, or picky, eaters. Parents of children with ASD frequently report selective eating behaviors, rigidity surrounding mealtime routines, delayed transitions to textured foods, and concerns for

nutrition and gastrointestinal problems. Children with ASD may struggle with changes in mealtime routines, refuse foods that are a specific color, texture, or temperature, and be less responsive to positive eating behaviors modeled by others. Over time, children with ASD or severe food selectivity may become progressively more restrictive in their food preferences, raising concern for nutritional deficiencies.^{2,20}

Initial recommendations may include consultation with physicians to consider GERD, food allergies, digestive problems, or structural abnormalities. Occupational therapists may also need to address underlying skill deficits or swallowing safety concerns, which may contribute to food refusal behaviors. When management of medical or skill problems has been optimized, children may continue to demonstrate ongoing food refusal or selective eating behaviors.

In addition to using behavioral strategies described earlier, children with food refusal or selectivity often benefit from environmental adaptations, including mealtime structure for consistent feeding times, reducing grazing or excessive liquid consumption outside meals, consistent eating locations, and consistent length of meals. These environmental strategies will promote hunger cues, limit access to less nutritious foods, and create structure within the meal to establish positive eating patterns.

Occupational therapists should also consider interventions to reduce tactile, gustatory, or olfactory hypersensitivity by introducing new smells and tastes carefully and gradually and by allowing children to explore foods using a playful approach. Foods that are similar to the child's preferred foods can be introduced before completely novel foods. Nonpreferred foods can be paired with preferred foods at mealtime, or interventions to reduce olfactory, gustatory, and oral tactile hypersensitivity can be applied outside meal sessions. The occupational therapist helps the family to balance meeting the child's nutritional needs while introducing a variety of foods to his or her diet.

A variety of alternative nutritional interventions has been proposed to help treat ASD, such as high-dose vitamin supplements and/or dietary restrictions. Scientific evidence for the effectiveness of these alternative interventions is inconclusive or not available.^{2,20} A thorough review of these interventions is beyond the scope of this chapter, but occupational therapists are encouraged to consider the impact of these interventions for children with severe food selectivity and food refusal behaviors. For example, children with ASD may not be willing to eat the foods or supplements recommended in the alternative diet.⁵⁹ The diet may further restrict the limited variety of food that the child is willing to eat, and consultation with a registered dietitian or physician may be necessary to monitor for negative side effects from high-dose supplements.

Delayed Transition to Textured Foods

Children who are unable to transition to age-appropriate food textures frequently have a combination of oral sensory and oral motor problems, and some may also demonstrate behavioral refusal. Occupational therapists may implement non-nutritive oral motor activities to reduce hypersensitivity and improve oral motor coordination. Jaw strengthening and repetitive chewing activities without the demand for swallowing may help the child build oral motor skills. [Figure 14-5](#) illustrates a child engaging

FIGURE 14-5 Using a resistive device to improve oral motor skills for advanced food textures.

in a jaw-strengthening activity. Increased tolerance for food textures can be addressed by placing crumbs on a piece of chewy tubing or slowly adding rice flakes to a puréed food. Children who consume baby foods should begin to transition to puréed table foods, allowing adjustment to stronger flavors and encouraging acceptance of a wider variety of oral sensations. Children may practice chewing foods encased in a mesh feeding bag to experience repetitive chewing with less risk for gagging or choking. Occupational therapists may provide praise or behavioral reinforcement for the child's participation in challenging new activities. When a child takes a few small bites of textured food safely outside primary meal sessions, occupational therapists may begin to integrate these new skills slowly during meals, such as during the first five to ten bites. Rapidly increasing demands during the meal session, before the child has adequate motor or sensory skills, may affect oral intake or nutritional status and create stressful child-caregiver interactions. [Box 14-4](#) is helpful in recognizing the foods that may be indicated and contraindicated in children with immature oral motor skills.

Delayed Transition from Bottle to Cup

A child may also have difficulty transitioning from breast-feeding or bottle feeding to drinking from a cup. Efficient cup drinking requires more mature oral motor skills than bottle feeding. Difficulty transitioning from the bottle to the cup can be caused by poor jaw stability or delayed lip and tongue control, affecting the child's ability to manage a liquid bolus. Children with a history of failure to thrive may have prolonged dependence on bottle feeding or breastfeeding as the most reliable method to meet their nutritional or hydration needs. When a child is orally hypersensitive, he or she may dislike the intermittent touch of the cup on the outside of the lips or the spillage that often occurs during early cup drinking activities.³³ Hypersensitive children may also seek the calming, organizing sensory input that comes from sucking during bottle or breast feeding.

To help children prepare for cup drinking activities, occupational therapists may initially work on jaw stability, lip closure, tongue movements, and oral sensitivity through

BOX 14-4 Properties of Foods for Children with Immature Oral-Motor Skills

Indicated Foods

Even consistency
Increased density and volume
Thick (liquids)
Uniform texture
Stays together (will not break up in the mouth)
Easy to remove and suck

Contraindicated Foods

Multiple textures and consistencies (e.g., tacos, vegetable soup, stews, salads)
Sticky (e.g., peanut butter)
Greasy (e.g., fried foods)
Tough (e.g., red meat, processed meats, diced fruit)
Fibrous and stringy (e.g., celery, citrus fruits, raw vegetables)
Skins (raw fruits, peanuts)
Spicy (pepper and horseradish)
Seeds and nuts (plain or in breads and cakes)
Thin liquids (e.g., water, broth, coffee, tea, apple juice)
Quickly liquefying (e.g., Jell-O, ice cream, and watermelon)
Foods that break up in the mouth (e.g., some cookies and flaky pastries)
Hard, crunchy (e.g., carrots)

positioning, handling, and oral motor activities. Cups with nonspill valves in the lid require stronger lip closure and oral suction abilities and may be more difficult to use by children with neuromuscular impairments. A spouted cup may initially make it easier for a child to suck the liquid or form a bolus in the mouth. Spouted cups may also provide similar sensory input to bottle feeding for children with sensory defensiveness. When drinking from a cup with a spout, the child may need to tilt the head back, which may create additional difficulties if the child has extensor posturing, poor head control, or pharyngeal swallowing problems. Use of a cut-out cup may help reduce head and neck extension and allows the occupational therapist to observe the flow of liquid and the child's mouth movements easily during drinking activities.

With free-flowing liquid from an open cup or nonvalved spouted cup, children should be positioned in a more upright position to encourage bolus formation in the mouth, without the impact of gravity creating an uncontrolled flow into the pharyngeal space. Children may also benefit from thickened liquids when first learning to drink from a cup to compensate for decreased oral control or pharyngeal swallowing skills.

External jaw support can be provided by the occupational therapist whose index finger placed underneath the lower mandibular bone and the thumb is placed on the anterior chin. Providing jaw support while sitting beside the child with the arm around the back of the child's neck may allow the occupational therapist to provide additional stability for the child to maintain adequate head alignment ([Figure 14-6](#)). Children often bite on the rim or spout of the cup to gain additional jaw stability. They also may push the cup into the corners of their lips or rest their tongue on the rim of the cup for additional sensory input.³³ These patterns should decrease over time

FIGURE 14-6 Jaw control and oral support. **A**, From the side. **B**, From the front.

as the child becomes more skilled in managing liquids from a cup.

Neuromuscular Interventions for Oral Motor Impairments

A wide range of children demonstrate oral motor impairments that affect the development of feeding skills. Oral motor problems are seen frequently in children with global neuromuscular impairments caused by cerebral palsy, traumatic brain injury, prematurity, or genetic conditions such as Down syndrome. Children without neuromuscular impairments may also demonstrate oral motor problems when they are delayed in transitioning from a bottle to a cup or from pureed foods to textured foods. Inexperience with normal feeding activities may contribute to oral motor weakness and coordination difficulties. Oral hypersensitivity may cause a child to retract the tongue into the mouth to avoid stimulation, contributing to maladaptive oral movement patterns. Occupational therapists include oral motor activities within a comprehensive intervention plan to promote strength and coordination for the development of more advanced oral feeding skills.

Whenever possible, oral motor activities should include foods or flavors to incorporate taste receptors and facilitate the integration of sensory and motor skills for a functional response.

Hypersensitive children may tolerate non-nutritive activities initially, before they are able to accept the additional sensory input that food flavors provide.

Jaw weakness is often seen in children with oral feeding difficulties. This may contribute to an open-mouthed posture at rest, drooling, food loss during feeding, difficulty with chewing a variety of age-appropriate foods, or poor stabilization when drinking from a cup. Jaw weakness and instability may also affect lip closure for spoon feeding and control during swallowing. Occupational therapists may facilitate jaw strength with a variety of non-nutritive or nutritive activities. Non-nutritive strengthening activities may include sustained biting or repetitive chewing on a resistive device or flexible tubing before the introduction of food textures. Nutritive jaw strengthening activities may include biting or chewing on fruits or vegetables encased in a mesh pouch or progressive resistive activities with a variety of solid or chewy foods placed over the molar surfaces.⁴⁵

Children with neuromuscular impairments may have strong patterns of abnormal oral movement. The child may exhibit a tonic bite by biting down forcefully in response to a stimulus and demonstrate subsequent difficulty opening or relaxing the jaw. A strong tongue thrust movement pattern may also be present, in which the tongue forcefully protrudes beyond the border of the lips during oral feeding activities. A well-supported and slightly flexed head position reduces these abnormal movement patterns. Children with tongue thrust may also benefit from oral motor activities to facilitate tongue lateralization and placement of the spoon or food bolus to the sides of the mouth, rather than at midline.¹¹

Children may demonstrate immature forward-backward tongue movements during feeding, poor dissociation of the tongue from the jaw, and poor tongue lateralization to control textured food over the molar surfaces. Occupational therapists may engage the child in activities to facilitate tongue movements, such as encouraging the child to make silly faces in a mirror or lick lollipops, frosting, or whipped cream from the corners of the mouth or within the cheeks. Stimulating the sides of the tongue and inside the cheeks with a Nuk brush or oral motor tool may also encourage tongue lateralization.

Problems affecting the lips and cheeks include abnormal tightness or weakness. A child may demonstrate lip or cheek retraction, making it difficult for the child to assume or sustain lip closure. Good lip closure and lip seal are needed to assist the child with oral food control and prevent anterior spillage during feeding. It is also very difficult to swallow with retracted lips and cheeks because the lips seal the oral cavity to create pressure to propel the food bolus into the pharyngeal cavity. Slow perioral and intraoral cheek stretches can help promote lip closure before initiating functional activities with spoon feeding or whistles.

Researchers and clinicians suggest that oral motor therapy is an important component of a global treatment approach for children with feeding problems.^{6,16,35} A recent systematic review by Howe and Wang³⁰ has indicated that research evidence supports the use of oral motor and physiologic interventions for preterm infants, children with neuromuscular impairments, and children with oral structure abnormalities such as cleft palate (see later). [Research Note 14-2](#) also describes a study evaluating oral motor intervention in children with cerebral palsy.

RESEARCH NOTE 14-2

Gisel, E.G. (1994). *Oral-motor skills following sensorimotor intervention in the moderately eating-impaired child with cerebral palsy*. *Dysphagia*, 9, 180–192.

Abstract

This study looked at the efficacy of oral sensorimotor treatment in children with cerebral palsy. Outcomes were reported for nutrition anthropometrics, such as weight and skin fold parameters. Additional outcomes were reported for functional oral feeding activities, including spoon feeding, biting, chewing, cup drinking, straw drinking, swallowing, and drooling. Twenty-seven American toddlers and school-age children with cerebral palsy completed the 20-week study. Comparisons were made among treatment groups; protocols comprised 20 weeks of oral sensorimotor treatment, 20 weeks of chewing-only treatment, and 10 weeks of no treatment followed by 10 weeks of treatment. During the treatment phase, oral motor therapy or chewing was completed daily for 5 to 7 minutes prior to snack or lunch. Oral motor treatment interventions were described in detail and included activities to stimulate tongue lateralization, lip closure, and chewing skills. The results showed a positive treatment effect at the end of the 20-week period for all three treatment groups, with improvements noted in the areas of spoon feeding, chewing, and biting skills. Each group showed improvements in different functional oral feeding skills; however, improvements were noted in the third group only after treatment was initiated in the second 10-week period. Improvements in nutrition anthropometrics, cup drinking skills, and videofluoroscopic swallowing results were not significant for any of the three treatment groups.

Implications for Practice

Oral motor and chewing interventions may be effective to improve some oral feeding activities; however, the research evidence continues to be limited. Occupational therapists should carefully, objectively, and regularly evaluate whether progress is being demonstrated in their patients. They may also supplement oral motor therapy with a variety of interventions, including food texture modifications, sensory-based activities, postural and respiratory activities, positioning adaptations, and behavioral techniques as part of a comprehensive treatment plan to improve feeding skills in this population.

Transition from Nonoral Feeding to Oral Feeding

Nonoral feeding with a gastrostomy, nasogastric tube, or other method is indicated when a child is unable to meet his or her nutrition or hydration needs by mouth. Nonoral feeding methods may be used when the child has dysphagia; complex heart, respiratory, or other medical conditions; or GI problems. Other children require nonoral feeding simply because they are unable to consume enough food or liquid by mouth for adequate growth and hydration. Inadequate nutrition or hydration can severely limit a child's motor development, cognitive development, and health.²⁶ The placement of a gastrostomy

tube or the use of other nonoral feeding methods can be a temporary measure to promote the child's nutritional status and growth.⁵³

When children receive nonoral feeding, they are at risk for developing oral motor and oral sensory impairments because of limited oral feeding experiences. Nasogastric and orogastric tubes may also create sensory distress for the child during placement of the tube. When these tubes are needed over a long period, they are typically re-inserted or replaced at least once per month, causing further sensory distress to the child. Occupational therapists may provide an intervention program to provide ongoing oral exploration activities and social engagement during nonoral feeding. The goal is to create positive social and oral exploration experiences on a daily basis and ultimately link these pleasurable experiences with the satiation of hunger.

If the child has a history of aspiration dysphagia or if oral feeding is not medically safe, the child may suck on a pacifier or engage in mouth play with teething rings, spoons, and toys during nonoral feeding. Occupational therapists and caregivers can engage in games that include touch and exploration around the face and mouth. Children may also benefit from games that encourage them to make different sounds with their mouth, give kisses, or blow whistles or bubbles. Whenever possible, occupational therapists should encourage families to include their child in mealtime routines, such as sitting with the family at the table during tube feedings and oral play activities.

When the child is medically cleared to have nutritive stimulation, occupational therapists and caregivers can provide flavors or tastes of foods by dipping a finger, pacifier, spoon, or toy into juice, formula, or puréed foods. Children who receive nonoral feeding may have limited opportunities to experience typical feelings of hunger. This is especially true when children require nonoral feedings on a continuous schedule, across many hours during the day. Children who are able to tolerate more compressed bolus feedings may have more opportunities to experience hunger, which may increase the child's motivation to consume some foods by mouth. As the child begins to advance oral intake skills, occupational therapists need to collaborate with physicians or nutritionists who can determine appropriate schedule changes and reductions in nonoral nutrition.

Children who have a tracheostomy often require nonoral feeding methods. The risk and complications of aspiration are significantly increased in a child with a tracheostomy because of the fragility of the respiratory system.¹ Increased risk of aspiration may occur in children with a tracheostomy, related to the changes in pressure created by the new opening in the laryngeal cavity or poor laryngeal mobility. Children with a tracheostomy may be ready for nutritive stimulation when they are able to manage their own saliva without frequent suctioning and can tolerate a speaking valve or cap, which may help create more normalized pharyngeal swallowing coordination.²⁹ Occupational therapists must collaborate with physicians and complete comprehensive assessments of swallowing before initiating nutritive oral feeding activities in children with a tracheostomy. Before receiving medical clearance for oral feeding, children with a tracheostomy will benefit from oral exploration and desensitization activities when oral feeding is not possible.

When children are medically cleared and have sufficient oral motor and swallowing skills to consume larger amounts of food by mouth, they may continue to demonstrate strong oral aversions, hypersensitivity, or refusal to engage in oral feeding activities. Transitioning from nonoral to oral feeding is a gradual process and may require a variety of oral sensory, skill development, and behavioral intervention activities over a period of time. This process is often complex and requires collaboration with physicians, nutritionists, and other professionals.

Cleft Lip and Palate

Approximately 1 in 700 infants is born with a cleft lip and/or cleft palate.¹² A cleft lip or palate is a separation or hole in the oral structures usually joined together at midline during the early weeks of fetal development. A cleft lip is separation of the upper lip, which may be seen as a small indentation, or a larger opening that extends up to the nostril. A cleft palate is a separation of the anterior hard or posterior soft palate and may occur with or without a cleft lip. Clefts in the lip and palate range in severity, may be unilateral or bilateral, and may be part of a larger constellation of medical problems associated with a specific syndrome, such as Pierre-Robin sequence, CHARGE association, Smith-Lemli-Opitz syndrome, Wolf-Hirschhorn syndrome, fetal alcohol syndrome, and orofacioidigital syndrome.³⁶ Children born with clefts typically require one or more surgical procedures to repair the lip or palate. These surgeries may be scheduled at various times in the young child's life, depending on other medical problems, growth and nutrition status of the child, and growth of the lip and/or palatal tissues.

Children born with cleft lip and/or palate often have oral feeding difficulties, including problems latching onto the bottle or breast, inefficient milk transfer, prolonged feeding times, milk leaking from the nose, and poor weight gain. Because of the lack of closure between the oral and nasal cavities, young infants with cleft lip or palate have difficulty creating suction to express liquid during breastfeeding or bottle feeding.²⁷ Infants born with clefts in the lip and palate, bilateral clefts, and syndromes that include other medical problems typically have more severe feeding problems. Infants born with only a minor cleft lip are often successful with breastfeeding or bottle feeding, with only a few simple adaptations.³⁶

Occupational therapists recommend compensatory positioning, adaptive feeding techniques, and specialized bottles for young infants with cleft lip or palate. Feeding the child in a more upright position (>60 degrees) may help improve milk transfer to the posterior oral cavity. Cheek and/or lip support may be recommended to help with gentle closure of a cleft lip to improve latching or suction during feeding. A variety of specialized bottles and nipples are available that use up and down compression movements (rather than suction) or allow the caregiver to squeeze the bottle to help deposit milk into the infant's mouth. The Special Needs Feeder (previously called the Haberman Feeder) and the Mini Special Needs Feeder both have soft nipples and one-way valves that can deliver milk with little to no oral suction.³⁶ Longer nipples may help deposit liquid toward the back of the infant's mouth, beyond the cleft. Soft squeezable bottles, such as the Mead-Johnson Cleft Lip and Palate Nurser, allow the parent to deposit small amounts of milk into the mouth in synchrony

with the infant's sucking efforts. Infants with severe cleft lip and palate may require additional medical interventions, such as a nasal trumpet or palatal obturator, to be successful with oral feeding. These devices are costly, require custom fitting, often need replacing as the infant grows larger, and may be challenging to use.³⁶ Therefore, it is often suggested to try positioning adaptations and specialized bottle systems as a first approach.

After surgical repair of a cleft, occupational therapists may perform scar massage, initiate therapy activities to reduce oral hypersensitivity, and reassess the oral feeding method. Some children may have ongoing problems with food or liquid entering the nasal cavity during oral feeding. Interventions for this problem include evaluating which food or liquid textures are more challenging for the child, alternating bites of food with sips of liquid, suggesting positioning changes during feeding, and recommending smaller sized bites of food or sips of liquid.

Other Structural Anomalies

Other structural anomalies affecting the feeding process include micrognathia and macroglossia. *Micrognathia* is defined as a small recessed jaw. *Macroglossia* is a term used when the tongue is disproportionately large in comparison with the size of the mouth or jaw. Occupational therapists need to consider the impact of the size and position of oral structures on respiration and oral movement patterns during feeding. They may use different nipples, utensils, or positioning adaptations to help compensate for these structural differences. For example, infants with micrognathia may benefit from a prone or side-lying position to help draw the tongue into a more forward position, allowing improved respiration and nipple compression during bottle feeding. Infants with macroglossia may require adaptations to reduce tongue-thrusting movements and anterior food loss during feeding.

Structural anomalies of the larynx and esophagus include laryngeal clefts, esophageal strictures, tracheoesophageal fistula, and esophageal atresia. Laryngeal clefts vary in severity and are the result of a malformation of the tracheoesophageal septum in utero.¹⁸ Tracheoesophageal fistula and esophageal atresia are both repaired surgically, often within the first few days of life. Children with a history of surgical repair to the esophagus are at increased risk of later developing esophageal stricture, a narrowing of the esophagus. Although these diagnoses are rare, children with structural anomalies of the esophagus are at increased risk for aspiration during swallowing, food refusal behaviors, delayed transition to textured foods, and poor esophageal motility.

Esophageal motility describes how quickly foods and liquids move through the esophagus and empty into the stomach. Liquids and smooth, runny foods empty into the stomach more quickly than thick, fibrous, or more solid foods. Children who have a history of esophageal structural anomalies may have problems advancing to higher food textures as a result of decreased esophageal motility. Occupational therapists may recommend adapting food textures to maximize oral intake, alternating bites of food with sips of liquid to help clear the esophagus, slowing the pace of feeding, or encouraging a subsequent dry swallow after each bite of food to help compensate for delayed esophageal motility.

Summary

The causes of pediatric feeding, eating, and swallowing disorders are diverse and complex. Occupational therapists consider the whole child during the assessment and intervention process, including multiple overlapping child factors and performance skills, activity demands and contexts, and family patterns (Case Study 14-1).

- A competent occupational therapy practitioner who provides services for feeding, eating, and swallowing has knowledge and skills in the following:
 - Anatomy and physiology of oral motor and swallowing functions
 - Growth and developmental milestones for oral feeding and self-feeding skills
 - Nutrition and medical conditions that influence the assessment and intervention process
- Diagnostic tests used with children with feeding and swallowing disorders
- Social, emotional, and behavioral factors that affect feeding and mealtimes
- Sensory processing skills that support feeding transitions
- Safety considerations for feeding and swallowing
- Environmental influences and adaptations
- Positioning modifications
- Adaptive equipment and oral motor techniques used in feeding intervention plans
- The assessment and treatment of pediatric feeding disorders often require interprofessional collaboration between the occupational therapist and other members of the child's treatment team.
- Inclusion of parents and other primary caregivers in all stages of the assessment and treatment program is mandatory to ensure the child's ultimate success in eating across environments.

CASE STUDY 14-1 Marco

Marco was a 4½-year-old boy referred for an evaluation of feeding, eating, and swallowing. His problems with oral feeding began early in infancy. He had difficulty latching on during breastfeeding attempts and did not have adequate weight gain, so he was transitioned to bottle feeding at 1 month of age. He coughed and sputtered during bottle feeding in infancy, often at the end of the feeding. Marco was very particular about what type of nipple was used with his bottle and did not take his bottle whenever a different nipple was attempted. Baby foods were first introduced at 6 months of age. With baby foods, Marco gagged, refused to open his mouth, and turned away after the first few bites. His parents stopped trying baby foods for a few weeks, and then they would try again. Marco demonstrated similar refusal behaviors with every attempt. Marco's parents later insisted that Marco sit at the dinner table at the start of family meals, where he was encouraged to try some new foods. When Marco refused to eat, his parents would allow him to leave the table after a few minutes.

As a toddler, Marco continued to be dependent on formula from a bottle, and he continued to have difficulty growing and gaining weight. At the advice of the primary care physician, Marco's mother stopped bottle feeding and only offered a cup and a variety of foods when Marco was 4 years old. Marco then refused to eat or drink anything for 3 days. He was admitted to the hospital for dehydration, and he started nasogastric tube feedings. After the tube feeding started, he never returned to accepting the bottle. After 3 weeks of nasogastric feeding, a gastrostomy tube was placed.

Marco lived in a rural community and had limited access to medical specialists and therapy services. Marco had never had a modified barium swallow study. He had no history of pneumonia, but he had occasional unexplained low-grade fevers, which the parents attributed to teething. Marco received a private speech-language evaluation approximately 2 months prior to the occupational therapy feeding

evaluation, and concerns were reported with receptive language, expressive language, and articulation. Marco was scheduled to enroll in a preschool class in the fall.

Evaluation Findings

At the time of the evaluation, Marco received 100% of his nutrition from PediaSure via his gastrostomy tube on a continuous schedule over 16 hours. He was unable to tolerate an increase in his tube feeding rate, with leakage around the gastrostomy tube site and behavioral discomfort noted.

Marco licked a potato chip during the parent-directed feeding observation. He refused to bite, chew, or swallow any foods or liquids that were encouraged by his mother. Marco grimaced during the occupational therapy oral-motor assessment, but he was able to participate with encouragement, clear expectations, and praise. He gagged when stimulation was provided on his tongue or palate and demonstrated retraction in his cheeks and tongue. Marco used a weak, nonrhythmic, immature munching pattern, with simulated chewing. He had a positive tongue lateralization response and a closed-mouth posture at rest, with no evidence of drooling. Oral-facial muscle tone appeared to be within normal limits.

Marco was ambulatory, alert, sociable, and able to communicate basic needs. During observations of play, he did not want to explore "squishy balls" with his hands during the evaluation, and he pulled away during a scissors activity when the paper began to touch the back of his hand.

Intervention Considerations

Prior to the start of treatment, Marco was referred for an evaluation by a gastroenterologist. An endoscopy was completed, which showed significant esophagitis and gastroesophageal reflux disease, but no evidence of allergies. Marco began antireflux medication. Marco was not referred for a videofluoroscopic swallow study because of the severity of his refusal to consume food or liquid by mouth. Marco was

CASE STUDY 14-1 Marco—cont'd

monitored throughout his treatment program for clinical signs of dysphagia.

Because Marco's family lived in a rural area, with limited availability of treatment services, he was referred for an intensive day treatment program to improve his oral feeding skills. He received intervention from an occupational therapist, behavioral psychologist, and speech-language pathologist. He also received consultations with a nutritionist, gastroenterologist, and social worker. Occupational therapy services were provided three or four times per week for 30- to 60-minute sessions for a total of 5 weeks. Occupational therapy sessions integrated sensory, motor, and behavioral treatment techniques to improve Marco's ability to consume a variety of foods, manage liquids from a cup, and improve self-feeding skills. Specific occupational therapy activities included the following:

Sensory

Marco demonstrated oral hypersensitivity, with symptoms of generalized tactile defensiveness. During treatment, Marco engaged in play-based sensory activities with finger paint, craft activities, squishy balls, Play-Doh, clay, rice, and water play. Oral sensory preparatory activities included slow, deep pressure touch beginning on the arms and shoulders before progressing to the outer cheeks and lips.

Behavior

Marco often refused to try new feeding and oral motor activities. The occupational therapist implemented behavioral strategies to offer choices when possible and set clear, consistent expectations. Enthusiastic praise and other reinforcements (e.g., favorite toy or game) were provided after participation in oral feeding and difficult activities. A timer was used to signal the end of the meal or therapy session. Activities were graded to provide a gradual increase in demands that were consistent with the child's oral-motor and oral-sensory skill levels. Toward the end of the treatment program, external toy reinforcements were gradually decreased to encourage self-motivated participation.

Oral Motor

Marco had oral motor impairments limiting his ability to manage a variety of foods. He demonstrated jaw weakness

and tightness or retraction in his cheeks, lips, and tongue. Initially during meal sessions, Marco was offered puréed foods to maximize his oral intake and compensate for his oral motor and oral sensory difficulties. During occupational therapy sessions (e.g., outside mealtimes), Marco quickly improved his tolerance for oral motor activities when they were combined with behavior management and sensory processing techniques. The occupational therapist was able to complete cheek and lip stretches to improve management of food in the buccal cavity during chewing. After these stretches, Marco was encouraged to activate these muscles by exploring a variety of whistles. Intraoral activities were provided with a Nuk brush, vibration, toothette sponge, flavor sprays, lollipops, and a regular toothbrush. Marco also participated in jaw-strengthening activities. Expectations were increased gradually when Marco's oral motor skills were adequate to manage more textured foods. Initially, Marco mashed small amounts of cracker crumbs placed in his mouth for mashing. He then began biting and munching small pieces of dissolvable solid foods and progressed to a wider variety of soft solids, such as cooked vegetables and canned fruits. Marco's cup drinking skills were also advanced gradually, with small single sips at first, leading up to consecutive sips and swallows from an open cup.

Discharge Status

At the time of discharge from the feeding program, Marco consumed 100% of his nutrition needs by mouth, ate a wide variety of foods, and self-fed almost all his food. He continued to be anxious when a new food was introduced and needed some physical prompts and behavioral strategies to "try it out" before he would attempt to eat the food independently. He demonstrated significantly improved jaw strength, oral motor coordination, and oral sensory responses. He consumed ½-inch pieces of soft solid foods during snack sessions. He continued to be somewhat slow with his chewing, so he ate fork-mashed texture in meal sessions. Marco was referred for weekly speech and occupational therapy services after discharge for continued work on higher food textures and language skills. Marco's mother was also provided with a comprehensive program to continue his oral feeding development at home.

Activities of Daily Living and Sleep and Rest

Jayne Shepherd

KEY TERMS

Activities of daily living (ADLs)	Prompts
Performance context	Video self-modeling (VSM)
Grading techniques	Assistive devices
Backward chaining	Environmental adaptations
Forward chaining	Adaptive positioning
Cues	Partial participation
	Sleep

GUIDING QUESTIONS

- What factors affect performance of the activities of daily living (ADLs) and sleep habits of children?
 - How do the environment and context of where the activity is occurring help or hinder performance?
 - How do body structures and functions, performance skills, performance patterns, and activity demands contribute to a child's ADL performance and sleep and rest?
- How and when do you evaluate ADL skills?
 - When do children typically perform ADL and sleep tasks independently?
 - What formal or informal evaluations are available?
- Which general intervention strategies and approaches are used to promote ADL skills and healthy sleep and rest?
- What evidence is available to support the use of specific intervention techniques with specific groups of children with disabilities?
- How can I modify the environment, equipment, or techniques to support ADL development and sleep in children with disabilities?
- What are the effects of context on a child's performance and parental expectations for ADL, sleep, and rest?

Activities of daily living (ADLs) encompass some of the most important occupations children learn as they mature. Self-care, or ADLs, include learning how to take care of one's body, such as toilet hygiene, bowel and bladder management, bathing and showering, personal hygiene and grooming, eating and feeding,

dressing, and functional mobility.³ Other ADL tasks include caring for a personal device and learning to express sexual needs.³ As the child matures, he or she learns to perform ADLs in socially appropriate ways so that he or she can engage in the other occupations within the family unit and community, such as education, play, leisure, rest and sleep, social participation, instrumental activities of daily living (IADLs), and work. Often, when a child is young, he or she performs ADLs as co-occupations of caregivers and children, especially when the child has a disability. Parents often establish the routines for bathing, dressing, feeding, and delegate more complex ADLs to others.³ In addition, rest and sleep occupations often affect ADL performance.

This chapter discusses the dynamic interaction of child factors, contexts, activity demands, and performance skills and patterns that allows a child to engage in ADL occupations in a variety of environments. Evaluation methods, intervention approaches, and evidence-based strategies for improving outcomes in ADL activities are reviewed. Typical development, limitations, and modifications for toileting, dressing, bathing, grooming, and performing other related ADL tasks are described (feeding is discussed in [Chapter 14](#)). Examples of adaptations to physical and social environments are provided, with consideration given to cultural, temporal, virtual, and personal influences.

Importance of Developing ADL Occupations

The foundations for mastering ADLs begin in infancy and are refined throughout the various stages of development. As unique individuals living in certain contexts, children learn these activities at varying rates and have occasional regression and unpredictable behaviors. Cultural values, parental expectations, social routines, and the physical environment influence when children begin to bathe, dress, groom, and toilet themselves. Overall, society and families assume that children develop increasing levels of competence and self-reliance to meet their own ADL needs. Growth and maturity allow the child to participate in various roles and environments, with decreasing levels of adult supervision for ADLs.^{65,119}

When a child is born with or acquires a disability, parental and child expectations for ADLs and daily living independence are modified. Occupational therapists are instrumental in collaborating with parents and children to learn how to modify

activity demands and routines so that children perform ADL tasks in their everyday environments. Active participation in ADLs has several benefits for the child, including maintaining and improving bodily functions and health (e.g., strength, endurance, range of motion [ROM], coordination, memory, sequencing, concept formation, body image, cleanliness, hygiene) and problem solving while mastering tasks that are meaningful and purposeful to the child. This task mastery leads to increased self-esteem, self-reliance, and self-determination and gives the child a sense of autonomy.^{33,97} When children dress themselves, they may choose their own clothing, participate in dress-up during playtime, put on a coat when going outside, change clothes for gym class, and/or dress in a uniform to participate in band or work at a restaurant. As the child learns new ADL tasks, he or she develops a sense of accomplishment and pride in his or her abilities. This increasing independence also gives parents, teachers, and other caregivers more time and energy for other tasks⁴⁷ while the child contributes to the family unit.

As a child learns new ADL tasks, routines or patterns of observable behaviors develop. These repetitive routines (e.g., morning routine for getting ready for school, bedtime routine) are embedded within the family culture and environment.^{38,144} Occupational therapists ask parents about daily routines and customs at home or school that may influence a child's ADL performance. Some examples of questions to consider asking are as follows:

- When are children expected to be toilet-trained or independent in brushing their teeth?
- How is your child expected to get from room to room in your house or in school?
- Can you please describe your morning routine?

Routines help satisfy or promote the completion of ADL tasks to meet role expectations in home, school, community, and work environments. They are culturally based and often are a combination of what is expected but also what is practical.⁴³ Each family, teacher, employer, or community organization may follow a unique routine for self-care tasks. For example, the family may require a toilet break whenever they are going somewhere, and teachers may allow students to use the toilet at fixed times during the day. Sometimes routines become damaging and hinder the performance of ADLs.^{1,38,144} For example, a child with autism or obsessive-compulsive disorder may be quite rigid about how he or she performs grooming tasks and is inflexible when Aunt Lou visits and the placement of items in the bathroom changes.¹⁷⁰ He or she also may routinely wash the hands after touching any object. These patterns of behavior now interfere, instead of support, ADL performance. Families may or may not have routines that affect ADL performance (e.g., when they eat, when bathing occurs, how often laundry is done, how children are expected to manage personal items such as glasses or retainers). As a child matures, he or she becomes more responsible for developing and maintaining routines that become habits to prevent further illness and maintain health and well-being. Checking skin conditions, maintaining cleanliness during toileting or bathing, preventing cavities through tooth brushing, maintaining personal care devices such as orthotics or catheters, and developing consistent bedtime and sleep habits are some of the healthy living routines that help the child meet role expectations for community living.

Factors Affecting Performance

Child factors, performance environment, contextual aspects, and specific demands of the self-care activity, as well as the child's performance skills, affect the child's ability to participate successfully in ADL occupations. ADLs are performed in a context of interwoven internal and external conditions, some from within the child (e.g., bodily functions and body structures related to the disability, personal and cultural contexts) and others around the child (e.g., social and physical environments; virtual, cultural, and temporal contexts).¹ As occupational therapists consider these factors, they determine the knowledge and performance skills (goal-directed actions) and patterns that the child needs to learn self-care.

Child Factors and Performance Skills

Occupational therapy intervention to increase ADL function considers what the child and family value and the context in which tasks occur. The levels of independence, safety, and adequacy of occupational performance of the child and expectations of the family determine the child's ADL occupations in various contexts.

Specific child factors (body structures and functions), performance skills, and performance patterns will affect ADL performance. For example, children with tactile hypersensitivity may cry during dressing and refuse to dress, despite having the motor and cognitive skills to do so. Children with visual impairments may need to use their sense of touch when brushing the hair. A child with cerebral palsy may not have the postural control to sit up during dressing but may have the sensory perceptual skills (e.g., right-left discrimination, figure/ground) to dress in a side-lying position. A child with attention-deficit/hyperactivity disorder (ADHD) may have all the motor and sensory perceptual skills to complete a self-care task, but his or her cognitive organization, sequencing, and memory may interfere with adequate and safe performance.¹⁴³

Interest level, self-confidence, and motivation are strong forces that help children attain levels of performance that are above or below expectations. Children with intellectual disabilities, traumatic brain injury, or multiple disabilities may have impairments in coordination, initiative, attention span, sequencing, memory, safety, and ability to learn and generalize activities across environments. However, with instruction and opportunity, ADLs sometimes become the tasks that these children perform most competently.¹¹⁴

The child's disability or health status may affect the ability to perform ADL tasks and may also affect caregiver-child interaction during ADL tasks. The child's capacity for learning and ability to complete difficult tasks safely are considered. Pain, fatigue, amount of time the child needs to complete the task, and the child's satisfaction with his or her performance influence the choice of ADL occupations.⁶⁷ Children who have had pain caused by medical procedures may avoid ADL tasks because they think that they will hurt.^{11,176} Rehabilitation studies of children with cerebral palsy (CP)^{119,169} have found that the severity of CP was the greatest predictor of a person's self-care (e.g., eating, grooming, bathing, dressing, toileting), mobility function (e.g., transfers, locomotion), and social function, as measured by the Pediatric Evaluation of Disability

CASE STUDY 15-1 Karina: Partial Participation

Four-year-old Karina is hospitalized every 2 months because of respiratory complications related to a muscular disorder. Like most 4-year-old girls, Karina has an opinion about and preference for how her hair is styled, and she likes to wear barrettes, ribbons, jewelry, and pretend makeup. Karina has a tracheotomy, poor endurance, limited strength, and limited

postural control to sit independently. Although sitting independently in bed to groom is limited by these client factors, with partial participation, Karina is still part of the activity. She can sit up and bend forward with physical support from the occupational therapists, reach and choose her barrettes, and, with assistance, comb her hair.

Inventory (PEDI). When gross and fine motor skills were less affected, the child's functional skills increased and the amount of caregiver assistance decreased.¹¹⁹

Providing intervention for foundational gross and fine motor skill development, including developing core strength and balance, may improve ADL outcomes for children.⁹ Recent rehabilitation research also suggests that constraint-induced movement therapy (CIMT) may improve and maintain functional upper extremity performance that may affect ADL participation.^{19,136}

Children who are acutely ill or who have multiple disabilities that require numerous procedures throughout the day (e.g., tube feeding, tracheotomy care, bowel and bladder care) may not have the time or energy to perform ADL tasks independently. For example, Jenna, a 10-year-old child with a C6 spinal cord injury and quadriplegia, can dress herself independently in a 45-minute period, but she and her family prefer that someone else dress her so that she has more energy for school tasks. Children with multiple disabilities may be physically unable to do all or any part of ADL tasks, but they can partially participate or direct others on how to care for them (*Case Study 15-1*). When children are hospitalized for long periods, they often need to have some control over their participation in self-care routines. *Figure 15-1* shows how doing a small part of self-care routines is possible and meaningful for children in the hospital with acute illnesses.

Performance Environments and Contexts

The initiation and completion of ADL tasks are influenced by the context of the tasks, including interwoven conditions internal and external to the child (e.g., personal, cultural, temporal, and virtual contexts) and around the child (physical and social environments). Children in early and middle childhood often perform ADLs in different settings. The four primary settings that children experience are home, school, community, and work. Once the occupational therapist understands the contexts in which occupation occurs, intervention strategies congruent with the demands of the activity are chosen or aspects of the environment that are barriers to the child's performance of ADL tasks are modified. Although this section has divided the contexts into various areas, all the areas are interrelated.

Personal and Temporal Contexts: Family Life Cycle and Developmental Stage

Age, gender, education, and socioeconomic status define the personal context for ADL occupations.¹ In assessing dressing, awareness of the personal context is critical in choosing age- and gender-appropriate clothing within the family's budget. The time of day or year, life stage of the child or other family

FIGURE 15-1 Partial participation. This child partially participates in hair combing and chooses her barrettes while therapists support her in her hospital bed.

members, family routines and occupations, and duration, sequence, or past history of the activity are included in the temporal context.¹ Consider Cory, who is learning to tie his shoes. A routine method is established so that he does the task the same way every time he tries it at home and school—first pull both laces tight, then make an X. Cory practices it every time he tries to tie his shoes but becomes frustrated easily. If mom and dad work, practicing shoe tying before going to school works if they all get up 15 minutes earlier in the morning, and Cory doesn't become frustrated with the time constraints. When the seasons change, Cory must not only tie his shoes, but also don boots and extra clothes (e.g., mittens, snow pants). With these additional time constraints, his parents may decide to practice shoe tying at a different time of the day or on the weekend.

Children typically master ADLs in a sequence, achieving specific tasks as overall competency increases. The sequence of ADL development helps occupational therapists and families form realistic expectations for children at different ages and helps determine the appropriate timing for teaching these occupations. By considering the child's age, occupational therapists determine when it is time to stop working on specific preparatory or therapeutic activities. For example, 6-year-old Tilly has received occupational therapy for 5 years to enhance eating by trying to increase her lip closure and develop a more efficient suck-swallow pattern. If she has not learned this over the past 5 years, what are her chances of learning it this year? It may be time for the occupational therapist to work on self-feeding

strategies or on an IADL activity, such as operating an appliance with a switch for meal preparation.

Families vary in their ability and availability to assist and encourage their child to perform ADLs. This ability often depends on where the family and child are in the family life cycle, personal factors or characteristics of the child, and family's ability to spend time and be flexible in everyday routines.^{10,14,148,170} When the child is an infant, parents often seek instruction on feeding, dressing, and bathing. By 3 years of age, the child's self-feeding, dressing, and toileting skills may become issues for parents. For example, if Mary is the youngest of seven children, increased ADL independence in feeding or dressing may be less important because her older siblings love to feed and dress Mary. As Mary transitions into a day-care setting or another sibling is born, learning basic ADL skills may become a priority.

Mothers of very-low-birth-weight children or children at risk tend to adjust to their child's motor and cognitive needs by giving more directive and positive emotional and social assistance during ADLs than parents of children who were born full term.⁷⁶ Sometimes, parental overinvolvement in a child's self-care provokes increased anxiety in the child.¹⁷⁶ Occupational therapists need to consider how caregivers actively support or hinder ADL participation by modifying the social and physical environment or by changing the demands of the ADLs.⁷⁶ First-hand knowledge of parents and caregivers about strategies that "work" with their child and within their family routines is essential to consider in planning ADL intervention.^{14,43,144}

When the child enters elementary school, typically by 6 years of age, functional mobility in the school environment, dressing (especially outerwear), toileting, socialization with peers, grooming (e.g., washing the hands and face), and functional communication (e.g., writing, drawing, expressing needs) become increasingly important. As older siblings become more aware of and sensitive to the child's disability, they may ignore their brother or sister in community settings or be more motivated by the occupational therapist to help the child learn ADL tasks.

During adolescence (13-21 years), parents and child can begin to have different concerns and goals for therapy. Both may be concerned about the adolescent's independence in ADL; however, adolescents may have more concerns about fitting in with a social group.¹⁰³ When children who require maximum physical assistance in ADLs approach adulthood, they may become a great concern to parents. For the first time, parents may not have the physical strength to handle the daily care needs of their child or may voice concerns about the child's safety if someone else provides the caretaking.

Increasing independence in ADL tasks during adolescence often determines whether a child will fit in with peers, obtain a job, or go to college outside the school and family environment. The child takes on increased responsibility for managing ADL routines, caring for personal devices, and perfecting grooming skills (e.g., shaving, hair styling, skin care, braces). During this stage, families further investigate current community resources as they think about future living arrangements, vocational opportunities, and the availability of other recreational activities for their child.¹⁶⁶ Additional IADL tasks are introduced to promote independence during this stage, including caring for clothing, preparing meals, shopping, managing money, and maintaining a household.⁶² Parent issues may focus

on the child's ability to express sexual needs, be safe in many environments, and respond appropriately to emergencies.

Social Environment

The social environment, family, other caregivers, and peers provide encouragement and support ADL independence. They also shape expectations regarding the child's ADL occupations. In large families, different members may be assigned to perform or help with specific ADL tasks for a child with a disability; in other families, the parent may be the sole person responsible for the daily living needs of the child. Family expectations, roles, and routines for managing daily living needs also influence the child's development of ADL and performance patterns.¹⁶⁶ For example, parents living on a farm may expect their child to get up at dawn, put on overalls and boots, do chores such as feeding the animals, receive home schooling, and help sell eggs to augment the family income.

When planning treatment, the occupational therapist considers personal characteristics of family members, such as temperament, coping abilities, flexibility, and health status (see Chapter 5).¹⁶⁶ For example, the mother may place her older child in the "mothering" role if she is depressed and unable to get out of bed and begin the morning routine. Parents with intellectual disabilities or mental health problems may need to see an occupational therapist modeling a behavior to learn how to cue and structure a task for their children.^{37,166} Parents with physical problems may need instructions and practice in using specific techniques and assistive devices safely.

An analysis of social routines helps determine when and how ADLs are taught. Routines may differ significantly across home, school, community, and recreational environments. The variation in routine may confuse or be disorganizing to children with intellectual disabilities, autism, or ADHD disorders but may be motivating to children without attention, sensory, or cognitive problems. When tasks are taught or practiced at times and places where they occur naturally, they more quickly become part of the child's behavior repertoire. For example, school-based occupational therapists may meet children at the bus to work on functional mobility and may be present as the child removes his or her coat to work on dressing. When tasks are embedded throughout all environments, children have multiple opportunities to practice activities and learn how to use the natural cues in the environment to modify their behavior. Social interactions and networks of peer buddies are extremely powerful in motivating children⁷⁰ and helping them succeed in self-care. Judie Schoonover, an occupational therapist and assistive technology specialist in Virginia, describes creative routines to practice ADL tasks within the school routine⁵⁹:

Rehearsing routines such as dressing and undressing for toileting with students with limited cognition is not meaningful when practiced separate from their daily routines. They do not understand why they are undressing, then pulling their pants right up without using the toilet! Instead, I have asked their mothers to send snacks to school in something that snaps, unbuttons, or zips. Guess what? Undoing fasteners to get a snack out is far more engaging, and doesn't require weekly OT sessions in the therapy room. Another strategy I've used for a child working on an IEP goal of shoe tying or buttoning (but who doesn't wear buttons or tie shoes!) is

to talk with her teacher about incorporating tying a bow as part of her behavior plan. Whenever the child accomplishes a task in class, she buttons a button on an incentive chart or ties a bow on a special dowel rather than put[ting] a sticker on a chart (p. 10).

Cultural Context

As occupational therapists work with children and families in an array of service provision models, they must be aware of their own and others' cultural beliefs, customs, activity patterns, and expectations for performance in ADLs.⁹⁴ An occupational therapist may become involved with a family because someone else believes that services are needed, and the family may not welcome the occupational therapist's personal questions about the child's and family's self-maintenance occupations and routines. Cultural expectations of the family, caregivers, and social group as a whole may determine behavior standards. Family beliefs, values, and attitudes about child rearing, autonomy, and self-reliance influence how parents perceive ADLs. In Anglo-European cultures, parents usually are concerned about children meeting developmental milestones,⁶¹ whereas other cultures (e.g., Hispanic) may be more relaxed about milestone attainment.¹⁷⁹ Children may not be taught to button their coats, tie shoes, or cut food until a later age because parents may value this role as part of their caregiving and affection for the child.

Social role expectations and routines are influenced by culture. In a study by Horn, Brenner, Rao, and Cheng, African American parents expected toilet training routines to begin at an earlier age (18 months) than white parents at a higher income level (25 months).⁶⁹ Many Anglo-European parents encourage children to become independent and self-reliant.⁶¹ In contrast, many Hispanic families¹⁷⁹ and Asian families may encourage dependency or interdependency in the family. Routines for dressing, feeding, bathing, going to bed, and carrying out household tasks vary among cultural groups. For example, bathing may occur less than once a day in some cultures, and hairstyles and head garments may be worn for different occasions, depending on the child's cultural group.

Culture also influences the type and availability of tools, equipment, and materials that a child uses to perform ADLs. Customs and beliefs may determine how parents dress their children, what they feed them, which utensils are used for self-feeding, how they prepare food, which type of adaptations are acceptable to them, and how they meet health care needs. For example, by custom, Muslim or non-Muslim families from the Middle East may only use their left hand for toileting.⁹³ Economic conditions, geographic location, and opportunities for education and employment can help determine the types of resources and supports available to families. Economics influence ADL tasks in many ways—shoes may be old and the wrong size, indoor plumbing may be nonexistent, or a nanny may be expected to dress, groom, and/or feed a young child with disabilities.

Physical Environment

Barriers in the physical environment, including terrain, furniture, and other objects, may hinder the child's ability to improve ADL performance. Inaccessible buildings and rooms crowded with furniture limit how children in wheelchairs move

throughout the environment. On the other hand, a large open space may be too much room to allow a preschooler to contain his or her excitement and complete ADL tasks. Differences in surfaces also affect mobility; for example, rugs can make using a walker or wheelchair more difficult. Other physical characteristics that the therapist assesses relate to the type of furniture, objects, or assistive devices in the environment and whether they are usable and accessible. What is usable in one environment (e.g., a particular type of toilet at home) may not be usable in other environments, such as a hospital or job site. Sensory aspects of the physical environment often influence performance (e.g., type of lighting, noise level, temperature, visual stimulation, tactile or vestibular input of tasks). In particular, children with autism or ADHD are often overly sensitive to and distracted by the sensory aspects of an environment.^{10,12}

The objects used to perform ADL tasks may help or hinder ADL performance. Clothing items (e.g., clothes with snaps, hook and loop shoes), grooming items (e.g., toothbrush, size and design of toothpaste dispenser), or bathing items (e.g., type of soap, bathing mitt, feel of towel) may motivate or distract the child. ADL objects or assistive devices need to be accepted, fit the child and family's preferences, and meet the demands of the social, cultural, and physical environment.

Activity Demands

The activity demands in certain contexts facilitate or impede the quality of ADL performance. A task analysis helps the occupational therapist understand the complexity and various aspects of the activity. This evaluation involves analyzing the objects used, space and social demands, sequencing and timing, and required actions and skills.¹ Activity demands vary in the clinic, home, school, and community. For example, when an adolescent with a traumatic brain injury is learning to style her hair, her performance skills may vary significantly in the occupational therapy clinic from those observed in her hospital or home bathroom. The child's unfamiliarity with the set up of the sink or bathroom may disrupt the flow of motor skills, and the spatial arrangements, lighting, and surface availability may cause process skill problems. For the activity, specific steps are followed and sequenced according to time requirements.

Verbal instruction in sequencing will support performance of ADL tasks. For example, "First you comb the knots out of your hair, then you part the hair and comb it. After a minute of brushing the hair, use the curling iron."

If the adolescent is doing this with friends, the demand on performance skills increases as the number of tasks or steps and social demand to share supplies and to converse increase. In summary, grading ADL performance involves considering adaptations to the environment, type of activity or interactions required, and sequence of the activity. Occupations are viewed according to the environments in which they occur, demands of the activity, and the child's abilities.

Evaluation of Activities of Daily Living

Families and their children play key roles in determining which evaluation procedures are used. By working collaboratively with families, occupational therapists learn about the child,

TABLE 15-1 Rating of Self-Care Skill Independence During Task Analysis

Level of Independence	Definition	Bathing Example
Independent	Child does 100% of the task, including setup.	Child gets out needed supplies and equipment and bathes, rinses, and dries himself or herself without assistance.
Independent with set up	After another person sets up the task; child does 100% of the task.	Caregiver places bathtub seat in tub and organizes bath supplies; child bathes, rinses, and dries himself or herself without assistance.
Supervision	Child performs task by himself or herself but cannot be safely left alone; he or she may need verbal cueing or physical prompts for 1%-24% of task.	Child bathes, rinses, and dries himself or herself without assistance but needs monitoring when getting into and out of tub and when washing lower extremities because of poor balance and judgment.
Minimal assistance or skillful	Child does 51%-75% of task independently but needs physical assistance or other cueing for at least 25% of task.	Child bathes and rinses body parts independently but needs physical assistance getting into and out of tub; he or she is cued to monitor water temperature and to dry body parts.
Moderate assistance (26%-50% partial participation)	Child does 26%-50% of task independently but needs physical assistance or other cueing for at least 50% of task.	Child adjusts water temperature and washes and rinses face, torso, and upper extremities independently; he or she needs physical assistance getting into and out of tub and for washing and rinsing lower extremities and back.
Maximal assistance (1%-25% partial participation)	Child does 1%-25% of task independently but needs physical assistance or other cueing for 75% of task.	Child independently washes, rinses, and dries face but needs verbal cues to wash torso; he or she needs physical assistance getting into and out of tub and for washing other body parts.
Dependent	Child is unable to do any part of the task.	Caregiver physically picks up child, places him or her in tub, and washes, rinses, and dries child's body parts; child does not lift body parts to be washed or dried.

various environments in which ADLs occur, demands of the activities, and expectations and concerns of the family. When children get older and are able to communicate, the occupational therapist includes them in determining which areas of ADLs are important to them. The parents and child often become more vested in the results if the occupational therapist gives them a chance to select or refuse evaluations and choose where and when the evaluation is completed.⁴⁸ This approach also gives occupational therapists a better understanding of the contexts in which the child performs occupations and of current performance patterns that may be valued by the family.

Evaluation Methods

Evaluation of ADLs begins with an analysis of occupational performance, which may involve collecting data from numerous sources. Interviews, inventories, and structured and naturalistic observations are evaluation methods typically used to measure ADL performance in occupational therapy. The occupational therapist uses these methods alone or in combination to analyze occupational performance (abilities and limitations), develop collaborative goals with children and their families, plan intervention strategies, and measure outcomes of treatment. The choice of instrument depends on the reason for the evaluation. Some instruments interview the caregiver or can be completed as an inventory, whereas others are scored while observing the child.

For ADL independence, the child must not only complete the task but also obtain and use the supplies the task requires.

The occupational therapist generally rates performance according to the child's ability to set up and complete a task and may assess performance by grading the child's level of independence. Table 15-1 presents one example of how the occupational therapist might rate a child's independence in bathing.

Ecologic or environmentally referenced assessments are appropriate for all children and are particularly useful for children with moderate to severe disabilities who have difficulty generalizing tasks from one environment to another.¹¹⁴ A *top-down approach* considers the contexts in which the child performs valued occupations in addition to what the child can or cannot perform.²³ With this approach, the therapist can do the following:

- Ask the parent and child what they want or need to do.
- Identify the environments or context in which the task occurs, the steps of the task, and the child's capabilities.
- Compare the demands of the task with the child's actual performance skills while completing the task.
- Identify and prioritize the discrepancies to develop an intervention plan.

With naturalistic or ecologic observation, the occupational therapist gathers information in the typical or natural setting in which the activity occurs. Usually, the occupational therapist completes a task analysis to identify the steps of the activity, sequence of these steps, and how the child adapts to the demands of the environment. For example, when observing a child's ability to use the toilet at school, the occupational therapist notes accessibility barriers and sensory characteristics

of the environment. How the child adapts to these factors, the typical classroom routines and expectations for toileting, and any cultural aspects of the toileting process (e.g., type of clothing the child is wearing, which hand is acceptable for wiping) are also noted. After identifying these contexts and the steps and sequence needed to complete the task, the occupational therapist chooses appropriate intervention strategies according to the demands of the activity in the school context.

Environmental observation is time-consuming but provides an abundance of information when used in a team effort.^{118,126} In addition to evaluating the performance skills and patterns used, the therapist identifies the level of assistance and the number of modifications needed to improve the child's independence. Anderson et al.⁶ have written *Self-Help Skills for People with Autism: A Systematic Teaching Approach*, which gives specific methods for collecting data set-up tasks and collect data, which is useful for all children.

Team Evaluations

Curriculum-referenced or curriculum-guided assessments are often used by interdisciplinary teams in settings such as early intervention or school system practice. Self-care is often an area of assessment. The Carolina Curriculum for Infants and Toddlers with Special Needs (CCITSN),⁷³ Carolina Curriculum for Preschoolers with Special Needs (CCPSN),⁷⁴ and Hawaii Early Learning Profile⁴² are typical curriculum-referenced assessments used in early intervention. Specific information about these assessments is found in Chapter 6.

Giangreco et al. have developed a useful transdisciplinary, curriculum-based assessment and guide, *Choosing Options and Accommodations for Children (COACH)*.⁴⁸ Therapists use COACH to identify areas of concern (not specific skills) for school-age children with moderate to severe disabilities and help plan inclusive educational goals with a family prioritization interview and environmental observations. The team identifies priorities, outcomes, and needed supports for specific environments and across environments in the areas of communication, socialization, personal management, leisure and recreation, and applied academics. Team members plan goals together, write interdisciplinary goals, and then decide which services the child needs. The team may decide that an occupational therapist is needed only as a consultant if the special education teacher is able to address the ADL task adequately.

Measurement of Outcomes

Health care and educational systems are demanding evidence-based practice and cost-effectiveness for therapy intervention. Within the past decade, professionals in the fields of rehabilitation and occupational therapy have developed universal assessments to measure the outcomes of therapy designed to enhance ADL skills. Outcomes may include improved occupational performance, adaptation, role competence, health and wellness, satisfaction, prevention, or self-determination and self-advocacy.¹ In addition to providing a means to evaluate children individually, the collection of aggregated ADL assessment results or outcome measures can help justify program expansion or changes in intervention strategies.

In rehabilitation, four primary assessments, which are valid and reliable, are used to measure occupational performance and

adaptation to ADL tasks in children and adolescents. Occupational therapists can use the Functional Independence Measure (FIM; ≥ 8 years) and Functional Independence Measure-II for Children (WeeFIM-II; ≤ 7 years).⁵⁸ The Pediatric Evaluation of Disability Inventory Computer Adaptive Test (PEDI-CAT)⁵⁷ is used for children from birth to 21 years of age.²⁵ Kothari, Haley, Gill-Body, and Dumas found the PEDI to be a valid measure of outcomes in children with brain injury.⁸⁴

The Assessment of Motor and Process Skills (AMPS) assesses ADL and IADL performance skills in various environments, familiar (home or school) and unfamiliar (occupational therapy clinic).^{36,40} It has been used in outcome studies with children older than 3 years and adolescents from different cultural backgrounds and with an array of disabilities.^{39,54} While the child performs a chosen task according to the instructions given, the occupational therapist rates the 16 ADL motor and 20 ADL process skills. The AMPS tasks use a top-down approach that gives a comprehensive view of how efficiently, safely, and independently the child is functioning in performance contexts.^{39,40} The AMPS is sensitive in identifying deficits in motor and process skills for children with ADHD (e.g., coordination, calibration, sequencing, memory).¹²²

School therapists may not find the PEDI-CAT, WeeFIM-II,⁶¹ or FIM to be a useful outcome assessment of school performance. As discussed in Chapter 23, the School Function Assessment (SFA) evaluates the child's participation in six different environments: transportation, transitions, classroom, cafeteria, bathroom, and playground.²⁴ This assessment gives the therapist a profile of valuable information about self-care performance and role performance in the school environment, which is used to develop individualized education program (IEP) outcomes. The Child Occupation Self-Assessment (COSA) is a self-rating tool that a child uses to describe his or her competence ("How well I do the task?") and the importance or value of doing a task ("How important is this to me?") in school, home, and community settings.⁸¹ Observations of ADL and IADL tasks, as well as managing emotions and cognitive tasks, are part of this assessment. Two versions are available, a checklist with visual symbols and a card sort version. For example, one item is "Keep my body clean." The child then rates how well he or she does the task and how important it is to him or her.

The Canadian Occupational Performance Measure (COPM) assesses a client's perception of his or her ADL skills, productivity, and leisure occupations over time and is useful for assessment and reassessment.⁸⁷ The self-assessment part of the COPM makes it more appropriate for children older than 8 years.⁸⁷ Another method to measure outcomes in ADL performance is using goal attainment scaling (GAS).^{4,15,95,105} This method allows the child, family, and occupational therapist to set goals and criteria for success and may be used in combination with the Canadian Occupational Performance Measure.^{28,52,94,104,135} It is an appropriate outcome measurement tool if standardized testing is not available or if outcomes are variable.¹⁰²

Before intervention, outcome measures are defined after talking with the child and family to find out what type of change would be meaningful. Data are collected over time and then goals are modified for incremental differences. Research Note 15-1 describes a review of the literature on GAS in pediatric rehabilitation¹⁵⁸ and gives suggestions for using GAS.

RESEARCH NOTE 15-1

Steenbeek, D., Ketelaar, M., Galama, K., & Gorter, J. W. (2007). *Goal attainment scaling in paediatric rehabilitation: A critical review of the literature*. *Developmental Medicine and Child Neurology*, 49(7), 550–556.

Abstract

In this article, a literature review of goal attainment scaling (GAS) was completed. Three studies in pediatric rehabilitation were reviewed to assess the psychometric properties of GAS. The authors concluded that additional research is needed because only one study investigated inter-rater reliability (found to be good), and only one study investigated content validity (found to be acceptable). Low concurrent validity was found in one study, and no construct validity or content reliability was reported. In six additional studies reviewed by the authors, the use of GAS demonstrated “good sensitivity to change.” The authors concluded that GAS is a promising, responsive method to use in pediatric rehabilitation to evaluate individual goals and progress. However, the authors suggested that additional research is needed related to the reliability of this method when used with children of different ages and types of disabilities and by therapists of different disciplines.

Implications for Practice

- GAS is a sensitive, practical, and easy way to measure small individual changes in ADL occupations using occupational therapy intervention.
- Goals are formulated by parents and children first and then clearly defined on a scale. Goals chosen should represent desired functional changes for performing future ADL tasks.
- Training in GAS is necessary to ensure that goals are objective, discrete, measurable, relevant, and realistic and use equal intervals for performance on the scale.
- If multiple raters are going to use GAS for measuring progress, interrater reliability should be checked by having the raters watch a video of children doing the task and then having them rate performance.

Intervention Strategies and Approaches

When planning intervention procedures, the occupational therapist considers the child’s characteristics, performance skills, and patterns in relation to the context and demands of the activity. Occupational therapists need to be sensitive to parents’ and other caregivers’ needs and concerns. It is helpful to listen to and reassure these individuals while engaging them in observations and problem solving. When planning treatment for children with performance problems in ADLs, the occupational therapist must ask himself or herself the following questions¹⁵³:

- Which ADLs are *useful* and *meaningful* in current and future contexts?
- What are the *preferences* of the child and/or the family?
- Are the activities *age-appropriate* (used by peers without disabilities)?

- Is it *realistic* to expect the child to perform or master this task?
- Which *alternative methods* can the child use to perform tasks (e.g., including the use of activity modifications or assistive technology)?
- Does learning this task *improve the child’s health, safety, and social participation*?
- Do *cultural issues* influence how tasks are taught?
- Can the task be assessed, taught, and *practiced in a variety of environments*?

Therapists use various approaches to improve ADL skills in children, including the following: (1) promoting or creating; (2) establishing, restoring, and maintaining performance; (3) modifying or adapting the task, method, and/or environment; and (4) preventing problems and educating others.¹ Occupational therapists often use a combination of these approaches and various theoretical orientations to help children participate in ADL occupations. Table 15-2 gives examples of these approaches and possible theoretical orientations for the occupational therapist to use when teaching a child to button his or her shirt. These approaches are discussed throughout each area of ADL tasks later in this chapter.

Promoting or Creating Supports

Occupational therapists often create supports within the environment that offer all children the opportunity to engage in ADL occupations that are age-appropriate and not related to a disability status.¹ This approach offers team or system supports for schools without focusing on the child with a disability.^{59,126} When using this approach, occupational therapists design a program in which school or community groups participate. Possible activities include the following: creating a module or center activity requiring zipping, snapping, and/or buttoning; developing a box of fine motor and self-care activities to distribute to all kindergarten classrooms in the district; giving an in-service presentation to the church or school about self-care development or healthy sleep habits; or participating as a building committee member to make recommendations about a universal design for the new bathrooms or gyms being built. When working with families, occupational therapists may promote opportunities in which everyone can participate using a morning checklist for self-care routines. A visual picture board may help all the children in the family to understand which tasks are needed for a morning routine.

Establishing, Restoring, and Maintaining Performance

The occupational therapist may attempt to establish ADL performance and patterns using a developmental approach or, if this is not possible, may try to restore or remediate the child’s abilities that interfere with performance. To establish ADL patterns, the occupational therapist establishes the child’s developmental and chronologic age and plans treatment according to a typical developmental sequence. In this approach, the occupational therapist examines underlying body structures and functions (e.g., strength, tactile discrimination), selects age-appropriate tasks and habits to target in intervention, and gives parents some expectations for skill development. During interventions to establish or restore performance, occupational

TABLE 15-2 Approaches to Improving the Performance of Activities of Daily Living

Approach	Appropriate Frame of Reference	Problem: Buttoning Buttons Without Use of the Right Hand
Create or promote	Person-environment-occupation (PEO) Developmental	Suggest opportunities to help all students learn skills needed for buttoning. Use activities such as dress-up clothes, smocks, lunch bags with buttons or snaps. Provide calendars or number lines with a button or snap activity. Provide a variety of fine motor activities for center time.
Establish, restore, and maintain	Developmental Motor control Biomechanical Neurodevelopmental treatment Sensory integration PEO	Use specific activities to establish hand use and prehension patterns for buttoning. Use coins in a piggy bank, board games with small, thin game pieces, and craft activities (e.g., friendship bracelets, mosaics) to work on hand strength and coordination before beginning with buttons. Provide tasks to develop, improve, or restore body functions (e.g., ROM of hand; weight bearing to decrease tone; increase sensory input by playing with foam or PlayDoh); use dexterity activities to improve motor skills (coordinate, manipulate, flow, calibrate, grip). Maintain performance patterns by using a dressing routine or other tasks that provide practice opportunities for buttoning on a regular basis (e.g., have a calendar on which the day of the week has to be buttoned to the calendar); maintain dexterity and strength through a daily exercise routine.
Modify, adapt	PEO Human occupation Rehabilitation Biomechanical Sensory integration Neurodevelopmental treatment	Revise current activity demands or the context to compensate for body function and body structure limitations that affect performance skills and performance patterns. Adapt the task method: Child uses one-handed buttoning technique, uses a pullover shirt so that buttoning is not an issue, or uses an extra-large shirt with buttons already buttoned; he or she wears the button shirt over a pullover shirt like an open jacket. Cueing performance may include verbal, gestural, physical, or visual prompts. Adapt the object or use assistive technology: Buttons are replaced with other buttons that have long shanks or that match the child's tactile preference; child uses a button hook, elastic sewn-on buttons, or pressure-sensitive tape; child and devices are positioned for stability during activity (e.g., child sits in a chair with arms to button a shirt). Adapt the task environment: Child practices buttoning in the bedroom, away from distracting toys or siblings; parent, sibling, or peer is asked to button the shirt; shirt with buttons is used because it is culturally important to a teenager not to wear a pullover shirt.
Prevention, education	Human occupation Developmental Rehabilitation Biomechanical Sensory integration Coping	Educate and prevent failure at buttoning. Occupational therapist models and teaches the child and parent how to use the above approaches and lets them practice the approach while he or she watches. Occupational therapist provides home ideas for developing opportunities to practice games or tasks and gives written, pictorial, verbal, or video instructions. Occupational therapist consults with day-care provider or teacher to ensure carryover of the method used. Occupational therapist helps child anticipate possible problems when purchasing clothing with different fasteners and how to ask for help if needed.

therapists identify gaps in skills and intervene to teach or remediate the underlying problem that is interfering with a child's ADL performance. This approach focuses on the child's deficits in body function and structure to perform ADL activities.

Occupational therapists often use biomechanical, motor control, cognitive orientation, neurodevelopmental therapy (NDT), sensory integration, and/or behavioral approaches to restore performance skills. For preschoolers with moderate fine motor delays, some ways to increase self-care skills are to provide play and targeted fine motor and praxis

interventions, which require in-hand manipulation, grasp strength, and eye-hand coordination. Using an NDT approach, the occupational therapist encourages the mother to relax the child and lower spastic muscle tone before dressing. In this case, the occupational therapist models by holding the child's pelvis when supine, slowly rolling the child's hips from one side to the other to reduce the tone and encourage trunk rotation. After this preparation improves the child's task performance, the occupational therapist encourages the parent to hold the child at the pelvis while helping him or her pull up his or her

pants. When using this approach, occupational therapists provide parents and children with suggestions on how to practice these rotational movement patterns in various tasks.

In a motor learning approach, a child may learn how to put on shoes through practicing the whole task in a variety of activities (e.g., dress-up, relay races, morning dressing routine) or environments (e.g., home, school, therapy session, gym class). During practice, the child receives specific feedback (e.g., “Pull the back of the shoe up when pushing the heel down in the shoe”). Jarus and Ratzon found that mental practice increased the acquisition of new bimanual motor skills for children faster than just physical practice.⁷¹ This technique may also help children acquire ADL skills (e.g., mental rehearsal of putting the shoe on the foot).

Mobility Opportunities Via Education (MOVE) is a structured interdisciplinary program that helps establish and restore sitting, standing, and walking skills for children with severe motor limitations.¹⁶ The MOVE team plans and provides motor intervention using a motor control or task-oriented approach. Primary goals are eating, toileting, and motor skills; progress is monitored; and goals are updated through systematic data collection.^{16,165,173} Child-centered goal setting helps the team target functional outcomes (e.g., to stand to pull up pants at the toilet). Activities are used to develop ADL skills for the context in which they are used. Teams are trained together, and it is often difficult to distinguish between occupational therapists and teachers. This approach is used with those in any age group with moderate to severe motor limitations and is appropriate for children with and without intellectual impairments. Some research studies have supported the effectiveness of this program for children and adults with severe motor disabilities.^{16,172,173}

Occupational therapists also use behavioral approaches to establish and restore ADL skills. They may use backward or forward chaining to teach the tasks. In *backward chaining*, the occupational therapist performs most of the task, and the child performs the last step of a sequence to receive positive reinforcement for completing the task. Practice continues, with the occupational therapist performing fewer steps and the child completing additional steps. This method is particularly helpful for children with a low frustration tolerance or poor self-esteem because it gives immediate success. In *forward chaining*, the child begins with the first step of the task sequence, then the second step, and continues learning steps of the task in a sequential order until he or she performs all steps in the task. *Forward chaining* is helpful for children who have difficulty with sequencing and generalizing activities. The occupational therapist gives varying numbers of cues, or prompts, before or during an activity. Therapist or person cues and environment or task cues may occur naturally or artificially in an environment. Occupational therapists can use verbal, gestural, or physical cues or a combination of all three.^{154,168}

Environmental or task cues may include picture sequences or checklists, color coding, positioning, and modifying the sensory properties of the environment or materials used in a task. Figure 15-2 illustrates a visual picture sequence for hand washing. Reese and Snell¹²⁵ have described a hierarchic approach to presenting artificial cues from least intrusive (verbal cues) to more intrusive (verbal and gestural cues) to most intrusive (verbal and physical cues). For example, they described this hierarchy of physical cues: (1) shadowing the child's

FIGURE 15-2 This simple picture sequence gives Adam the needed cues to wash his hands independently. (Courtesy Judith Schoonover, Loudoun County Public Schools, Loudoun County, Virginia; Picture Communication Symbols from Mayer-Johnson, Solana Beach, CA.)

movements, (2) using two fingers to guide the child, and (3) using a hand-over-hand approach to guide movement. The occupational therapist or parent uses the fewest cues necessary and fades out cues to promote independence. Figure 15-3 shows examples of these different types of cues, which can be used as a child performs various self-care occupations. Research Note 15-2 presents a review of studies that used different cues

FIGURE 15-3 Hierarchy of cues, from most intrusive to least intrusive. **A**, A hand-over-hand approach is used for squirting soap onto the child's hands. **B**, Two fingers are used to guide zipping of the child's coat. **C**, The occupational therapist shadows her hand over the top of the child's hands to cue hand movements for hand washing. **D**, The occupational therapist verbally cues the child on how to wash the hands.

for persons with severe and profound disabilities and gives practical suggestions to consider.

Once self-care routines and patterns have been developed, it is important to maintain them and any of the environmental supports that promote continued ADL success. Repetition and the development of habits and routines are essential organizers, particularly for children who take a long time to learn new skills, have a poor memory, or thrive on routine or practice. Schedules for toileting or dressing, visual prompts displayed on the wall, a set place for items when grooming, and a checklist for how to clean a splint or contacts are all examples

of contextual supports. Health maintenance activities (e.g., self-catheterization, wheelchair push-ups, ROM exercises, taking medication regularly, eating nutritious meals) support task performance in all occupations, including ADLs such as maintaining a bowel and bladder routine, transferring to the toilet, and dressing.

Adapting the Task or Environment

When adapting or modifying an activity (using a compensatory approach), the occupational therapist uses alternative physical

RESEARCH NOTE 15-2

Lancioni, G. E. & O'Reilly, M. F. (2001). *Self-management of instruction cues for occupation: Review of studies with people with severe and profound developmental disabilities*. Research in Developmental Disabilities, 22, 41–65.

Abstract

Learning and maintaining occupations is often difficult for children with severe and profound developmental disabilities. The authors of this paper reviewed studies about this population for the last 15 to 20 years and identified five main strategies of instructional cues: (1) cards with picture cues, (2) computer-aided and stored picture cues, (3) cards with object cues attached, (4) audio recording equipment that stores verbal cues, and (5) self-verbalization of what is being done. The effectiveness of these strategies and the practicality of using the different types of instructional cues were discussed.

Implications for Practice

- When choosing cues to facilitate ADL performance, occupational therapists need to consider the effectiveness and practicality of the cues.
- It is important not to infer that all children with moderate to severe disabilities respond the same way to different prompts or that only one type of prompt is appropriate.
- Ask the child and caregivers their preferences for the type of cue to be given for completing the task. Attitudes can sabotage the effectiveness of cue use.
- After learning one cue for one step, try to use one cue to do two steps of the self-care task. This helps decrease dependency on the cues for a multistep ADL task.
- Collect data to see which cueing system works best. For example, does the child remember the steps for dressing with picture card cues or cues stored in a recording device or PDA, or a combination of cues?
- For complex tasks, consider using other types of cues such as videos, video monitoring, video self-monitoring, or verbal cues. Take baseline data and data during the intervention to see if performance is improving.

techniques, substitute movement patterns, or other adaptive performance patterns to enable the child to complete a task. Adaptation strategies may include modification of the task or task method, use of assistive technology, and/or modification of the environment. Occupational therapists often use a combination of these strategies to improve a child's performance, considering the performance context. Table 15-3 provides examples of typical adaptation approaches used with different functional problems in ADLs.

Occupational therapists practice adaptation or compensatory strategies in various contexts and modify them until they become functional. For example, a child with a bilateral upper extremity amputation may use several compensatory strategies for ADL tasks. As an adapted method, the child may use the feet or mouth to write or dress or may learn new movement patterns to operate a prosthetic arm (assistive device) for manipulating objects. Adapting the social environment by using a personal assistant or peer in the home or school environment is another adaptation strategy. Modification of the

bedroom set up for easier accessibility and placement of clothes in lower drawers that are reachable from a wheelchair can increase dressing independence.

Adapting or Modifying Task Methods

The occupational therapist often modifies tasks by using grading techniques. Grading is the adaptation of a task or portions of a task to fit the child's capabilities. By using a task analysis, the occupational therapist rates subtasks of the activity and varies them according to their degree of ease or difficulty for the child. The occupational therapist may modify the activity demands to compensate for limited capabilities and performance skills. He or she may grade the tasks according to specific qualities (e.g., simple to complex). Grading a task may include gradually increasing the number of steps for which the child is responsible, fading the amount of personal assistance or cueing the child receives, and reducing the strength needed or length of time the child takes to complete an activity.¹⁵⁴

Each ADL involves a series of task steps that are performed together in a specific sequence. When a child cannot complete a task independently or when completion of the task requires too much of the child's energy, occupational therapists may suggest *personal assistance*, which the child directs.¹⁵² *Partial participation* occurs when a child performs some steps of the task and a caregiver completes the remaining steps; this allows the child to practice and often improves performance of the ADL task.

Adapting the Task Object or Using Assistive Technology

Assistive devices are commercially available or are custom-made by the occupational therapist, skilled orthotist, or rehabilitation engineer. By using local and national databases, publications, and Internet searches on product comparison, occupational therapists can keep informed about the availability of new assistive devices to find equipment for unique or specific problems.

The choice of an assistive device is a cooperative decision made by the child, parents, therapists, and other team members who work with the child.²² Together, these individuals systematically evaluate what the child needs to do, his or her performance contexts, the child's abilities and limitations, the capabilities of the device itself, and the child's perception of using the device.^{63,124} Teams choose the device that has the best environmental fit. The occupational therapist and team offer comprehensive support, education, and coaching to the family, caregivers, child, and others about how to use the device.¹²⁴ Adolescents who are striving to identify with their peers tend to reject devices that call attention to their disabilities. To be worthwhile, an assistive device should meet the following requirements:

- *Assist in the task* the child is trying to complete without being cumbersome.
- Be *acceptable* to the child and family and in the contextual environments in which it will be used (e.g., in terms of appearance, functions, upkeep, storage, amount of time to set up or learn how to use the device).
- Be *practical and flexible* for the environments in which it will be used (e.g., have acceptable dimensions, portability, and positioning, be usable with other assistive devices).
- Be *durable* and easy to clean.

TABLE 15-3 Typical Adaptation Principles Used with Children and Adolescents with Disabilities

Behavior or Disability	Adaptation Principles
Low vision or hearing (or both)	Use intact or residual senses. Amplify sensory characteristics of objects (e.g., color, size, tactile and auditory features). Give cues consistently to determine whether activity is beginning or ending. Use tactile, verbal, visual, or object cues (e.g., put hand on washcloth or say, "It's time to wash your face"). Use gestures (e.g., point to arm that is put in sleeve first). Decrease auditory and visual distractions.
Dislike of being touched (tactile defensive)	Prepare child for touch by giving deep pressure and applying organized, rhythmic touch. Give choices for tactile preferences (e.g., clothes, washcloths, brushes). Let child perform touching on himself or herself (e.g., use toothbrush or wash face or body). Allow child to wear snug clothing (e.g., turtleneck) or loose clothing in accordance with his or her preference.
Inability to find clothes or understand top, front, or bottom	Amplify characteristics. Reduce distracters (e.g., place only one utensil on countertop for cooking activity). Use visual or gestural cues (e.g., mark medial border of shoes with "happy faces" to keep shoes on correct feet). Use systematic scanning when searching for objects (e.g., clothes in closet).
Inability to sit up or maintain balance	Provide support externally (e.g., use positioning device). Change position of child (e.g., have child sit to put on shoes or dress in side-lying position). Change position of activity (e.g., keep grooming items together in a bucket on top of the sink).
Limited reach	Reduce amount of reach needed. Change position of activity.
Difficulty grasping objects	Lengthen handles (e.g., use long-handled bath sponge or reacher). Build up handles of objects (e.g., brushes, spoons). Substitute assistive devices so that grasping is not necessary (e.g., use universal cuffs or straps). Stabilize objects with other body parts (e.g., in teeth or between legs).
Weakness, with little endurance	Eliminate gravity (e.g., prop elbow or dress in side-lying position). Use lightweight objects. Use power equipment.
Difficulty controlling movement	Provide stable base of support (e.g., sit on floor with wide base). Eliminate need for fine control (e.g., use an enlarged zipper pull). Use weighted devices to give proprioceptive feedback (e.g., weighted toothbrushes and cups).
Poor memory; inability to remember sequences or directions	Establish and practice set routines and sequences. Use partial participation, grading techniques, and backward and forward chaining. Use visual cues (e.g., pictures, labels, checklists, color coding). Substitute assistive technology (e.g., alarm on watch or timers). Use verbal cues (e.g., "First, then second"; jingles, rhymes, songs). Use real-life materials in the setting in which the occupation occurs.
Tendency to become easily frustrated; outbursts	Identify purpose of "problem behavior" (e.g., escape, avoid, attention, obtain, transition, or stimulate) by analyzing antecedents and consequences. Limit exposure to context associated with misbehavior. Use preferred tasks and give choices. Reinforce, coach, and expand appropriate alternate behaviors. Avoid personal assistance and coaching (use partial participation). Use grading, prompting, fading prompts, and generalization.

Adapted from Geyer, L. A., Kurtz, L. A., & Byram, L. E. (1998). Prompting function in daily living skills. In J. P. Dormans & L. Pellegrino (Eds.), *Caring for children with cerebral palsy: A team approach* (pp. 323–346). Baltimore: Paul H. Brookes; and Koegel, L. K., Koegel, R. L., Kellegrew, D., & Mullen, K. (1996). Parent education for prevention and reduction of severe problem behaviors. In L. K. Koegel, R. L. Koegel, & G. Dunlap (Eds.), *Positive behavioral support: Including people with difficult behavior in the community* (pp. 3–30). Baltimore: Paul H. Brookes.

- Be *expandable*—that is, able to meet the child's needs now and when the child has grown and has more sophisticated abilities.
 - Be *safe* for the child to use (e.g., physical, behavioral, or cognitive child factors such as drooling, throwing, or difficulty with sequencing do not interfere with use of the device).
 - Have a *system of maintenance or replacement* with continued use.
 - *Meet the cost constraints* of the family or purchasing agency.
- Overall, the child should complete tasks at a higher level of efficiency using the device than he or she could without it. Trial use of a device is highly recommended; this helps determine the feasibility of its use and demonstrates its value to the child and primary caregivers. Caregiver roles are lightened by using assistive devices and modifications.
- Computers and cognitive prosthetic devices have come into use to give children the visual and/or auditory prompts needed

Use your left hand to pick up the right lace close to the knot and slide your fingers up the lace.

FIGURE 15-4 Sample talking book. This frame from *Talking Shoes* was created with Microsoft PowerPoint. (Courtesy Laura Pal and Kelly Showalter, Virginia Commonwealth University, Richmond, VA.)

to initiate, sequence, sustain, and terminate ADL and work activities.²⁹ For example, a talking book from Microsoft's PowerPoint helps a child learn how to tie a shoe, dress himself or herself, and set a table if the technology is nearby. As shown in Figure 15-4, for tying shoelaces, the child or adolescent uses the talking book as a visual and auditory prompt on his or her computer, tablet, personal digital assistant (PDA), or smartphone. Other cognitive prosthetic devices that assist in ADL tasks include portable memory aids (e.g., checklists, voice-activated tape recorders), medication alarm pill boxes, watches with specialized features (alarms, schedules, talking), alarm organizers, pagers, sound-activated key rings, and simple switches that program up to three steps.

Assistive technology for ADLs includes videos, computers, tablets, televisions, PDAs, smartphones, and digital memo devices. Talking books, visual schedules, stories using digital pictures, computer-generated checklists, or CDs may be used as cues to improve dressing, toileting, hand washing, and other ADL skills.^{80,148,156,158} These electronic devices give the prompts needed to help children and adolescents begin the ADL task and sequence the routine so the task is completed.^{45,46,77,78} Recent research has demonstrated the effectiveness of using video modeling of others (VMO) or videos of the child performing a task (video self-modeling [VSM]).^{15,99} These may be played on an MP3 player, PDA, computer, tablet, or smartphone and uploaded to a website for use at other times. Video modeling has been used successfully with hand washing¹³² and toileting.⁸⁰

Adapting the Physical Environment

In all the approaches discussed, the occupational therapist uses the interactions among the child, environment, and contexts to improve performance. Adaptation of the physical environment may include simple modifications to lighting, floor surface, amount and type of furniture or objects, and overall traffic pattern of the room or building. For some children, occupational therapists minimize sensory stimuli and eliminate visual and auditory distractions. Other children may require increased environmental stimulation (e.g., color or music) to cue their

performance. Table 15-4 presents adaptation examples of the physical environment to promote ADL performance.

Work Surface

The work surface supports the child, materials, tools, and assistive devices in an activity. The boundaries of the work space help children keep within usable or safe environments. For example, a cut-out surface on a table or a lip on a wheelchair tray or sink countertop can serve as a boundary. The occupational therapist adds various textures, colors, and pictures to the work surface area to give sensory cues about boundaries or to structure the task. Even with these modifications, some children (e.g., those with weakness in one side of the body) need assistance in stabilizing objects. Table 15-5 presents suggestions for stabilizing objects when they are placed on the work surface or held by the child.

Characteristics of the work surface amenable to adaptation include height, angle of incline, size, distance from the body, distance from other work areas, and general accessibility. Changes in these features enhance the child's function in various ways, including improving arm support, increasing the visual orientation of a task, adapting seat height for easier transfers, and optimizing table height for wheelchair access. See Chapter 20 for more specifics of positioning.

Positioning

Occupational therapists consider the position of the child and of the materials or activity when planning intervention. When possible, the occupational therapist uses the most typical position for a given activity, with the fewest restrictions or adaptations to stabilize the body for function. Children who have problems with posture and movement often lack sufficient control to assume or maintain stable postures during activity performance and thus benefit from adaptive positioning. Adaptive positioning may include using different positions (e.g., sitting instead of standing), low-technology devices (e.g., lap boards, pillows, towel rolls), or high-technology devices (e.g., customized cushions, wheelchairs, orthotics). If an adaptive device or orthotic is used, the occupational therapist needs to consider systematically whether the device assists or hinders ADL performance. Chafetz et al. have found that some children wearing a thoracolumbosacral orthosis had better posture but actually performed less efficiently with dressing when wearing the orthosis.²⁰

Alternative body positions are extremely helpful to children with disabilities. These changes help compensate for physical limitations in body functions such as strength, joint movement, control, and endurance and provide relief to skin areas and bony prominences. The occupational therapist considers positions that maximize independent task performance. Key points for stability that enable the child to use available voluntary movement are the pelvis and trunk, head, and extremities. The following questions guide decision making about positioning:

- Is the child aligned properly? Are the hips, shoulders, and head in aligned with each other?
- Which positions or devices increase trunk stability (e.g., using a hard seat insert or lateral or orthotic supports, using a surface to support the feet, widening the sitting base by abducting the legs)?
- Is support adequate to maintain an upright posture, with the head in the midline?
- Can the child use his or her hands and visually focus on the task?

TABLE 15-4 Environmental Adaptations for the Home When Accessibility Is Limited

Architectural Barrier	Structural Changes	Possible Assistive Devices	Task Modifications
Entrances and exits	Hand rails Hand stairs Ramp Built-up terrain to door height Stair lift In-home elevator Increased door width (33-36 inches minimum) Step-back hinges Door rehinged to open in or out Pocket or folding door Electric door openers	Straps or loop door handle Lever handles Portable doorknob Built-up key holders Combination locks Environmental control unit	Use different entrance. Remove inside doors. Use curtains for privacy. Use hip or wheelchair to open doors.
Bathroom	Increased door width (33-36 inches minimum); French doors or accordion door Enlarged room Sink mounted low Open space under cabinet Showers with built-in seat Placement of tub faucets changed Ramped shower stall Toilet bidet installed Linen closet shelves with no door	Safety rails Seat reducer Raised commode seat Step placed in front of commode Wheelchair commode Insulated pipes Single-lever faucets Tub seats Wheelchair shower chair Hydraulic lifts Toilet paper tongs Toilet paper mounting Angled mirror Wall-mounted hair dryer with switch Suction-cupped bucket to hold supplies	Freestanding commode in secluded area Urinal bed bath Sponge bath Liquid soap Soap on a string Shampoo pump Dry shampoo
Bedroom	Downstairs bedroom Enlarged space Enlarged closet doors Low closet pole Closet storage system with shelves Built-in bookshelves at low and medium heights Holes cut in work surfaces for holding objects and electrical cords Built-in dressers or dressers bolted to the wall Special glides for wall drawers	Leg extenders Bed rails Firm mattress Straps or rope ladders Mounted shoe rack Environmental control units or switches for television, radio, and light access Enlarged drawer handles or loops added Positioning devices Adaptive chairs	Place bed on floor. Keep most-used clothes in accessible drawers. Use shelves instead of dresser drawers for clothes. Store toys in shoe bag.
Kitchen	Enlarged space Lowered countertops Lowered cabinets No cabinets under sink Built-in range top Sliding drawers and organizers in cabinets Wall-mounted, side-by-side oven Dishwasher mounted higher or has front opening Front-opening washing machine		Keep most-used items in low cupboards or on accessible surfaces. Hang bowls and pans on wall instead of storing in cabinets. Eat on wheelchair lap tray instead of table. Keep water in insulated pump bottle on table. Use a stool for washing dishes.

Sitting and sometimes standing are the most appropriate positions for the child to perform ADL tasks. In addition to postural alignment, the therapist recommends positions that provide the child with the following: (1) good orientation of his or her body to the work surface and the materials being used; (2) good body and visual orientation to the therapist (if instruction is being given); and (3) the ability to get to the place where the ADL occurs independently, maintain the necessary position, and leave. The occupational therapist modifies

chair heights so that the child's feet are touching the floor to support postural stability and facilitate transfers. If the occupational therapist raises the seat height, a foot rest is also provided. The occupational therapist shortens or lengthens chair legs with blocks or leg extenders.

Kangas advocates a task-ready position for children with moderate to severe motor disabilities.⁷⁹ Instead of positioning the child's hips, knees, and ankles at 90-degree angles, Kangas positions them so that they are ready to move. In the task-ready

TABLE 15-5 Stabilization Materials and Application Procedures

Material	Application Procedures
Tape	Applies quickly but often is a temporary solution; includes masking, electrical, and duct tapes (duct tape is sturdy and has holding power).
Nonslip, pressure-sensitive matting	Fits under objects or around them and can be glued to objects; friction between materials minimizes slipping and sliding of objects; available in rolls or pads.
Suction cup holders	Hold lightweight materials, maintaining suction between object and work surface; single-faced suction cups can be applied permanently to objects (e.g., with nails, screws, or glue); double-faced suction cups can be moved from object to object.
C-clamps	Secure flat objects to lap trays, table edges, and other surfaces.
Tacking putty	Sticks posters onto walls; holds lightweight objects on surfaces such as tables, lap trays, angle boards, and walls.
Pressure-sensitive hook and loop tape (Velcro)	Sewn to cloth or glued to the base of objects and work surfaces; soft loop tape is used on areas that will contact the child's skin or clothing.
Wing nuts and bolts	Secure objects to a table surface or lapboard when holes are drilled through the object and holding surface; sturdy and more permanent.
Magnets	Affix to an object; stabilize objects on metallic surfaces such as refrigerator doors, metal tables, and magnetic message boards.
L-brackets	Hold objects in an upright plane; holes are drilled in the work surface and object to correspond with the L-bracket holes; objects are secured with nuts and bolts.
Soldering clamps	Hold small items for intricate work (e.g., mending a shirt, sewing on a button, putting on a bracelet); mounted to free-standing base; bases are weighted, suction cupped, or held to the surface with a C clamp.
Elastic or webbing	Attach to or around objects or positioning devices to hold them down; they also secure flat objects straps onto a work surface; straps are secured by tying, pressure-sensitive hook and loop tape, D rings and buckles, grommets, or screws.

position, the pelvis is secure, the trunk and head are slightly forward so that the shoulders are in front of the pelvis, the arms and hands are in front of the body, and the feet are flat on the floor or behind the knees. The occupational therapist removes or loosens as many restraints or chair adaptations as safely possible so that the child has maximal potential for movement. Such movement, even when subtle, provides visual, vestibular, proprioceptive, and kinesthetic feedback. A carved or molded seat and seat belt across the thighs give additional sensory feedback and are used for positioning the pelvis and for safety.

Prevention and Education

Problem Solving: Cognitive Approach

Anticipatory Problem Solving

Children learn and perform ADL tasks in a variety of environments, not just in the clinic or where the task typically occurs. Anticipatory problem solving is a preventive approach that prepares children and their families for unexpected events that may occur during self-care occupations.¹²³ Typically, parents do this with young children during toilet training. They anticipate that the child will have accidents in the beginning and bring two changes of clothes in case this does occur. In a study by Bedell, Cohn, and Dumas, parents used anticipatory problem solving to help prevent meltdowns for their children with brain injuries.¹⁴ By thinking ahead (e.g., remembering not to have the child dressed in overalls on gym day, having children wear splints on the weekend and not during the week), parents ensure that their children can actively participate in school activities.

Children and youth also need to be part of anticipatory problem solving. By anticipating problems and generating solutions ahead of time, children can often reduce the anxiety they

experience when trying a new task or entering a new environment.¹⁴⁰ Using contextual cues, such as noticing the floor is wet in the bathroom, and practicing different scenarios may be helpful. Schultz-Krohn suggested asking the following questions¹⁴⁰:

1. What is the task to be completed and where will it occur?
2. What are the objects needed to complete the task?
 - a. Are these objects available and ready to be used?
 - b. If the objects are not available (e.g., misplaced, broken, being used by someone else), what else could be used, and who and how will the child ask for help?
3. What safety risks or hazards are within the environment or related to the objects being used by this student or other students? How can these risks be avoided?

Planning a natural teaching incident to occur during an activity ("sabotage")¹⁵⁹ gives the child, caregivers, teachers, and occupational therapists a good idea of how well the child can adapt and possibly use the anticipatory problem-solving solutions generated (Case Study 15-2). Giving the child an opportunity to choose a different way to complete or adapt a task promotes self-determination.

Cognitive Orientation Approach

In a similar model, occupational therapy researchers have developed a model of intervention called the Cognitive Orientation to daily Occupational Performance (CO-OP).¹²⁰ Researchers have studied the application of the CO-OP model in occupational therapy intervention on children with brain injuries, developmental coordination disorders (DCDs), and autism. These studies have demonstrated improvement in skills using the CO-OP approach.^{120,129,130} In this model, children learn verbal problem-solving approaches and cognitive strategies to apply when they incur performance challenges. Talking about the task first, practicing it, and then practicing and talking about the task (dual tasking) are the three main steps used in

CASE STUDY 15-2 Nadia

Nadia was injured in a car accident and is now using a wheelchair for functional mobility in middle school while her femur and tibia fractures mend. Before Nadia's injury, she was identified as having a learning disability, with problems with spatial relations. Using the anticipatory problem-solving questions from Schultz-Krohn,¹²⁴ the outlined questions were answered during therapy. Mom is transporting Nadia to and from school, and her tasks to complete are to move safely around the school environment in the halls, classroom, band room, school nurse's office, restroom, and cafeteria. She needs a wheelchair, lap tray, and/or book bag, map of the school, and a way to keep her schoolwork organized.

If these objects do not work or are unavailable, the occupational therapist and Nadia generated some solutions. If a wheelchair does not fit within a small classroom space, she could use her crutches for short distances or a rolling computer chair and ask someone else to push her closer to the table. The occupational therapist, teacher, and mother discuss how to transfer from the wheelchair to a rolling chair or

separate bench, and Nadia practices these transfers in case she needs to make these transfers. In addition, the occupational therapist and Nadia discuss her seating arrangements in each class and decide that a change in desk placement is needed. If a lap tray is not available, she asks others to carry her cafeteria tray or classroom materials. A divided book bag, which should help with organization, is placed on the back of her wheelchair. A side pocket on the armrest is used for pencils, money, and personal grooming items. Because of Nadia's poor spatial relations, time is taken to review and practice how to use the wheelchair without running into walls or other people. A safe distance from people is established, and she asks her teachers to be excused 5 minutes before classes end so she is not in the crowded hallways. Wheelchair maintenance and safety also are discussed, as well as deciding who may assist with the wheelchair. To enhance Nadia's anticipatory problem solving, the occupational therapist may place a barrier to her mobility performance and provide a natural teaching incident by moving classroom chairs to impede her pathway.

the CO-OP model. [Research Note 15-3](#) describes a small study that used the CO-OP approach with boys with DCD.

Coaching and Education

Child and caregiver collaborative education is essential in all therapy for children. By developing collaborative partnerships through coaching, role modeling, and problem solving with others, the occupational therapist helps prevent injuries and possible failure in occupational performance and provides emotional support to caregivers.^{124,150,174} This collaboration helps children perform ADLs in their environments and helps teachers, caregivers, and children learn safety information, specific techniques, and coping strategies. When providing information, occupational therapists consider the learning capacity, preferences, and environmental contexts of children and their families and caregivers, as well as the demands of the activity.⁶⁷

Hanft, Rush, and Shelden have suggested using a coaching approach with children, parents, caregivers, and teachers based on an understanding of their knowledge, skills, and desired outcomes.⁶⁰ This requires asking the right questions and having all parties reflect on their progress. Questions that are reflective, comparative, and interpretive are used throughout the coaching process. Questions to reflect (e.g., what, who, when, where), compare (how), and interpret (e.g., Why did this work? What other issues may arise?) give the occupational therapist needed information to help coach the child and family. Hanft et al. suggest observing, listening, responding, and planning collaboratively with all parties involved in the task.⁶⁰ Observing the child where the task naturally occurs is essential. Observing the child and caregiver and then the child and occupational therapist, and using self-observation via videotape of all or any of the parties, helps everyone reflect and understand how the child completes the ADL task. Occupational therapists need to listen respectfully and objectively to all parties to understand preferences, concerns, and areas of need when working together. Responding to concerns, giving feedback, and

collaboratively deciding how to proceed with a task helps all parties. Finally, coaching requires careful planning:

- Which strategies will they try this week?
- How will the occupational therapist modify the routine if this does not work?
- How will the teacher and the therapist give each other feedback?

Graham, Rodger, and Ziviani used occupational performance coaching (OPC) to give a structured approach for goal setting and specific instruction while providing emotional support.^{52,53} This approach helps parents identify ways to promote more successful occupational performance by considering how the child, environment, and task interact with each other. Preliminary results found that OPC for ADL performance for children ages 5 to 12 years and their parents improved occupational performance and was sustained for 6 weeks postintervention. The mother's self-competence and occupational performance in coaching also appeared to generalize to goals other than ADL.

Occupational therapists present child or caregiver education in various ways by using coaching and other educational methods. They often demonstrate, or model, how to do the task (e.g., tub transfers) when instructing. In addition, the occupational therapist may use visual aids, written instructions, audiotapes, videotapes, and checklists. Drahota, Wood, and Sze Van Dyke used cognitive restructuring to help parents see the necessity of children doing their own self-care skills at developmentally appropriate times and to see small gains as success.³²

An educational approach provides parents and children with the chance to make informed choices about the services, methods, assistive technology, and environmental adaptations they will use.⁴ Grading, forward and backward chaining, partial participation, and modeling help train caregivers.¹⁶⁷ In this chapter, anticipatory problem solving or CO-OP, as well as coaching and educating caregivers and children, is assumed to

RESEARCH NOTE 15-3

Rodger, S., & Liu, S. (2008). *Cognitive Orientation to (daily) Occupational Performance: Changes in strategy and session time use over the course of intervention*. OTJR: Occupation, Participation and Health, 28(4), 168–179.

Abstract

In this study, the authors used the Cognitive Orientation to daily Occupational Performance (CO-OP) intervention to help improve the motor performance of four 6- to 9-year-old boys with developmental coordination disorder (DCD) in daily occupations. Ten treatment sessions were videotaped for each subject, and a computer analysis examined the cognitive strategies and changes in strategies used during the sessions. “Session time use referred to the duration of Talking About Task (describing the task or plans that will be executed), Practicing Task (actually doing the task or activity), and Dual Tasking (both talking and doing) coded during video segments observations” (p. 168). The authors examined the use of cognitive strategies within the subjects and across all four subjects during the 10 individual sessions. Each subject had varied results, and no patterns of cognitive strategy use were evident. The authors concluded that each child has a unique way of interacting with a task and the environment, and this emphasized the need for client-centered intervention that is individualized, which is the purpose of the CO-OP model.

Implications for Practice

- ADL instruction must be individualized for children and is dependent on the interaction of the child factors, interests, and performance skills with the demands of the task and characteristics of the environment.
- When planning ADL intervention, such as washing the face of a child with DCD, consider using some of these CO-OP strategies:
 1. Talking about the task: Determine which face cleanser and cloth to use; where, when, and how it will be used; and which safety precautions are needed for face washing (e.g., water too hot, soap in the eyes).
 2. Practicing the task: Grade the set up of the activity by the occupational therapist doing it first; practice first with a washcloth with no soap, then practice with soap; try it in an isolated environment without distractions, try it within therapy sessions, then try it at home.
 3. Dual tasking: While face washing, discuss how he or she is or is not following safety precautions, and what is working, such as the pressure he or she is using or the pattern he or she is using to wash the entire face.

be integral to intervention approaches for helping children develop ADL skills.

Specific Intervention Techniques for Selected ADL Tasks

Specific intervention strategies for toilet hygiene and bowel and bladder management, dressing, bathing and showering, personal

hygiene and grooming, and sexual activity are described in this section. Interrelationships among child factors, contexts, and activity demands are considered. Combinations of approaches and strategies that help children become as independent as possible in ADL occupations are presented. As with all occupational therapy, the therapeutic use of purposeful and meaningful activities, consultation, and education are methods used to help others learn ADL occupations.

Toilet Hygiene and Bowel and Bladder Management

Typical Developmental Sequence

Independent toileting is an important self-maintenance milestone, and its achievement varies widely among children. It carries considerable sociologic and cultural significance. Self-sufficiency is often a prerequisite for participation in day-care centers, school programs, recreational and community opportunities, and secondary school vocational programs. Like other ADL tasks, toileting is a complex task requiring a thorough analysis of the demands of the activity and how the context and child’s capabilities influence performance skills and patterns. To begin to learn this task, a child must be physically and psychologically ready. In addition, parents or caregivers need to be ready to devote the time and effort to toilet training the child. A communication system between caregivers and the child is essential:

- What cue, word, or gesture is used to say it is time to urinate or defecate?
- What is expected before, during, and after the toileting task?
- Is there consistency in how caregivers in different environments help the child manage the task?

At birth, a newborn voids reflexively and involuntarily. As the child matures, the spinal tract is myelinated to a level that allows for bowel and bladder control at the lumbar and sacral areas, and the child learns to control sphincter reflexes for volitional holding of urine and feces. Children are often physiologically ready for toileting if they have a pattern of urine and feces elimination.

Bowel control precedes bladder control, and studies indicate that girls are trained an average of 2.5 months earlier than boys.¹⁴¹ Independence in toileting requires that the child be able to get on and off the toilet, manage fasteners and clothing, clean after toileting, and wash and dry hands efficiently, without supervision. Children progress in a developmental sequence, according to each child’s unique maturational pattern. The typical developmental sequence for toileting is presented in Table 15-6.

Typical Factors That Interfere with Toileting Independence

Children with spinal cord injury, spina bifida, or other conditions that produce full or partial paralysis require special management for bowel and bladder activities. Loss of control over these bodily functions and the odor that results can cause embarrassment and reduce self-esteem. School-age children are characteristically modest about their bodies, and adolescents are struggling with identity issues and the need to be like their peers.

The type of bladder problem depends on the level and type of neurologic impairment. When the lesion is in the lumbar

TABLE 15-6 Typical Developmental Sequence for Toileting

Approximate Age (yr)	Toileting Skill
1	Indicates discomfort when wet or soiled Has regular bowel movements Sits on toilet when placed there and supervised (<5 min)
1½	Urinate regularly Shows interest in potty training
2	Stays dry for 2 hours or more Flushes toilet by self Achieves regulated toileting with occasional daytime accidents (32.5-35 mo)
2½	Rarely has bowel accidents Tells someone that he or she needs go the bathroom (31.9-34.7 mo) May need reminders to go to the bathroom May need help with getting on the toilet Wakes up dry at night Washes hands independently (29-31 mo) Wipes urine independently (32 mo)
3	Goes to the bathroom independently; seats himself or herself on toilet (33-39 mo) May need help with wiping May need help with fasteners or difficult clothing
4-5	Independent in toileting (e.g., tearing toilet paper, flushing, wiping effectively, washing hands, managing clothing)

Adapted from Coley, I. (1978). *Pediatric assessment of self care assessment* (pp. 145, 149). St. Louis: Mosby; and Orellove, F., & Sobsey, D. (1996). Self-care skills. In F. Orellove & D. Sobsey (Eds.), *Educating children with multiple disabilities* (2nd ed., pp. 342-). Baltimore: Paul H. Brookes; and Schum, T. R., Kolb, T. M., McAuliffe, T. L., et al. (2002). Sequential acquisition of toilet-training skills: A descriptive study of gender and age differences in normal children. *Pediatrics*, 109(3), E48.

region or below, the reflex arc is no longer intact, and the bladder is flaccid (lower motor neuron bladder). When the lesion is above the level of bladder innervation, the result is an automatic bladder (upper motor neuron bladder). The child undertakes training programs to develop an automatic response for the upper motor neuron bladder. In children with a flaccid bladder, training will be ineffective because the bladder has insufficient tone and requires assistance in emptying.

The occupational therapist works with physicians and nurses to determine bladder training and management programs after medical testing and collaborative discussions with children and their parents. Four main methods are used to manage urine: (1) condom catheterization (for males), (2) indwelling catheters, (3) intermittent catheterization (every 4 to 6 hours), and (4) ileal conduits. Parents are asked to restrict the child's fluid intake before program sessions to prevent bladder distention.

When girls have partial control of bladder function, they wear disposable diapers or incontinence pads.

A basic principle for success in bowel re-education is to have a regular and consistent evacuation of the bowel. Bowel program timing is a matter of choice, but a consistent schedule is needed. In some cases, the child receives suppositories and a warm drink before evacuation. This stimulates contraction and relaxation of muscle fibers in the walls of the intestine, moving the contents onward. Other techniques include digital stimulation, massage around the anal sphincter, and manual pressure using the Credé method on the abdomen. Occasionally, removal of the stool by hand or by a colostomy is recommended. As with an ileostomy, colostomy collection bags are emptied and cleansed on a regular basis, and the child learns to do this independently as soon as possible.

Children with congenital or acquired neurologic disorders often undergo catheterization or bowel programs. Compared with the toileting practices of their peers, these additional bowel and bladder tasks require more time, higher cognitive functions to plan, organize, and remember to perform the procedure, and established routines.¹⁶² In addition, children may have difficulty in any of the following areas: maintaining a stable yet practical position; hand dexterity (praxis and speed); perceptual awareness; strength, ROM, and stability; and accuracy in emptying collection devices. Memory, safety, and sensory awareness are needed for many of these procedures. Although nurses are often the professionals who teach bowel and bladder control methods, the occupational therapist may help establish the hand skills necessary, adapt the context by providing assistive devices or adapted methods, and/or establish a routine that becomes habitual and easy for the child and helps prevent future infections or embarrassment. Levan, an occupational therapist, has described a "penis paddle" made to assist a young man with self-catheterization.⁹⁰ By collaborating with the school nurse, the device was incorporated into the self-catheterization routine.

Closely associated with bowel and bladder care is perianal skin care. The skin is cleansed thoroughly to protect the tissue against the effects of contact with waste matter and eliminate odor. All children with decreased sensation are susceptible to *decubitus ulcers*, pressure sores that develop rapidly when blood vessels are compressed (e.g., around a bony prominence, such as the ischial tuberosity). Daily inspection of the buttocks with a long-handled mirror is needed.

Children with Limited Motor Skills and Bodily Functions

Diapering becomes a difficult task when infants or children have strong extensor and adduction (muscle and movement function) patterns in their legs. Occupational therapists teach the mother restorative or remedial methods to decrease extensor patterns before diapering and to incorporate these methods into the diapering routine. For example, the mother may first place a pillow under the child's hips, flex the hips, and slowly rock the hips back and forth before she helps the child abduct the legs for diapering.

Toileting independence may be delayed in children of all ages with limitations in strength, endurance, range of motion, postural stability, and manipulation or dexterity. With an unstable sitting posture, the child has difficulty relaxing and maintaining a position for pressing down and emptying the bowels.

With weakness and limited ROM, the child may be unable to manage fastenings because of hand weakness or may have problems sitting down or getting up from the toilet seat because of hip-knee contractions or quadriceps weakness.

Cleansing after a bowel movement is difficult if the child cannot supinate the hand, flex the wrist, or internally rotate and extend the arm. An anterior approach may work. The occupational therapist must caution girls against contamination from feces, which causes vaginitis. If possible, girls should wipe the anus from the rear. Solutions to cleansing problems are difficult and often discouraging. These children may require remediation strategies to improve body capacities (e.g., active ROM) or adaptation strategies (e.g., wiping tongs, use of a bidet) to perform the toileting task.

Children with Intellectual Limitations

Children with intellectual disabilities take longer to learn toileting, but they often become independent.¹¹⁴ Problems with awareness, initiation, sequencing, memory, and dexterity in managing their clothes are typical. As with all children, physiologic readiness for toileting is a prerequisite for training programs. The occupational therapist uses task analysis to determine which steps of the process are problems, and he or she then determines which cues and prompts are needed to achieve the child's best performance. The occupational therapist also evaluates which methods work as successful reinforcement.¹⁶⁸

According to a large longitudinal study by Joinson et al., school-age children with developmental delay, difficult temperament, and/or who have mothers with depression or anxiety are at risk for problems with bowel and bladder control during the day.⁷⁵ Occupational therapists need to consider if any of these factors are interfering with toilet training and if additional time, procedures, suggestions, or referrals are needed. Some parents of children with developmental delay or autism may use a behavioral approach to incontinence.⁸⁹ The Azrin and Foxx⁸ training method for toileting is behaviorally based and requires the child to be at least 20 months of age and able to complete prerequisites (e.g., sit independently, imitate, stay dry a couple of hours.). Caregivers spend 4 to 6 hours training in the bathroom with their child while giving positive reinforcement and overcorrection for errors. A few studies have reported success with the Azrin and Foxx method, but studies that compare the effectiveness of different toilet training methods for children with disabilities are limited.⁸² The Evolve website gives additional resources on toileting.

Adaptation Strategies for Improving Toileting Independence

Adaptation strategies include remodeling or restructuring the environment, selecting assistive devices or different types of clothing, or devising alternative methods to enhance independence. The occupational therapist also addresses caregiver needs as the child becomes heavier and more difficult to assist with toileting.

Characteristics of physical and social environments at home or school influence how a child manages toileting hygiene. Privacy is particularly important for the older child and adolescent; helping children determine where to perform the procedure and how to manage it in school and recreational environments is often a challenge. Social routines and expectations are also important variables for the occupational therapist

to consider when making recommendations for managing toileting. These expectations depend on the child's age and abilities and how the family perceives the child's ability to manage this aspect of his or her ADLs.

Social Environment and Temporal Context

Of all ADL tasks, toileting requires the most sensitive approach on the part of those who work with the child on a self-maintenance program. Children may purposely restrict their fluid intake at school to avoid the need for elimination. Unfortunately, limited fluid intake promotes infections, which increases the difficulty of regulating the bowel and bladder. Families, teachers, nurses, and paraprofessionals work with occupational therapists to evaluate the social environment and find the best place, time, and routine for the child. When self-catheterization is done in the school or community environment, the child can ensure privacy by using the health room or a private bathroom stall or perform this ADL when children are usually not taking bathroom breaks. Carrying catheterization supplies in a fanny pack or a small nylon (nontransparent) bag also protects the child's privacy.

Occupational therapists help children who lack bowel and bladder control to develop routines and health habits that eliminate possible odors. By focusing on performance patterns, the occupational therapist reinforces and incorporates regular cleansing and changing of appliances (collection bags for ileal conduits and colostomies) and urine collection bags into daily schedules. A good fluid intake also is recommended to prevent odors and bacterial growth.

Children with autism often have a difficult time with toileting practices. Wheeler has offered a practical guide to toilet training for children with autism and related disorders.¹⁷¹ The discussion of support strategies, such as modeling and social stories, and numerous examples of common problems and solutions associated with training individuals with autism are excellent. Wheeler used social context and many visual prompts to structure the steps for toileting. In a small study of preschoolers with autism, video modeling with operant conditioning was more successful in establishing toileting than operant conditioning by itself.⁸⁰ Table 15-7 defines methods to adapt toileting and improve toileting independence.

Physical Environment

The bathroom often is the most inaccessible room in the house, yet it is essential that every family member have access to it. The floor space may be insufficient to allow the child to turn a wheelchair for a toilet transfer. The location and height of the sink, faucets, towels, soap, and toilet paper may make them inaccessible to young children. Children with olfactory hypersensitivity may have difficulty tolerating bathroom odors (e.g., air freshener, perfumed toilet paper or soap). Therefore, the bathroom's space, equipment, and objects may need to be adapted or modified.

Toileting Adaptations

Numerous adaptations are available to assist the child in positioning and maintaining cleanliness after toileting. Urinals, catheters, leg bag clamps, long-handled mirrors, positioning devices to provide postural stability or hold the legs open, and universal cuffs with a catheter or digital stimulator attached are some examples of assistive devices that occupational therapists may provide. For children with good postural control but limited ROM or grasp, simple inexpensive aids include various types of toilet paper tongs and toilet paper-holding devices.

TABLE 15-7 Analysis and Interventions for Toileting

Area	Analysis	Intervention Ideas
Required (task analysis)	Recognizes signal to go to the bathroom (visual or sensation) Goes to bathroom and closes door Pulls clothes down (only as much as needed) Sits or stands at toilet Urinate or defecates (or words child uses) Gets toilet paper Wipes, then throws toilet paper in toilet Flushes once Pulls clothes up Washes and dries hands Throws away trash Leaves bathroom	Have visual routine on wall (objects, pictures, or action words). Make tasks smaller or larger, depending on child's abilities (e.g., separate washing and drying of the hands). Add task if child is omitting it or is having trouble (e.g., if child is smearing feces, use "wipe" as one of the steps). Child uses too much toilet paper: (1) Remove toilet paper roll and use Kleenex, or pull off correct amount to be used and hand it to child; or (2) place a tape mark on the wall of how much paper to roll out. Child does not sit: Use timer and instruct child to stay "seated" until timer rings; use potty that is close to the floor.
Client factors (body functions and structures)	Sensations (bladder fullness, voluntary control, emptying bladder, wet or dry, toilet paper texture, noise of flushing) Physiologic readiness Strength, coordination, and endurance to manage clothing and fasteners Balance to stand at or sit on toilet Emotional readiness—fears of flushing or disease, need for privacy, attitude toward toileting	Use habit training if no pattern is evident: Go at the same times every day. Have child dress in easy-to-manipulate clothing. Use preparatory activities at other times to build strength and coordination for fasteners. Support child's body (e.g., grab bars, foot support, ring reducer, potty chair on floor). Change toilet papers or use different material, such as wet wipes or cloth.
Environment, contexts (cultural, social, physical, personal, temporal, cognitive)	<i>Cultural:</i> Family and societal expectations of toileting; words used; whether child uses a public bathroom and sits on the toilet seat; institutional practices (e.g., co-toileting in preschool, language used) <i>Social:</i> Acceptance of use of a diaper; how child indicates need to toilet (e.g., pee-pee, gestures), others in bathroom, flushing, gender-specific public bathroom rules <i>Physical:</i> Size, temperature, sounds; set up; way to flush, height of toilet, adaptations (toilet seat or potty chair; grab bars or safety frame around toilet); faucets and other fixtures <i>Personal:</i> Chronologic age, grade in school, gender <i>Temporal:</i> Previous experiences, fears of flushing or disease, need for privacy, attitude toward toileting	Spell out expectations in the beginning. Dedicate a bathroom to toilet training, if possible. Play soft music or toilet song on a tape player. Public bathrooms: Boys need cueing for bathroom behavior and may need a social story: leave a space between yourself and someone else at a urinal; keep your pants up over your buttocks while urinating at a urinal; don't talk or look others in the eye while at the urinal; be quick and leave when you are finished; only you will touch your body while in the bathroom (unless catheterization training). If child dawdles in bathroom, have him or her go with a peer buddy or go at a less busy time. If child is fearful, have him or her open door for escape, then flush.
Performance skills (sensory—perceptual, motor—praxis, cognitive, emotional regulation, communication, social)	Posture, mobility, coordination, strength, and effort needed <i>Cognitive:</i> Initiate, sequence, and terminate How child communicates need to go to bathroom (e.g., physically or by speaking)	Provide way to indicate a need to go: • Picture cues of entire sequence • Object cues or transitional object • Social story • Timer • Spoken cues • Positioning body on toilet • Sensitivity to smells and sounds • Physical, gestural cues • Ear plugs, timing, not after another person used the toilet

TABLE 15-7 Analysis and Interventions for Toileting—cont'd

Area	Analysis	Intervention Ideas
Performance patterns (habits, routines, roles)	Recognizes typical routines in the family for eating and drinking Recognizes typical times and patterns when child urinates or defecates Uses habit training to go at a certain time of the day, every day Cleans up accidents by himself or herself without harsh reprimanding Behavior challenge may be provoked by changes in routines	Limit or increase liquids. Use wet-dry chart to determine typical times for toileting. Use visual schedule for toileting steps (including wiping) and times, as well as times for drinking fluids. Use same routine and rituals for toileting (e.g., particular times or when waking, before trips, after meals). Urge family, school, and day-care center all to follow the same routine and collect data.
Activity demands (objects, spatial, social, sequencing, timing)	Placement of potty chair or toilet seat; height of toilet, flushing mechanism, toilet paper dispenser Space in bathroom, arrangement of items Door shut or closed; whether child announces it's time to go Steps to toileting, flushing after going potty; when to close door, get toilet paper or paper towel Public bathroom social expectations	Change layout of objects or accessibility of environment. Include "shut the door" as part of toileting sequence. Discuss public bathroom expectations; have social story available to talk about them. Public bathroom (boys): Use private stall first, then move to urinal.

Adapted from Wheeler, M. (1998). *Toilet training for individuals with autism and related disorders*. Arlington, TX: Future Horizons.

FIGURE 15-5 Electrically powered bidet makes it possible to clean the perianal area independently, without using hands or paper.

A combined bidet and toilet offers a means of total independence. Several models are available that attach to a standard toilet bowl. A self-contained mechanism spray washes the perianal area with thermostatically controlled warm water and dries it with a flow of warm air. The child operates the controls with the hand or foot (Figure 15-5). Various special cushions designed to prevent tissue trauma are available commercially.

The type of clothing worn during toileting often hinders the child's independence or caregiver's ability to promote independence. Tight stretch garments are often recommended to

help with postural control, but these may result in problems with toileting independence or incontinence.¹¹² For children who wear diapers, a full-length crotch opening with a zipper or hook and loop (e.g., Velcro) closure makes changes easier. When children are first learning toilet training, the use of elastic-waisted diapers that pull up gives them the opportunity to practice this part of the toileting sequence while protecting clothing from accidents. As children mature, they may be responsible for changing their own diapers or caring for their appliances and equipment. Girls may wear wraparound or full skirts because these are easy to put on and adjust for diaper changes or toileting. The child reaches and drains leg bags with greater ease when the pants have zippers or hook and loop closures along the seams. Flies with long zippers or hook and loop closures make it easier for boys to urinate or catheterize themselves when in wheelchairs.

Adaptations for Unstable Posture

When children sit on the toilet, they need postural security. When toilet seats are low enough that the feet rest firmly on the floor, the abdominal muscles that aid in defecation effectively fulfill their function. Reducer rings are used for small children to decrease the size of the toilet seat opening and thus improve sitting support. A step in front of the toilet helps small children get onto it. Safety rails that attach to the toilet or wall can assist with balance and allow free use of the child's hands. For the child who has outgrown small training potties, free-standing commodes may be useful when wheelchair access to the bathroom is impossible. A toilet chair that rolls into place over the toilet is another option. Commodes that feature such modifications as adjustable legs, safety bars, angled legs for stability, and padded, upholstered, and adjustable back rests and head rests are often helpful to caregivers. Commodes are also available with seat reducer rings, seat belts, and adjustable footrests.

Menstrual Hygiene

In adolescence, girls need to learn how to care for their menstrual needs. As puberty begins, hormones increase and moodiness, emotional turmoil, irregular bleeding, menstrual cramps, and poor hygiene may emerge.¹²³ For girls with intellectual disabilities, understanding the changes in their body and learning new hygiene skills may be difficult. Depending on the child's disability, puberty may occur between 9 and 16 years of age, and avoiding abuse and reproductive concerns require consideration. These topics are discussed in this chapter's section on sexual activity.

Puberty is often a difficult time for parents, and they may approach their child's physician for menstrual suppression medication and contraception.¹²³ Options for gynecologic care are important to discuss with parents and the youth. A pelvic or breast examination is part of maintaining health and is necessary to detect possible health problems. The California Department of Developmental Services has developed a manual for physicians about how to conduct a gynecologic examination for women with disabilities and is a helpful resource for parents.¹⁴⁹ Menstrual management is part of toileting hygiene, and many skills, routines and habits, and adaptations may be recommended for the young adolescent girl with a disability and her caregivers. Similar to girls with normal development, young girls with disabilities need to be prepared before menarche for the changes that will occur to their body. They need reassurance that bleeding and sometimes cramps are part of growing up and are normal. Parents and occupational therapists may work with the young adolescent to understand changes in the body and moods, as well as the methods and hygiene habits necessary for managing menstruation (e.g., wearing pads or tampons).

Teaching Methods for Girls with Limitations in Cognition

For girls with autism, Wrobel suggests using stories and visual cues to help girls learn about menstruation and advising them to inform their teacher or parent when bleeding occurs.¹⁷⁷ Techniques suggested are using photosequencing cards, red food coloring placed on a sanitary pad, repetitive practice of how to place the pad in the panties, wearing the pad for a few days at a time before the onset of menarche, and instructions in proper wrapping and disposal of the pad. Specific stories, pictures, and examples are given related to the hygiene of menstruation, changing pads at school, getting cramps, and keeping menstruation private. These same techniques and ideas are applicable for girls with intellectual disabilities, and practicing the actual hygiene task during menses is most effective.³⁴ Alarms on watches, PDA timers, or cues can be used to help the adolescent change her pad every 3 to 4 hours or remind her that her period may begin this week. Using anticipatory problem solving, parents and caregivers can ensure that the adolescent has extra supplies or clothing to manage any mishaps.

Teaching Methods for Physical Limitations

For girls with significant physical and/or cognitive disabilities, therapists can train caregivers to help with menstrual care ADLs.⁵⁶ Adaptive devices for menstrual care are similar to aids used for toilet hygiene. Long-handled mirrors, positioning devices to provide postural stability (e.g., grab bars, toilet safety frames) or hold the legs open, toilet paper tongs, and universal cuffs with a tampon inserter attached are some examples of assistive devices that occupational therapists may provide. If a

bidet is available, it may help with cleanliness during menstruation. In Australia, occupational therapists are involved with the Health and Well-Being Network and provide intervention strategies to address menstrual needs of adolescents and women with disabilities. Together with other team members, they created a booklet and kit to help families and professionals explore attitudes, practical strategies, and other options for managing menstrual care.³⁰

Dressing

Typical Development

For a typical child, achieving independence in dressing usually takes 4 years of practice. Characteristically, learning to undress comes before learning to dress. Caregivers introduce self-dressing in a natural way, at bedtime, by allowing the child to complete the final step in pulling off a garment. Similarly, when the child becomes more goal-directed and motivated to be independent, he or she is ready to try the more difficult tasks of learning to put on clothing. Often, the caregiver uses backward chaining by putting the garment on the child and allowing the child to complete the action. Gradually the child performs more of the task, and the caregiver performs less. A parent-friendly book that assists caregivers in using backward chaining and collecting data has been written by Turner, Lammi, Friesen, and Phelan.¹⁶⁷ Table 15-8 presents the typical development of dressing.

Dressing requires children to use a variety of performance skills and patterns to meet the unique demands of the activity. They need to know where their bodies are in space and how body parts relate while they use visual and kinesthetic systems to guide arm and leg movements. Visual and somatosensory systems enable the child to understand form and space and how clothing conforms to and fits on the body. Dynamic postural stability is important as the child reaches, bends, and shifts his or her center of gravity while getting dressed. If the child avoids crossing the midline and performs dressing tasks on the right side of the body with the right hand and those on the left with the left hand, he or she most likely will have difficulty with tasks that require both hands to work together, such as fastening clothing and tying shoelaces. How the child coordinates the two sides of the body, manipulates the clothing, grips fasteners, and calibrates the amount of strength and effort determine how the activity is completed. Cognitive skills such as choosing appropriate clothing, temporally organizing and remembering the steps of the task, and adapting to contextual changes (e.g., new materials, noise in the environment, placement of clothing) also affect dressing outcomes.

Typical Problems and Intervention Strategies

Limitations in Cognitive and Sensory Perceptual Skills

Children who have underlying cognitive and perceptual deficits may also have problems in processing performance skills. They may demonstrate problems with choosing, using, and handling clothing. These may include difficulty distinguishing the right and left sides of the body, putting a shoe on the correct foot, turning the heel of a sock, differentiating the front of clothing from the back, or identifying the correct leg or sleeve. Temporal organization, especially initiating, continuing, sequencing, terminating, and organizing the dressing task, is often problematic

TABLE 15-8 Typical Developmental Sequence for Dressing

Age (yr)	Self-Dressing Skills
1	Cooperates with dressing (holds out arms and legs) Pulls off shoes, removes socks Pushes arms through sleeves and legs through pants
2	Removes unfastened coat Removes shoes if laces are untied Helps pull down pants Finds armholes in pullover shirt
2½	Removes pull-down pants with elastic waist Assists in pulling on socks Puts on front-buttoning coat or shirt Unbuttons large buttons
3	Puts on pullover shirt with minimal assistance Puts on shoes without fasteners (may be on wrong foot) Puts on socks (may be with heel on top) Independently pulls down pants Zips and unzips jacket once on track Needs assistance to remove pullover shirt Buttons large front buttons
3½	Finds front of clothing Snaps or hooks front fastener Unzips zipper on jacket, separating zipper Puts on mittens Buttons series of three or four buttons Unbuckles shoe or belt Dresses with supervision (needs help with front and back)
4	Removes pullover garment independently Buckles shoes or belt Zips jacket zipper Puts on socks correctly Puts on shoes, needs assistance in tying laces Laces shoes Consistently identifies the front and back of garments
4½	Puts belt in loops
5	Ties and unties knots Dresses unsupervised
6	Closes back zipper Ties bows Buttons back buttons Snaps back snaps

Adapted from Klein, M.D. (1983). *Pre-dressing skills*. Tucson, AZ: Communication Skill Builders.

for children with intellectual disabilities or autism. When children have difficult organizing the task, the occupational therapist often recommends modifying the demands of dressing in various environments. Artificial cues such as color coding or labeling dressers or bins with pictures or words help children locate objects for dressing in the bedroom environment. Picture charts and checklists help the child remember the sequence of steps in a task and provide a routine for completing it.

Behaviorally, the child may become frustrated with the complexity of certain dressing tasks. Language deficits may restrict the child's ability to express personal preferences or frustrations. Frustration may increase when the child is faced with

tasks that require fine manipulations if coordination is limited or the child has sensory modulation problems. Often, a behavioral approach helps the child acquire independence. After making a baseline assessment, the occupational therapist carefully analyzes the demands of each dressing task. Once he or she determines the limitations and strengths in performance skills and patterns, partial participation and backward and forward chaining methods are used. Environmental and task adaptations include visual charts or pictures, social stories, checklists, video modeling, and clothing that is easy to manipulate (e.g., slightly larger clothing, stretchy materials, pullover shirts, loafers). Simultaneous prompting in the dressing activity itself helps children learn the task.¹⁴⁵ Figure 15-6 presents an example of a visual story used for a child who has sensory deficits and who dislikes changes in routines or dressing for outside play. It is purported that the repetition of positive statements makes the child more ready to follow the routine in the story and initiate the task. When using social stories, it is important to use the criteria set by Gray to construct the story.⁵⁵ Read the story to the child before he or she begins the task and suggest that it be read daily. Similar to any prompting, the occupational therapist needs to fade the story as the child's abilities or behavior improves or increase use of the story if progress is limited. Evidence for the use and effectiveness of using social stories is limited, although they are frequently used with children who have behavior issues, intellectual disabilities, or autism spectrum disorder (ASD).^{127,137} Teachers rate improvement in a child's ability after using a social story, but this is confounded by the inconsistency in following the guidelines set by Gray⁵⁵ and reporting how outcomes are measured.

VMO and VSM are well-researched techniques used by a variety of professionals to teach children with autism and intellectual disabilities and may be helpful in promoting ADLs.^{15,98,101} By giving children the visual role model, they are motivated to try the task themselves. For children with intellectual limitations, video modeling is helpful because reading is not necessary.⁹⁸ In the VMO technique, a child learns a specific skill (e.g., dressing skill) by watching a video of a peer or an adult do the task (putting on a coat). In the VSM technique, by contrast, videos are edited so a child watches himself or herself putting on the coat correctly. The VSM method is labor-intensive; it takes skill to produce and edit a 2- to 3-minute video of the child doing the task. A meta-analysis of video modeling case studies suggested that using an adult as a model (VMO) for children with autism is more effective than VSM, particularly when reinforcement is paired with VMO.¹⁰⁰ Research Note 15-4 describes a review of these techniques and provides suggestions for using VMO and VSM collaboratively with teams.

Physical or Motor Limitations

Children with various conditions find dressing difficult because of the coordination, ROM, and strength required for pulling clothes on and off and connecting fasteners. Children with DCD can have difficulty completing dressing (and managing toileting and utensil use) because of slowness, disorganization, frustration, and a history of depending on others to do the task.¹⁰⁹ Dunford, Missiuna, Street, and Sibert found that children with DCD (5-10 years of age) reported concerns about their self-care skills, even though occupational therapists and parents did not identify these concerns.³³ Children with the use of only one hand find it difficult to zip trousers, tie shoelaces, and button shirts or blouses. Establishing or restoring the child's

FIGURE 15-6 This example of a story is used before Mimi goes out for recess to help her rehearse what she is going to do and help her understand why. (Courtesy Rebecca E. Argabrite Grove, Loudoun County Public Schools, Loudoun County VA.)

strength or coordination may help, but in most cases the child learns adaptive techniques, often through his or her own experimentation or the use of assistive technology. Children with cerebral palsy often have difficulty balancing and controlling arm and leg movement when donning and removing clothing. Limited dexterity may also interfere with dressing. Occupational therapists can suggest methods to modify the demands of the activity, such as supportive positioning or the use of adaptive aids such as button hooks, rings on zippers, one-handed shoe fasteners, or hook and loop closures. Because clothing manufacturers recognize the value of universal design, many of these adaptations are now available commercially.¹⁴² **Table 15-2** gives other examples of how to adapt or improve fastening skills.

Adaptive Methods for Dressing Children with Motor Limitations

Although it is common to dress an infant while he or she is lying in the supine position, this position frequently increases extensor tone in infants with neurologic impairment. For this reason, some occupational therapists advocate placing the infant prone across the knees, with the infant's hips flexed and abducted, thereby inhibiting leg extensor and adduction tone. When the infant gains head and trunk control, the caregiver dresses him or her in a sitting position, with the child's back resting against and supported by the caregiver's trunk. In this position, the infant has an opportunity to observe his or her own body during dressing.

When dressing an infant with increased extensor tone, the caregiver carefully bends the infant's hips and knees before putting on shoes and socks (Figure 15-7) and brings the infant's shoulders forward before putting the arm through a sleeve. Flexing the child's hip and knee decreases postural tone and makes dressing easier. When a child achieves sitting balance,

FIGURE 15-7 When dressing a child who is hypertonic, the caregiver should carefully flex the child's hips and knees before putting on socks and shoes.

RESEARCH NOTE 15-4

Mason, R. A., Ganz, J., B., Parker, R.I., Burke, M.D. & Camargo, S. (2012). *Moderating factors of video-modeling with other as model: A meta-analysis of single-case studies*, Research in Developmental Disabilities, 33, 1076–1086.

Abstract

A meta-analysis of 42 studies (single-subject design) of children and young adults with autism spectrum disorder (ASD) and developmental disabilities was completed by the authors. Video modeling of others (VMO) effectiveness was reviewed because this is a less complicated technique to use than video self-modeling (VSM). The participant age, diagnosis, and targeted outcomes were analyzed. The results of the meta-analysis suggest that video modeling of others meets evidence-based practice criteria as a strategy to address behavioral functioning, social communication skills, and functional skills across settings.

Implications for Practice

- Video modeling of others (VMO) or video self-modeling (VSM) is a successful technique for increasing the success of the intervention for play and social communication across all ages for students with ASD and is most effective for children ages 6 to 10 years.
- For children with ASD, a short video (2-3 minutes) of another peer or adult doing the task (e.g., putting on a shirt) prior to working on the task itself may help make learning the task sequence go more quickly and improves when paired with positive reinforcement.
- For children, adolescents, and young adults with developmental disabilities, VMO is moderately effective and appears to be more effective when paired with other programming such as prompting, error recognition, and positive reinforcement.
- Videos of ADL skills placed on home or school tablets, PDAs, phones, computers, or television incorporates this intervention strategy into home or school routines to increase the rate of improvement.

a good way to proceed with dressing is to place the child on the floor and later on a low stool, continuing to provide support where needed from the back. Orientation to the child's body parts should remain a focus in the social interaction. The caregiver helps the child understand how the body relates to the clothes and to the various positions (e.g., "The arm goes through the sleeve" and "The head goes through the hole at the top of the shirt").

When the child is older and heavier, there may be no alternative but to dress the child while he or she is in the side-lying or supine position, placing a hard pillow under the child's head. If it is possible to maintain the child in a side-lying position, this posture may make it easier for the caregiver to manage the child's arms and legs and for the child to assist in the dressing task (Figure 15-8).

Adaptive Methods for Self-Dressing

The child who has hand coordination but poor balance may be able to take advantage of the function that he or she possesses when in a side-lying position, with the effect of gravity lessened. For the child who sits but is unstable, a corner of two adjoining

FIGURE 15-8 The side-lying position may reduce stiffness and make dressing easier.

walls or a corner seat on the floor may provide enough postural support for independent dressing. Sitting balance is more precarious as the child reaches when donning overhead garments or pants and shoes; therefore, the child needs additional external support. Sitting in chairs with arms or sitting on the floor against a wall may improve performance.

The occupational therapist helps improve the child's dressing by offering the parent and child various problem-solving strategies from which the child and parents may choose. Once the method is chosen, anticipatory problem solving is used to help prepare the child for unexpected events in the environment. Table 15-9 offers choices in problem solving that are used for putting on and taking off different garments. Clothing selection, assistive technology, and adaptations to the task are methods for improving a child's performance in self-dressing.

Attention to the needs of individuals with disabilities has increased over the past decade, with some adaptive clothing becoming available through catalogue supply companies. These companies generally offer attractive fashionable clothing that meets functional requirements but conforms in appearance to the child's peer group standards and fashion trends. When possible, clothing should conceal physical disabilities, or at least should not attract attention to them, and hence contribute to the wearer's sense of well-being. Functionally, the clothing design should enable the wearer to take care of personal needs, help maintain proper body temperature, and provide freedom of movement.

Most clothing is made for individuals in a standing position. For those who spend long hours in a wheelchair, the sitting position causes pulling and straining on some areas of the garment and a surplus of fabric in others. The caregiver makes alterations to provide more comfort in sitting (e.g., pants that are cut higher in the back and lower in the front and cut larger to give additional room in the hips and thighs).¹⁴² A longer inseam also allows the proper hem height for pants when sitting (rests on top of shoe). Pockets in the back may cause shearing or skin breakdown with prolonged sitting. Instead, pockets are placed on the top of the thigh or on the side of the calf for easy access. Front and side seams are sewn with hook and loop fasteners or zippers and wrist loops to assist in donning. Pull-over tops with raglan and gusset sleeves allow more room when

TABLE 15-9 Adaptation Strategies for Dressing with Different Types of Garments

Garment	Design Features of Clothing or Assistive Technology Adaptations for Easier Dressing	Adaptations to Task Method
Pull-up garments	Large size Stretchy material Loops sewn into waistband Elastic waistbands, but not too tight Pressure-sensitive tape Zipper pulls Dressing sticks	Sit on chair. Lie on floor. Lie on side and roll side to side to pull up pants. Use chair or grab bar to stabilize oneself while pulling up pants. Put weak or affected extremity in first.
Pullover garments	Large, easy opening for head Flexible knit fabric Large armholes and sleeve openings; raglan sleeves Elastic cuffs and waistbands	Lay garment on lap, floor, or table, front side down; put arms in and flip over head. Use a template to position garment as above. Pull garment over head, then put arms in first. Put weak or affected extremity in second.
Front-opening garments	Loose style Fullness in back of garment On shirt or jacket, collar of different color from main garment Short-sleeve garments first, proceeding to long-sleeve garments Raglan sleeves Garment with no closures or one or two buttons (e.g., sweater, jacket)	Lay garment on lap, floor, or table, with neck of garment toward child; put in arms, duck head, extend arms, and flip garment over the head; shrug shoulders and use arms to help garment fall into place. Put weak or affected arm in first, pull up to shoulder; follow collar, then put in other arm. Use a template for placement of garment.
Buttons	Flat, large buttons Buttons contrast in color with garment Buttons with shanks (easier to grasp) Buttons sewn on loosely Buttons sewn on one side; hook and loop tape on both sides to close shirt or pants Front buttons first, proceeding to side and back buttons	Use pullover styles instead of those with buttons. Button all but the first two or three buttons and put shirt on like a pullover. Begin buttoning with bottom button (easier to see and align). Use a button hook. Use elastic thread to sew on sleeve buttons; put on sleeve without buttoning.
Zippers	Nylon zippers (easier than metal) Zipper tabs or rings Zipper pulls Hook and loop tape instead of zipper while pulling up zipper tab with other hand Longer zippers (more space for donning and doffing clothes) Front zippers first, proceeding to side and back zippers	Use backward chaining. Sit to gain stability. Stand to keep jacket zipper flat. Hold zipper taut with one hand at bottom of zipper. For side zipper, lean against wall to hold bottom of zipper.
Socks	Soft, stretchy socks Large size Tube sock (no set place for heel) Ankle socks first, proceeding to calf or over the calf Loops sewn into socks Sock aide or donner	Sit on stable surface (e.g., chair, floor). Lie on back and prop foot on opposite knee. Fold or roll sock before putting it over the toes and pulling up. Use backward chaining.
Shoes	Long-opening shoes (many eyes) with loose laces Broad shoe (not tight) Slip-on shoes Hook and loop tab closures Elastic laces already tied Elastic curly laces that do not need tying Tabs at heels for pulling shoes on Long-handled shoe horns	Sit on stable surface (e.g., chair, floor). Prop up foot on stool or chair. Lie on back and prop foot on opposite knee. Flex legs and point toes downward. Use gravity to help push heel into shoe (e.g., push down on a hard surface).

maneuvering a wheelchair. If the shirt is cut longer in the back and shorter in the front, it is easier to keep a neat appearance. Rain or winter capes are comfortable in a wheelchair. They are cut longer in the front to cover the child's legs and feet and shorter in the back so that they do not rub against the wheel of the wheelchair.¹⁴²

For children who wear orthoses for spinal support, front openings that extend from the neck to the lower abdomen make self-dressing easier, whereas back openings are easier when others dress the child.^{88,142} Caregivers should use larger clothing that fits over orthoses but should avoid loose sleeves for children who push wheelchairs. The child who wears an ankle-foot orthosis may need to have clothing reinforced to protect against rubbing. This is done by sewing fabric patches inside the garment where friction and stress occur and by adapting pants with side seams and hook and loop closures so that the pants fit easily over the orthosis.

When children require gastrostomy feedings, tracheotomy care, catheterization, or diapering, they need clothing that allows easy access. Caregivers can sew moisture-resistant fabric into the seat of pants, on collars, on attaching bibs, and on sleeve cuffs (if the child bites clothing).¹⁶¹ Jumpsuits or shirts with hook and loop closures at the gastrostomy site, neckline, shoulder, crotch, or pant leg allow caregivers to perform medical procedures without removing the child's clothing.^{88,142,161} Refer to the Evolve website for Internet resources on dressing methods, clothing, and other suggestions.

Bathing or Showering

Typical Development

A child's interest in bathing begins before 2 years of age, when he or she begins to wash while in the tub. By 4 years of age, children wash and dry themselves with supervision. It is not until 8 years of age that children independently prepare the bath and shower water (e.g., the appropriate depth and temperature) and wash and dry themselves independently.

Good grooming habits are important for all children but take on added significance for children with disabilities. At an early age, the caregiver needs to encourage and help the child with a disability to achieve cleanliness to maintain his or her health. Bathing should be a pleasurable activity. For the parent of a child who lacks postural stability, bathing becomes a tedious task that requires constant attention and alertness. The work involved multiplies as the child grows and becomes larger and heavier.

Cultural expectations and social routines for bathing vary, and the occupational therapist should consider them when assessing a child's independence. He or she must respect family preferences as to how often a person bathes and with whom (e.g., parent and child bathing together).

Establishing or Restoring Performance

Occupational therapists often use bathing therapeutically to improve body capabilities that interfere with independence. A warm bath may calm a child who is distressed and may decrease tonic activity and increase ROM and independent movement. When a child is hypersensitive, water play, rubbing with a washcloth, and deep pressure or rubbing while drying the child may help reduce the child's sensitivity to touch. For children who have difficulty interacting with others or the environment, bath play

may motivate the child to explore objects, engage in pretend play, and interact with a sibling or parent.

For children with motor limitations, the occupational therapist may prepare the child to participate more fully in self-bathing. The occupational therapist may use activities to improve ROM, bilateral coordination, grasp, postural control, and motor planning before teaching bathing. Activities or games (e.g., "Simon Says") that require a child to reach above or behind or down to the toes may give him or her the body awareness and necessary movement for self-bathing. While the child is in the tub, many bath toys (e.g., pour, squeeze or wind-up toys, soap crayons, floating boats) are useful to increase ROM, coordination, play skills, and interactions with others. Body paints are useful in cueing and motivating the child to "wash the part with the paint or X on it."

Adapting the Task or Environment

The caregiver's positioning and handling are prime considerations in adapting bathing of children. Children with cerebral palsy may lose their balance when startled. Keeping the child's head and arms forward when lifting and lowering him or her into the tub prevents a reaction of full extension. The caregiver should use slow gentle movements with the child and provide simple verbal cues about the steps of bathing. Draining the tub and wrapping the child in a towel before lifting him or her from the tub makes the child feel more secure.

Parents often need suggestions for bathing a child who is hypersensitive to touch or temperature. This child may avoid bathing at all costs and is at risk of getting hurt while in the tub. Understanding the child's sensory needs and using adaptive techniques may help bathing become a positive experience for parent and child. Preparatory activities that give the child deep pressure before bathing are sometimes helpful, especially deep pressure to the head before shampooing. The child may prefer washing the back and extremities first, and then the stomach and face, using rhythmic, organized, deep strokes. Some parents and children find a hand-held shower with an eye guard hat useful for removing soapsuds (especially during hair washing) and avoiding getting soap in the eyes. Adjusting the water flow or temperature of the hand-held shower and allowing the child to operate it gives the child more control over the direction of the water pressure on his or her body. Sometimes, with children who have tactile sensitivity, using a cup with water is a more relaxing way to rinse off than a shower spray. Wrapping the child in a tight towel after bathing and holding the child with deep pressure also helps.

Adaptive positioning or special equipment may provide support that helps the child feel safe and secure. Bath hammocks hold the body fully and enable the parent to wash the child thoroughly (Figure 15-9, A). A light inconspicuous bath support offers design features well adapted to the needs of children with motor deficits (see Figure 15-9, B). The front half of the support ring swings open for easy entry and then locks securely, holding the child at the chest to give trunk stability. Various types of bath seats and shower benches (see Figure 15-9C) are available to the older child for help in bathtub seating and transfers. For the child with severe motor limitations who is lying supine in the tub in shallow water, a horseshoe-shaped inflatable bath collar supports the neck and keeps the child's head above water. A bath stretcher is constructed like a cot and fits inside the bathtub at rim or midtub

FIGURE 15-9 Adapted seating equipment for bathing. **A,** The hammock chair is adjustable and equipped with oversized suction feet. It fully supports the child who has no sitting balance and poor head control. **B,** A trunk support ring is lightweight and compact and fits all bathtubs. **C,** A shower bench aids seating and transfers. **D,** An inflatable bath collar can be used when the child is in either the supine or the prone position.

level to minimize the caregiver's bending while transferring and bathing the child. As noted, sometimes home modifications such as rolling shower stalls or built-in bath benches are better solutions to increase independence and/or protect the caregiver's back.

Prevention and Education for Bathing Safety

Parent and child education about bathing safety helps prevent injury. Constant monitoring until the child demonstrates safety in the tub is necessary. Sometimes, parents do not teach independence in bathing because they worry that the child may injure himself or herself if left alone. Following a safe routine for bathing, teaching the child what he or she is and is not allowed to do in the tub or shower, and grading the amount of assistance and monitoring help develop independence. Nonslip bath mats beside and in the tub are essential for safety. Grab bars and their placement require careful thought and planning in each individual case. A rubber cover for the bathtub faucet prevents injury if the child touches it or slips and hits the head. Faucets need to be marked for temperature, and children can be directed to begin running their own bath water by first putting on the cold water and then slowly adding hot water.

Through coaching and/or educational materials, parents are taught to use good body mechanics during bathing to prevent back injury. To lessen strain, it is best for the adult to sit on a stool beside the tub or kneel on a cushion. Lifting is done with the knees bent and the back straight, with the legs used for power. As children get older and heavier, a Hoyer lift or an easily accessed shower stall arrangement may be necessary. Parents may need assistance in planning renovations that will assist the child in being independent and/or assist them for the future growth of the child.

Personal Hygiene and Grooming

Skill Development

By 2 years of age, children imitate their parents when brushing their teeth. Supervision of tooth brushing continues until about 6 years of age. Tooth brushing is especially difficult for the child with oral sensitivity. The child should use his or her preferred brushing methods until tolerance improves and he or she accomplishes more thorough cleaning. A small soft brush is easier to move around in the mouth, especially if the child has a tongue thrust or gag reflex. When the child's gums are tender, the caregiver may substitute a soft, sponge-tipped Toothette for a brush. For the child who brushes independently, an electric toothbrush allows more thorough cleaning. This is a good solution for children with limited dexterity, although for children with weakness, an electric toothbrush may be too heavy to manage.

If a child has problems with a weak grasp, the caregiver can enlarge the toothbrush handle with sponge rubber or add a hook and loop strap. One-handed flossing tools are available in large and small sizes and can be adapted by increasing the width or length of the handle. A hand-over-hand technique helps a child learn how to direct the toothbrush in the mouth and reach all teeth (Figure 15-10). As the child starts doing the movement, gestures or only verbal prompts may be needed. As always, a routine sequence for tooth brushing, gradual fading out of cues, and visual pictures about the process assist the child with underlying memory or performance skill problems.

FIGURE 15-10 A hand-over-hand approach works well for Lydia, who is sensitive to tooth brushing. She is participating in the activity and directing which part of the teeth she wants to brush first.

Face washing, hand washing, and hair care are typical grooming activities taught to preschoolers and young children. The family's culture and values and individual interests strongly influence the timing of the development of grooming independence. Adolescence begins at the onset of puberty and is a period of remarkable growth toward physical, sexual, emotional, and social maturity. The physiologic changes that occur at puberty are attributable in part to the increased output of hormones by the pituitary gland. For example, body hair grows, and the sebaceous glands become more active, producing oily secretions. With these physical changes and different social expectations (depending on the culture), new self-maintenance tasks emerge, including skin care, hair styling, hair removal, and application of cosmetics.

In their book, *Caring for Myself*,⁴⁴ Gast and Krug give verbal and visual sequences for brushing teeth, getting a haircut, hand washing, bathing, and going to the doctor. The book offers practical prompts, optional considerations for working with sensory issues, and ways to generalize skills and embed self-care activities within a routine. Templates for social stories, which are modifiable for different children, can be used for children who need a script or visual cuing to initiate, sequence, and complete grooming tasks.

Intervention

Grooming is an aspect of ADLs that is highly influenced by cultural values. The occupational therapist must respect the child and family's preferences in regard to hairstyle, cosmetics, and routines. The family and child or adolescent need to take the lead in identifying their concerns and priorities. Problem solving follows the principles and approaches identified in the first sections of this chapter. [Case Study 15-3](#) is an example of an adolescent who desires independence in grooming.

Sexual Activity

While the therapist is working with children on ADL tasks such as bathing or personal hygiene, sexuality questions may arise. Sexuality includes the physical and psychological nature of feeling attractive and/or engaging in intimacy through touch,

CASE STUDY 15-3 Josie

Josie demonstrates incoordination, poor memory, and limited judgment, but she wants to be independent in her grooming. Josie has worked on improving her coordination so that she can brush her own hair or manipulate the grooming materials, but adaptation strategies are essential to increase her independence in grooming. The occupational therapist recommends that Josie use a brush with a built-up handle, rest her elbow on the table while brushing her hair to stabilize her ataxic

movements, use a checklist and visual model, and ask a peer to help style her hair. Josie and her parents are educated about ways to incorporate grooming tasks into everyday routines by placing visual and natural cues in the environment, such as keeping the deodorant on the dresser. Leaving facial cleansing equipment out on the sink gives Josie a visual cue to use it before applying makeup.

kissing, hugging, or intercourse.¹¹ Although society often still views persons with disabilities as asexual beings,¹⁰⁶ children and adolescents of all disabilities are sexual beings, and adolescence is a critical time when sexual identity is developed.¹¹⁰ Adolescents with chronic health care conditions may have delayed puberty and growth, as well as observable physical disabilities that make them feel unattractive.⁹¹

Sexual activities need to be discussed to prevent social exploitation, abuse, sexually transmitted diseases, and pregnancy.¹⁵⁷ Children with developmental disabilities are more prone to the risk of exploitation, often because of the following: (1) they must depend on others for basic needs; (2) they frequently have multiple caregivers; (3) their connection with authority figures is one of learned helplessness or nondiscriminatory compliance; and (4) they have difficulty with social, reasoning, judgment, and problem-solving skills.^{31,160} Children with limited communication are at high risk for exploitation, and specific phrases or comments may need to be programmed into their augmentative communication device to protect them from exploitation.²¹

For occupational therapists working with children on very personal daily living activities, it is important to help children differentiate between necessary touch (e.g., diaper changing, catheter instruction, menstrual care, hygiene) and intimate touch. Hinsburger has suggested that occupational therapists and parents always do the following⁶⁴:

- Ask permission before touching.
- Describe what they are doing and why.
- Facilitate participation when performing necessary touch activities.
- Communicate with the child about what was done and why and about any feelings after intimate touch.

Parents may be receptive to discussing their child's sexuality, or they may feel unprepared to address these issues. If parents and professionals begin talking about sexuality education in early childhood (e.g., body, gender, touching, privacy, expressing affection, boundaries), the need to approach complex subjects such as refusal behavior, dating, birth control, and sexuality rights will not be as difficult a transition.¹¹⁰ Melberg-Schwier and Hinsburger have written an excellent book to guide parents as they embark on this topic.¹⁰⁴ If the child is younger than 18 years, occupational therapists must obtain parental permission to discuss sexuality issues. Occupational therapists need to consider the contextual aspects of the child's family and social groups and determine whether it is appropriate to discuss sexuality and who should discuss it (receiver and informant). Occupational therapists who decide to enter a discourse

on sexuality must consider their own knowledge, beliefs, and attitudes so that they give children and their families the correct information nonjudgmentally. They may refer the child to someone who is more knowledgeable about sexuality and more comfortable discussing it. Responsible occupational therapists are careful to separate their personal values with regard to sexuality from those of the client and family. The Evolve website gives a number of online resources for talking about sexuality with children with disabilities.

Children and adolescents with cognitive problems related to intellectual disabilities or a traumatic brain injury often need guidelines for expressing their sexuality appropriately in various contexts.^{26,27} Appropriate touch from others, dress and hygiene, masturbation, touching of others, and appropriate interactions with the opposite gender are areas in which education is required to prevent abuse and prosecution for sexual misconduct. Adolescent girls and boys need preparation for the changes that will occur in their bodies at puberty. As children are transitioning into adolescence, questions about how a specific disability (e.g., spina bifida, spinal cord injury) affects sexual abilities and activities often emerge.¹³⁸ Older adolescents with chronic health conditions need specific answers and ideas for expressing sexuality in a healthy way.⁹¹ An adolescent may question the physical and psychosocial aspects of sexuality and his or her ability to conceive. Information about contraceptive use and techniques for avoiding intercourse are essential for the adolescent to avoid unwanted pregnancies. As adolescents with disabilities consider conceiving and bearing children in the future, it may be helpful to talk to other parents with disabilities or become aware of online support groups and resources. [Table 15-10](#) presents the information that children need about sexual activity across the age span.

Annon has developed the PLISSIT model to teach people with disabilities about sexuality.⁷ This model is based on four phases of information giving: (1) Permission to ask about sexuality, (2) Limited Information given, (3) Specific Suggestions, and (4) Intensive Therapy (usually provided by a trained counselor or psychologist who understands sexuality in individuals with disabilities). This model teaches staff about sexuality issues and informs clients about who is willing to discuss sexuality with them. Taylor and Davis have proposed using an extended PLISSIT model, in which giving permission to talk about each phase is required before proceeding.¹⁶³ In some settings, staff members wear a button saying "I'm askable" to designate comfort in talking about sexuality. While practicing bed mobility, dressing, personal hygiene, positioning, and communication and interaction skills, the adolescent often asks sexuality

TABLE 15-10 Typical Sexuality Concepts Discussed with Children and Adolescents with Disabilities

Age (yr)	Typical Behaviors or Concepts to Learn
Birth-2	Touches genitals for sensory pleasure Experiences affection and touch
3-5	Shows interest in genitals of the opposite sex Learns proper names of genitals (social demands) Plays "show me" games with other children Understands that others should not touch his or her genitals Learns that some behaviors are acceptable in public, others to be done in private (e.g., masturbation, undressing) Begins to learn privacy rights (e.g., close doors, knock and wait to enter, close blinds) Begins to learn rules for touch and affection boundaries and authority figures
6-8	Knows differences between boys and girls Names body parts correctly Learns basic elements and language of reproduction and pregnancy Learns about relationships (e.g., friends, mutual respect) and decision making Thinks about social responsibility Understands appropriate and inappropriate social and sexual behaviors Understands necessary (e.g., personal hygiene) and intimate touch
9-11	Avoids and reports sexual exploitation (understands necessary touch and intimate touch) Shows interest in social relationships Discusses body image Discusses sexuality within family Understands personal boundaries Knows how to use refusal skills Understands body changes that will occur during puberty (and any impact on his or her disease or disability) Knows about reproduction and pregnancy Learns about sexually transmitted diseases and the need to abstain from sexual intercourse
12-18	Avoids or reports sexual abuse (understands necessary touch and intimate touch) Is sensitive and private about body Compares body with others and may be critical Asks questions about changes occurring (physical and emotional) Shows more interest in caring for body (e.g., hair, face, exercise) Discusses sexuality and sexual identity with friends Uses preventive health care routinely (e.g., breast, gynecologic, testicular examinations) Begins dating and learning about communication and love Uses values to guide actions in intimacy Expresses sexuality through dress, body movement, or intercourse Understands reproduction, pregnancy, and birth control Knows how to use contraceptives and prevent diseases (safe sex) Asks for or is given genetic counseling Identifies and uses community sexual health services

Sexuality education for children and youth with disabilities. *NICHY News Digest*, 1(3), 1–6.

questions. Depending on the situation and therapy setting, occupational therapists address these questions in the context in which the questions are asked.⁹¹ For example, while practicing bed mobility, 17-year-old Belinda, who recently suffered a spinal cord injury, asks, "How can I ever have sex with a guy? Can I have a baby?" With prior parental permission, this may be an opportune time to discuss contraceptives, positioning, use of intact senses, control of distracting environmental stimuli, and the medical need to empty her bladder or bowels before sexual activity. Referral to her physician or a gynecologist is appropriate, as is referral to her psychologist or counselor.

If the parents approve, occupational therapists give additional information in a written, oral, or video format and

provide the adolescent with the opportunity to talk to older adolescents or adults who have similar disabilities. Sexuality education needs a team approach, and occupational therapists may work with physicians, nurses, or pharmacists to discuss the use of certain medicines and how they affect sexual function. Memory aids for medicine schedules or contraceptive use may also be helpful.

Care of Personal Devices

With maturity, children learn to take care of their personal devices, such as hearing aids, glasses, contact lenses, orthotics, prosthetics, catheters, and/or a variety of pieces of assistive

technology used for toileting, grooming, feeding, and dressing. As the child learns how to use these devices, it is essential that he or she know how to clean and maintain them. How many glasses are lost or broken because they are not put back in a case, and how many splints melted by being left in a car? By encouraging children to take responsibility for these devices, perhaps many of these mishaps could be avoided.

Performance Patterns

Developing routines and habits for maintaining items helps children care for their assistive devices. In collaboration with the child, parent, or teacher, occupational therapists can help establish a routine for daily or weekly maintenance of items. Embedding this routine at a naturally occurring time helps the child remember to do the task. For example, the child cleans her or his catheter when getting home from school; before bed, he or she places it back in the fanny pack for the next day. This is often an opportune time to discuss health maintenance activities and routines. Table 15-11 gives an example of health care maintenance for typically developing children and children with spina bifida. Case Study 15-4 shows how developing a routine can help a child care for an assistive device.

Directing Others

Not all children have the motor and praxis skills to clean their glasses, wash their adaptive utensils, or fill a wheelchair cushion with air. Asking someone else to do the task or put equipment away and directing others on how to care for an adaptive aid are possibilities. The child may say, “My wheelchair is riding rough. Would you mind checking the tire pressure?” or “My splint strap is broken.” Educating children about their adaptive devices gives them a feeling of responsibility for the device and may help prevent breakdown or nonuse of the device. This also incorporates the skills needed for self-determination and self-efficacy.

Sleep and Rest

Sleep and rest are essential for a child’s growth and well-being because it allows children and their parents to restore energy for everyday occupations, including ADLs. Lack of sleep may compromise a child’s occupational performance and their physical growth, health, and ability to behave.^{139,178} When

TABLE 15-11 Health Care Maintenance for Typically Developing Children and Children with Spina Bifida

Age (yr)	Health Care Maintenance with Typical Development*	Additional Health Maintenance Issues for Child with Spina Bifida
5-9	Follows safety rules at home and school Informs others of emergencies Uses basic first-aid techniques for minor injuries Tells other when he or she is sick Cares for health care items with reminders (e.g., glasses, toothbrush) Routinely washes hands; takes a bath and washes hair with reminders Assists in getting medicine ready	Does pressure reliefs and checks for skin breakdown (e.g., legs, buttocks, and feet) with reminders Tells others when he or she is injured or feels sick (e.g., headache, pain, swelling, change in bowel and bladder patterns) Cares for personal adaptive devices (e.g., crutches, wheelchair, catheters) with reminders Performs self-catheterization at home and school Carries a list of current medicines and doctors’ names
10-14	Recognizes when he or she is getting sick or needs to see a doctor Knows emergency procedures (e.g., phone numbers, who to call, what to do) Cares for health care items (e.g., glasses, braces, retainers, facial scrubs) Uses first-aid procedures Eats nutritious meals with supervision Exercises with supervision Takes medicine with supervision Avoids cigarettes, drugs, and sexual abuse	Recognizes when he or she is injured or feels sick (e.g., headache, pain, swelling, change in bowel and bladder pattern) Knows dosage of medications Knows names of doctors (e.g., primary care, urologist, neurologist, orthopedist) Cares for personal adaptive devices (e.g., wheelchair, walker, braces) or instructs others in how to maintain devices Performs self-catheterization in community environments Prevents further health care problems (e.g., drinks to avoid bladder infection, exercises [push-ups]; avoids latex; maintains good hygiene, eating, and exercise practices)
15-18	Recognizes when a change in medicine or health intervention is needed Makes appointment to see doctors Eats nutritious meals Exercises regularly Cares for personal hygiene and follows good health habits Uses first-aid procedures for major and minor injuries Takes medicine when needed Uses birth control as needed	Takes medications independently and knows side effects Knows how to access therapy, doctors, and other health care services Knows how to obtain and pay for medical supplies Prevents secondary disabilities (e.g., manages weight, follows routine medical care, skin care, equipment maintenance)

*Adherence to protocols for medicines, personal devices, health routines, and so on.

K., Brown, J., & Cole, J. (1994). Spina bifida: The transition into adulthood begins in infancy. *Rehabilitation Nursing*, 19(4), 229–238.

CASE STUDY 15-4 Feddah

Feddah is 9 years old and has worn hearing aids for 2 years, after having viral meningitis. Until last month, her parents cared for the hearing aids until Feddah “wanted to do it herself.” Because her parents are encouraging Feddah to be self-determined, they thought this was a good idea. Unfortunately, last week, Feddah had a very severe ear infection that the doctor attributed to improper cleaning of her hearing aids. Mom happened to mention this problem to the occupational therapist, who was seeing Feddah to increase her written production and dexterity in manipulating objects. The therapist collaborated with Mom, the audiologist, and Feddah to develop a routine and visual schedule to clean her hearing aids. Feddah’s hearing aid case is left on the dresser as a naturally occurring cue to remind her to remove, clean, and put away the hearing aids each night. By using

anticipatory problem solving,¹²⁴ the therapist and Feddah discussed the task and where the wipes and hearing aid case should be kept. They also discussed how to clean the hearing aids when wipes were not available and how she would handle the care of her hearing aids when on a sleepover. Feddah anticipated that her friend’s little sister might try to play with her hearing aids and that she had better ask her friend’s mother to help her find a safe place for her hearing aid box. If she forgot her hearing aid box, she would ask for a baggie to store the aids. Figure 15-11 gives an example of a task analysis and data collection sheet for tracking Feddah’s routine and success in caring for her own hearing aids. By means of this tracking sheet, the occupational therapist could see if Feddah’s performance was improving.

Name: <u>Feddah</u> Week of: <u>May 21st</u> Activity: <u>Cleaning hearing aid</u> Environment: <u>Home, in bedroom</u> Verbal cue: <u>“Time to go to bed and take out your hearing aids”</u> Physical set up: <u>Feddah is at her dresser that is waist high.</u> Visual cues: <u>Tissues, wipes, hearing aid box is out on dresser top as a visual reminder to do this every night.</u>

inadequate sleep occurs, cycles of REM (rapid eye movement) and NREM (non-rapid eye movement) sleep are shortened, and memory, muscle repair, and hormone release are stunted. As a result, an illness or its symptoms may be exacerbated.^{50,92,117} Babies who are more easily awakened have more episodes of apnea when they are sleep-deprived.⁴¹ Recent studies have shown that sleep deprivation affects cognitive, attention, and social skill development.^{117,133,164} Chronic deprivation of sleep may result in a propensity for depression or suicidal ideation.^{116,133} In addition, when parents and other household members become sleep-deprived because a child has difficulty sleeping, their ability to meet role expectations (at school, home, work, or in the community) may be affected.^{85,121,178}

Sleep disturbances are often tolerated for a few days. They may occur with children occasionally because of illness or special events and emotions (e.g., special party or upcoming concert, moving to a new classroom, staying up later than usual). When sleep is chronically disrupted for weeks at a time, negative effects are inevitable, and possible causes for the sleep disturbance need to be determined.^{36,115}

Evaluation of Sleep and Sleep Needs at Different Ages

The International Classification of Sleep Disorders has identified more than 80 different types of sleep disorders.² The National Sleep Foundation¹¹¹ recommends regular sleep routines and patterns, with similar amounts of sleep each night.⁸⁶ Sleep disorders in children are identified as five main problems: bedtime resistance or falling asleep, awakening during the night, irregularity of amount of time in sleep, snoring, and sleepiness during the day.¹¹⁵ Occupational therapists have a vital role in helping parents develop the bedtime and self-care routines needed to promote healthy habits and patterns for sleep.⁴ Table 15-12 describes the typical amount of sleep needed for children and youth at different ages and lists possible factors impeding sleep.

Sometimes, parents are so concerned with the medical needs of their child that sleep is low on their priority list to discuss with physicians or occupational therapists. Physicians and health care professionals need to ask all parents and/or children about their sleep habits.¹⁰⁸ If a caregiver or child reports sleep difficulties consistently to a physician, a sleep screening questionnaire may be given, as well as a nocturnal polysomnography or actigraphy.⁸³ Screening questionnaires help identify what may be interfering with a child's sleep. A variety of screening questionnaires for sleep disturbances in infants, children, and adolescents have been developed.¹⁴⁶ The Evolve website lists sleep questionnaires most commonly used in research.

Polysomnography measures brain wave, muscle, cardiovascular, and breathing activity during sleep by placing 16 electrodes on the body. Figure 15-12 demonstrates what this might look like for a child. For some children with sensory sensitivities, these procedures are invasive and difficult to tolerate. Actigraphy uses an actimeter that is worn on the wrist or sewn into clothing to measure circadian rhythms and muscle movements during sleep and wake periods.¹³⁴ Research suggests that actigraphy and polysomnography results are similar in identifying the quality of sleep.⁶⁶

Assessment of a child's activity level, bedtime routines, sleep habits, and sleep environments often indicates what may be

FIGURE 15-12 Bella is having electrodes attached to have a nocturnal polysomnography test.

hindering sleep. As always, it is important first to determine the routines and whether cultural considerations influence the sleep habits of the family or child.¹⁴⁷ For example, some parents may sleep in the same room or bed with the infant or child, or the infant sleeps in the family living area instead of a bedroom. Some parents place the sleeping baby in a hammock or in a tightly swaddled prone position. Asking caregivers questions about sleep is essential to begin to understand their values and understanding of sleep hygiene:

- Does your child have regular sleep patterns (bedtime, nap-times, amount of uninterrupted sleep)?
- Where does the child sleep?
- With whom or what (e.g., stuffed animal) does the child sleep?
- When is the child put to bed or to sleep?
- What are typical bedtime routines?
- How long does it take your child to fall asleep?

Table 15-13 gives definitions of quality of sleep, assessment ideas, and questions to ask parents or caregivers to determine if a child has a sleep problem.

Sleep Issues for Children with Disabilities

Children with disorders such as asthma, ADHD, allergies, diabetes, cerebral palsy, epilepsy, sickle cell disease, obesity, or brain injury often have sleep disturbance issues.^{50,92,117} Children

TABLE 15-12 Typical Amount of Sleep Needed at Different Ages and Possible Factors Impeding Sleep

Age	Amount of Sleep Needed	Naps	Factors to Consider When Child Has Sleep Problems
Newborn, 1-2 mo	12-18 hr 50-60 min REM-NREM cycle	Throughout day	No established sleep/wake cycle Interrupted sleep related to feeding, comfort needs (diaper changes), medical procedures, sleep apnea alarms (if used), or too much sleep during the day When asleep and put to bed, baby wakes up with change in position
3-11 mo	12-18 hr	Three or four times daily, 30 min-2 hr	Usually cannot sleep through the night without feedings until 6 mo of age 70%-80% sleep through the night by 9 months Separation anxiety interferes with sleep Has not learned to self-soothe and is dependent on parents (needs to be drowsy or already asleep to be placed in crib) May be insecure with attachment or always wants to engage with others
Toddler, 1-3 yr	12-14 hr	Once or twice daily (18 mo, once a day), 1-3 hr	Fewer naps needed Needs independence Anxiety about going to sleep (may relate to separation anxiety, inability to self-soothe, imagination, fear of being alone, nightmares) Difficulty with transitions
Preschoolers 3.1-4.11 yr	11-13 hr	Once daily	Gets out of bed independently Bed wetting Nighttime fears or nightmares because of imagination developing (e.g., fear of being alone, the dark, tigers under the bed) Peak age for sleepwalking and sleep terrors Television watching too close to bedtime
School age, 5-10 yr	10-11 hr	0	Outgrown the need for naps and not sleepy when put to bed Bed wetting (typical until age 7) Medical issues—tonsils enlarged, facial profile is convex, has cross bite, reflux or medical procedure (e.g., positioning, suction) Unaware of social cues for calming down to go to sleep Increased demands for schoolwork or other extracurricular activities More interest in computers and internet Caffeine consumption or eating close to bedtime Electronic use in the bedroom or too close to bedtime (e.g., computers, televisions, tablets, video games) Erratic sleep schedule
Teens, 10.1-17 yr	8.5-9.25 hr		Lack of understanding of the importance of healthy routines for sleep Increased demands of school, work, social life, or other activities Anxiety or emotional event during the day Caffeine consumption or eating close to bedtime Electronic use in the bedroom or too close to bedtime (e.g., computers, televisions, tablets, video games, smartphones) Erratic sleep schedule especially weekend versus weekday nights Internal clock of teens—like late nights and waking up later in the morning Lack of understanding of importance for healthy routines for sleep

Data from Mindell, J. A., Meltzer, L. J., Carskadon, M. A., & Chervin, R. (2009). Developmental aspects of sleep hygiene: Findings from the 2004 National Sleep Foundation Sleep in America Poll. *Sleep Medicine*, 10, 771–779; National Sleep Foundation (2013). *Children and sleep*. Retrieved from <http://www.sleepfoundation.org/article/sleep-topics/children-and-sleep>; and National Sleep Foundation (2013). *Understanding children's sleep habits*. Retrieved from <http://www.sleepforkids.org/html/habits.html>.

who are typically developing have a prevalence of sleep disorders ranging from 10% to 50%, whereas 50% to 80% of children with ASD have sleep disorders.^{1,68,128} Parents report that anxiety or resistance to going to sleep often disrupts their child's sleep.^{49,51,72,96,117,155}

Children who are recently adopted or who are abused may have sleep latency and awakening problems because they may feel anxious and insecure when going to sleep or waking up.¹⁸ Parents of children with physical disabilities identified concerns

about child comfort and safety, and more than 50% thought that positioning aids or orthotics during bedtime hindered sleep.¹⁷⁸

Occupational Therapy Interventions for Sleep Disorders

Occupational therapists work with physicians, other health care professionals, parents, teachers, and the child to help determine

TABLE 15-13 Sleep Quality Definitions and Assessments for Children with Sleep Issues

BEARS Algorithm (Measurement of Sleep Quality)	Definition	Assessment	Questions to Ask Parents, Caregivers, or Child	Possible Reasons for Sleep Issue
Bedtime or sleep latency	Time between trying to sleep and actually going to sleep	Sleep log Routines used when going to bed Consistent bedtime? Nocturnal polysomnography or actigraphy Sleep questionnaires	How long does it take your child to fall asleep? Is your child resistant to go to bed or has difficulty going to bed? Does he or she get out of bed frequently prior to sleeping? Does he or she seem anxious when going to bed?	Lack of routines Too early or too late to bed Family discord Social, emotional issues
Excessive tiredness during the day	Ability to stay awake during the day	Parent, child, or teacher questionnaire Youth self-report Actigraphy Sleep questionnaires	Is your child hard to wake up in the morning? Does your child fall asleep during the day outside of scheduled naps? Does he or she complain of being tired or is he or she drowsy, moody, irritable, and/or looks tired to you?	Not enough sleep Irregular sleep Sleep apnea Illness Stress or anxiety
Awakenings at night	After going to sleep, number of times the child awakens at night	Sleep log by parents Sleep log by youth, if able Nocturnal polysomnography or actigraphy Sleep questionnaires	Does your child wake up at night? What interrupts his or her sleep? How many times does he or she wake up? Does he or she go back to sleep? Does he or she sleep walk or talk?	Sleep terrors or nightmares Environment is noisy or overstimulating Lack of exercise during the day Eating too close to bedtime Restless leg syndrome Illness
Regularity and duration of sleep	Time child goes to sleep and amount of time sleeping (when sleep began and ended)	Sleep log by parents or youth, if able Environmental assessment Nocturnal polysomnography or actigraphy Sleep questionnaires	How many hours does your child sleep? Does he or she have a regular bedtime on weekdays and weekends? What is the bedtime? How many hours does your child sleep?	
Snoring	Amount and loudness of gasping, choking, or snoring while sleeping	Observation of parents while child sleeps Reports of youth or sibling who sleeps in same room Testing for sleep apnea Sleep questionnaires	Does your child snore at night? Does he or she gasp for air or choke while sleeping? How often? Is the snoring loud or has it changed?	Sleep apnea
Movement or sleep efficiency	Amount of movement during sleep (may have restless leg syndrome)	Observation of parents or siblings who sleep in same room Report of youth, if able Nocturnal polysomnography or actigraphy Sleep questionnaires	When your child sleeps, are the legs restless or move a lot? Are the covers in disarray? Does your child change positions frequently when sleeping? Does your child end up at the other end of the bed after being asleep?	Restless leg syndrome

Adapted from National Sleep Foundation (2013). *Children and sleep*. Retrieved from <http://www.sleepfoundation.org/article/sleep-topics/children-and-sleep>; and Owens, J., & Mindell, J. (2005). *Take charge of your child's sleep: The all-in-one resource for solving sleep problems in kids and teens*. New York: Marlowe.

what interventions may help a child sleep better. Physicians may prescribe medication to sleep, and the parent may have tried a variety of strategies that have already worked. Nurses, respiratory therapists, and psychologists may have similar or additional ideas to promote healthy sleep habits. Children and youth often describe what distracts them when they are trying to go to sleep. Contextual modifications may make a difference in a child's sleep, such as establishing bedtime and wake-up routines and habits.^{4,5} Occupational therapists are often aware of the sensory aspects of the routine or environment and may suggest modifications.

Bedtime Routines and Habits

Bedtime routines related to ADLs can support or hinder sleep, based on the individual preferences of the child or caregiver. For example, if Johnny hates taking a bath, giving him a bath may have an alerting effect prior to bedtime, and he will be resistant to going to sleep. Meanwhile, Taniqua enjoys bathing, becomes calm after bathing, and gets very drowsy while reading a book after her bath. As noted, children with sensory processing disorders may find tooth brushing; face washing; texture, weight, or tightness of clothing or blankets; or donning and doffing splints as being aversive, which may affect the child's readiness to go to sleep, bed, or the mat for naptime. If healthy self-care routines are aversive to a child, these activities can be completed after dinner (or after a snack at school), and then a more relaxed child can experience a quiet and enjoyable time prior to naptime or bedtime.¹³¹ In addition, medications, eating, or exercising immediately before bedtime may disrupt the onset of sleep.

Occupational therapists can help caregivers, teachers, children, and youth develop a routine for naptime, rest time, or bedtime that works for them. They can emphasize the need for a consistent routine and similar times and amounts of sleep during naps (if age-appropriate) and during the night (for weekends and weekdays). The following suggestions related to the social and temporal environment may be helpful to caregivers, children, and youth to develop a routine^{4,35,111,113,107,147,175}:

- Establish a quiet time prior to bedtime for reading, rocking together in a chair, singing quiet rhythmic songs, or giving the child a back rub (no electronics, television, roughhousing, eating, or exercising right before bed)
- Use checklists, visual schedules, social stories, pictures, video modeling, or object cues (e.g., favorite stuffed animal or blanket used as a transitional object for going to bed).
- Keep the routine and environment the same each time the child goes to sleep (e.g., lights, music or noise machine, door open or closed, transitional object, small drink of water, singing), and keep the wake-up routine the same.
- Use a routine for going back to sleep if the child wakes up during the night.
- Avoid activities prior to bed that are upsetting or alerting to children.
- Put children to bed alone when drowsy but not asleep so they learn to self-regulate.
- Keep the same schedule for bedtime and wake-up time during the week and weekend.
- As children get older and more responsible, have them keep a log of their sleep and a checklist of healthy habits (e.g.,

television watching, caffeine use, what they are doing prior to bed, exercise during the day). (See Evolve website for different resources for this.)

- Adjust bedtimes according to the day's activity level (e.g., days when the child slept all day in the car or was outside for field day).

Physical Aspects of the Environment

The location and sensory aspects of the sleep environment and type of bedding and clothing may facilitate or hinder the quality of sleep. In addition, as children grow, they may need different firmness in a mattress or type of bed (e.g., from a crib to a youth bed [once a child is 35 inches tall], or a longer bed for the teen who is now 6 foot 4 inches tall!). The sleeping area needs to be quiet and away from noise and activity. Bedrooms should be used for sleeping and not for other activities or punishment. The following suggestions relate to modifying the physical sleep environment, if needed^{4,111,147,175}:

- Limit the amount of auditory stimulation during sleep that arouses the child or teen (e.g., music box or CD, white noise, or are they listening to fast beat or loud music on an electronic device while trying to sleep?). Use a story on tape or calm music if not distracting.
- Keep the temperature consistent and determine if vents, windows, or fans that are near the bed are problematic or if the child may be too cold or hot (may need a sleeper pajama versus a nightgown).
- Consider if smells are alerting or calming in the room (e.g., kitchen smells, deodorant in a diaper pail, smell of sheets or clothing).
- Reduce visual stimulation. Use dim or frosted night lights if needed. Keep lights off and remove pictures or mirrors in the bed or on the wall that are reflecting light, toys in bed, lights in hallway, and visually stimulating sheets or blankets.
- Consider the weight, texture, and visual attractiveness of clothing and bedding and the personal preference of the child.
- Use pillows or stuffed animals in the bed to help children feel more secure (not for babies).
- Raise the head of the bed slightly if the child has reflux or difficulty breathing.
- Secure outside doors or windows if sleep walking or escape from the house are issues. Sometimes alarms are installed so that parents are alerted if children are leaving the sleep environment ([Case Study 15-5](#)).

Sleep and rest are essential for children with disabilities, and educational programs about healthy bedtimes and sleep hygiene are beneficial to all children at school, home, and rehabilitation centers, and to their teachers and caregivers. AOTA^{4,5} materials on sleep may be used as part of handouts for parents, as part of an article for a Parent Teacher Organization or Early Intervention newsletter or part of health fairs given by local hospitals or centers. In addition, obesity prevention materials or programs about healthy eating and daily exercise or activity suggestions may be helpful to educate caregivers and children and youth.^{4,13,17,151} See the Evolve website for more information.

CASE STUDY 15-5 Carson, the Ever-Ready Bunny, Day and Night

Carson is an extremely active 5-year-old who is seen in an outpatient clinic for evaluation. Mom complained about his high activity level and aversive reactions to bathing and tooth brushing and identified problems with Carson's irregular sleep patterns and his inability to stay in bed or asleep for more than 2 or 3 hours. On evaluation, Carson's Vineland II scores were above average for communication and motor skills, but below average in socialization and daily living skills.

Carson had difficulty with sleep latency (getting to sleep) and night awakenings (remaining asleep). Sensory modulation issues appeared to be one issue, but there was also no regular bedtime in the household. Because Carson continually got out of bed and refused to go to sleep, Mom brought Carson to bed with her so that she could keep "an eye on him." Mom also revealed that she was involved in continuous conflict with Carson's father regarding custody and support, which could be adding stress to bedtime, because they often talked in the evening, after she put Carson to bed.

A variety of approaches were used to address Carson's activity level, his sensory modulation difficulties, and lack of consistent, calming routines at bedtime. Sleep patterns were addressed by educating Mom about the need for consistent meal times and sleep routines to help Carson know what to expect and function better the next day. Some suggestions included having Mom and Carson take Buffy, their dog, for a short walk to get a little exercise. Ideas about reducing food and drink consumption at nighttime and a checklist were developed for the routine after dinner. Tooth brushing was done immediately after dinner because Carson became irritated during this activity, and then Mom and Carson would play a quiet board game. A regular bedtime routine was developed to allow Carson time to wind down and prepare to sleep. The television was turned off; "sandwich activities" hugs for deep pressure and a calming bathing routine was developed. Deep pressure was given during the washing and drying-off process and when applying lotion after the bath. Special soaps (with smells that Carson liked), washcloths, rhythmic songs (e.g., "This is the way we wash our face..."), and checklists for bathing were used to give Carson some

control and cues for bathing. One parent read a nightly bedtime story while Carson rested under heavy blankets (Figure 15-13). Blankets were left in place to provide deep pressure and proprioceptive input throughout the night. A small nightlight in the hallway and a white noise machine seemed to comfort Carson but not distract him from sleep. His bed was moved away from the vent that blew air directly on him. Mom worked hard to keep Carson in his own bed for sleeping and gave him stickers for staying in his own bed each night. When Carson earned enough stickers, he was able to buy the favorite Disney movie that he was wanting.

Carson was also referred for a psychological assessment because his activity level continued to be high and his attention span was limited during the day at school. This assessment was also important because of the stress of the family going through a custody hearing. In addition, because Carson seemed to appear bored and unchallenged during the day and was not getting enough exercise or activity, his parents enrolled him in different camps during the summer months.

FIGURE 15-13 Carson sleeps with his bunny and heavy blanket for sensory input.

Summary

This chapter presents a wide range of options for enhancing ADL skills and sleep in children and adolescents with disabilities. Occupational therapists collaborate with children, parents or caregivers, and teachers to problem solve which method works best for each individual child. Summary points when promoting ADL function and healthy sleep habits include the following:

- Typical developmental sequences are useful in determining what children need to learn.
- Assessing ADL and sleep habits requires a variety of informal and formal methods related to the caregiver and child's

preferences, environment and context in which the task occur, child's capabilities, and demands of the task.

- Observing children and youth in the natural environment and during the typical routine of the family, school, or worksite is useful.
- Re-evaluation of ADL skills is needed as children develop, and new expectations occur (e.g., puberty or declining health, change in schools).
- Body functions and structures, performance skills, parent or teacher expectations, and performance patterns and routines at home, school, or work influence ADLs and sleep.
 - Establishing or restoring strength, balance, or gross or fine motor skills may influence a child's ability to perform ADL skills.

- Developing healthy habits and routines for ADL and sleep may improve the child's overall health and quality of life.
- As children get older and continue to have difficulty with ADLs, goals for partial participation or instructing others may become more important.
- Intervention strategies for ADL and sleep include positioning, task adaptation, visual supports, assistive technology, and environmental modifications.
- Research supports using visual supports, video modeling, prompting, and cognitive and collaborative approaches to teach ADL tasks.
- Occupational therapists offer adaptations to routines, activities, and sleep environment to promote healthy sleep habits. Whatever the pediatric setting, occupational therapists have the essential skills needed to evaluate ADLs and sleep and collaborate with others to suggest meaningful and useful interventions.

Instrumental Activities of Daily Living, Driving, and Community Participation

M. Louise Dunn • Kathryn M. Loukas

KEY TERMS

Instrumental activities of daily living	Adult role acquisition
Community participation	Social cognition
Self-determination	Disability awareness
Family chores	Objectives

GUIDING QUESTIONS

1. What are the instrumental activities of daily living during childhood?
2. How does participation in instrumental activities of daily living (IADL) and community activities contribute to occupational development for children and youth of all abilities?
3. What are the developmental opportunities and expectations for participation in IADL and community participation for children and youth?
4. What are the theoretical foundations of occupation-based interventions for improving participation and performance of IADL and community activities? What evidence supports these interventions?
5. What assessments specifically evaluate IADL and community participation for children and youth? How do practitioners select a measurement tool?
6. What approaches/strategies does an occupational therapy practitioner use to increase participation and performance of IADL and community activities for children and youth with special needs?
7. How would an occupational therapy practitioner apply information about development of IADL and community participation to case descriptions of children and youth?
8. How are emotional well-being, health, peer relationships, and life satisfaction associated with IADL and community participation?

Peter is a 14-year-old boy who has autism. His parents are worried about how he will take care of himself in the future. They are unsure about his role in the home and how much to ask of him. At school, the occupational therapy practitioner uses a sensorimotor approach to Peter's intervention, yet she now sees the need for more skills in independent living for Peter. The education team wonders how much to include Peter in life skills and vocational programming.

Kayla is a 12-year-old girl with spastic quadriplegic cerebral palsy. Her occupational therapy practitioner applies a motor control/neurodevelopmental treatment (NDT) and adaptation/compensation approach to her physical needs during her K-6 schooling. Since her transition to middle school, psychosocial concerns have become a priority for her family and teachers. Kayla has expressed concerns regarding her future: Will she ever be able to leave her parents' home? Will she ever be able to have a boyfriend or marry? Can she work or go to college after high school? Will she live independently or interdependently and meet her daily living needs as well as financial, food shopping and preparation, laundry, and other responsibilities of adult life?

Instrumental activities of daily living (IADL) are the more complex aspects of daily living that children and youth develop as they reach adolescence and begin to participate in the community with more autonomy. These activities include care of others, care of pets, child rearing, use of a communication device, community mobility, financial management, health management and maintenance, home management, meal preparation and clean-up, shopping, safety procedures, and emergency responses.⁴ Occupational therapists are experts in IADL, task analysis, and independent/interdependent living (Figure 16-1).

Children typically acquire more skill with IADL when they reach adolescence and begin to participate in the community with more autonomy. They continue to develop competence in these activities through adolescence into young adulthood. Instrumental activities of daily living and community participation include activities that promote self-determination, self-sufficiency, health, and social participation for children/youth of all abilities. Instrumental activities of daily living competence can be categorized as part of the “magnificent mundane”¹⁶ and is noted more by its absence than its presence. The magnificent mundane refers to the everyday presence of these tasks and reflects the tacit manner in which children/youth learn and understand their roles in these occupations. As preparation for independent living in the community, IADL include home management (e.g., clothing care, cleaning, and household maintenance), shopping and money management, meal preparation and clean up, community mobility, health maintenance (e.g., taking medications, exercise and nutrition), care of pets and care of others, and safety procedures and emergency responses.⁴

An integral relationship exists between IADL and community participation. For example, shopping is an IADL task that requires interaction with others in the community. Methods for learning to participate in the community may be tacit, such

FIGURE 16-1 Precise pouring is necessary in the IADL of meal preparation and clean up.

as learning through observation and assisting with shopping, or more explicit, such as finding and enrolling in community activities. Community participation includes social, play, and leisure activities with peers, and structured activities within the neighborhood and community.^{8,52}

Recent studies contribute to our understanding of the diverse and complex challenges involved in preparing youth for optimal community participation. A recent analysis of secondary transition indicates that nonacademic behaviors associated with transition to adult roles include disability awareness and activities that lead toward employment and independence. Youth and adults with physical disabilities reported that they lacked opportunities to direct their health care services such as making their own appointments and asking questions of medical and health personnel.^{33,40} Adults with physical disabilities reported dependence in shopping, home cleaning, laundry, and use of public transportation.⁶ Youth in foster care often lacked knowledge and experience with independent living, especially safety and home and health maintenance.^{61,62} Children and youth with cognitive/behavioral disorders such as traumatic brain injury (TBI), intellectual disability, and autism spectrum disorder (ASD) often lacked opportunities to engage in household tasks and community activities such as shopping and recreational activities.^{9,10,55}

Parents and caregivers reported that engagement in domestic tasks, recreation and leisure activities, and community activities was critical and important to health for children and youth of all abilities.^{1,11} These parental/caregiver perspectives support the importance of examining participation in home and community activities for children with and without disabilities. However, Bedell and colleagues found that parents and caregivers of children with disabilities (e.g., both physical and cognitive/behavioral) had more barriers to participation in community activities. These barriers included the physical environment, the social environment, and resources for families and programs. These findings support a need to monitor and promote children's participation in these activities from preschool age and through young adulthood.

This chapter provides an overview of the development of IADL skills and community participation, and a description of

theoretical tenets, models, and approaches that guide practices to promote competence in IADL and full participation in community living. It further explains how emotional well-being, health, peer relations, social cognition, and life satisfaction are associated with competence and independence in IADL and community living skills. Evaluation and intervention are discussed and illustrated using case examples.

Occupational Development of Instrumental Activities of Daily Living and Community Participation

Successful independent/community living is measured by outcomes related to employment, residing in the community, and community participation. A large longitudinal study demonstrated that 2 years after leaving school, youth with special needs were more likely to be unemployed, live with their parents, and lack engagement in community activities with peers than youth without disabilities.⁹⁰ In a second longitudinal study, youth with special needs showed increased employment and engagement in community activities; however, their involvement lagged behind that of their peers without disabilities.⁹⁰ Youth with special needs continued to lag behind non-disabled peers in living independently in the community.

Self-determination has been identified as a factor that promotes independent community living. Defined as “a combination of skills, knowledge, attitudes, and behaviors that enable a person to engage in goal-directed, self-regulated, autonomous behavior,”²⁸ self-determination encompasses many of the behaviors and attitudes often referred to as *life skills* that are both innate and learned.⁵³ These skills include managing personal care and health needs, taking care of one's belongings and space, managing home repairs, arranging transportation, and living interdependently with others. Opportunities to develop problem-solving skills, understand one's own strengths and limitations, and make choices are critical to developing these skills. The importance of self-determination to independent community living has strong research evidence. In fact, youth with mild intellectual and/or learning disabilities who have higher self-determination had greater employment rates, earned higher wages, and had more community involvement at 1 and 3 years out of school than similar youth with low self-determination.^{92,93}

To illustrate IADL expectations for children and adolescents, we present a description of typical IADL function in four age groups starting with late adolescence. We present this information in reverse developmental order because late adolescence is the time when most attention is drawn to IADL function. The use of this reverse developmental order illustrates a progression of skill development from the most complex tasks that require more cognitive and motor skills to less complex tasks. As we progress backward, you will note the many opportunities exist even for younger children to develop IADL skills used for both home and community participation.

Late Adolescence (16 to 18 Years)

By late adolescence, youth are more autonomous and show greater breadth in their IADL and community participation than do early adolescents (Figure 16-2). Many spend most of

their time outside the home, driving or taking public transportation, arranging transportation for community events, working a part-time job or volunteering, shopping, managing money, and maintaining a healthful regimen (e.g., taking responsibility for medications, exhibiting awareness of healthful behavior

FIGURE 16-2 Two adolescents participate in a local running event as community participation.

with partners).^{22,57,79,84} At this age, many youth prepare hot and cold meals, help with clean up, and manage their laundry. **Box 16-1** provides IADL and community participation expectations for older adolescents.

Client factors may limit opportunities to engage in IADL tasks and community participation for many youth with physical and/or cognitive disabilities; but with adaptations and accommodations, many become competent in occupational performance. Behavioral concerns such as lack of confidence, dependency, or weak social skills may also influence task performance of youth with physical disabilities, especially in community activities.⁵⁶ Coaching, technology, and visual supports for youth with TBI promote adaptation and compensation for their difficulties with memory, problem solving, and self-management to initiate and complete tasks, sustain focus on tasks, and interact with others when completing work.²⁷ For example, youth with TBI are likely to need specialized coaching and assistance to manage the social demands of using public transportation on their own, to maintain and shift focus within this noisy and stimulating background, and to multitask (e.g., find a seat, count money, greet and respond to others).

Youth with autism spectrum disorder (ASD) may do well with household tasks such as making a snack, yet require supports to accomplish tasks that require more interaction, such as shopping. Cognitive/behavioral interventions assist these youth to manage tasks that involve relating to others, as would be needed to manage health care needs. Supports and opportunities for engaging in structured and unstructured leisure activities such as recreation, team sports, shopping, or

BOX 16-1 Instrumental Activities of Daily Living and Community Participation: Older Adolescents (16-21 Years)

Meal Preparation and Clean Up

- Plans and prepares simple hot and cold meals
- Puts dishes in dishwasher/puts dishes away
- Safely operates stove, oven, toaster, blender, microwave, and dishwasher

Community Mobility

- Can obtain driver's license
- Uses public transportation on own

Health Management and Maintenance

- Transfer to adult health care provider
- Responsible for managing medications
- Attends part of medical appointments alone
- Keeps record of medical history

Household Maintenance and Management

- Looks into housing choices
- Attendant services and supported living options
- Does home repairs (e.g., replaces light bulb, replaces fuses)

Clothing Management

- Launders own clothes
- Mends clothes as needed

Use of Communication Devices

- Keeps in touch with friends by phone, texting, and computer (webcam, e-mail)

Shopping and Money Management

- Practices budgeting and banking skills
- Purchases

Safety and Emergency Response

- Knows how to use fire extinguisher
- Knows what to do in case of fire or emergency

Community Participation

- Makes plans with peers for informal leisure and recreation activities
- Engages in community programs for youth/adults that match leisure or athletic interests
- Works part time and/or volunteers in community

Performance Skills

- Motor and sensory skills well developed or adaptations and accommodations identified
- Emphasis more on psychological, social, and cognitive skills
- Takes more responsibility for own routines

Data from Dunn, L., Coster, W. J., Orsmond, G. I., & Cohn, E. S. (2009). Household task participation of children with and without attentional problems. *Physical and Occupational Therapy in Pediatrics*, 29(3), 234–251; Bloorview Life Skills Institute. (2007). Growing up ready timetable & checklists. Retrieved June 3, 2009, from <http://www.bloorview.ca/resourcecentre/familyresources/growingupready.php>; Nollan, K. A., Wolf, M., Ansell, D., Burns, J. Barr, L., Copeland, L., et al. (2000). Ready or not: Assessing youth's preparedness for independent living. *Child Welfare*, 79(2), 159–618; Rodger, S. (2006). I can do it: Developing, promoting, and managing children's self-care needs. In S. Rodger, & J. Ziviani (Eds.), *Occupational therapy with children* (pp. 200–221). Oxford, UK: Blackwell.

volunteer activities facilitate participation for youth with ASD.³⁰ Coaching, peer mentors, and reverse inclusion are client-centered interventions to increase participation of youth with disabilities to seek out and to engage in IADL tasks and community activities. Many late adolescents with disabilities can arrange transportation to get together with friends, access community activities, and perhaps learn to drive through use of technology, assistance, and supports.

Early Adolescence (12 to 15 Years)

For young adolescents, teachers and parents emphasize not only learning from academics and vocational exploration, but also home and health management, shopping and meal preparation, and community participation^{33,66,79} (Figure 16-3). School programs attempt to establish adolescents' independence and interdependence working with others. Young adolescents have increased responsibility for caring for others, managing their laundry, and preparing simple, hot meals and snacks.^{57,79,84} Technology, such as the microwave, cell phones, e-mail, and instant messaging/texting, increases young adolescents' opportunities for communication and community participation. Box 16-2 provides IADL and community participation expectations for young adolescents.

FIGURE 16-3 Children participate in the IADL of meal preparation in their home.

BOX 16-2 Instrumental Activities of Daily Living and Community Participation: Younger Adolescents (12-15 Years)

Meal Preparation and Clean Up

- Plans and prepares simple hot and cold meals
- Puts dishes in dishwasher/puts dishes away

Community Mobility

- Starts to find way around local community
- Arranges rides to friends' houses
- Arranges rides to structured leisure and recreational activities
- Uses public transportation without assistance

Health Management and Maintenance

- Begins to look for adult health care providers
- Attends some medical appointments alone
- Assists with making medical and dental appointments
- Takes more responsibility for managing medications

Household Maintenance and Management

- Participates in discussions with parents about where he or she might live as an adult
- Cleans own space and shared (family) space
- May look after or babysit others or younger siblings
- Vacuums, dusts family space
- Puts away own laundry

Use of Communication Devices

- Uses phone, pens, and computers to send and receive information

Shopping and Money Management

- May use bank card to deposit or withdraw money
- Purchases items with bank card or money
- May receive allowance, earn money from part-time work
- May purchase own goods at store

Safety and Emergency Response

- May take course in basic first aid
- Educates self about what to do in case of fire or emergency
- Responsible for personal safety when crossing street, obeying traffic and road signs

Community Participation

- Engages in informal and structured leisure and recreation with peers
- Keeps in touch with friends by phone, e-mail
- May volunteer in community

Performance Skills and Patterns

- Motor and sensory skills developed or adaptations and accommodations identified
- Emphasis more on psychological, social, and cognitive skills
- Has developed routines for daily activities, yet may need prompting

Data from Dunn, L., Coster, W. J., Orsmond, G. I., & Cohn, E. S. (2008). Household task participation of children with and without attentional problems. *Physical and Occupational Therapy in Pediatrics*, 29(3), 234–251; Growing up ready timetable and checklists. Retrieved June 3, 2009, from <http://www.bloorview.ca/resourcecentre/familyresources/growingupready.php>; Nollan, K. A., Wolf, M., Ansell, D., Burns, J. Barr, L., Copeland, L., et al. (2000). Ready or not: Assessing youth's preparedness for independent living. *Child Welfare*, 79(2), 159–618; Rodger, S. (2006). I can do it: Developing, promoting, and managing children's self-care needs. In S. Rodger, & J. Ziviani (Eds.), *Occupational therapy with children* (pp. 200–221). Oxford, UK: Blackwell.

Youth with disabilities often need additional practice and opportunities to promote autonomy with IADL and community participation.^{9,26} Coaching and role playing help prepare young adolescents with physical disabilities to direct others or seek assistance as needed with IADL and community tasks. Some may be reluctant to express their lack of knowledge about how to prepare a meal and simply wait until someone does it for them. Participating in the planning needed to perform tasks such as moving around the home and community helps young adolescents develop more autonomy despite their cognitive/behavioral and social skill deficits.⁵⁶ Addressing assertiveness in interventions helps these young adolescents increase their engagement in leisure and recreational activities.

Similar client factors and various levels of functioning may also impede participation and performance of youth with TBI, ASD, and learning and/or intellectual disabilities. Client factors that include communication challenges and rigid occupational patterns may make it difficult for young adolescents with TBI and ASD to participate in volunteer work or arrange transportation to structured recreational activities. Lack of safety awareness and difficulty understanding the needs of others may make taking care of younger siblings or others difficult for young adolescents with disabilities. For example, clients with autism who insist on rigid routines and tend to be inflexible around changes, make negotiating with others difficult, a skill needed in many recreational activities such as group outings.

Youth at the early adolescent levels are often interested in driving and gaining independence in the community. For youth with disabilities, learning to drive often occurs later if at all. Driving involves factors such as vision, attention, motor control, and executive functioning. Limitations in safety awareness and motor coordination can make learning to drive and, therefore, accessing the community, more difficult for young adolescents with disabilities.

Middle Childhood (6 to 11 Years)

In middle childhood (6 to 11 years), children participate in household chores and neighborhood activities. However, other than school systems that offer a formal Life Skills program, few formal learning opportunities related to IADL and community participation are available. Children in the middle years prepare for future independent/community living through their engagement in everyday family, afters-school, community, and school activities.^{51,67} These occupations give children opportunities to make choices, solve problems, and identify interests and skills that help them develop self-determination, social skills, and competency with IADL and community activities.^{72,85,91}

In middle childhood, many children engage in family and household routines; however, diversity in what they do and with whom is common. Parents report that they expect their children to take care of their space and materials, help with clean up after meals, prepare simple cold meals, help with putting away groceries, and care for siblings with supervision²² (Figure 16-4). As they engage in these tasks, children develop communication, cognitive, and social interaction skills (e.g., problem solving on encountering difficulty). Community activities include formal structured activities such as sports or music lessons, as well as informal unstructured activities such as riding

FIGURE 16-4 Children engage in household chores, an important part of occupational development.

bikes. Box 16-3 provides IADL and community participation expectations for children of middle childhood age.

Physical, cognitive, and social functioning deficits may make it difficult for children with disabilities to develop the skills necessary to participate in these activities. Children with physical disabilities may participate in recreational activities by observing rather than doing.⁷⁸ Some may not assist with IADL such as setting or clearing the table because of the time it takes them to do these tasks or because their physical impairments limit their participation.¹⁸ For children with physical and/or cognitive/behavioral disabilities, generalization of learning to different settings may require specific cognitive and behavioral strategies.^{74,76} Children with cognitive/behavioral disabilities such as attention-deficit/hyperactivity disorder (ADHD) may clean up after preparing food in a community setting yet not carry over this learning to their home life.³⁸ Supports to help children with ADHD transfer skills to the home environment include educating parents on increasing expectations and modifying the environment to cue the child to complete the steps of the task (e.g., using a visual schedule).

Client- and family-centered interventions may increase participation of children with TBI in family routines such as preparing simple cold meals and picking up shared areas. Coaching, visual cues, and opportunities for practice and repetitions may increase their participation in routines so that they can organize their belongings for school and non-school-related activities. Accommodations such as use of social stories for preparation and shopping at less busy times and in smaller stores may help to create an environment of success and reduce emotional outbursts at the supermarket or mall for children/youth who exhibit over-responsiveness to sounds, sights, and smells.

Preschool (3 to 5 Years)

In preschool, participation in home, day care, and community activities frequently occurs with supervision from caregivers or parents. Therefore family involvement is essential to development of IADL and community participation.^{42,80,83}

Availability of free play allows children the opportunity to identify interests, make choices, and learn how to share and

BOX 16-3 Instrumental Activities of Daily Living and Community Participation: Middle Childhood (6-11 Years)**Meal Preparation and Clean Up**

- With supervision, puts dishes in dishwasher/puts dishes away
- Gets own snacks
- Sets and clears table

Community Mobility

- Rides bicycle, uses rollerblades, scooter around neighborhood
- Makes arrangements with parent for rides to friends' houses, video store, etc.
- Uses public transportation with supervision

Health Management and Maintenance

- Participates in medication routines (as needed)
- Assists with naming medical concerns (e.g., allergies, asthma, seizures)

Household Maintenance and Management

- Puts away own materials, vacuums and dusts own room
- Puts away groceries, helps with recycling
- Organizes materials for school and after-school events

Use of Communication Devices

- Keeps in touch with friends by phone, e-mail
- Answers phone, takes messages

Shopping and Money Management

- May have a savings account
- Shops with parent or caregiver
- Finds items on shelves at supermarket

Safety and Emergency Response

- Can name places to find help or be safe
- Aware of safety with food, fire, and strangers

Community Participation

- With assistance, gets together with peers for leisure activities, hobbies, movies
- May participate in after-school programs, community center activities
- Visits with friends or relatives in neighborhood

Performance Skills and Patterns

- Motor planning and sensorimotor skills continue to develop and are further refined, may be problem areas
- Starting to follow routines for daily activities but requires prompting

Data from Dunn, L., Coster, W. J., Orsmond, G. I., & Cohn, E. S. (2008). Household task participation of children with and without attentional problems. *Physical and Occupational Therapy in Pediatrics*, 29(3), 234–251; Growing up ready timetable and checklists. Retrieved June 3, 2009, from <http://www.bloorview.ca/resourcecentre/familyresources/growingupready.php>; Nollan, K. A., Wolf, M., Ansell, D., Burns, J. Barr, L., Copeland, L., et al. (2000). Ready or not: Assessing youth's preparedness for independent living. *Child Welfare*, 79(2), 159–618; Rodger, S. (2006). I can do it: Developing, promoting, and managing children's self-care needs. In S. Rodger, & J. Ziviani (Eds.), *Occupational therapy with children* (pp. 200–221). Oxford, UK: Blackwell.

take turns. In Head Start programs, much emphasis is placed on promoting self-determination by assisting children to identify when they need help and guiding them to solve problems on their own.^{32,83} Furthermore, children with and without disabilities are involved in many naturally occurring learning opportunities through community activities such as shopping, going to neighborhood playgrounds, attending library story hours, taking walks in the neighborhood, or participating in events at community centers.²⁵ In the home, preschool children assist with many household tasks such as putting away their own toys, making their beds, putting away their clothes, helping to set the table, and preparing cold snacks.⁷⁹ Most families emphasize the child's learning to accomplish basic self-care routines and to take care of his or her belongings.

Instrumental activities of daily living participation for preschool children with disabilities has not been researched. For children with physical disabilities, opportunities to perform tasks such as picking up one's toys, making choices about snacks, or pointing to items at the supermarket may provide ways to develop routines and be part of the family. With coaching and positive supports, children with TBI, ADHD, or ASD can learn to pick up their toys and to make choices about snacks or community activities.

In summary, age and functional abilities contribute to the extent of children's and youth's participation and performance of IADL and community activities. Instrumental activities of daily living and community participation are both the means

and ends for development of motor and process performance skills.

Personal and Contextual Influences on Instrumental Activities of Daily Living and Community Participation

Multiple inter-related internal and external factors influence children's and youth's engagement in IADL and community activities. The occupational therapist addresses personal and contextual factors that may support or limit the child's or youth's participation in IADL and community activities.

Personal Influences

Personal influences for children and youth include their *interests*, *preferences*, and *motivation* to engage in activities. Engagement in IADL and community activities requires interest and motivation. Initially, motivation may be promoted with external support; however, to continue to engage in tasks and use skills, children and youth must internalize reasons to engage in IADL.⁷⁵ A client-centered approach that targets client interests and choices may increase internal motivation for performing IADL tasks. This, in turn, can lead to increased responsibility and opportunities to engage in occupations of choice or to earn money in the home and/or community.^{13,40} For example, a

client who initially only wishes to engage in swimming in the community, may be inclined to work folding towels for the pool to pay for his admission. This interest in swimming could also be used to motivate the client to access public transportation or contact others for transportation support.

Contextual Influences

Contextual influences, external to the child, include (1) the natural and built environment (physical context); (2) supports and relationships (social context); (3) attitudes, values, and beliefs (cultural context); (4) computers and assistive technology (virtual); (5) stages of life, time of year, and duration (temporal); and (6) service systems and policies.^{2,95} Service systems and policies—eligibility and insurance coverage—also influence opportunities available to children and youth. These contextual influences can either support or limit children's and youth's participation IADL and community activities.

The natural and built environment (physical context) includes the sensory and physical qualities of the setting (e.g., noise, lighting, temperature, terrain, crowding), building design, and accessibility to materials.⁵⁶ Within the home, access to different areas and materials supports participation of children and youth in family activities. In the community, buildings that have accessible entrances and activities on a flat terrain support inclusion of children and youth with physical limitations. Examples of barriers are homes without access to all areas and community centers with activities on multiple levels that lack ramps or elevators. Crowding (e.g., group size) and sensory aspects of the environment are potential barriers for children and youth with physical, sensory, cognitive, and intellectual disabilities.^{43,65} For children and youth with TBI, ADHD, ASD, and intellectual disability, the noise from people talking and the movement of people in a crowd may contribute to behavioral outbursts, anxiety, and aggression, thus decreasing their participation. Noise, visual stimulation, and crowding limit participation because these factors interfere with balance, mobility, and communication for children and youth with physical disabilities.⁶⁵

Supports and relationships (social context) are particularly salient factors that influence participation of children and youth in IADL and community activities. At home, support is crucial for participation with family members in everyday activities. Families provide children with opportunities and encouragement to learn household tasks such as mealtime preparation and care of common spaces. Modeling of task performance and discussion of tacit planning processes make learning and understanding these tasks more tangible to children and youth. For example, at home children can observe not only their parents but also their siblings. In addition, children may be mentors to their siblings and guides for their parents. As children mature, they may take on the role of caring for their siblings when parents are out of the home. In the community, children may begin by attending structured after-school activities such as sports or recreation groups (see [Figure 16-2](#)), or they may meet with peers to socialize at the mall. As they approach older adolescence, they may also take on roles as mentors at recreational centers or scouting events.

The social environment for IADL participation varies by setting (e.g., school, home, community, or work). Children observe parents and siblings doing household tasks and often

attempt to model their actions. For example, social outcomes from participating in mealtime preparation and household tasks include promoting a sense of family, interacting with family members, and demonstrating positive social behaviors.^{22,66} A long-term social outcome includes preparation for adult roles with preparing meals and engaging with family members. Lack of support and diminished opportunities for participation in these mundane everyday tasks can impede development of community living skills (e.g., such as the example of youth in foster homes).⁵⁷

Cultural values and beliefs significantly influence opportunities for IADL and community participation. Family beliefs about routines and perspectives on how children spend their time influence participation of children and youth in the home and community.^{28,34,88} For example, parents of Asian background tend to value academics and place much less emphasis on IADL activities and autonomy for their children.⁹⁷ In contrast, Latino and Navajo families tend to focus on interdependency and promote engagement in household and IADL tasks.⁸¹

The value of interdependency versus autonomy may influence a family's willingness to support the independence of a child or youth with a disability. Families from African American and Hispanic backgrounds are more likely to plan to have their children with developmental disabilities live with them when the children become adults.¹³ These values may also influence the opportunities to engage in IADL tasks and community activities for children and youth with disabilities. Parents of children with disabilities, particularly those from lower socioeconomic levels, were less likely to involve their children in household tasks and in interacting with others in the community.⁹⁷ Values for engaging in interdependent activities also influence participation in household tasks. For example, parents of children with ADHD tend to emphasize household tasks that involve managing one's own belongings with less focus on shared tasks such as helping at mealtimes.²⁵

Community programs that include children and youth of all abilities are supports for community participation.⁶⁵ Inclusive community participation opportunities may include recreation, summer camps, sports programs and teams, inclusive arts, and other community programs. Occupational supports may include access to physical space and equipment, modifications in rules to support skill levels, social supports such as a buddy system, and behavioral coaching to design activities and programs that include children of all abilities. The occupational therapy practitioner should take into consideration and prepare youth and families for the possibility of social stigma, bullying, and marginalization.^{56,65}

Technology, computers, online resources, and assistive and augmentative communication devices are supports used commonly with children and youth who have disabilities to promote their participation in IADL and community activities. Technology and online resources afford opportunities for children and youth of all abilities to connect with others. Information about community activities, employment, shopping, banking, meal planning, public transportation, and health are available online. A growing number of support groups for children and youth with many differing disabilities have set up websites that provide peer mentoring for learning how to live in the community and care for their own needs.

Examples of *service systems* that promote inclusion of children and youth with disabilities are inclusive aftercare and recreational programs, programs with adaptive equipment, and transportation. *Policies*, rules, and standards that govern these services ensure that they are accessible and enable optimal participation of persons with disabilities.^{56,95} For children and youth with disabilities, lack of transportation or length of time required to transition to programs can be a barrier to participation in community activities.⁴³ Another barrier is the lack of policies and funding to cover costs of additional supports that may be needed for inclusion of children and youth with disabilities in out-of-school activities.⁴³

Evaluation of Instrumental Activities of Daily Living and Community Participation

Children, youth, and their families or caregivers play strategic roles in the evaluation process. Parents and caregivers provide relevant information about the settings and contexts in which the children or youth engage in IADL and community activities. Providing youth with opportunities to engage in the evaluation process increases their autonomy and prepares them for decision making and management of their health, IADL, and community participation. In addition, families may increase IADL and community participation expectations of the child/youth as a result of the evaluation process and discussions.

Occupational therapists evaluate IADL and community participation using a combination of the following methods: chart review/history, observation, occupational profile/interview,

inventory/questionnaire, performance measures, and interest checklists. The evaluation may be part of a school-based triennial evaluation required under IDEA, a transition plan at the request of a pediatrician or health care practitioner, a request from the parent as part of a hospital-based assessment, or a community program such as foster care. Occupational therapists administer evaluations individually with the child/youth and caregiver, as a team evaluation, or as part of a program evaluation. At school, this process may occur when the educational team, which includes the youth and family, develops the individual transition plan (ITP). This evaluation process also may occur when children and youth return to school after hospitalization secondary to medical concerns such as traumatic brain or spinal cord injury. Interdisciplinary team evaluations often occur in psychiatric facilities, foster care programs, juvenile justice programs, and as part of community system services. Team members often include, but are not limited to, children and youth, caregivers, occupational and physical therapists, speech language pathologists, nurses, psychologists, social workers, and psychiatrists. Interprofessional information is helpful for a holistic and realistic appraisal of the child or youth's performance and potential in a variety of settings. [Table 16-1](#) provides a listing of measures used by occupational therapists to assess IADL.

Measurement of Outcomes

Occupational scientists and therapists along with professionals in rehabilitation and health have developed assessments to measure outcomes of IADL and community participation (see

TABLE 16-1 Instruments for Assessing Instrumental Activities of Daily Living and Community Participation for Children and Youth

AMPS <i>Assessment of Motor and Process Skills</i> (5th ed.) Fisher (2003a,b) AMPS Project International P. Box 42 Hampton Falls, NH 03844 www.ampsintl.com	Areas addressed Person Task Method Observation Age range 3 years to adult	- AMPS is a criterion-referenced test for activities of daily living (ADL) and instrumental activities of daily living (IADL) tasks that assess underlying motor and process performance skills used to perform the task. - Examiner training—formal training procedure through course attendance, observation, and calibration of scoring through AMPS International required. - Established reliability and validity with normative data for typical individuals - Assessment of life skills, developed on children and youth in foster care, that is completed online and then automatically scored. - Life skills categories include home and money management, health, safety and emergency, transportation - Criterion-referenced - Good reliability and validity
Ansell-Casey Life Skills Inventory Nollan et al. (2000) Online assessment available at www.casselifeskills.org	Areas assessed Person Task Method Interview Observation Age range 8-18 years	- Measures performance (what child does) and capacity (what child is capable of doing) for personal care, dressing, eating, locomotion, stairs, play, transfers, and standing skills - Excellent reliability and validity - Child and/or parent report - Takes ≈30 minutes first time, 10 minutes for repeat tests - Summed scores allow comparison of individuals across time
ASK <i>Activity Scale for Kids</i> Young et al. (2000) Nancy Young, PhD nancyyoung@sickkids.on.ca ASK manual (1996) The Hospital for Sick Children Toronto, Ontario	Areas assessed Person Task Methods Interview Questionnaire Observation Age range 5-15 years	

TABLE 16-1 Instruments for Assessing Instrumental Activities of Daily Living and Community Participation for Children and Youth—cont'd

CHORES <i>Children Helping Out: Responsibilities, Expectations and Supports</i> Dunn (2004) Contact Louise Dunn, ScD OTR/L ldunn@brenau.edu	Areas assessed Person Environment Task Methods Interview Questionnaire Age range Grades 1-8 ≈6-14 years	• Parent report measure that examines children's participation in household tasks • Has excellent internal consistency and test-retest reliability for school-aged children (Dunn, 2004) and youth (Dunn, in preparation) • Takes ≈15-20 minutes to complete • Scoring: summary scores allow comparison of individuals across time. • Additional open-ended questions about parents' perspectives on importance and satisfaction with their children's household task participation
COACH <i>Choosing Options and Accommodations for Children</i> (2nd ed.) Giangreco, Cloninger, & Iverson (1997) Paul Brookes Publishing PO Box 10624 Baltimore, MD 21285 www.brookespublishing.com	Areas assessed Person Task Methods Interview/questionnaire Observation Age range 3-21 years	• COACH is a curriculum-referenced transdisciplinary team assessment and curriculum with four domains: personal management, community, home, and vocational • Used as a team planning tool; does not assess specific skills • Intended for children with moderate, severe, or profound disabilities but has been used with children with mild disabilities
LIFE-H <i>Life Habits Questionnaire</i> Noreau et al. (2007) Contact Luc Noreau, PhD Luc.Noreau@rea.ulaval.ca	Areas assessed Person Environment Task Methods Interview Questionnaire Age range 5-18 years	• Parent and youth report measure based on ICF participation. Excellent reliability and validity. • Examines 6 categories of participation: interpersonal relationships, communication, personal care, mobility education, and recreation. Examines daily activities (e.g., personal care, mobility, nutrition) and social roles (e.g., recreation, responsibility) • Takes ≈15-20 minutes to complete. Youth may complete as part of interview.
<i>Participation and Environment Measure for Children and Youth (PEM-CY)</i> Coster et al. (2011) Available at: http://participation-environment.canchild.ca/en/participation_environment_measure_children_youth	Areas assessed Person Environment Task Methods Questionnaire— electronic, paper Age range 5-17 years	• Summary scores permit individual comparison over time • Parent/caregiver report measure based on ICF classification of participation at home, school, and in community. Excellent reliability and validity. • Takes ≈25-30 minutes to complete. Youth may complete as part of interview. • Population-based measure. Summary scores permit individual comparison over time.
<i>Pediatric Evaluation of Disability Inventory-Computer Adaptive Test (PEDI-CAT)</i> Haley, Coster, Dumas, Fragala-Pinkham, Moed, et al. (1992; 2012) Available at: http://www.Pedicat.com Cost ~ \$99	Areas assessed Person Environment Task Method Questionnaire Electronic Age range Birth to 20 years	• Revised with increased attention to ICF classification of participation at home, school, and in community. Excellent reliability and validity. • Takes ≈30 minutes to complete • Summary scores permit individual comparison over time

Table 16-1). Using the International Classification of Functioning, Disability, and Health for Children and Youth, health-related outcomes include participation patterns, activity performance, quality of life, client satisfaction, and contextual supports and barriers.⁹⁵

Assessments for IADL and community participation are relatively few; most are inventories that are completed by a caregiver. The Assessment of Motor and Process Skills (AMPS) is standardized and appears to be sensitive to the progress that children make.^{30,31} Studies demonstrated that the AMPS can identify differences in IADL for children with and without ADHD³⁸ and for children with hemiplegic cerebral palsy.⁸⁹

Several new participation assessments have recently become available (see Table 16-1). The Participation and Environment Measure for Children and Youth (PEM-CY)¹⁹ and the Life Habits Questionnaire (LIFE-H)⁶⁸ measure participation at home, school, and in the community. These measures produce change scores that can be used to examine outcomes from individual intervention or programmatic outcomes. Measures may be completed by the caregiver or teacher and by the child or youth for comparison of perspectives.

The PEM-CY has been used to obtain information about participation for children of all abilities from 5 to 17 years.¹⁹ Some examples of PEM-CY home items include socializing

Household tasks (SC = Self-care) (FC = Family-care)	Not expected (1)	Child cannot (2)	Lot of assistance (3)	Some assistance (4)	With supervision (5)	When asked (6)	On own initiative (7)
Puts away own clothes (SC) ☐ Yes ☐ No							
Makes self a cold meal (SC) ☐ Yes ☐ No							
Puts own laundry in hamper (SC) ☐ Yes ☐ No							
Sweeps or vacuums own room (SC) ☐ Yes ☐ No							
Feeds pet (FC) ☐ Yes ☐ No							
Sets or clears the table (FC) ☐ Yes ☐ No							
Takes out garbage/recycling (FC) ☐ Yes ☐ No							
Cares for younger sibling (FC) ☐ Yes ☐ No							

FIGURE 16-5 Examples of items and ratings for the Children Helping Out: Responsibilities, Expectations, and Supports (CHORES) Program.

with technology, household chores, homework, indoor play and games, and computer and video games.⁵⁵

The LIFE-H obtains information about social participation for 5- to 13-year-old children and youth with physical disabilities, TBI, or developmental disabilities.⁶⁸ *Life habits* refer to participation in valued everyday activities, such as nutrition, fitness, communication, and personal care, and valued social roles such as responsibility and community life.

Educational personnel, health professionals, and caregivers often address preparation for independent and interdependent living during adolescence; however, research supports monitoring and assessing these performance areas before adolescence. Because children and youth with disabilities often require additional support to learn and perform these tasks, assessment and planning before adolescence are needed. The Children Helping Out: Responsibilities, Expectations, and Supports (CHORES) program was developed for these purposes and provides information about participation in household tasks and some aspects of IADL.²¹ In CHORES, household tasks include domestic tasks as well as caring for others. Household tasks are organized into two groups: self-care tasks and family-care tasks.⁹⁴ Self-care refers to household tasks for which the outcomes primarily affect the individual, such as picking up one's clothing or making a cold meal for oneself. Family care refers to household tasks for which the outcomes primarily affect others, such as caring for pets and preparing meals (see Figure 16-3).

Scoring on CHORES provides a way to measure change for individuals across time. Changes are measured by comparing

the number of tasks performed and the assistance required to perform household tasks. Two open-ended items provide information about the importance of household task participation to parents and parents' satisfaction with their children's household task participation. Refer to Figure 16-5 for examples of items and rating scales for CHORES.

The information gathered from CHORES contributes to development of intervention goals for household task performance and family participation. This information can promote discussions about expectations and opportunities and preparation for independent living for children and youth of all abilities.

Transition Planning

Inclusion of the families or caregivers of children with disabilities promotes and reinforces positive self-esteem and self-determination skills.^{35,60,86,93,96} Occupational therapists facilitate psychosocial skills and community participation-based interventions in elementary grades and well before formal transition planning. Occupational therapists often provide services in the school setting to children who experience difficulties with occupational performance of self-care or functional mobility, rendering a prime opportunity for therapists to implement needed skills for independent living. In addition, the school-based occupational therapist understands both the assets and functional challenges of the youth and family, making

them the ideal professional to facilitate the transition to adult roles.⁴⁶ The American Occupational Therapy Association (AOTA) promotes the role of occupational therapy in transitions. Specific roles for occupational therapists for clients in transition to adulthood include preparation of student and families for changes in roles and routines; representing and advocating for the needs of the student; evaluating and implementing supports for employment and/or continuing education; building skills for employment and volunteer roles; facilitation of self-determination and social integration into the community; evaluation and intervention for occupation-based mobility, including the possibility of driving or using public transportation; and promoting and fostering self-advocacy skills.³

As children begin their transition to adult roles, occupational therapy practitioners focus on independent or interdependent community living.¹⁸ This is best accomplished by engagement in meaningful IADL occupations in the natural environment. Ideas include use of cottage industries, student-led planning and implementation of community events, providing support groups for young adults and families, use of public transportation as an intervention activity, and simulated activities such as money exchange and social interactions. As Orentlicher and Michaels note, the adolescent's goal is to achieve full status as an adult:

*Disability is a natural part of human experiences and it does not diminish the right of the individual to live independently, enjoy self-determination, make choices, contribute to society, pursue meaningful careers, and enjoy full inclusion and integration in the economic, political, cultural and educational mainstream of American society (p. 2).*⁶⁹

Transition planning is concerned with the continuing process of moving from a supported home environment to a role of living in the adult community. Adolescents with disabilities or those who are at risk may require more planning, intervention, and support than a typical student.^{44,45,64,69,70}

Occupational therapists understand and appreciate the important link between occupations and identity.^{17,49} Desired outcomes for adolescents with lifelong disabilities include safe, independent or interdependent engagement in occupation in the natural occurring contexts of IADL in the home or community² and the formation of a strong, positive disability identity (Case Study 16-1).⁴⁸

Theoretical Models and Intervention Approaches

Occupational therapy practitioners use a number of overarching *philosophical tenets* in intervention for individuals, groups, and populations. Overarching tenets pertinent to IADL and community participation include client- and family-centered practice, engagement in occupation to promote health and identity formation, and occupation as means and ends. In different contexts and according to the client pattern of strengths and limitations, *intervention approaches* such as remediation, skill acquisition, adaptation/compensation, environmental modification, education, and/or prevention approaches are

applied.³⁶ In addition, occupational therapists use *Models of Practice* and *Frames of Reference* to guide their clinical reasoning or decision making when planning and implementing intervention.¹⁴ For more information on practice models in occupational therapy with children, see Chapter 2.

Family- and Client-Centered Models of Practice

Family- and client-centered involvement and decision making are an essential part of intervention planning and implementation in IADL and community participation as adolescent and young adult clients move forward in their occupational development. Client-centered practice implies a strong collaborative approach with the client/family, mutual respect and open communication, and facilitation of family/client choice in intervention planning.³⁶ Examples of client-centered interventions include helping families connect to support groups, offering choices and opportunities to participate, and involving clients in goal writing and documentation of progress. This empowerment is essential in building IADL and community participation occupational performance skills.

Self-Determination and Advocacy

Occupational therapy practitioners and the interdisciplinary team often use a client-centered model or approach to enhance the child's or youth's sense of control and his or her independence. Empowering an adolescent toward self-determination can facilitate independence.^{33,84,92,96} One way the occupational therapy practitioner promotes self-determination is by including the child/youth in intervention planning, making choices, and problem solving. Collaborative decision making with the youth and family can foster an intentional relationship that leads to increased occupational performance.⁸⁷ This strategy can be replicated in any area of the child or adolescent's program. Health care and education professionals provide supported opportunities to prepare youth for taking care of their daily needs (e.g., taking medications), making appointments, and assessing accessibility in the community.⁸⁶ Decision making and increasing independence are crucial to the adolescent feeling competent and in control. These feelings can create "strands of coherence" (p. 236)⁷³ as the adolescent becomes an adult.

Self-determination can be facilitated through interventions that emphasize self-advocacy, goal setting and attainment, self-awareness, and problem solving.⁷³ For example, the occupational therapy practitioner can facilitate positive changes to the client's physical appearance, IADL skills, and self-empowerment by encouraging or adapting use of make-up, jewelry, or fashionable clothing. Encouraging involvement in school-based, recreational, and/or Special Olympics sports or athletics can improve performance and social participation.⁵⁸ When using group sessions, the occupational therapist can enhance and facilitate positive peer relationships and social roles. Davidson and Fitzgerald advocate for a client-centered approach that includes exploring realistic potential careers and facilitating all areas of adult independence.²⁰

Discounting and empowering are complementary strategies that help to empower adolescents and young adults with disabilities. Discounting, or reframing, is a technique that redefines a disability in terms of what a person can do versus what

CASE STUDY 16-1 Kayla

Kayla is a 12-year-old girl who is spirited and full of life. She is a child with athetoid cerebral palsy that affects her movement in all areas of motor performance, yet her process skills are intact. She is small and thin for her age and has some significant postural control difficulties and fine motor challenges. Occupational therapy services primarily used an ecological model and sensorimotor interventions during her primary school years. The occupational therapist made modifications for her to participate in a therapy swim group and used modifications and adapted strategies for eating and feeding, clothing management, writing, physical education, music, and art-based activities. She was fully included in school classes with modifications and the assistance of an intervention aide.

As Kayla entered middle school, she was less tolerant of occupational therapy in the inclusive setting. She no longer wanted to use her adaptations for eating and feeding in the cafeteria and often did not wear her ankle foot orthotics. Once happy and fun-loving, she became sullen, was rude to her intervention aide, was abrupt with other children, and would often sit and cry. The occupational therapist implemented an intervention plan based on a client-centered model with emphasis on self-determination in a revised intervention plan.

Self-Perception and Increasing Disability Awareness

Kayla was discouraged after being the only child with significant physical disabilities in her school for 6 years. She felt different from others. She was frustrated and angry about not being able to perform activities independently. She was self-conscious about her physical differences and did not want to stand out in any way.

Kayla had developed habits of being somewhat dependent on others. As she entered adolescence, she developmentally wanted to be more independent and break away, but physically could not. Having an aide kept her feeling dependent and not in control of her life and social activities. She also began having more difficulty keeping up with her peers academically.

Kayla was beginning to understand the “lived body” experience and to develop a “disability identity,”³⁵ but she had no one to talk to about this emerging identity. She understood the need for adaptations but did not want them to stand out. She was torn between wanting to perform well at school and not wanting to have things done “differently.”

In the assessment interview, the occupational therapist helped Kayla vent her frustrations and talk about her current and future roles. It became apparent that she was concerned about her future and doubted her own capacities. In an educational team meeting, more comprehensive occupational therapy services were put in place to improve Kayla’s independence, IADL skills, and psychosocial functioning. Goals were written to improve life skills and community participation.

1. Given support group, psychosocial facilitation, and increased responsibility in the home and school, Kayla will

improve self-perception, disability awareness, and self-advocacy as measured by self-report.

2. Given graded increased expectations for home chores, clothing management, small meal preparation, pet care, money management, cell phone use, and shopping, Kayla will gain independence in IADL skills as measured by a checklist.
3. Given alternative mobility options including a power scooter, Kayla will successfully access three community events as measured by self and family report.
4. To transition to adult roles, Kayla will develop a realistic plan for future continuing education, interdependent living, and employment.
5. Using adaptations in the school environment, Kayla will effectively identify, manage, and advocate for her own needs/modifications in a polite and responsible manner as reported by aide and occupational therapist observation.

Intervention Strategies

Support Group and Responsibility

Kayla was asked if she would like to train her new teacher and aide about her use of equipment and her writing, dressing, eating, and reading adaptations. She practiced with her occupational therapist during a summer session, and then she presented her needs to her new teachers the day before school began. This increased her sense of control and improved her compliance with her adaptations. In addition, her family was committed to improving her independence and began involving Kayla in family chores. Chores selected by Kayla and her family included setting the table, dusting, vacuuming, and pet care. Kayla also worked with the occupational therapist to gain the skills to make her own lunch and to use the stove, oven, and dishwasher. This improved meaning and responsibility in her family role identity. In addition, the occupational therapist consulted with the family in assisting Kayla with the fine motor use of her cell phone. These skills increased to the point that Kayla began using her cell phone for programming numbers and emergency contacts. She also learned how to monitor her minutes and keep the phone costs within the billing plan. The use of the cell phone created new access to socialization outside of school and she became more involved in after-school events.

Discounting and Empowering

One issue that had emerged was that Kayla did not want to wear her ankle-foot orthotics (AFOs) and would come to school in mid-high-heeled shoes. This caused her to lose her balance and slip, to the point of its being dangerous. Through community events, the occupational therapist helped Kayla realize it was much safer to be comfortable and stable. The occupational therapist persuaded Kayla to try some sports activities for people with disabilities. Kayla tried Special Olympics, and she excelled in horseback riding and swimming. School sports were discounted, and adapted sports were highlighted. This improved her community participation as well as her ADL and IADL skills as she traveled. The outcome was positive and reinforcing once she started winning medals. The

CASE STUDY 16-1 Kayla—cont'd

school supported her by congratulating her over the intercom and displaying her ribbons and medals in a school trophy case.

Developing a Disability Identity⁴⁸

Kayla's occupational therapist was able to arrange for her to visit Jim, an occupational therapist colleague who had cerebral palsy. Kayla, her mother, and the occupational therapist visited Jim at his outpatient clinic. Kayla watched him work doing hand therapy and conversed easily with him and his client. Jim talked about his wife and two children and how he really learned about independence by going to an Easter Seals camp when he was about her age. He talked about choosing hand therapy because he felt that he could not perform mobility-based occupational therapy. He talked about being a better therapist because clients respected his own disability experience. Kayla and Jim continued to e-mail each other after that visit. Kayla confided to the occupational therapist that she asked him about things she would not discuss with others.

Sexuality and Body Image

Kayla's physical development during adolescence provided opportunities for the occupational therapist and Kayla to problem solve the logistical problems and wonderful opportunities of becoming a woman. Her mother helped her find fashionable clothing that was functional for her to put on independently. She decided to cut her hair stylishly short, because it was difficult to take care of her long hair. The occupational therapist consulted with Kayla's mother about discussing sexuality with Kayla. These natural, dynamic, and developmental techniques supported her IADL skills of self-care and independent living.

Exclusive and Inclusive Programming

As mentioned, Kayla attended the Special Olympics two to three times a year and went to Easter Seals Camp in the summer for 2 weeks. Attending camp away from her family was an important step in the development of independence and disability identity. The occupational therapist also encouraged her to participate in school-based activities such as the school play. Academic support was added that included more small-group learning. In the small groups, Kayla was granted the time with assignments to effectively use her adapted computer and keep work output at a reasonable pace. With more support and a more reasonable pace, Kayla's frustration decreased and her school success increased. She improved in her written communication and numerical abilities when engaged in community activities where these skills were necessary.

Developing a Future Vision

The local college added a group home-based dormitory that helped college students with disabilities. Kayla, her occupational therapist, and her family discussed an article about the dorm, and Kayla was very interested; in fact, her aunt was attending that college. Kayla understood that she might always need assistance but could live an interdependent life. She became more tolerant of her intervention aide's assistance and they developed good communication about how and when to assist. She began to take more initiative in her ADL and IADL in the home environment. In collaboration with the occupational therapist, she organized her bedroom and clothing, began a filing system that was large and open to accommodate her fine motor needs, and began online banking with her adapted computer.

Community Mobility

Occupational therapy practitioners arranged for Kayla, her family, and team members to attend a wheelchair clinic, and she obtained a scooter for community mobility. She also had a technology consultation to ensure that her academic technology support was optimal for future education needs. Kayla used her power scooter in the community for longer travel such as field trips, shopping, and sporting events. These were important steps in establishing her capacity to participate in the community. Kayla again began to thrive.

Outcomes

Individual education program goal areas of community participation, improved independence, and disability identity increased 100% as measured by the educational team. After occupational therapy consultation, the aide in the classroom, although still needed for adaptive assignments and programming, took a less central role and covered the needs of children other than Kayla. Through interviewing and self-assessment, Kayla listed the most significant strategies to her success as her time at summer camp, Special Olympics, and establishment of the mentorship with the occupational therapist with cerebral palsy. She indicated that she felt more in control of her life and more positive about the future. Kayla's family also reported positive outcomes from the comprehensive intervention plan to increase IADL and community participation, noting that their perception of Kayla's future had shifted toward more independence. Kayla's IADL skills in home management, telephone/cell phone use, money management, food preparation, shopping, social interaction, and community mobility had improved along with her confidence, self-determination, self-advocacy, and positive disability identity.

he or she cannot do.^{35,50,62} For example, Evans, McDougall, and Baldwin found that participation of youth with disabilities in many community-based activities at their level of ability, fostered development of relationships and social behaviors.²⁶ The fact that the young people with disabilities are not doing the same work as typical peers is "discounted" and "reframed" as productive work. The researchers found that involvement of

youth with disabilities in community participation correlated with increased employment and self-determination in young adulthood. Reframing can be applied to other areas that may be difficult for a child or adolescent to succeed in (e.g., sports and other physical activities). Placing less importance on one skill may close the gap between values and perceived competence, a strategic element to self-esteem and self-identity.⁴⁶

The research literature supports the importance of self-determination to youth's development of self-image, independent living skills, problem solving, and active involvement.⁸⁷ Inclusive services that are strength based and widely accessible give adolescents opportunities to succeed in social relations and life tasks. Examples of this type of programming are the Community Capacity-Building project, which provided a forum that brought together youth, families, and community stakeholders to increase a youth's communication and opportunities.⁹⁶ A second example is an occupational therapy program that created a "Life Skills Institute" as a comprehensive framework to support youth with disabilities and their families in the transition to adult services.³³

Incorporation of Sexuality and Body Image

Adolescents are developing physically and psychologically, and occupational therapists support these positive moves toward adulthood. Noticing and appreciating the growth, changes, new interests, moves toward independence, and physical attractiveness can help build self-esteem in children and adolescents. Comments about growth and positive changes can be incorporated into personal care, because both male and female clients may have new personal hygiene needs as well as evolving desires to dress and groom themselves differently. It is important to understand that adolescents with disabilities experience the same hormonal changes as in typical adolescents and perhaps have more questions about what these changes may bring. Families often struggle as their child with a disability becomes a sexual being. The occupational therapist has a key role in supporting this area of occupational performance and adolescent development.⁷⁶ One strategy to accomplish this is to establish clear boundaries in youths' relationships and personal space with caregiving adults versus strangers or acquaintances. This is an essential safety strategy for young people with disabilities, who are recognized to be vulnerable to sexual abuse as they move toward further levels of independent living.⁷⁶

The Circles Program facilitates the establishment of physical boundaries for adolescents with developmental disabilities.⁸⁶ (See Chapter 12 for further information on social participation.) By teaching safe relationships, appropriate personal space, and sexuality to adolescents with developmental challenges, the practitioner can demonstrate to clients with intellectual disability how close to let people into their personal space. The concepts of personal space are taught with actual circles around the client: The closest circle indicates the space of closeness with family, the middle circle at forearm length indicates friends, and a wider circle of a full arm's length is taught for keeping personal space between the youth and acquaintances and strangers.⁸⁶

Occupation as Identity

Many youth with disabilities do not know what their future might hold. Occupational therapy practitioners work with clients and their families to recommend possible avenues for prevocational and vocational programming, as well as independent living. Through this process, adolescents may see a hopeful and positive future leading to behaviors that support transitions.⁶³ Although inclusive programs have expanded the opportunities for children and youth with disabilities, inclusion also separates youth from role models with similar disabling conditions. To develop a disability awareness of their own, youth

with disabilities need exposure to role models of adults with disability working and thriving in the community. Visiting work sites and group homes can help youth with disabilities and their families form a positive future vision.^{33,96}

The use of mentors or positive role models for IADL and community participation skill development is an intervention strategy that can be effectively used to help the youth with disability gain perspective and increase positive self-regard.⁵ The adolescent client may also serve as a mentor for others by assisting in a younger classroom, tutoring students in simple reading or math subjects, or bringing cookies to elders in the community. An adolescent can be encouraged to mentor a younger child with a similar disability. A mentoring program that pairs a successful adult from the community with an adolescent with a similar disability can also help to increase the adolescent's confidence.^{5,63} Peer and cross-age tutoring in reading or other academic tasks can assist with positive role identity and improve behavior in youth with disabilities.^{5,81}

Emphasizing adolescents' assets and abilities is essential. Changing the context from one in which the adolescent client struggles to one in which he or she can succeed is essential to this strategy.⁴² For instance, cooking may be an area in which clients with cerebral palsy or other physical impairment have difficulty. Beginning an IADL session with a safe and physically simple task such as wiping the kitchen surfaces may lead to greater success. The adolescent can be encouraged to compare him- or herself with other adolescents with similar disabilities, instead of with typically developing peers. Special Olympics camps for children with special needs or support groups are places in which adolescents can experience more success and less competition. Inclusion within the community is positive, but it is also important to establish esteem and disability identity with like peers.⁴⁸ Individualized and person-centered programming such as Special Olympics, specialized summer camp experiences, handicapped ski programs, adaptive sports, support groups, and other avenues should be explored to help the adolescent client develop a disability identity.^{48,86} Bedell and colleagues emphasize the importance of creating opportunities for learning daily tasks and social skills for school-aged children with brain injuries.¹¹ These authors advocate for involving parents in creating opportunities in the community to teach youth cognitive functions and behavioral regulation within the context of daily life occupations.¹¹

Support Groups

A number of studies showed positive outcomes from a family/client-centered, peer-run support group for parents of children transitioning to adulthood.^{53,77} A peer support group may help parents gain new knowledge and become future oriented in preparing for their child's transition into adulthood. Loukas and co-workers (in process) found that use of a parent support group as part of transition planning programs enhanced IADL participation in the home and led to greater involvement in the community for young adults with high functioning autism.

Creating community connections for support is an important transition component to adulthood for youth with disabilities.⁹⁶ Creation of networks that include parents, teachers, occupational therapists, and community agencies can facilitate and support the process of transition to adulthood and entry to the workforce for clients with disabilities.^{54,96} When communities have support networks, virtual support groups and

websites can be helpful, although an adult should monitor the adolescent's online activity. In addition a growing number of technological tools are available to enhance independence and function, including software apps. (See Chapter 19 for more information on assistive technology.)

Ecological Models

Ecological models that emphasize adaptation/compensation and environmental modifications are frequently used to facilitate participation of individuals with disabilities in IADL and community life. In ecological models, the child's physical and social environments are adapted to improve occupational performance. See Table 16-2 for specific ideas for adaptive success for common physical, cognitive, and psychosocial challenges.

Our introductory client, Peter, is a 14-year-old youth with autism. Occupational therapy services in the middle school used an ecological model to promote Peter's acquisition of skills that are needed in the adult roles of employment and independent living.¹⁵ The practitioner established a lunch group and obtained the adaptive equipment and assistive technology that Peter needed to make lunch with his peers. Environmental adaptations included use of ear protectors in the noisy kitchen, picture symbols in his schedule, and a scripting mechanism for communication. Peter worked with money, interacted with customers, and used adaptive strategies for a new skill in sandwich making. These skills can directly transfer to future employment in a lunch preparation cottage industry.

In addition, Peter became more involved in adapted leisure activities. He competed in Special Olympics in skiing,

TABLE 16-2 Adapted Instrumental Activities of Daily Living

Common Client-Based Challenges	Adaptive Strategies	Application Physical Challenges
Physical Challenges		
Decreased range of motion	Position for limited motion Change the task Provide assistance or interdependence	Write a check Provide stable seating and position hand on inclined tabletop Use online banking Have joint checking account
Decreased strength, endurance, and/or functional mobility	Use work simplification/energy conservation techniques Consider time management to work in small chunks of time Use modern energy-saving devices Plan out tasks to maximize energy	Shop Use a scooter or cart Determine best time of day and shop in small increments of time Use a reacher or other device Pay using debit card Plan with list and determine most efficient route in store
Decreased hand function	Build up utensils or use adapted equipment Use universal cuff or other grip substitute Buy precut or prepared items or energy-saving devices	Prepare a meal Use proper equipment Slide items if necessary Use scissors or devices for opening prepared foods Buy items that are pre-prepared
Cognitive Challenges		
Safety awareness	Develop strict rules and reinforce them Use of equipment such as wire gloves when cutting in the kitchen Use of a "buddy system" Have a safety plan	Use the bus system Follow directions Travel with a friend Learn bus etiquette, including making sure the bus is stopped before entering Alert the driver to safety needs Have an emergency phone
Difficulty with judgment and decision making	Provide an outline or structure to planning Role play outcomes of decisions Decrease impulsivity through use of strategies such as counting before acting Budget money	Go on an outing Plan the outing Budget money needs Role play possible social scenarios, including a sexual advance from a stranger (use the Circles Program, described in text discussion of sexuality and body image) Identify possible scenarios for decision making
Decreased overall cognitive ability	Simplify tasks Simplify instructions or use pictures Repeat needed information Present information in small steps and have the client practice	Cook Choose prepared foods Simplify directions by using pictures Keep kitchen organized with pictures on cabinets Work in small groups with small steps to the task Reinforce needed concepts

Continued

TABLE 16-2 Adapted Instrumental Activities of Daily Living—cont'd

Common Client-Based Challenges	Adaptive Strategies	Application Physical Challenges
Psychosocial Challenges		
Difficulty engaging in social communication	Use scripted-language role play	Go to a movie Script and practice asking for a ticket and stating the name of the show Practice asking for popcorn and managing the conversation and money Practice money management Review finances at a prescribed weekly time Set up a reinforcement system to review finances without outburst Use breathing techniques for relaxation Personal grooming Shave (face, legs), put on deodorant/make-up Set up a routine Provide tactile brushing before shaving Use guided imagery during grooming Go to a dance Review Circles Program Plan clothing Social stories to reinforce safe and appropriate behavior Sexual education at client's level
Behavioral outbursts	Structured routine Positive behavioral supports Reinforcement system for positive behavior Relaxation techniques	
Anxiety	Preparation ahead of time Role play Relaxation techniques Sensory diet (if applicable)	
Overly friendly or flirtatious behavior	Use Circles Program to learn proper boundaries Reinforcement for positive behavior Role play appropriate behavior Monitor clothing	

Adapted from Kieckhefer, G. M. (2002). Foundations for successful transition: Shared management as one critical component. Keynote presentation at the Hospital for Sick Children, Toronto, Canada.

swimming, and track and field. These outings required community participation to practice in various venues. The traveling with families to compete also afforded Peter and his family new modeling and opportunities to use IADL and community participation skills in natural environments. Using a contextual approach, occupational therapists see the “development of everyday activities as embedded in and inseparable from societal effort to offer occupational opportunities and social processes that are part of participation in everyday activities” (p. 261).⁴² Therefore occupational therapy practitioners facilitate IADL and community participation by creating accessible contexts for performance. Humphry and Wakeford advocate for the creation of niches or small communities that foster development of roles, patterns, and skills.⁴² The use of therapy techniques in the context of real experiences and natural environments enables the generalization and transfer of these skills. By adapting and modifying natural physical and social contexts to enhance children’s development, occupational therapy practitioners give children natural opportunities to observe, imitate, and practice new skills ([Case Study 16-2](#); [Research Note 16-1](#)).

Reverse Inclusion

Although inclusion is an important aspect to school-based practice, sometimes the special needs and accomplishments of young people with disabilities are best met in an alternative context. Reverse inclusion involves bringing typical children into a program designed for children with special needs, instead of including one child with a disability into a program designed for the skill level of typical children. This opportunity for peer modeling can improve age-appropriate behaviors and social skills targeted in the goals and objectives for the children with

RESEARCH NOTE 16-1

Dunn, W., Cox, J., Foster, L., Mische-Lawson, L., & Tanquary, J. (2012). *Impact of a contextual intervention on child participation and parent competence among children with autism spectrum disorders: A pretest-posttest repeated-measures design*. *American Journal of Occupational Therapy*, 66(5), 520–528.

Dunn et al. (2012) examined the feasibility of a contextual intervention to increase participation of children with ASD in everyday life situations and to increase parental competence. The researchers collaborated with caregivers on identifying goals and on exploring strategies to address each caregiver’s selected goals for his or her children (aged 3 through 10) with ASD. Results from this 10-session intervention yielded significant clinical gains in the children’s participation in home and community activities and a significant increase in caregiver’s parenting competence.

- Although children with ASD received services through school, caregivers reported a significant need for support for their children in home and community settings. Often these services were not provided through school programs.
- Findings support use of coaching to build on caregivers’ strengths and problem-solving abilities to increase participation of their children in everyday activities at home
- Findings support use of interventions within natural contexts
- Promoting problem solving and planning around intervention strategies with caregivers by practitioners trained in coaching methods offers promise for occupational therapy interventions.

CASE STUDY 16-2 Brenda

Brenda is an experienced school-based occupational therapist. Her practice has evolved to include a group of children with disabilities in the middle and high schools. Brenda has a large caseload and has provided services to these middle school students for many years. She knows the children very well and has a positive relationship with the families. After many transition plans for her middle school students, Brenda decided to increase her use of ecologic approaches and to work more actively with families and clients to write goals that target their future aspirations, including IADL skills, independent or interdependent living, and community participation, including prevocational skills.

In collaboration with the speech therapist, Brenda designed a program for a life skills group. This group began with kitchen tasks, in which students planned, implemented, and worked together. She implemented safety rules and supervision and targeted the unique needs of each of the four students involved. Brenda designed the kitchen program to meet each student's client factor needs. Randy, a boy with muscular dystrophy, needed adaptations for his physical disabilities; Amanda, a girl with autism, required scripting to communicate with others; Troy, a youth with intellectual disability and associated behavioral problems, was assisted by use of a behavioral report card; and Susan, a girl with intellectual disability, followed recipes through a picture-based cookbook. The cooking group required planning and supervision to meet the individual needs of each student as the various IADL skills (e.g., planning a meal; shopping; safe use of cutting utensils; following a recipe; use of the stove, oven, and dishwasher; and safe handling and storage of food) were developed by each youth. In addition, working as a team, communication, social skills, hygiene, table manners,

and polite eating were enhanced in the kitchen group participants.

The kitchen group that planned, shopped, prepared, and sold lunches to the school community worked so well that Brenda and the team of students decided to expand the group's activities to working and caring for plants. She convinced the school administration to add a greenhouse to the middle school. The students and Brenda traveled to a greenhouse and performed prevocational activities with a local farmer. They chose the plant varieties and followed directions to help the plants grow in their own greenhouse. This evolved into a school and community sale in which the students gained the IADL skills of pricing items, budgeting, and managing money. The greenhouse program also assisted with communication skills. The students took great pride in their accomplishments. With input from the students, school team, and parent volunteers, Brenda now plans to add a cottage industry of making greeting cards with photographs and stamping. The students find great meaning in these activities, and their IADL skills have improved significantly. In addition, the school community has embraced these endeavors, and the students have improved their self-esteem and future visions of success.

Occupational therapy becomes identity building when therapists provide environments that help persons explore possible selves and achieve success in tasks that are instrumental to identities they strive to achieve, and when it enables them to validate the identities that they have worked hard to achieve in the past (p. 55).¹⁷ This case example was used to demonstrate how occupation as means and ends can meet individual needs in an occupation-based group context.

disabilities.⁸² In reverse inclusion, typical peers become participants in occupational therapy groups, special recreation, adapted physical education, or other groups. Benefits have been documented both for typical peers serving as role models and for youth with disabilities.⁸²

Supported Inclusion

Young people with disabilities can be supported in natural environments through the use of assistants, peer partners, and educated classmates. To promote participation, supported inclusion usually requires adapted coursework and activities that are consistent with the physical and cognitive abilities of the client.⁴⁶ An example of supported inclusion in IADL is partnering a youth with intellectual disability with a peer partner for a community outing. The occupational therapist facilitates the partners to support the student with a disability to make his or her own decisions while role modeling appropriate decisions and behavior in the community.

Chores and Household Tasks

Occupational therapy practitioners can consult with families regarding ways to include young people with disabilities in household activities. Participation in household activities, including chores, facilitates skills and helps the youth to develop

a family role through productive participation in home management and caring for others.²¹ Parents and caregivers teach children to use the telephone and cell phone, manage their health, and handle and manage money. They also teach children safe interaction with strangers and use of public transportation systems. Parents may need information and assistance from occupational therapists on how to adapt these skills or modify the environment so that their children can gain competence and confidence in IADL. Occupational therapists can also help families understand the link between the child's independence in IADL and eventual employment.⁷⁷

Community Participation

Occupational therapy practitioners advocate for increased community participation for children and youth through shopping, attending school or community events, recreational activities, and/or other avenues of involvement. Practitioners can consult with the family and teachers on strategies to facilitate the child's telephone use, money management, and public transportation access. The practitioner can challenge the youth's physical, cognitive, and social skills through incremental, planned activities in the school and community.

Many IADL and community participation skills are dynamic, complex, and multistep activities, such as cooking, doing

laundry, shopping, childcare, driving, and accessing transportation. These tasks are further developed when they are applied in a context that holds meaning for the client. Therefore finding a task that is meaningful and social and serves a purpose of importance to society will enhance performance. The occupational therapy practitioner can create occupational opportunities as part of educational curriculum or programs through establishing cottage industries whereby the adolescents create and sell merchandise, establish a work-based role, or plan and implement an outing, party, or celebration.

Driving and Community Mobility

Occupational engagement and participation in everyday occupations require young people to safely and effectively access the community. Social participation is greatly enhanced when young people can access communities and social gathering places (Figure 16-6). Safe and effective participation in occupational performance is the goal of such intervention. Driving

FIGURE 16-6 Adolescents enjoy occupations outdoors as part of community mobility and participation.

evaluation and intervention for teens is an emerging niche for occupational therapy practice.⁴ Occupational therapists evaluate the client to facilitate decisions about driving potential and to develop an intervention plan, which can include assessment of complex vision, visual perception, cognition, motor, and emotional skills.

Other aspects of community mobility to consider during the teen years are use of power mobility to access the community for longer distances and amounts of time. Often young people with mobility impairments should consider a scooter or other power means of mobility in order to access sporting events, shopping malls, field trips, college campuses, and travel destinations. This adaptive approach should be complemented by continued ambulation for those clients who are capable, to assure that the power mobility device does not inhibit ambulatory status, but rather facilitates access to the community.

Summary

Occupational therapists provide services to enhance the complex processes of IADL and community participation in the lives of children, youth, and their family/support systems. Through the occupational therapy process of evaluation, intervention, and outcomes analysis, the occupational therapy practitioner uses critical thinking to facilitate IADL skills and community participation into practice. Occupational development is unique to each individual and leads to the acquisition of roles, interests, independence/interdependence in community living, and meaningful and productive vocation. As children and youth develop maturity and skills, the roles of parents, professionals, and the youth themselves also evolve. See Table 16-3 for the developmental role continuum.

Professional reasoning that includes the philosophical tenets, broad theoretical models, and intervention approaches guide the practitioner to facilitate occupational performance in IADL and community participation for youth with disabilities. Family and client-centered models provide a collaborative springboard and facilitate adult roles. Ecological models help the practitioner focus on creating contexts to support

TABLE 16-3 The Developmental Role Continuum

Stages	Occupational Therapy Practitioner or Other Professional	Parent/Family	Young Person
Late adolescence	Resource for future planning and implementation of adult roles, routines, and community participation	Consultant to youth; supports and guides decisions. Ensures a safety net.	The youth leads and supervises the program through self-determination.
Early adolescence	Consultant for school success, community participation, vocational programming, empowering client, advocacy, transition, and family planning	Supervises and monitors program, advocates for the child/youth. Implements IADL and community programming.	Active involvement in direction, plan, and method of programming. Input is given and received. Independence and advocacy are facilitated.
Middle childhood	School- or community-based intervention for education and life skills	Manages and monitors education program. Begins chores and roles in the home.	Participates in program and intervention planning.
Early childhood	Direct intervention and support to child and family	Provides care and makes decisions.	Receives care and follows directions.

occupational performance through establish/restore, adapt/modify, alter, prevent, and create techniques.¹⁵ Finally it is the core tenet of engagement in meaningful and age-appropriate occupations as an agent of change that drives occupational therapy practice.³⁶ Use of active engagement of the client in occupation as means and ends in the IADL and community participation across life contexts is best practice.

Summary Points

- Instrumental activities of daily living that develop during childhood include meal preparation, community mobility, health management and maintenance, household maintenance, clothing management, use of communication devices, shopping, money management, safety and emergency response, driving and community mobility, and community participation.
- Participation in instrumental activities of daily living (IADL) and community activities prepares children and youth for work, vocational roles, and independent and interdependent community living.
- Occupational profile, self/caregiver report, and observational assessments specifically evaluate IADL and community participation.
- Theoretical models that include family/client-centered, ecological, and occupation-based models are used in the professional reasoning of occupational therapy practitioners to improve participation and performance of IADL and community activities for children and youth with special needs.
- Specific, evidence-based, intervention approaches/strategies have emerged from the theoretical foundations for improving participation and performance of IADL and community activities for children and youth.
- Use of strength-based approaches, self-determination, self-advocacy, social participation skills, and social relationships supports youth's independent or interdependent IADL performance and community participation.

Play

Kari J. Tanta • Susan H. Knox

KEY TERMS

Form	Play as an intervention modality
Function	
Meanings	Play as an intervention goal
Playfulness	
Play assessments	

GUIDING QUESTIONS

1. What is the relationship of play to occupational therapy?
2. Which play theories have shaped occupational therapy's lens on play?
3. Which assessment tools do occupational therapists use for evaluation and intervention planning purposes?
4. What are hallmarks of play at different ages?
5. How do individual and environmental factors facilitate and/or inhibit play?
6. How is play used in occupational therapy intervention?
7. How do occupational therapists advocate for play in today's society?

That's the real trouble with the world, too many people grow up. They forget. They don't remember what it's like to be twelve years old.

—Walt Disney

In today's fast-paced world, the ponderings of Walt Disney become all the more relevant for adults and children. In some ways it seems that society is losing sight of the importance of play, for it is through play that we keep mind and body healthy, cultivate social relationships, and learn about ourselves and the world around us. Occupational therapists have a critical role in helping children and families embrace the value of play throughout their lives.

Play ... is the way the child learns what no one can teach him. It is the way he explores and orients himself to the actual world of space and time, of things, animals, structures, and people. Through play he learns to live in a symbolic world of meanings and values, of progressive striving for deferred goals, at the same time

exploring and experimenting and learning in his own individualized way. Through play the child practices and rehearses endlessly the complicated and subtle patterns of human living and communication, which he must master if he is to become a participating adult in our social life (pp. v-vi).³⁷

Watching children play is like looking through a window into their very being. Play has been identified as one of the primary occupations in which people engage.³ Parham and Fazio define play as “any spontaneous or organized activity that provides enjoyment, entertainment, amusement or diversion” (p. 448) and “an attitude or mode of experience that involves intrinsic motivation, emphasis on process rather than product and internal rather than external control; an ‘as-if’ or pretend element; takes place in a safe, unthreatening environment with social sanctions” (p. 448).⁷⁶

There are two sides of play: the science of play, in which play is a critical aspect of human development that deserves serious study, and the art of play, in which the therapist and the child are players, where there is joy, pleasure, and freedom. Occupational therapists need knowledge and skill in both aspects, and in order to facilitate playfulness in a child an occupational therapist must be playful him- or herself.⁶⁹ This chapter describes play as the child's occupation from a historical perspective, defines hallmarks of play at different ages, explains the use of play in occupational therapy assessment and intervention, and proposes that occupational therapy practitioners advocate for children's play opportunities in today's society.

Play Theories

As a field, the profession of occupational therapy has built on the work of other disciplines, such as psychology and anthropology, in a quest to address the occupational nature of play. As with other occupations, the occupation of play can be explained through the substrates of form, function, meaning, and context²⁵:

- As an activity having certain characteristics (i.e., its form, including motor skill requirements and products)
- As a developmental phenomenon contributing to a child's development and enculturation (i.e., its function, including purposes, processes, and experiences)
- As an experience or a state of mind (i.e., its meaning, including what motivates or satisfies the individual)

FIGURE 17-1 Infants and toddlers enjoy sensory play such as water play. Exploratory play allows them to learn about their environment.

Play, like any other activity, takes place within context, which denotes the individual's environments and the personal, physical, and social elements of each environment.

Form

Many play theorists describe play as categories of activities in which children engage.^{12,23,26,33} These may include such activities as games, building and construction, social play, pretend, sensorimotor play, symbolic or dramatic play, team sports, and digital play. Children's play activities change over time and reflect their development,^{12,73} as well as in response to changes in their own interests and abilities, and societal norms.

Sensorimotor and exploratory play predominate in infancy as infants develop mastery over their own bodies and learn the effect of their actions on objects and people in the environment.^{79,88} Sensorimotor play peaks in the second year of life and then declines. Children continue to use sensorimotor play when they learn new motor skills. Exploratory play begins in infancy, and by the end of the first year, infants actively explore their surroundings, demonstrate a beginning understanding of cause and effect, and are interested in how things work (Figure 17-1). In the second year, play centers on combining objects and learning their meaning. Children begin to classify objects and develop purpose in their actions. Exploratory play gradually declines through the preschool years, but it reappears when the child is learning new skills.¹²

Constructive play has identifiable outcomes and predominates during the preschool years, as seen in activities such as sandbox, puzzle, and block table play. Constructive play remains high during middle childhood and adolescence but becomes more abstract. It may develop into arts and crafts. Symbolic play and pretense develop at the end of the first year and through the second, peaking at around 5 years of age and evolving into dramatic and socio-dramatic play. These make-believe games form the foundation for self-regulation, civility, and empathy and enhance a child's capacity for creativity and cognitive flexibility.⁹¹ During middle childhood, symbolic play and fantasy play are seen in mental games, secret clubs, and

FIGURE 17-2 Social play begins in infancy with the infant looking at parent's face.

daydreaming, and in language play such as riddles or secret codes.¹² Television, computer and video games, and movies are also ways of engaging in fantasy play.

Social play begins very early with interaction between the infant and parent (Figure 17-2), and by age 3 children are able to engage in complex social games. Children use role play to learn about social systems and cultural norms. Garvey described four types of roles seen in group play:

1. Functional roles, such as pretending to be a doctor or barista
2. Relational roles, such as pretending to be mother and baby
3. Character roles, such as those from television, movies, and video games
4. Roles with no specific identity³⁸

Social play combined with motor play develops into rough-and-tumble play such as play-fighting, pillow fights, or wrestling.¹²

Games with rules teach children to take turns and to initiate, maintain, and end social interactions.⁴⁹ This type of play predominates during the school-age years.¹² Social play and games with rules are particularly influenced by the culture. The physical environments available for play, peer groups, and the types of play encouraged by parents have changed as our society has become more urbanized.⁷³ Currently, time, places, and types of play are more planned and structured, such as with organized sports and "play dates" (Figure 17-3).⁵⁶ Additionally, "screen time" as play time has also increased and has been identified as the primary free time activity.⁹² It is estimated that in North America, children over the age of 2 average 13 hours per week of video game play.⁴⁶

Adolescents are concerned with autonomy and being socialized into adult roles. (See Chapter 4 for more on adolescents.) This is a period of transition as obligations, time available for play, changes and refinements of interests, family, and peer pressures all affect teen activity.⁷³ In a study by Csikszentmihalyi and Larson, the most frequent single activity of adolescents was socializing.³⁰ Second was television and third was sports, games, hobbies, reading, and music. More recently, "screen time" (television, computers, smart phones, video games,

CASE STUDY 17-1 Play as a Modality: Trevor

Trevor is a 14-year-old boy who is an eighth grader at a suburban middle school. He is highly capable but displays difficulties with social interaction, inability to stay focused in the classroom, and a lack of consistently appropriate social skills. He goes about his days at school generally alone and does not participate in school or extracurricular sports or other activities. His parents both work outside the home and his older siblings are generally too busy with their own lives as high school students to engage in positive interaction with him on a regular basis. Trevor spends most of his

out-of-school free time engaged in virtual social interaction on X-Box Live with other teens. For hours each day he dons his headset to enthusiastically joke with other kids, talk about his day, and collaborate on gaming strategies with other teens. These conversations have evolved into friendships, regular online play dates, and insider jokes. They have helped Trevor develop important social competencies and self-esteem.

This case example illustrates the use of play through technology to improve social participation.

FIGURE 17-3 Play today is often highly structured; for example, young children participate in tee-ball.

tablets), has taken center stage for adolescent leisure time and social interaction as teens interact with each other virtually on their phones and through online gaming portals.

The prevalence of digital technology is altering the way children are learning and playing, blending physical, social, and digital play for children of all ages⁶² (Case Study 17-1). The Lego Learning Institute identified six areas of play that are distinctly different from past generations of children, including:

- *Sharism*: Children are more likely to engage in co-creation of ideas at a fast pace versus individual construction. Such play can be seen in video games such as Minecraft played on X-Box Live with friends.
- *Shifting identities*: Boundaries between “mine” and “yours” are blurring. Platforms for movie making and video editing are examples of boundary blurring in the digital realm.
- *Border crossing*: Children are moving between virtual and physical worlds constantly, resulting in a more global view of the world. Games such as Skylanders allow children to integrate online gaming with physical characters that they can connect to others anywhere in the world.
- *Literacies beyond print*: Children are engaging in more active reading and writing with processes such as “earmarking” and “tagging” and are using mix-and-match media rather

than creating. E-readers and a multitude of apps make it appealing for youth to read and create on digital devices they can take anywhere.

- *Gaming culture*: Children expect for their worlds to be forgiving and responsive, that they can always press an “undo” button. The child whose Lego Star Wars character has been blown apart can make the character come back to life.
- *Bricoleur culture*: Children are eager to hack and modify, program, and recycle. The explosion of robotics and programming opportunities for children allows them to become engineers.⁶²

As society continues to embrace digital technology, occupational therapists can embed meaningful play using digital media, tablet and computer games, and virtual social networks into intervention sessions.

It may be said that play is easy to see, but hard to define, and scholars have found this to be true through the years as many have attempted to categorize play by lists of attributes and by specific types of play. To date, scholars of play have not identified a single characteristic common to all kinds of play but have suggested many qualities or characteristics that differentiate play from non-play. These characteristics include intrinsic motivation (the child engages in play by her own desire), suspension of reality (the child escapes into her imagination fully—she really IS a princess!), internal locus of control (play is child-directed), and being spontaneous, fun, flexible, totally absorbing, an end in and of itself, nonliteral, and challenging.^{26,33,45,63,74,85}

Most recently, Burghardt (2011)²⁶ proposed a set of five essential criteria that behavior must meet in order to be confidently identified as play within any species or culture, that embrace the qualities and characteristics identified by earlier scholars but that can provide a more succinct method of identifying play within occupational therapy. These include:

- Behavior is incompletely functional within the context it is performed (play is an end in and of itself)
- Behavior is spontaneous, voluntary, rewarding, or pleasurable (fun and intrinsically motivated)
- Behavior differs from other behaviors in form or timing (e.g., the behavior may only occur in infancy or may be extremely exaggerated)
- Behavior is repeated, though not rigidly (flexible)
- Behavior is initiated when one is relaxed and in the absence of stress (totally absorbing)

Function

Another way of looking at play is in relation to function, or how play influences adaptation. Play functions include processes, experiences, and purposes. Historically, play has been described as the way a child develops the skills necessary for life,⁸⁸ as a way of expending surplus energy,⁸⁹ or for recreation and relaxation.⁸⁸ Modern or contemporary theories emphasize the value of play in contributing to the child's development or to acculturation. They include using play to achieve optimal arousal^{13,33} and develop ego function³⁴ and cognitive skills.^{18,79,100} Sociocultural explanations include the development of social abilities,^{77,94} role development,⁸⁵ and play's contribution to culture.^{45,90} As presented in the prior section of this chapter, Burghardt (2011)²⁶ challenges us to look at play in a broader context using criteria that transcend a more limited view of play behavior. By using criteria to identify play as a whole construct, rather than an isolated behavior, such as play with a toy or engagement in a single leisure pursuit, occupational therapists using such criteria can better address the occupation of play within context.

Occupational therapists are interested in the first-hand experiences of players as a means of identifying what constitutes play through the eyes of the player. Miller and Kuhaneck conducted interviews on the perceptions of play experiences and play preferences in 10 children between the ages of 7 and 11.⁶⁹ The children described "fun" as the core category, with four categories of characteristics that explained their play choices: relational, activity, child, and contextual. The authors developed the Dynamic Model for Play Choice to describe four characteristics—child, activity, relational, and contextual—that affect the child's perception of fun and can be used to create play in occupational therapy intervention. Using dynamic systems theory, this model conceptualizes how choice, emotion, meaning, preference, mastery, challenge, and the characteristics of the child, environment, and activity are inter-related and influence child's perception of play. Miller and Kuhaneck further stressed the need for therapists to be playful, choose play as a meaningful goal, remember the importance of fun in therapy, and weave a child's preferences into the session.

Meaning

Play meaning refers to the quality of the experience, a person's state of mind, and the value that the play experience has for the individual. The attitude a person assumes during play is termed *playfulness* and is closely related to the development of cognitive abilities.⁷⁻¹⁰ Each person has an internal disposition to play and playfulness that could be described along five dimensions: physical spontaneity, cognitive spontaneity, social spontaneity, manifest joy, and sense of humor.⁶⁴ Children give and receive social cues to denote they are playing, lying along a continuum of three elements of playfulness: intrinsic motivation, internal control, and the ability to suspend reality.^{19,20} Bundy theorizes that "it is the sum contribution of these three elements that tips the balance toward play or nonplay, playfulness or nonplayfulness" (p. 219).^{19,20}

Knox, in a qualitative study of preschool children's play, identified actions and behaviors that characterized playful children.⁵⁴ The playful children showed flexibility and spontaneity in their play and in social interactions, curiosity, imagination,

creativity, joy, the ability to take charge of situations, the ability to build on and change the flow of play, and total absorption. Nonplayful children were less flexible and had difficulty with transitions or changes, expressed negative or immature affect or speech, often withdrew either physically or emotionally from play sequences, did not have control over situations, and tended to prefer adults or younger children for play.

Children have been found to readily identify environmental and motivational factors that add meaning to their play and facilitate engagement in play activity. Children in one study mentioned that active outdoor play was facilitated through use of a mobile phone to keep in touch with parents, and they were motivated to engage in active play to prevent boredom, be free from adult control and rules, "be themselves," and socialize with friends.¹⁷ For maximum effectiveness, occupational therapy practitioners must engage in active dialog with children and their parents to determine their meaning of play when designing intervention programs and play spaces.²²

Context

Play also obtains meaning through context. Children's activities can never be isolated from the environment within which they are playing nor from familial, social, and cultural influences.³ The presence or absence of other persons or animals, the physical setting, and the availability of toys and other objects with which to interact all have a profound effect on children's play (Figure 17-4). Play context includes cultural and societal expectations of play. The environment, quality of care, and types of interactions between caregivers and children can affect play behavior. For example, higher socioeconomic status links to greater levels of imaginary play; permissive home environments encourage creativity; and in childcare centers, high program quality improves children's social interaction and level of play.^{10,12,44,48} Access to a variety of materials and opportunities with which to explore and interact and children's ability to control their activities are associated with improved quality of play. In addition, caregivers and peers who are emotionally and verbally responsive help to improve the child's quality of play. Cultural and ecologic factors, such as child-rearing and parental

FIGURE 17-4 Playful environments with age-appropriate toys allow children to play.

FIGURE 17-5 Teens enjoy technology as a form of play.

influences, peer experiences, the physical environment, the schools, and the media (Figure 17-5),^{11,92} also influence the way children play.^{49,88}

Indoor play venues for children warrant special attention. In addition to children playing in their own homes and in the homes of their peers, businesses and nonprofit organizations have also identified this shift in play context and have responded. Franchise operations such as Little Gym, Gymboree Play and Music, Jump Planet, and a host of others offering everything from laser tag to indoor skydiving offer spaces for children of all ages to engage in play at a price. Children's museums across the United States have also been increasing in popularity, creating inspiring venues for imaginative play. Environments such as these can be especially beneficial for families seeking out safe and novel play contexts with enhanced opportunities for social interaction.⁴²

All environments offer affordances for and constraints to an individual's behavior. Factors that promote play include the availability of objects and persons, freedom from stress, provision of novelty, and opportunities to make choices.^{53,68} Factors that may inhibit play include external constraints, too much novelty or challenge, limited choices, and overcompetition. Contextual components that appear to promote play and playfulness include:

1. Familiar peers, toys, and other materials
2. Freedom of choice
3. Adults who are nonintrusive or directive
4. Safe and comfortable atmosphere
5. Scheduling that avoids times of fatigue, hunger, or stress^{88,92}

With recent technological advances in the “digital world,” it has been suggested that with the ready availability of electronic media and toys, such digital play is replacing the less structured outdoor play of the past and indoor spaces are becoming more prevalent as play venues.^{17,62} It is also important to note that the context of play in today's society is rapidly changing and it is no longer as simple as indoor or outdoor play. In the “digital realm,” the environment in which a child learns, plays, socializes, and creates is a hybrid of physical and virtual activity and an environment, it could be argued, that is fully immersive.^{46,62} Such immersion may be seen when children wear headphones to engage in online gaming.

Play in Occupational Therapy

Play has always been a part of the pediatric occupational therapist's repertoire, although its importance has altered over the years.⁹² It is important to know how the profession has evolved related to the occupation of play in order to successfully plan for the future. Adolph Meyer wrote of work, play, rest, and sleep as being the four rhythms that shape human organization.⁶⁷ In one of the earliest articles on play in the occupational therapy literature, Alessandrini referred to play as a “serious undertaking, not to be confused with diversion or idle use of time. Play is not folly. It is purposeful activity, the result of mental and emotional experiences” (p. 9).¹ Richmond spoke of play as the vehicle for communication and growth of the child.⁸⁶ Play in the early years of occupational therapy was used for a variety of purposes, such as diversion, development of skills, or remediation.

Mary Reilly was instrumental in bringing play into the forefront of occupational therapy in the late 1960s. She described play along a continuum that she called occupational behavior.⁸⁵ Through play, children learn skills and develop interests that later affect choices and success in work and leisure. Play is the arena for the development of sensory integration, physical abilities, cognitive and language skills, and interpersonal relationships. In their play, children practice adult and cultural roles and learn to become productive members of society.^{12,63,85} Reilly felt that play is a multidimensional system to adapt to the environment and that the exploratory drive of curiosity underlies play behavior. This drive has three hierarchic stages: exploration, competency, and achievement. Exploratory behavior is seen most in early childhood and is fueled by intrinsic motivation. Competency is fueled by *effectance motivation*, a term defined by White as an inborn urge toward competence.¹⁰¹ This stage is characterized by experimentation and practice to achieve mastery. Achievement is linked to goal expectancies and is fueled by a desire to achieve excellence. Using this frame of reference, other scholars studying under Reilly expanded the concepts of play. Florey offered a developmental framework of play and explored the concept of intrinsic motivation as being central to play.³⁶ Takata developed a taxonomy of play and described play epochs based on Piagetian stages,^{97,98} and Knox examined play in relation to development for the purposes of evaluation.⁵³ Robinson described how play is used for the child to learn rules and roles.⁸⁷

Occupational science developed in the late 1980s as an academic discipline to study the nature of occupation and how it influences health. Because play is the primary occupation of children, a number of researchers have studied various aspects of play. In studies of parent-child routines and how play is orchestrated into daily routines, Primeau proposed that parents use two types of play strategies: segregation and inclusion.⁸² In the segregated strategy, play times were separate from other daily routines, whereas in the inclusion strategy, play was incorporated into daily routines. Parents use play routines to support their children's learning. Pierce studied object play in infants.^{80,81} She described three types of object rules learned by children: (1) object property rules (the child's internal representation of the properties of objects), (2) object action rules (the repertoire of actions on the objects), and (3) object affect rules (those factors affecting object choice and keeping play enjoyable).

Play Assessment

Although play is considered the child's major occupation, and most occupational therapists would agree that it is important to the child, few therapists routinely evaluate it.^{27,29,60} In a 1998 study, Couch et al. found that 62% of pediatric occupational therapists who responded to her questionnaire stated that they evaluated play, but less than 20% used criterion-referenced play assessments.²⁸ Play was usually evaluated through clinical observations or as a part of developmental tests.²⁷ A decade later, Kuhaneck et al. replicated the survey, finding that 38% or 24% fewer of respondents assessed play. Furthermore, few occupational therapists used play assessment tools, with 4% using the Knox Preschool Play Scale and 3% using the Test of Playfulness⁵⁹ (Research Note 17-1).

RESEARCH NOTE 17-1

Kuhaneck, H., Tanta, K. C., Coombs, A., & Pannone, H. (2013). *A survey of pediatric occupational therapists' use of play*. *Journal of Occupational Therapy, Schools, and Early Intervention*, 6(3), 213–227.

Abstract

In a 1998 study, Couch, Dietz, and Kanny surveyed pediatric occupational therapists with regard to the use of play in their practice. Results indicated that play was primarily used as a modality to address skills in other developmental areas, not play itself. In the years following this study a significant body of literature promoting the use of play in occupational therapy was published. Kuhaneck et al. (2013) adapted the original Couch et al. mail survey to study whether or not practice patterns had changed. The researchers randomly surveyed 500 pediatric occupational therapists, who were AOTA members of the school system and sensory integration special interest sections, working with children age 3 to 7 years. Results of the survey, with a 40% response rate, yielded similar findings to the original survey by Couch et al. Few therapists focused on play as a therapeutic outcome or assessed play specifically, and most used play as a modality when working on other skill areas. The researchers concluded that minimal changes have occurred since the original Couch et al. study related to the role of play in pediatric occupational therapy, despite the promotion of play within the occupational therapy profession.

Application to Practice

- Occupational therapy practitioners need to advocate for the role of play in the lives of children.
- Play is a child's primary occupation and evidence supports the importance of play to child development.
- Occupational therapists need to seek out continuing education opportunities, including review of the research and literature, to expand their knowledge of play.
- Occupational therapists need to include play in their assessments and intervention plans to positively impact a child's overall development, health, and well-being.
- Along with using play and playfulness as a modality to reach intervention goals, practitioners should target play and playfulness as intervention goals.

Play assessments may be categorized into those that assess developmental competencies and those that assess the way a child plays, including playfulness and play style.

Developmental Competencies

Using a developmental frame of reference, the Revised Knox Preschool Play Scale is an observational assessment designed to describe play competency in children through 6 years of age.^{16,52,53,55,57} Revised recently by Knox,⁵² the scale describes play in terms of 6-month increments through age 3 and yearly increments through age 6. Four dimensions are examined: space management, material management, pretense/symbolic, and participation. Space management is the manner in which the child learns to manage his or her body and the space around it. Material management assesses how the child manages his or her material surroundings. The pretense/symbolic dimension rates how the child learns about the world through imitation and the development of the ability to understand and separate reality from make-believe. Participation is the amount and developmental level of social interaction. Children are observed indoors and outdoors and rated on all four dimensions.⁷⁶

Other assessments rate the developmental skills of the child through play, such as the Transdisciplinary Play-Based Assessment, which assesses the child in cognitive, social-emotional, language, physical, and motor development through naturalistic play.⁶⁵ This assessment and its complementary curriculum are used by inter-professional teams in early childhood programs.

Play, Playfulness, and Play Style

The third way therapists assess play is to analyze the child's experience or state of mind when playing (i.e., playfulness and play style). Bundy developed the Test of Playfulness (ToP) to assess the individual's degree of playfulness.^{20,21} The scale contains 34 items representing four elements of playfulness: intrinsic motivation, internal control, ability to suspend reality, and framing. The child is rated on scales of extent, intensity, and skill. The ToP can be scored from direct observations or videotapes of children engaged in free play.⁹³

Bundy and her associates also developed an assessment of the environment's capacity to support playfulness, the Test of Environmental Supportiveness (TOES).⁹³ The primary purpose of the TOES is for consultation with caregivers to determine a player's motivation for play, and it is meant to be administered along with the ToP.⁹³ Extensive information on utility in practice and case studies is found in Parham and Fazio's *Play in Occupational Therapy for Children*, 2nd ed.⁷⁶

The previous assessments are based on behavioral observation and parent interviews. Because play is unique to the individual, it is important to obtain the child's own perspective of his or her play, and this is usually done through self-report. The Pediatric Interest Profiles consist of three age-appropriate profiles of play and leisure interests and participation for children from 6 to 9 years of age, from 9 to 12 years, and from 12 to 21 years.⁴¹ The profiles assess what activities the child is doing, the child's feelings about the activity, how skilled they perceive themselves, and with whom they play. They can be used in evaluation to (1) identify children and adolescents who

may be at risk for play-related problems, (2) establish play-related goals, and (3) identify play or leisure activities to use in intervention. Although this assessment holds promise for use by occupational therapists, particularly with regard to obtaining information on meaning of play activity for children, recent surveys do not show that it is being used in practice.⁵⁹

The recently revised Child Occupational Self-Assessment (COSA, version 2.2) helps practitioners find out from the child what he or she finds interesting and meaningful.⁵⁸ The COSA also provides a structure to determine how a child perceives his or her competency. Children identify their interest in a variety of occupations (including play, self-care, chores) and rate how well they feel they perform this activity. This flexible format allows the practitioner to hear from the child directly, helps in establishing a rapport, and aids in intervention planning. This tool can be effective in helping practitioners design play sessions.⁷⁵

Interpreting Play Assessments

Assessment of play should be a part of every occupational therapy evaluation to develop a complete picture of an individual's competence in his or her occupational performance and to plan intervention that focuses on helping that individual participate in meaningful and self-satisfying occupations. Play assessments provide the therapist with a picture of how the individual engages in play in his or her daily life. An analysis of children's play is also helpful in assessing physical and cognitive abilities, social participation, imagination, independence, coping mechanisms, and environment.^{12,38}

Play may be informally evaluated in routine, self-chosen, familiar activities in naturalistic settings, providing the therapist with a picture of everyday competencies. Identifying what the child can do in play enables the therapist to focus on the child's abilities rather than disabilities. Because play is an interaction between the child and the environment, the human and physical factors in the environment can substantially influence the child's play.⁵⁶ The Revised Knox Preschool Play Scale is a good example of a play assessment that can be used in a naturalistic environment. Play assessments that are designed to take place in standardized settings, such as those that are embedded within developmental assessments with standardized toys, significantly alter and may inhibit the child's play. In addition, although play specifies its own purpose, observed behaviors may have different meanings and serve different purposes for different people. It is difficult for an observer to assess the meaning of play to the participant; therefore practitioners may benefit by interviewing children. The COSA is an assessment tool that helps practitioners understand the meaning the child ascribes to occupations, such as play and school.⁵⁸

Therapists must determine whether the sample of behavior is sufficient, typical, and representative of true play. When observed over a prolonged time, a child's play can vastly differ at different times.⁵⁶ To capture a variety of play behaviors, a therapist may need to observe a child multiple times and in a variety of settings. An analysis of play is especially helpful in assessing a child who does not respond well to standardized developmental testing. Knowledge of the individual's play skills, interests, and play style assists in intervention planning. The questions listed in [Box 17-1](#) may help practitioners observe play to develop intervention goals.

BOX 17-1 Questions to Examine Play and Playfulness

- In which activities does the child become totally absorbed?
- What does the child get from these activities?
- Does the child engage routinely in activities in which he or she feels free to vary the process and outcome in whatever way he or she sees fit?
- Does the child have the capacity, permission, and support to do what he or she chooses to do?
- Is the child capable of giving and interpreting messages that convey "This is play; this is how you should interact with me now"?²⁰
- Where does the child play? Indoors? Outdoors?
- With whom does the child play? What are the ages and abilities of their peers?
- Does the child have a place of his or her own to escape?
- How does the caregiver support the child's play?
- Is the child rigid or rough with toy use? Does the child use the toys in a traditional or nontraditional manner?

Constraints to Play

The effects of the environment on play can be seen in children who have experienced neglect or long hospitalizations. Extreme examples of constraints to play have been seen in some of the reports of children in Romanian orphanages.³⁰ These children showed severe sensory problems, extreme delay in developmental skills, and difficulties in interacting with others. Children who experience severely deprived environments also exhibit self-stimulation, limited repertoire of activities, decreased social play, and either increased or decreased fantasy play.³¹

When children are hospitalized, they often experience stress of separation, fear of illness, painful procedures, enforced confinement, and disruption of routines.⁵⁰ Some of the effects on play behavior include regression to earlier stages of development; decreased endurance and movement; decreased attention span, initiative, and curiosity; decreased resourcefulness and creativity; qualitative decrease in playfulness; decreased affect; and increased anxiety.^{51,61} Occupational therapy and Child Life services may overlap with children in hospital settings, and such teamwork can be beneficial to helping children cope with medical procedures.

Effects of Disability on Play Behavior

The play of children with varying disabilities has been described often in the literature.^{50,71} However, problems arise in attempts to generalize across or within disabilities. Children are individuals and respond uniquely in different situations, whether or not they have a disability.

Descriptions of the play of children with disabilities must be interpreted cautiously.⁵⁰ Although it is helpful to examine some of the problems that certain conditions may impose on the child, in actual practice, each child must be considered individually. Bundy stated that although a child's play may not be typical, it was more important for "children to be good at what they want to do" (p. 218).²⁰

FIGURE 17-6 Matthew, who has cerebral palsy, shows playfulness as he participates in the pregame rally by playing the drum. (Courtesy Jill McQuaid.)

Children may have conditions that limit physical interaction with the environment, toys, and people. The child with a physical impairment may display limited movement, strength, and pain when performing daily activities. Social contacts with family and peers may be disrupted by hospitalizations.⁴⁹ The play characteristics of children with physical limitations may include fear of movement, decreased active play, and preferences for sedentary activities. The child may also have problems with manipulating toys and show decreased exploration. Interestingly, children with physical disabilities may actually demonstrate higher levels of playfulness—the positive and pleasurable attitude of play—than children without physical disabilities^{1,35} (Figure 17-6).

Children with cognitive impairment often show delayed or uneven skills, difficulty in structuring their own behavior, or lack of sustained attention. These characteristics may be manifested in play preferences for structured play materials, limited or inflexible play repertoires, decreased curiosity, destructive or inappropriate use of objects, decreased imagination, decreased symbolic play, decreased social interaction, decreased language, and increased observer play.^{50,71} These children may need more structure and external cues to develop their play skills.

Children with visual impairment have delays in developing an integrated perception of the world caused by lack of vision and delayed motor exploration of surroundings and objects. Children often have difficulty in constructive play, delays in developing complex play routines with others, and decreased imitative and role play.^{50,71}

The child with a hearing impairment is believed to have problems with decreased inner language, decreased social interactions, and decreased understanding of abstract concepts. Imagination becomes more restrictive with age and increased time is spent in noninteractive construction play. Children with hearing impairments demonstrate decreased symbolic play and increased solitary play.^{50,71}

Children who have difficulty interpreting and integrating sensory input often have a limited or distorted perception of themselves and their world, decreased ability to plan and

FIGURE 17-7 Matthew takes to the snow using an adapted sled. (Courtesy Jill McQuaid.)

execute motor and cognitive tasks, and poor organization of behavior. Play characteristics of these children include either excessive movement or avoidance of movement, decreased exploration, decreased gross motor or manipulative play, increased observation or solitary play, increased sedentary play, a restricted repertoire of play, resistance to change, distractibility, or destructiveness.^{4,5,19,75}

Children with an autism spectrum disorder (ASD) generally follow a different course of play development than other children and can be at risk for a lack of reciprocal relationships throughout their life span.⁹⁹ Their play is characterized by a lack of inner and expressive language, stereotyped movements or types of play, decreased imitation and imagination, lack of variety in play repertoires, motor planning problems, decreased play organization, decreased manipulation of toys, decreased construction and combining of objects, and decreased social play.^{6,95} Children with ASD appear to have a fundamental deficit in play greater than what would be expected in examining specific skills. Incidental teaching, integrated playgroups, peer-mediated intervention, and community integration have been well documented as strategies to improve the play skills of children with an ASD.⁹⁹

Children with cerebral palsy may show difficulties across skill areas. They may show limited and abnormal movement, sometimes have decreased cognitive abilities, exhibit multisensory impairments, and often lack opportunities for social play.³⁵ In play, cognitive abilities are the most decisive factor in limiting play, and children with good cognitive abilities can make adaptations to their physical limitations. Other problems include decreased physical interaction with environment and less interactive play time.^{14,15} Therefore occupational therapists must evaluate each child carefully and individualize intervention to the child's strengths and limitations.

Most of the studies of the play of children with disabilities stress the obstacles that the disabling conditions place on the children. The occupational therapy practitioner explores supports for play and begins intervention with the child's play strengths. With adaptations, a child can overcome great obstacles to engage in a favorite activity (Figure 17-7).

CASE STUDY 17-2 Play as a Modality: Sarah and Her Magic Beads

Sarah is a 2½-year-old girl with mild spastic diplegia. She is playful, talkative, and extremely imaginative. A former premature infant, her primary motor impairment is independent ambulation, and despite the ability to walk, she is generally fearful of taking more than a few steps. Her favorite activity in occupational therapy is to play dress-up and direct everyone in the play theme of the day. Costumes are always involved for both Sarah and her therapist, as are long strings of colorful beads. Most of the time she crawls around in costume with her beads dragging along the therapy mats, or she walks holding her occupational therapist's hand. As a means of improving Sarah's confidence with walking, and to decrease her reliance on others, her occupational therapist begins using a string of Sarah's beads to gradually wean

her from holding hands. First, the occupational therapist simply holds the beads in her palm as she holds Sarah's hand. Next, the occupational therapist has Sarah help her hold the beads between their clasped hands. Then, the occupational therapist begins to lengthen the beads from a ball in the palms to a single strand of bead, one end held by Sarah and one by the therapist. As Sarah's confidence grows, the occupational therapist gradually lengthens the bead fully out between them—a distance of about 18 inches—and then she eventually lets go of the bead chain completely! Sarah keeps walking with a big smile on her face, waving her “magic beads”!

This case example illustrates the use of play as a treatment modality (e.g., to meet performance goals).

Play in Intervention

What differentiates free play from therapeutic play? Free play is intrinsically motivated, fun, and performed for its own sake rather than having a purpose. The child directs the play. However, in therapy, goals and objectives are established by the therapist (with input from parents and child), who directs the play. However, when external constraints are placed on play, it may be perceived as work and no longer contains playful elements. How then can play be used successfully in intervention?

Rast stated:

Play offers a practical vehicle to enlist a child's attention, to practice specific motor and functional skills, and to promote sensory processing, perceptual abilities, and cognitive development. It also serves to support social, emotional, and language development. In the therapeutic setting, play often becomes a tool used to work towards a goal, despite the fact that the goal-oriented, externally controlled aspects of the therapy situation conflict with the essence of play itself. (p. 30)⁸⁴

Play and leisure activities are used in occupational therapy in two primary ways:

1. As intervention modalities (e.g., using a play activity to improve specific skills in an area other than play) ([Case Study 17-2](#))
2. As an intervention goal (to improve the occupation of play itself)

For play to be used successfully in intervention, the child should feel that he or she is choosing or directing the play episode. This is particularly important when the goal is to increase competence in play development. Play and leisure activities are important methods for promoting a child's performance and skills because they have meaning to the individual. See [Box 17-2](#) for sample goals.

In their 1998 study, Couch et al. found that 91% of pediatric occupational therapists rated play as important to their interventions.²⁸ For 95% of the respondents, play was used primarily to elicit motor, sensory, or psychosocial outcomes; only 2% used play as an outcome by itself. The therapists also primarily used adult-directed play versus child-directed play. In

BOX 17-2 Sample Play and Playfulness Goals

Overall Area	Sample Measurable Goal
Work cooperatively with peers.	Child will enter a play session without disrupting the play of his or her peers at least twice during a 30-minute play session.
Take turns when playing a game.	Child will share toy with a peer at least three times during a 30-minute play session.
Use play scripts of social stories.	Child will complete two out of four steps of the social story during the 30-minute play session.
Follow the rules to a game.	Child will follow three out of three rules to a simple board game during a 10-minute session.
Engage in rough-house play without hurting others.	Child will exhibit increased body awareness by gently tagging peers (so they do not fall or experience pain) while engaged in outside playground game of tag for 30 minutes.

a replication of this study a decade later, Kuhaneck et al. found similar results, with 88% of respondents reporting a predominant use of play as a means of improving skills in an area other than play (such as fine motor). Only 4% reported the predominant use of play as an intervention outcome.⁵⁹

The way play is used in intervention is influenced by a number of factors: the therapist's frame of reference, the institution's emphasis on improving performance components and skills, and the family's values and concerns for the physical aspects of the child's disability. Goals and objectives are established in accordance with how the child's disability affects his or her daily occupations and on analysis of occupational performance.³ A major barrier for children with disabilities is the ability to participate in play and leisure activities on par with their peers. Occupational therapists have a key role in facilitating play and leisure participation for children and youth ([Case Study 17-3](#)).

CASE STUDY 17-3 Play as the Goal: Rachel

Rachel is a 9-year-old child in the third grade. Rachel has been diagnosed with generalized anxiety disorder, bipolar disorder, and attention deficit disorder. Her home environment is unstable and Child Protective Services is involved with the family, who struggles financially. Rachel lives with her mother (who has depression, substance abuse, and bipolar disorder) and brother (who was recently incarcerated because of substance abuse). Rachel enjoys arts and crafts and likes to be involved in afterschool activities. She can be pleasant and talkative to adults, but seems to stand on the sidelines with peers and has episodes in which she gets very angry with peers when waiting her turn. Rachel exhibits good gross and fine motor skills. However, she sometimes completes schoolwork quickly and shows poor attention to details. She is struggling in the classroom.

The occupational therapist completed the Child Occupational Self-Assessment (COSA) with Rachel and found

that she was not good at socializing with peers. However, Rachel said this was not important to her. After further conversation, Rachel admitted she would like to have some friends at school. The occupational therapist designed intervention to help Rachel learn to play with peers and express her frustration in appropriate fashion. The occupational therapist modeled play behaviors, engaged Rachel in some individual sessions with arts and crafts, and later invited peers to join. Rachel began to share objects with peers once she realized these items would also be available to her. She began to interact with peers and complete arts and crafts projects together. The occupational therapist focused sessions on increasing Rachel's belief in her own abilities (self-competency) to increase her ability to play with peers.

This case illustrates the use of play as the goal of the intervention session.

FIGURE 17-8 Being silly is an aspect of play and playfulness. These boys show playfulness as they tease that they are being chased by the bear!

Playfulness in Occupational Therapy

Play is used therapeutically to facilitate playfulness, development of play skills, and acquisition of new behaviors. Often what individuals play with and how they play may not be as important as the affective quality of their play. Some children with significant or multiple disabilities manage to get great joy and benefit out of play. On the other hand, therapists often see children who are not playful and do not derive pleasure out of even the simplest play interaction (Figure 17-8). Facilitating playfulness in the child can be an important goal of therapy.

Morrison and Metzger stated:

The more playful child may generalize this flexible approach into environmental interaction beyond play and into other aspects of his or her life. For the child with a condition that impedes his or her ability to interact

with the social or physical environment, a flexible (playful) approach may enable the child to succeed more frequently in these difficult situations. (p. 540)⁷²

The therapist should express a playful attitude through speech, body language, and facial expressions. Novelty and imaginary play can be used to facilitate playful participation on the part of the child. Bundy stated that the therapist must know how to play to be able to model play for the child.¹⁹ To develop playfulness, the child must develop intrinsic motivation, internal control, ability to suspend reality, and ability to give and read verbal and nonverbal cues when interacting with peers and caregivers.

Facilitating playful interactions is important for a child of any age. For example, therapists working in a neonatal intensive care unit or with infants in the community can help parents learn to read their infant's cues and adapt to the infant's behavioral tempo to develop mutually positive experiences that form the basis for playful processes as the infant matures.⁴³ For those who work in schools or who provide consultation for mixed-age programs, therapists can teach educators, parents, and childcare providers the value of having children engage in mixed-age play and interaction, which yields increased leadership skills in older children and creativity and imagination in their younger playmates.⁴⁰

Play Spaces and Adaptations

Critical to creating a play atmosphere for children is considering the environment and the objects, equipment, and opportunities within it. To foster play, environmental spaces, toys, and equipment should have some flexibility in usage (Figure 17-9).

Bundy et al. examined changes in playfulness in a group of typically developing children, ages 5 to 7 years, after new materials (e.g., cardboard boxes, bicycle tires, hay bales, plastic barrels, wood, foam) were introduced to the playground.²² They found that scores on the Test of Playfulness rose significantly after the intervention, and the teachers felt that the

FIGURE 17-9 One aspect of playfulness involves using objects in unconventional ways. These toddlers have used buckets for space helmets.

children's play had become more active, creative, and social as a result. Occupational therapists working with children in schools can suggest the inclusion of carefully selected materials to motivate imagination and promote engagement in new games during recess.

In addition, toys and play equipment may need to be adapted for the child to access them optimally. Adaptation of toys and the environment is an important role of the occupational therapist, particularly for the severely involved child. Play spaces should offer a variety of experiences and allow for creativity, illusion, change, and chance. Children need to be able to control the space, that is, have objects, toys, and people to move and change and the freedom to move them.²⁴ The therapist must know the properties of toys as well as how to adapt them appropriately. Switches, adaptive keyboards, or provisions for sensory impairment may be necessary for the child to benefit from and be more independent in play. Play can be enhanced through a variety of augmentative devices ranging from very simple adaptations to complex electronic devices.³²

Indoor and outdoor playgrounds and group play spaces need to be designed to promote universal access for children with physical limitations and to encourage socialization (Figure 17-10). Therapists working in school-based practice need to advocate for school playgrounds that are accessible and that offer opportunities for physical exercise, sensory exploration, motor and cognitive skill development, and social skill practice.⁹⁶

In designing playful spaces for children, occupational therapists should consider the following key points:

- Use of color and texture
- Novelty of equipment and supplies
- Attention to the senses (sight and sound options)
- Consideration of age and developmental levels
- Convertibility of play spaces to allow for varied levels of ability and interest
- Comfort, size, and safety (smaller spaces are typically best)
- Ability to suggest themes or allow for varied thematic play
- Therapeutic use of self and others (playfulness is best facilitated by others who are playful!)

Parent Education and Training

Working with parents in relation to play is important for carryover of the skills and abilities learned in therapy into the child's everyday life. Children with physical disabilities may be involved in therapeutic regimens throughout the day and consequently may be deprived of play opportunities. Four barriers to free play in children with physical disabilities are:

1. Limitations imposed by caregivers
2. Physical and personal limitations of the child
3. Environmental barriers
4. Social barriers⁷⁰

Interventions that support the child's free play and include recommendations about play things and play spaces help support the importance of play in overall development. For example, occupational therapists can help parents perform "toy inventories" (Box 17-3) and suggest that parents create play spaces throughout the home (e.g., a special cupboard in the kitchen or a toy workbench in the garage or craft area).

Helping parents understand the importance of play for their child and helping them to interact with their child playfully are key goals of therapy. Parents may need guidance in creating a balance between doing things for their child and allowing the child to form and carry out his or her own intentions. The therapist may need to model play behavior for the parent, encourage the parent to enter into and contribute to play sequences without directing or controlling them, and help the parent organize or adapt the play environment to meet the needs of the child. By actively involving the parents or caregivers, the therapist helps them appreciate their child's strengths, learn the fun of playing with their child, and develop play skills that match their child's interests.

Societal Concerns

As society continues to rely more heavily on technology, and virtual play opportunities increase, parents and caregivers need to have the necessary tools to be able to embrace and integrate potential new opportunities for play and social engagement,

BOX 17-3 Toy Inventory

Occupational therapists can share this toy inventory with parents to promote play and playfulness in the home. Parents often ask for ideas of gifts for their children before a child's birthday or holiday. This inventory may help educate others on the play needs of the child.

Step 1

Explain that "good toys" have the following qualities:

- Are appropriate for the child's age and developmental level
- Keep the child's interest
- Have longevity (in other words they are toys that will stand the test of time and can be used by the child in a variety of ways for years, such as Legos)
- Are safe and durable
- Stimulate learning

Step 2

Encourage parents to create a list of toys in their home by the following categories:

- Active toys (ride-on toys, outdoor or sports equipment)
- Manipulative toys (construction toys, puzzles, dressing toys, beads, blocks, bath toys, and sand or water toys)
- Make-believe (dolls, stuffed toys, puppets, role play, transportation toys)
- Creative toys (musical toys, arts and crafts materials, digital music or tablet devices with creativity apps)
- Learning toys (games, specific-skill toys such as science models, computer or tablet devices with learning applications, books)

Step 3

Review toy inventory with the parent. Make suggestions for home play spaces and play things that relate to the child's intervention goals.

while balancing the technology with real-world, physical play and interaction.

In the last few years, play for all children has diminished. The amount of unscheduled time in the day of an average school-aged child continues to decline as families' work and extracurricular demands rise.^{66,92} Because of changing family lifestyles, challenges in education, technology, and safety concerns, children today have little time and space for free play. Singer et al. examined the role of play and experiential learning in 16 nations, divided into developed countries, newly industrial countries, and developing countries.⁹² They gathered information from mothers of 2400 children. They found similarities in all nations, with mothers describing the lack of free play and experiential learning opportunities. A major portion of children's free time was spent watching television.

Other studies have shown many barriers to play. One is overstructuring and overscheduling of the child's day.^{39,56,66,78} Children's afterschool hours are filled with classes, planned activities, and homework. Another barrier is an overemphasis on early academic achievement. Schools are increasingly moving to eliminate the "playful" parts of school, including recess, gym, sports, and art programs.^{39,78} Some states have eliminated recess altogether because it is not considered academic. Academics are being stressed earlier in our educational systems,

and parents often feel that, for play to be worthwhile, the adults need to "teach" things during play. A third barrier to play results from parents' concerns for the safety of their children in a culture they perceive as increasingly violent. Outdoor play has decreased markedly and parents schedule "play dates," or planned play experiences. Places for play have decreased also. Many metropolitan areas are severely lacking in park space,⁶⁶ and many school playgrounds are often simply asphalt pads with no playground equipment.

The decreases in unstructured, physical play have had a dramatic effect on children. The rise in childhood obesity, as well as in the health problems that accompany obesity, is a major problem facing parents. The over-reliance on television and computers has changed the type of play that children choose and leads to more passivity and reliance on others for entertainment. The increased media exposure has also exposed children to violent themes and content, often without the benefit of parental supervision. Active video games are becoming increasingly popular and offer increased energy expenditure over passive gaming, but the level of physical activity afforded does not match the equivalent of real-world physical activity.⁴⁶

Many organizations, including the American Academy of Pediatrics,⁴⁰ the Association for Childhood Education International, and the American Association for the Child's Right to Play,^{1,41,47} have issued declarations promoting the importance of and need for active play for children.

Occupational therapy practitioners are in a unique position to act as advocates for play, not only for their clients but also for children in general. In 2008, AOTA published a societal statement on play including the following recommendations:

Occupational therapy practitioners support, enhance, and defend children's right to play as individuals and as members of their families, peer groups, and communities by promoting recognition of play's crucial role in children's development, health, and well-being; establishing and restoring children's skills needed to engage in play; adapting play materials, objects, and environments to facilitate optimal play experiences; and advocating for safe, inclusive play environments that are accessible to all. (p. 707)⁸²

Occupational therapists can advocate for play in many ways to respond to the AOTA statement, including:

- Presenting in-services for school personnel and playground monitors
- Offering community classes for parents
- Volunteering to serve on community and school playground building committees
- Working with children's museums to develop play venues
- Distributing the AOTA Tip Sheets "Learning Through Play," which can be found at <http://www.aota.org/Play-Skills>, and "Recess Promotion," which can be found at <http://www.aota.org/Practitioners-Section/Children-and-Youth/New/Recess.aspx.FT-.pdf>
- Working with organizations such as the Starlight Children's Foundation to provide playful family experiences for children with chronic and critical health conditions.
- Working with state and national occupational therapy associations and other organizations that promote early learning

and childhood development to advocate for play and play spaces in the community.

- Collaborating with community organizations that provide play opportunities, such as YMCAs, scouts, playrooms, swimming programs, and gymnastic programs, to enhance their accessibility and provide accommodations for all children.

Summary Points

- Play is the primary occupation of childhood and its place within occupational therapy practice ranges from a focus on the development of play skills themselves to a modality to address skills in a variety of developmental domains.
- Occupational therapists' view of play stems from the theoretical underpinnings of many fields, with a focus on the form, function, meaning, and context of play as childhood occupation.
- Occupational therapists use a variety of assessment tools for evaluative and treatment planning purposes. These include the Revised Knox Preschool Play Scale and the Test of Playfulness, both developed by occupational therapists.
- Play is a developmental phenomenon that relates to skills across sensory, motor, cognitive, communication, and social domains. Occupational therapists need to have knowledge of typical play development to effectively evaluate play skills and plan intervention. Play development is influenced by context, including personal, social, cultural, virtual, and societal factors.
- Occupational therapists are in a unique position to advocate for the preservation of play in today's society, including opportunities for the creation of safe and accessible playgrounds, the preservation of recess in schools, and education related to the need for unstructured, physical play to reduce incidence of childhood obesity.

KEY TERMS

Literacy
Handwriting readiness
Functional written communication
Legibility

Domains of handwriting
Models of practice
Handwriting intervention outcomes

GUIDING QUESTIONS

1. What is the role of the occupational therapist in evaluation of and intervention for children with handwriting difficulties?
2. Which factors contribute to handwriting readiness for young children?
3. How would an occupational therapist evaluate handwriting and functional written communication?
4. How do performance skills, client factors, performance patterns, and context influence the student's participation in the writing process?
5. How does handwriting fit into the educational writing process?
6. How do remedial and compensatory strategies improve a student's written communication?
7. How do occupational therapy practitioners use pediatric occupational therapy models of practice and handwriting intervention programs to improve children's handwriting?
8. Which handwriting interventions and programs are supported with research evidence?

Occupational therapy practitioners view the occupations of children to be activities of daily living, education, work, play, and social participation. In the area of education, school-aged children's occupations encompass academic skills such as literacy (including reading and writing), calculation, and problem solving, as well as nonacademic or functional tasks. Functional tasks may include navigating around classroom furniture and classmates, sharing school supplies with a peer, placing a notebook into a locker, constructing a papier-mâché planet, cutting with scissors, and writing words on paper—all of which support a student's academic performance in the classroom. These academic skills and functional tasks are expected to evolve and strengthen throughout a student's school years.²¹

Writing is a tool for communication; it provides a means to project thoughts, feelings, and ideas. Writing is required when

children and adolescents compose stories, complete written examinations, copy numbers for calculations, and write messages to friends and family members. Although computers allow students to type letters and reports, they continue to need legible handwriting to complete forms, write personal notes and messages, and maintain records. Handwriting is more than a motor skill; it requires connecting the letter name with a letter form and recalling a clear visual picture of the letter form from memory, as well as being able to execute the motor pattern for each form.³⁸ Writing is a complex process requiring the synthesis and integration of memory retrieval, organization, problem solving, language and reading ability, ideation, and graphomotor function. The functional skill of handwriting supports the academic task of writing and allows students to convey written information legibly and efficiently while accomplishing school assignments in a timely manner.^{16,48}

Handwriting consumes much of a student's school day and is an essential skill for students to master.²⁰ In a study of elementary grade classrooms, McHale and Cermak⁷⁷ found that 31% to 60% of a child's school day consisted of fine motor activities. Most of these fine motor activities (85%) were paper-and-pencil tasks, indicating that students may possibly spend up to one fourth to one half of their classroom time engaged in paper-and-pencil tasks.

When children are having difficulty with handwriting, problems with written assignments follow. Students with neurologic impairments, learning problems, attention deficits, and developmental disabilities often expend extensive time and effort learning to write legibly.⁴ Consequences of handwriting difficulties at school may include the following: (1) teachers may assign lower marks for the writing quality of papers and tests with poorer legibility but not poorer content^{28,52}; (2) students' slow handwriting speed may limit compositional fluency and quality^{49,64,121}; (3) students may take longer to finish assignments than their peers⁴⁶; (4) students may have problems with taking notes in class and reading them later⁴⁶; (5) students may fail to learn other higher-order writing processes such as planning and grammar; (6) writing avoidance may develop, contributing later to arrested writing development; (7) students may omit details of what they know⁷⁹; or (8) students submit shortened or incomplete written responses because of the intense concentration and motor effort required to correctly form letters.²³ The ability to write legibly remains an important skill beyond elementary years; for example, the College Board SAT test requires students to handwrite the essay portion of the test.

Berninger et al.¹⁷ explain that it is critical for children to learn to write automatically to accomplish the extensive written

composition required of them in later elementary grades. Handwriting instruction is important to ensure that children learn the “building blocks of written discourse automatically so that they can focus on other important aspects of writing, such as choosing and spelling words, constructing sentences, and organizing the discourse of composing written texts” (p. 4).¹⁷ Studies support the importance of a direct and structured approach to handwriting instruction.^{60,100} Because of curriculum demands for increased literacy and math instruction, handwriting instruction has decreased in recent years, resulting in more students struggling with handwriting skills.^{35,36}

Teachers often request that occupational therapists evaluate a student’s handwriting when it interferes with performance of written assignments. In fact, poor handwriting is one of the most common reasons for referring school-aged children to occupational therapy.^{7,73}

The role of the occupational therapist is to view the student’s performance, in this case handwriting, by focusing on the interaction of the student, the school environment, and the demands of school occupations.² During the evaluation and intervention processes, the practitioner stays focused on (1) the occupation of handwriting, determining which domains of handwriting (e.g., near-point copying or dictation) and which components (e.g., spacing or letter formation) are problematic for the student; (2) the school context (e.g., the curriculum or physical classroom arrangement related to the child’s performance); (3) the student’s personal context (e.g., cultural, temporal, spiritual, and physical aspects); and (4) student experiences that are interfering with handwriting production. Occupational therapy offers a variety of services to improve handwriting. Therapists provide intervention directly to the child or through consultation with the teacher. In addition, the approach may focus on remediating potential causes of handwriting (i.e., impaired hand strength) or concentrate on the activity of handwriting itself.

The Writing Process

The No Child Left Behind (NCLB) Act of 2001⁸⁵ increased the emphasis on literacy and the contributions of school professionals to developing literacy skills in children. Literacy begins with the basic ability to read and write (functional literacy), which is required in everyday life, and proceeds to advanced literacy, which includes reflecting on knowledge of significant ideas, events, and values of a society.⁵⁸ Based on an occupation-focused approach,³ occupational therapists strive to improve children’s access to and engagement in early literacy activities.¹² When practitioners consider writing as an important early literacy communication skill, in addition to it being a complex motor task, their approaches to supporting writing expand and easily integrate into the curriculum.^{25,42} Occupational therapy intervention focused on supporting writing within the context of meaningful literacy experiences improves not only writing but also a broad set of literacy skills.⁹

Preliteracy Writing Development of Young Children

Handwriting is a complex skill that develops over years of practice. Many children begin to draw and scribble on paper

FIGURE 18-1 Three year old imitating writing after observing the therapist.

shortly after they are able to grasp a writing tool (Figure 18-1). As young children mature, they write intentionally meaningful messages, first with pictures and then with scribbles, letter-like forms, and strings of letters.⁷⁷ The development of a child’s writing process in the early elementary grades includes not only mastering the mechanical and perceptual processes of graphics, but also the acquisition of language and the learning of spelling and phonology. Furthermore, early writing competence is highly correlated with later success in reading.⁸⁴ Typically, children’s writing and reading skills develop in parallel processes with one another.⁷⁷ Consequently, if a young child is unable to recognize letterforms and understand that these letterforms represent written language, occupational therapists and educators cannot expect the child to write. Although children vary in the rate they progress through these stages, all children, including those with special needs, progress through these stages.¹⁹

As children develop, their scribbling and pictures evolve into the handwriting (i.e., language symbols) specific to their culture. Children progress through the following stages of prewriting and handwriting: (1) controlled scribbles; (2) discrete lines, dots, or symbols; (3) straight-line or circular uppercase letters; (4) uppercase letters; and (5) lowercase letters, numerals, and words.¹⁰⁸ Table 18-1 details the development of prewriting and handwriting with approximate age levels for children in the United States.

Writing Development of School-Aged Children

Most children learn to write letters in kindergarten but do not develop fluency until the third or fourth grade, and they do not demonstrate adult speed in writing until the ninth grade.⁴⁹ Handwriting requires the integration of both lower-level perceptual-motor processes and higher-level cognitive processes.⁵³ Correlational studies have found that handwriting skill is linked to eye-hand coordination²³ and is moderately associated with dexterity.²⁹ A number of correlational studies found that visual-motor integration is the strongest predictor of handwriting legibility.^{114,120} The perceptual-motor processes of handwriting include visual perception (e.g., when copying from a model), auditory processing (e.g., when words are dictated),

TABLE 18-1 Development of Prewriting and Handwriting in Young Children

Age Level	Performance Task
10-12 mo 2 yr	Scribbles on paper Imitates horizontal, vertical, and circular marks on paper
3 yr	Copies a vertical line, horizontal line, and circle
4-5 yr	Copies a cross, right oblique cross, some letters and numerals, and may be able to write own name
5-6 yr	Copies a triangle, prints own name, copies most lowercase and uppercase letters

Bayley, N. (2005). *Bayley scales on infant development* (rev. ed.). San Antonio: Psychological Corporation; Beery, K. E., & Beery, N. (2005). *The Development Test of Visual-Motor Integration*. Cleveland: Modern Curriculum Press; Weil, M., & Amundson, S. J. (1994). Relationship between visual motor and handwriting skills of children in kindergarten. *American Journal of Occupational Therapy*, 48, 982–988.

and visual motor integration (e.g., when combining the components to write). The cognitive processes involved include executive planning and use of working memory. Handwriting also requires specific language processes,¹¹⁴ including the ability to hear a word and identify which letters form that word (i.e., turning spoken language into written language).

When young children first learn to write their letters, they use their vision to guide their hand movements. Although adults rely more on kinesthetic input when writing,¹⁴ children learn the skills by visually analyzing form and space, then linking the image of a letterform to a motor plan. With practice in visually guiding their hand movement, children develop a kinesthetic memory of letterforms. At this point in their learning, writing becomes automatic.¹⁴ In primary grades, when students are learning handwriting by copying letters, visual-motor coordination and motor dexterity are critical skills.¹¹⁶ In older students, who are required to produce substantial amounts of writing, cognitive processes become more important (e.g., planning and linguistic skills). The association between lower level (perceptual-motor) handwriting skills and higher-level (memory and cognition) skills was documented by Graham,⁴⁵ who found that difficulties with handwriting can interfere with the execution of the composing processes. Because handwriting requires perceptual-motor processes and cognitive processes, students with illegible handwriting may have deficits in either area.

Graham et al.⁴⁸ found that handwriting fluency is a predictor of compositional fluency and quality. Once a student has achieved automatic writing, he or she can focus on other aspects of writing (e.g., spelling, grammar, planning, organizing information for writing tasks) and therefore improve composition quality.

Handwriting Readiness

Some controversy exists as to when children are ready for formal handwriting instruction. Differing rates of maturity,

environmental experiences, and interest levels are all factors that can influence children's early attempts and success in copying letters. Some children may exhibit handwriting readiness at 4 years of age, whereas others may not be ready until they are 6 years old.¹¹⁶ Researchers recommend that children master handwriting readiness skills before handwriting instruction is initiated, suggesting that when children are taught handwriting before they are ready they may become discouraged and develop poor writing habits.^{114,115}

Letter formation requires the integration of the visual, motor, sensory, and perceptual systems. Performance components associated with handwriting include kinesthesia, motor planning, eye-hand coordination, visual-motor integration, and in-hand manipulation. As described in the previous section, kinesthesia provides the ongoing feedback about movement errors, creates memory of motor patterns, and allows automaticity to develop. In addition, it provides information about directionality during letter formation. Kinesthetic perception also influences the amount of pressure applied to the writing implement. Sufficient fine motor coordination is also needed to form letters accurately.

Benbow¹⁴ described six developmental classifications that underlie skilled use of the hands that contribute to greater adeptness in operating a pencil: (1) upper extremity support, (2) wrist and hand development, (3) visual control, (4) bilateral integration, (5) spatial analysis, and (6) kinesthesia. Other authors define readiness for handwriting on the basis of a child's ability to copy geometric forms. Researchers suggest that handwriting instruction be postponed until after the child masters the first nine figures in the Developmental Test of Visual-Motor Integration (VMI), that is, a vertical line, a horizontal line, a circle, a cross, a right oblique line, a square, a left oblique line, an oblique cross, and a triangle.^{10,30,118} Most typically developing kindergarten children should be ready for handwriting instruction in the latter half of the kindergarten school year.

Problems in Handwriting and Visual Motor Integration

Handwriting requires the ability to integrate the visual image of letters or shapes with the appropriate motor response. Visual-cognitive abilities may affect writing in a variety of situations. Children with problems in attention may have difficulty with correct letter formation, spelling, and the mechanics of grammar, punctuation, and capitalization. They also have difficulty formulating a sequential flow of ideas necessary for written communication.⁷⁸ For a child to write spontaneously, he or she must be able to re-visualize letters and words without visual cues. A child with visual memory problems may have difficulty recalling the shape and form of letters and numbers. Other problems seen in the child with poor visual memory include mixing small and capital letters in a sentence, writing the same letter many different ways on the same page, and being unable to print the alphabet from memory. In addition, legibility may be poor, and the child may need a model to write.

Visual discrimination problems may also affect the child's handwriting.¹⁰² The child with poor form constancy does not recognize errors in his or her own handwriting. The child may be unable to recognize letters or words in different prints and therefore may have difficulty copying from a different type of

print to handwriting. The child may also show poor recognition of letters or numbers in different environments, positions, or sizes. If the child is unable to discriminate a letter, he or she may have difficulty forming it. A child with figure-ground problems may have difficulty copying because he or she is unable to determine what is to be written; the child therefore may omit important segments or may be slower than peers in producing written products.

Visual-spatial problems can also affect a child's handwriting. The child may reverse letters such as *m*, *w*, *b*, *d*, *s*, *c*, and *z* and numbers such as 2, 3, 5, 6, 7, and 9. If the child is unable to discriminate left from right, he or she may have difficulty with left-to-right progression in writing words and sentences. The child may over space or under space between words and letters and may have trouble keeping within the margins. The most common spatial errors in handwriting involve incorrect and inconsistent spacing between writing units and variability in orientation of major letter features when the letter is written repeatedly.¹¹⁷ A child with visual-spatial difficulties may be unable to relate one part of a letter to another part and may demonstrate poor shaping or closure of individual letters or a lack of uniformity in orientation and letter size.¹²³ The child may have difficulty placing letters on a line and adapting letter sizes to the space provided on the paper or worksheet. Researchers have not demonstrated strong relationships between handwriting skills and visual perceptual functions, and further research is necessary to better understand the role of visual perception in handwriting.¹¹⁴

Failure on visual-motor tests may be caused by underlying visual-cognitive deficits, including visual discrimination, poor fine motor ability, or inability to integrate visual-cognitive and motor processes, or by a combination of these disabilities. Evaluating visual motor skills may help pinpoint children who need close monitoring or specific interventions to prevent the development of handwriting problems.⁷⁵ Therefore careful analysis is necessary to determine the underlying problem.

Pencil Grip Progression

The development of pencil grip in young children follows a predictable course for typically developing children but may vary among cultures.¹¹² Children commonly begin by holding the pencil with a primitive grip—characterized by holding the writing tool with the whole hand or extended fingers, pronating the forearm, and using the shoulder to move the pencil. Between 18 and 30 months, children use a transitional pencil grip, with the pencil being held with flexed fingers, and the forearm is pronated (thumb side downward) or supinated (Figure 18-2A,B). In the mature pencil grip, the pencil is stabilized by the distal phalanges of the thumb and index, middle, and possibly ring fingers; the wrist is slightly extended yet dynamic; and the supinated forearm rests on the table.^{103,112}

Mature pencil grips include the dynamic tripod grasp, the lateral tripod, the dynamic quadripod, and the lateral quadripod.^{32,68} Schneck and Henderson¹⁰³ reported in their study of 320 typically developing children that by the age of 6.5 to 7 years, 95% had adopted a mature pencil grasp, either the dynamic tripod (72.5%) or the lateral tripod (22.5%). Outside the United States, Tseng¹¹² noted that Taiwanese children use the lateral tripod grip (42.9%) almost as frequently as the dynamic tripod (44.1%). In 120 typically developing and

FIGURE 18-2 Primitive and transitional grasps of the marker.

nonproficient fourth grade students, Schweltnus et al.¹⁰⁴ found no difference in perceived effort during a sustained handwriting task for different pen grips from dynamic tripod to lateral tripod (Figure 18-3).

Handwriting Evaluation

When a child with poor handwriting has been referred to occupational therapy, the methods to gather evaluation information must be carefully selected and sequenced. A comprehensive evaluation of a child's handwriting includes (1) the occupational profile and (2) the analysis of occupational performance.

Initially the student's performance in the context of classroom standards should be the focus (before moving toward standardized testing). Assembling data and information from various sources gives the occupational therapist an integrated picture of the child's written communication.

Occupational Profile

The occupational profile describes the student's occupational therapy history, experiences, patterns of daily living, interests, values, and needs. It is designed to gain an understanding of the client's perspective and background.⁸² The information for the occupational profile can be gathered by interviewing the child, parent(s), teacher, and other team members.

FIGURE 18-3 Mature pencil grips in elementary school children. **A**, Dynamic tripod; **B**, lateral tripod; **C**, dynamic quadripod; and **D**, lateral quadripod.

Interviews

Interviewing the child helps the therapist to understand what is important and meaningful to the child. This information helps the therapist gain an understanding of the child's perspective and background. Because teachers observe their students' daily performance in class, they can share information about the student's abilities and achievements and how the student responds to instruction. A sampling of questions to facilitate discussion between the teacher and the occupational therapist is listed in [Box 18-1](#). The educator provides a background picture of the student's capabilities, behavior, and struggles at school. Teachers report that they evaluate students' handwriting by comparing it with that of classroom peers (37%) or comparing it with student handwriting in a book (35%).⁵⁴

Parents provide a different perspective on the child and the child's handwriting abilities. Not only can parents describe the child's developmental, medical, and familial background to the educational team, but they can share invaluable information about the child's interests, social competence, and attitudes toward learning and school.

As members of the educational team, parents also provide important perspectives regarding the child's home activities, resources, and supports, and the child's participation in contexts outside school. To facilitate discussion about the child and his or her writing, therapists may ask parents: (1) Do you expect the child to complete school assignments or written work at home? (2) What is the child's response

BOX 18-1 Questions to Facilitate Discussion among Educational Team Members

1. What are the student's educational strengths and concerns?
2. What is his or her handwriting performance compared with that of peers?
3. Which handwriting method (D'Nealian, Zaner-Bloser, Palmer, Italics) is being used and what is the student's history with this method?
4. What are the learning standards or curriculum of his or her grade?
5. What seems to be causing the poor handwriting?
6. When does he or she do his or her best written work?
7. When does the performance break down?
8. Which strategies for improvement have been tried? Have they worked?
9. Is a student portfolio available on the student's writing development and progress?
10. Are there other daily tasks (e.g., using scissors, getting along with peers, keeping organized) that raise concern for the teacher?

to written homework? (3) How does the child perform his or her written assignments at home and at school? (4) Which other writing tasks are expected of the child at home (e.g., corresponding with relatives, recording telephone messages)?

Analysis of Occupational Performance

In addition to interviewing teachers, parents, and the child, a comprehensive evaluation of a child's handwriting includes (1) examining written work samples, (2) reviewing the child's educational and clinical records, (3) directly observing the child when he or she is writing in the natural setting (i.e., school, home), (4) evaluating the child's handwriting legibility and speed, and (5) assessing performance skills suspected to be interfering with handwriting.

Work Samples

As part of the evaluation process, the occupational therapist accesses the child's handwritten class work or homework. Written work samples may include spelling lessons, mathematical problems, or stories. Ideally these samples should represent a typical handwriting performance of the child. When reviewing the child's written product, a comparison of the writing samples of the child's peers can clarify the classroom standards and teacher expectations. Informal evaluation of the work samples for alignment, size, letter formation, legibility, and slant may indicate the need for further evaluation. The use of non-letters may indicate a lack of motor skills or letter knowledge, because both skills are needed for creating accurate letter formations.⁴³

File Review

Relevant information regarding past academic performance, special testing, or receipt of special services can be found in the referred child's educational cumulative file. Medical or clinical reports related to the child's education may also be located in the child's regular or special education files. The child's parents may share academic records and reports with clinic- and hospital-based occupational therapists. This documentation may trigger further conversations among the child's parents and team members.

Direct Observation

Observing the student during a writing activity in the classroom is an essential step in the evaluation process (Figure 18-4). The

FIGURE 18-4 A student completes a written assignment at her desk.

therapist focuses on task performance, attention to task, problem solving, and behavior of the child. Practitioners also note the student's organizational abilities, interactions with the teacher and peers, transitions between activities, and overall performance of other school tasks. School contextual features (e.g., the classroom arrangement, lighting, noise level, instructional media), as well as the teacher's instruction, should be considered in relationship to the student's performance. In addition to a structured protocol for direct observation, the occupational therapist may ask the teacher:

1. Which writing tasks (e.g., copying sentences from the chalkboard, composing a story) are most problematic for the child?
2. Which writing tasks does the child enjoy?
3. Which behaviors are manifested when the child is required to write? For example, does the child chew on the eraser of the pencil or blow the pencil across the desktop to avoid writing?
4. Can the child engage independently in the task of writing or does he or she need physical and verbal cues from the teacher or educational assistant?
5. How does the child interact with and access writing materials?
6. Is the child easily distracted by visual and auditory stimuli during writing, such as a delivery truck driving by the school window?
7. Where does the child sit in the classroom?
8. What is the writing curriculum (that may or may not include handwriting)?
9. Where is the teacher located when he or she gives assignment directions?
10. How does the observed difficulty interfere with the child's learning?

Measuring Handwriting Performance

In evaluating the actual task of children's handwriting, the following areas need to be examined: (1) domains of handwriting, (2) legibility components, (3) writing speed, and (4) ergonomic factors. Whether the student writes in manuscript (print), cursive (joined script), or both, these four aspects will help the educational team and parents uncover problematic areas of handwriting and establish a baseline of handwriting function. With accurate and relevant handwriting assessment data, the occupational therapist, the child's parents, and the educational or clinical team identify specific goals and objectives for the development of written communication.

Domains of Handwriting

Evaluating the various domains of handwriting allows the occupational therapist to determine which tasks the child may be having difficulty with and address those tasks in the intervention plan. Handwriting tasks demanded of students, and helpful for intervention planning, include the following:

- Writing the alphabet in both uppercase and lowercase letters along with numbers requires the child to remember the motor engram, form each individual letter and numeral, sequence letters and numbers, and use consistent letter cases.

- Copying is the capacity to reproduce numerals, letters, and words from a similar script model, either manuscript to manuscript or cursive to cursive.
- *Near-point copying* is producing letters or words from a nearby model, commonly on the same page or on the same horizontal writing surface, as when a student copies the meaning of a word from a nearby dictionary.
- Copying from a distant vertical display model to the writing surface is termed *far-point copying*, demonstrated by students writing the words “Happy Valentine’s Day” on construction paper cards from these words on the class chalkboard.
- More advanced than copying, manuscript-to-cursive transition requires a mastery of letterforms in both manuscript and cursive as the child must transcribe manuscript letters and words to cursive letters and words.
- Writing dictated words, names, addresses, and telephone numbers is a skill children use at school and at home. A higher-level handwriting task combining integration of auditory directions and a motoric response is dictation.
- Composition is the generation of a sentence or paragraph by the child demonstrated by writing a poem, a story, or a note to a friend. The composing process uses the cognitive functions of planning, sentence generation, and revision and requires complex integration of linguistic, cognitive, organizational, and sensorimotor skills.

Legibility

Legibility is often assessed in terms of its components—letter formation, alignment, spacing, size, and slant.⁵ However, the bottom line of legibility is readability. Of primary importance is whether what was written by the child can be read by the child, parent, or teacher. Letter formation may be the most critical element to determine legibility.⁵³ Five features affecting legibility include: (1) improper letterforms, (2) poor leading in and leading out of letters, (3) inadequate rounding of letters, (4) incomplete closures of letters, and (5) incorrect letter ascenders and descenders.¹ *Alignment*, or baseline orientation, refers to the placement of text on and within the writing guidelines. *Spacing* includes the dispersion of letters within words and words within sentences⁶⁹ and text organization on the entire sheet of paper. Another component of legibility, *size*, refers to the letter relative to the writing guidelines and to the other letters. Finally, the uniformity or consistency of the *slant* or the angle of the text should be observed. Figure 18-5 illustrates errors of letter formation and size in a child’s cursive writing. Typically, legibility is determined by counting the number of readable written letters or words and dividing it by the total number of written letters or words in a writing sample. Therefore if a child produces 20 legible letters when writing the lowercase alphabet, his percentage legibility is 77% (20/26). Experts suggest “cut-off” legibility percentages for poor and good handwriting. Occupational therapy practitioners often

use the range of 75% to 78% to discriminate between satisfactory and unsatisfactory handwriting legibility. Students who score above 75% on the Evaluation Tool of Children’s Handwriting tend to achieve satisfactory handwriting grades and those below 75% tend to receive unsatisfactory grades.⁶⁷ In a large study of 900 students, legibility scores were found to be consistent across grades one through four, improve between fourth and sixth grade, and to maintain in middle school.⁴⁹

Determining appropriate educational and therapeutic services for children requires assessment beyond legibility scores and involves an entire team, including the child’s parents. Thus, the occupational therapist must carefully and comprehensively assess the nature of the child’s handwriting problems and give recommendations based on this process.

Writing Speed

In addition to legibility, a child’s rate of writing, or the number of letters written per minute, is a cornerstone of functional handwriting. Students may take longer to complete written assignments, have difficulty taking notes in class,⁴⁶ lose their train of ideas for writing,⁷⁴ and become frustrated when their handwriting speed is slower than that of their peers. Writing speed typically decreases when the amount of written work or complexity of the writing task increases.¹¹⁹ Upper elementary and older students need not only an adequate writing speed, but also the ability to adjust their speed from a hurried, rough draft to a neat, well-paced final one.¹¹⁹

Studies of handwriting speed in elementary age students show that handwriting speed increases gradually, becoming faster in each succeeding grade.^{49,55,90,124} However, the studies’ findings also suggest that the increase in speed may not be linear but marked by various spurts and plateaus. Handwriting speed per grade level has been found to be highly variable when different study designs and writing conditions are used.

Because of the wide range of handwriting speeds, children’s writing rates need to be considered individually within the context of their classroom. Teacher expectations and classroom standards may influence children’s writing speeds. Thus, it is appropriate to compare a student’s writing speed performance with the rates of classroom peers. In general, handwriting speed is problematic when a student is unable to complete written school assignments in a timely manner.

Ergonomic Factors

Ergonomic and environmental factors influence handwriting performance, and therefore the biomechanics of writing posture, upper extremity stability and mobility, and pencil grip are analyzed as the child writes. The therapist observes the student’s typical sitting posture when writing. Does the child rest his or her head on the forearm or desktop when writing? Is the child falling out of or slumping in his or her chair? Does

FIGURE 18-5 Cursive handwriting sample exemplifies improper letterforms and disproportionate letter size.

the child stand beside the desk or kneel in the chair? Are the desktop and the chair at suitable heights?

Stability and mobility of the upper extremities (i.e., the ability to keep the shoulder girdle, elbow, and wrist stable) allow the dexterous hand to manipulate the writing instrument. Does the child write with whole-arm movements? What are the positions of the trunk and writing arm? Does the nonpreferred hand stabilize the paper? Does the child apply excessive pressure to the writing tool?

Which grasping pattern is used? Does the student use a variety of atypical grasps or mature, dynamic grasps, as defined? When biomechanical and ergonomic factors are optimal the efficiency in handwriting performance significantly improves.⁹⁸

Handwriting Assessments

Formal or standardized tests are important for assessing the performance of children, as they provide objective measures and quantitative scores, aid in monitoring a child's progress, help professionals communicate more clearly, and advance the field through research. Assessment tools commonly used by occupational therapists in the United States are listed in Box 18-2.

Each of these assessment tools possesses various features regarding domains of handwriting tested (e.g., far-point copying, dictation), age or grade of child (e.g., first and second grades), script examined (e.g., cursive), scoring procedures of the writing performance (e.g., legibility of manuscript), and

scores obtained (e.g., percentiles). Typically, tests measure handwriting legibility and speed of handwriting. Scoring procedures for legibility use rating techniques ranging from global and subjective to detailed and specific.¹¹³ For tool selection, the occupational therapist should keep in mind the characteristics of each assessment as well as the strengths and limitations of the tests regarding normative data, reliability, validity, and other psychometric properties (see Chapter 7). Because scoring legibility always has a subjective element, most legibility assessments have low inter-rater reliability.³⁴ The assessment chosen should provide information about child's handwriting concerns, analyze handwriting performance, and allow for effective intervention planning among the occupational therapist, the child's parents, and other team members.

Interplay of Factors Restricting Handwriting Performance

To understand more fully which element may be interfering with a child's ability to produce text, the occupational therapist considers a child's *performance skills*, *client factors*, *performance patterns*, and *contextual elements*.³ The example in Case Study 18-1 illustrates how various factors may restrict a child's handwriting performance. This example illustrates the complex interactions that determine which factors influence a child's ability to engage in an occupation such as handwriting.

Like Natasha, children with poor handwriting typically have a web of factors that restrict their handwriting performance. For example, Natasha's client factors (i.e., short attention span,

BOX 18-2 Handwriting Assessments

Evaluation Tool of Children's Handwriting (ETCH)

Description: Criterion-referenced test measuring a child's legibility and speed of children's handwriting in grades 1 through 6. Domains (manuscript or cursive) include alphabet writing of lowercase and uppercase letters, numeral writing, near-point copying, far-point copying, manuscript-to-cursive transition, dictation, and sentence composition.

Author: Susan J. Amundson, MS, OT (1995)⁵
Publication: O.T. KIDS, Inc.

Here's How I Write: A Child's Self-Assessment of Handwriting and Goal-Setting Tool (HWII)

Description: Criterion-referenced tool for students in the second through fifth grade, which uses the students' own assessments of handwriting to set goals for improvement. Interviews are conducted using picture cards to assess handwriting performance, feelings about handwriting, and physical factors related to handwriting.

Authors: Sarina Goldstand, Debbie Gavir, Sharon A. Cermack, and Julie Bissell (2013)⁴⁴
Publication: Therapro Inc., www.therapro.com

Minnesota Handwriting Assessment (MHA)

Description: Norm-referenced test that looks at quality and speed of manuscript handwriting of a near-point copying task. Models are in Zaner-Blöser or D'Nealian script for children in grades 1 and 2.

Author: Judith Reisman, PhD, OT (1999)⁹⁵
Publication: Therapy Skill Builders/ Psychological Corporation

Shore Handwriting Screening for Early Handwriting Development

Description: Screening tool that examines handwriting skills for students from ages 3 to 7 by assessing postural control, head control, letter and number formation, and environmental factors.

Author: Leann Shore (2003)¹⁰⁵
Publication: Pearson Shorehandwriting.com

Test of Handwriting Skills

Description: Norm-referenced test that examines both manuscript and cursive handwriting through dictation, near-point copying, and alphabet writing from memory. Normative data are provided for children 5-11 years old.

Author: Morrison F. Gardner (1998)⁴¹
Publication: Psychological and Educational Publications, Inc.

The Print Tool

Description: The Print Tool is a complete printing assessment for students age 6 and older. The Print Tool assesses capitals, numbers, and lowercase letter skills. The skills evaluated include memory, orientation, placement, size, start, sequence, control, and spacing.

Authors: Jan Z. Olsen, OTR and Emily F. Knapton, OTR/L (2006)⁸⁷

CASE STUDY 18-1 Natasha

Natasha, a 9-year-old girl with a traumatic brain injury, has an illegible script marked by overlapping letters, poor use of writing lines, and many dark erasures. When evaluating Natasha's writing performance in her classroom, the occupational therapist observes that her performance skills, particularly her fine motor coordination, are limited. In-hand manipulation skills are poor as Natasha struggles to turn her pencil from the writing position to the erasing position, manage her worksheet, and use her eraser for correcting errors. When she engages in classroom activities, the occupational therapist observes that Natasha demonstrates a short attention span and impulsiveness. Natasha has difficulty sustaining her attention to desktop work and the teacher's verbal instructions.

Furthermore when the occupational therapist examines a story that Natasha wrote earlier during the day, it is apparent that she has not incorporated the habit of writing her text on the lines of the paper. Because she does not adopt this performance pattern, Natasha's text bumps above and below the writing baseline on her paper, resulting in an unreadable story. Finally, the occupational therapist is told by a classroom paraprofessional that Natasha uses English as a second language because of her recent emigration to the United States. Consequently the occupational therapy practitioner recognizes that her cultural context may be affecting her overall performance in the classroom.

impulsiveness) and cultural context (i.e., English as a second language) interact with one another to restrict her handwriting performance. Natasha's short attention span diminishes not only her ability to learn handwriting, but also her ability to learn new concepts, including her second language, English. Because she has limited understanding of language symbols, words, and syntax of the English language, she has difficulty reading English. Furthermore, because reading and writing are parallel learning processes, it is probable that Natasha's handwriting is limited. Natasha's handwriting is more likely to improve once effective compensatory and remedial techniques are in place to improve her attention span and her knowledge and use of the English language.

Educator's Perspective

State standards for written language and literacy, as well as the district curriculum, should be used to guide evaluation and intervention. When educators speak of the writing or composing process, they view it as a goal-directed activity using the cognitive functions of planning, sentence generation, and revision. The actual text production occurs in sentence generation; thus, the child who needs to pay considerable attention to the mechanical requirements of writing may interrupt higher-order writing processes, such as planning or content generation. Hence, most educators view the mechanical requirements of handwriting as an integral subset of the writing process.

Handwriting Instruction Methods and Curricula

During the past decade, an educational debate has focused on teaching handwriting systematically through commercially prepared or teacher-developed programs, or learning it through a "whole-language" approach. The whole-language philosophy purports that both the substance (meaning) of writing and the form (mechanics) of writing are critical for learning to write.⁴⁶ Thus, when using the whole-language method as children are learning and mastering handwriting, the teacher gives advice and assigns practice on an individual, as-needed basis. For example, if an educator sees a first-grader struggling to form the letter *m* while writing a story about monsters, he or she

may instruct the child regarding the correct letter formation of *m* and encourage extra practice of the letter during the story composition period. Conversely, in a traditional handwriting instruction approach, students are introduced to letter formations and practice them outside the context of writing. For children with learning disabilities and mild neurologic impairments, regular practice in forming letters is essential in the early stages of handwriting development, yet handwriting should have a meaningful context. Thus, a combination of systematic handwriting instruction and whole-language methods may be most beneficial to this group of children.⁴⁶

In the United States, traditional handwriting instruction programs vary among school districts, schools, and grades. It is not uncommon for occupational therapy practitioners to receive a referral for a child with poor handwriting who has never had handwriting instruction! See [Table 18-1e](#) on the Evolve website for evidence on classroom instruction.

The most common instruction methods include Palmer, Zaner-Blöser, Italics, and D'Nealian. Unlike the United States, a few countries, such as the United Kingdom, New Zealand, and Australia,^{1,63,124} have adopted national curricula for handwriting to improve the standards of handwriting assessment and instruction within their school systems (see [Table 18-2e](#) on the Evolve website for handwriting curricula). Early childhood handwriting curricula should include at least six skill areas: (1) small muscle development, (2) eye-hand coordination, (3) holding a writing tool, (4) basic strokes, (5) letter perception, and (6) orientation to printed language. See [Table 18-3](#) for research on handwriting programs. What appears to be important is the implementation of a formal curriculum that allows for ongoing handwriting instruction and practice. Hoy et al.,⁶¹ in an extensive literature review, supported that effective handwriting interventions require 20 or more instructional sessions.

Several handwriting programs have been developed by occupational therapists, which include the Write Start program, Handwriting Without Tears, and Loops and Other Groups.¹³ Write Start is a classroom-embedded, co-taught handwriting program for first grade children that can be implemented with high fidelity by a trained occupational therapists and teachers (see [Case Study 18-2](#)). This program links handwriting and writing, emphasizes frequent feedback to students, and encourages self-evaluation and self-regulation. Using a small group format for practicing handwriting and writing, the teacher and

TABLE 18-2 Activities to Promote Handwriting Readiness

Areas of Handwriting Readiness	Selected Readiness Activities
Improving fine motor control and isolated finger movements	Roll one-fourth- to one-eighth-inch balls of clay or Silly Putty between the tips of thumb and the index and middle fingers. Pick up small objects (e.g., Cheerios or raisins) with a tweezers. Pinch and seal a Ziploc bag using the thumb opposing each finger. Twist open a small tube of toothpaste with the thumb and index and middle fingers. Move a key from the palm to the fingertips of one hand.
Promoting graphic skills	Draw lines and copy shapes using shaving cream, sand trays, or finger paints. Draw lines and shapes to complete a picture story on blackboards. Form and color pictures of people, houses, trees, cars, or animals. Complete simple dot-to-dot pictures and mazes.
Enhancing right-left discrimination Improving orientation to printed language	Connect dots at the chalkboard with left-to-right strokes. Label children's drawings based on the child's description. Encourage book-making with child's favorite topics (e.g., special places, favorite foods). Label common objects in the classroom.

**CASE STUDY 18-2 Write Start Handwriting/Writing Program for First Grade Students**

Write Start is a classroom-embedded handwriting and writing program that is co-taught by the first grade teacher, an assistant, and an occupational therapist. This team plans and implements 24 sessions (12 weeks) in the first half of the first grade year. All students, with and without individualized educational programs (IEPs), are included. The program incorporates evidence-based instruction, small group activities to promote practice and learning of handwriting, and individualized interventions for students with handwriting difficulties. The sessions follow the following format:

Session One

- The therapist teaches two to three lowercase letters, modeling and using consistent verbal cues (e.g., basement letters, tallies and smallies)
- The students practice the letters on small white-boards.
- The students work in small groups (six to eight students) on handwriting-related activities that reinforce skills (e.g., motor planning, visual motor integration)

Session Two

- The therapist leads a review of the letters learned in session one.
- The students complete a writing sample to evaluate their progress.

- The teacher leads a writing workshop (based on the first grade writing curriculum) with all students participating.
- Students write stories to practice their best handwriting and “publish” their stories.

The interventions emphasized in this co-taught program are:

1. Students practice handwriting and writing with intense repetition.
2. Using the small group format, the teachers and therapist provide immediate and specific feedback to students.
3. The teachers and therapist encourage students' self-evaluation.
4. The teachers and therapist encourage and facilitate peer evaluation, peer modeling, and peer supports during the handwriting activities.
5. Each session is based on evaluation of individual and group progress in handwriting and writing (from the weekly writing sample and writing workshop products).

The goals of the Write Start program are to prevent handwriting problems, promote students' interest in writing, help students understand that legible handwriting enables others to read their stories, and provide inclusive services to students who need additional supports to achieve legible handwriting.

See Case-Smith, J., White, S., & Holland, T. (2014). Effectiveness of a co-taught handwriting program for first grade students. *Physical and Occupational Therapy in Pediatrics*, 34, 30–43.

occupational therapist encourage peer support and peer evaluation of handwriting.²⁶ Students who participated in the 12-week program made highly significant gains in handwriting legibility and speed and writing fluency.^{25,27} Handwriting Without Tears (HWT), developed by an occupational therapist for multiple grade levels, is a full curriculum for developing prewriting and writing skills. This program emphasizes multi-sensory activities presented in developmentally appropriate sequences.⁸⁸ The HWT pre-K program for preschool children

promotes prewriting skills by incorporating playing and singing. The activities are designed to enhance sensorimotor skills, social and emotional development, body awareness skills, cognitive and language skills, and visual-perceptual skills that are foundations for handwriting.⁸⁸ Lust and Donica⁷¹ found that supplementing the Head Start Curriculum with HWT Pre-K significantly improves handwriting readiness. See Table 18-2 for activities to promote handwriting readiness.

TABLE 18-3 Handwriting Programs Research

Author(s)	Age/Grade and No. of Children	Program(s)/Frameworks Used	Time	Measures	Effectiveness
Benson, Salls, & Perry (2010) ¹⁵	6 first grade teachers	Handwriting Without Tears (HWT) (used by 3 teachers) Peterson Directed Method (previously used by all 6 teachers; currently used by only 3)	2007-2008 school year	Quarterly journals regarding teachers' experiences and thoughts about curriculum, students' engagement, and garner perceptions were completed by each participant.	Teachers reported that both programs were effective and easy to use but felt each method failed to fully meet their needs and expectations. Less satisfaction was reported with the Peterson method than HWT. Teachers using the Peterson method felt that they had to make more adaptations to the program than those using HWT.
Berninger, Vaughan, Abbott, Rogan, Brooks, Reed, & Graham (1997) ¹⁶	144 first graders	Handwriting styles used: D'Nealian or standard ball and stick Treatment Groups: 1. Motor imitation 2. Visual cue 3. Memory retrieval 4. Visual cue + memory retrieval 5. Copy 6. Control group Rosner's Auditory Analysis Program	Twice a week in 20-min sessions for 24 lessons	Timed measures of handwriting: 6 finger function tasks; 3 timed handwriting tasks; 3 other tasks; Writing Fluency subtest of the Woodcock-Johnson Psycho-educational Battery-Revised; Vocabulary subtest of the Wechsler Intelligence Scale for Children-3rd ed.; Word Attack subtest of the revised Woodcock Reading Mastery Test	Combining numbered arrows and memory retrieval was the most effective treatment for improving handwriting and compositional fluency.
Case-Smith, Holland, & Bishop (2011) ²⁴	19 first grade students	Pilot program	12 weeks	Write Start program—a co-teaching model with OT and teachers	Students made large gains in handwriting legibility (25%) that were maintained through the end of the school year.
Case-Smith, Holland, Lane, & White (2012) ²⁵	36 first grade students	Write Start Intervention implemented as a co-teaching model with occupational therapist and teachers.	12 weeks	Evaluation Tool of Children's Handwriting-Manuscript (ETCH-M); Woodcock-Johnson Fluency and Writing Samples subtest of Woodcock Johnson III Test of Achievement (WJIII)	Students showed highly significant improvement in legibility of lowercase letters. There was also significant improvement in speed of lowercase letters and legibility of uppercase letters. Students also made significant gains in writing fluency and written expression. Students performing lower on subtests showed greater improvement.
Case-Smith, Holland, & White (2014) ²⁷	67 first-grade students, 37 in Write Start classrooms, and 30 in standard classroom instruction	Write Start and standard handwriting instruction	24 45-min sessions that were implemented 2x/week for 12 weeks	Evaluation Tool of Children's Handwriting manuscript, Woodcock Johnson Fluency, and writing samples	Students in Write Start improved significantly in legibility and fluency over regular instruction. Gains in speed and written expression did not differ significantly between groups.

Donica, Goins, & Wagner (2013) ³⁷	58 Head Start students	Fine Motor and Early handwriting Pre-K curriculum (FMEW) HWT-Get Set for School Program	16 weeks	Shore Handwriting Screening for Early Handwriting Development	Handwriting readiness programs are a positive addition to Head Start Center Time
Delegato, McLaughlin, Derby, & Schuster (2013) ³¹	5 preschool students	HWT Program with and without a teacher-made handwriting racetrack	6 weeks	Worksheets scored 0-10	Performance was higher when HWT and racetrack were used than HWT alone.
Graham & Harris (2006) ⁵⁰	30 first-grade students (15 were chosen for program)	CASL First Grade Handwriting/Spelling Program described in article	48 20-min lessons divided into 8 units, with 6 lessons in each unit	Not specified	Students who participated in program made greater gains in spelling, handwriting legibility and fluency, sentence writing, and vocabulary diversity in their compositions immediately after instruction
Howe, Roston, Sheu, & Hinojosa (2013) ⁶⁰	72 public school elementary students in first and second grade	Examine effectiveness of two approaches: intensive HW practice and visual-perceptual-motor activities	12 weeks	Handwriting club on HW speed, legibility, and visual-motor skills	Students in the intensive handwriting practice group demonstrated significant improvements in handwriting legibility compared with the visual-perceptual motor group
Lust & Donica (2011) ⁷¹	Preschool students ages 4-5 in one of two rural Head Start classes	HWT-Get Set for School (HWT-GSS) (intervention group) Standard Head Start curriculum (control group)	Three times a week, for 20 min, from October to March (total of 47 sessions)	Pre Writing Domain of the Learning Accomplishment Profile, 3rd ed. (LAP-3); Check Readiness; Bruininks-Oseretsky Test of Motor Proficiency, 2nd ed. (BOT-2)	Improvements in scores for both groups on all measures. Significantly higher levels of improvement in these skills among students in the intervention group.
Keller (2001) ⁶⁵	Third- and fourth-grade boys	HWT; use of many sensory integration activities including the program How Does Your Engine Run?	Twice a week for 30-min sessions (reported as not being long enough)	Not specified	Students improved cursive writing skills and social skills. They learned which sensory activities helped them to focus and self-regulate. Students felt more confident in handwriting abilities.
Mackay, McCluskey, & Mayes (2010) ⁷²	32 children in Australia; ages 6-8 (first and second grade); received a score of 30 or less on the Minnesota Handwriting Assessment (MHA)	Long Handwriting Program (LHP), which utilizes task-specific training	8 weekly sessions, lasting 45 min, conducted in groups of two or three	Minnesota Handwriting Assessment	Evidence that the approach is clinically worthwhile based on statistically significant improvements in legibility, form, alignment, size, and space. No improvements in speed.

TABLE 18-3 Handwriting Programs Research—cont'd

Author(s)	Age/Grade and No. of Children	Program(s)/Frameworks Used	Time	Measures	Effectiveness
Marr & Dimeo (2006) ⁷⁴	26 students ages 6.2-11.9 Grades 1-6	HWT	1 hour per day for 2 weeks	Evaluation Tool of Children's Handwriting (ETCH); Likert ratings provided by parents pretest, posttest, and 3 months posttest	Significant changes in legibility of writing the uppercase and lowercase alphabets. Improvements in two subtests of ETCH and in parent ratings.
McGarrigle & Nelson (2006) ⁷⁶	16 first-grade students (13 completed end-program testing)	Interventions developed by third-year occupational therapy students. Frameworks used: sensorimotor, biomechanical, teaching-learning principles, and principles of practice when working with indigenous children.	80-min sessions once a week for 6 weeks	Beery-Buktenica Developmental Test of Visual-Motor Integration (VMI); Connors' Abbreviated Symptom Questionnaire (ASQ); non-standardized handwriting measures; non-standardized scissor skills measure	Significant improvements in sitting posture, pencil grasp, pencil pressure, and paper stabilization/positioning. Students improved their tracing and copying accuracy and letter inclusion, legibility, and formation when writing their names and letters of the alphabet. Improved in aspects of handwriting, scissor skills, and behavior.
Peterson & Nelson (2003) ⁸⁹	59 first graders (30 selected for intervention group) Students' mean age: 7.1 yr	D'Nealian handwriting; frameworks: biomechanical, sensorimotor, and teaching-learning principles	30-min sessions, twice a week, for 10 week	Minnesota Handwriting Test	Intervention group demonstrated a significant increase in scores on the posttest of the Minnesota Handwriting Test when compared with scores of the control group.
Ratzon, Efraim, & Bart (2007) ⁹⁴	52 first-grade students (24 participants in intervention group)	Graphomotor intervention program developed by Efraim (2002) Activities and tools based on Benbow's recommendations. Frameworks: motor learning, multisensory, and research that found associations between dexterity skills and normal development of visual-motor proficiency	12 sessions, once a week, for 45 min	Beery-Buktenica Developmental Test of Visual-Motor Integration (VMI); Developmental Test of Visual Perception (DTP-2); Motor Development Scale of the Bruiniks-Oseretsky Test of Motor Proficiency	Students in intervention group made significant gains in the total score on the graphomotor test (DTP-2) and on the fine motor test (Bruiniks-Oseretsky Motor Development Scale)
Roberts, Siever, & Mair (2010) ⁹⁶	72 fourth to sixth grade students identified by teachers as having handwriting difficulties	Remediation group based on the Loops and Other Groups Program provided by occupational therapist in small groups after school	60-min sessions, once a week, for 7 weeks	Copying a Phrase; Handwriting subtest of the Test of Written Language; Alphabet Samples; Test of Writing Language (TOWL) Handwriting subtest; Handwriting Evaluation Scale (HES); Speed of copying task; Development of the Attitude Scale to measure satisfaction, Parent/Teacher Report	Improvements in scores on the TOWL that were not found to be related to grade, gender, or amount of homework. Improvements in HES for connected alphabet and all areas except size in unconnected alphabet. Increases in speed and personal satisfaction scores. Improvements more substantial for copying than composition.

Salls, Benson, Hansen, Cole, & Pielielek (2013) ¹⁰⁰	31 typically developing first grade children	Compared the effects of HWT and Peterson Directed Handwriting Curriculum	9-month school year	Print Tool, VMI, Minnesota Handwriting Assessment	Implementation of a structured curriculum may be key to developing good handwriting skills
Shimel, Candler, & Neville-Smith (2009) ¹⁰⁵	50 third grade students without identified handwriting problems	Compared the effects of cursive handwriting programs in improving letter legibility and form	10-15 min per day for 6 weeks	A shift in instruction using either HWT, Loops and Other Groups, or a control (continued use of Zaner-Blöser)	All improved with no significant differences between groups—a shift in handwriting instruction method did not interfere with learning
Taras, Brennan, Gilbert, & Reed (2011) ¹⁰⁹	211 students in 14 kindergarten classes from 12 schools in San Diego (participating in program) 171 students from similar classes (not participating in program)	Write Direction handwriting skill development program used for treatment group	30-min lessons, once a week for 14 weeks	Routine district-level functional measurement tool which included: • Legibility • Formation • Line approximation • Line orientation • Proportion • Directionality and reversals • Spacing	Statistically significant improvement in letter tasks (approximation, line orientation, proportion, and directionality) and sentence tasks (line orientation and proportion) for those participating in the Write Direction program
Weintraub, Yinon, Hirsch, & Parush (2009) ¹²¹	55 second to fourth grade students in Israel, with handwriting difficulties (scored 1 SD below the mean on the Brief Assessment Tool for Handwriting [BATH])	Sensorimotor intervention: • Focused on lower and higher level functions • Preparatory activities focused on motor based skills • Letters taught using multisensory techniques Task-oriented intervention: • Focused on higher level functions • Direct practice and feedback • Focused on writing words and sentences Nontreatment control group	Programs offered in altering order, four times a year for 2 years. Each program consisted of 8 weekly 1-hour sessions.	BATH; Motor Accuracy Test (MAC) subset of SJPT; Developmental Test of Visual Perception-2 (VTVP-2); Balance and Upper-Limb subtests of Bruninks-Oseretsky; Test of Motor Proficiency; Pediatric Examination of Educational Readiness at Middle Childhood; HHE as outcome measure	Control group did not show significant improvements. Both groups found to significantly improve legibility and formation. Long-term measures (4 months after intervention) found significantly higher scores for task-oriented group than sensorimotor group only with spatial organization.

Manuscript and Cursive Styles

In most elementary schools, manuscript writing is taught in grades one and two, and cursive writing is taught at the end of grade two or the beginning of grade three.⁸ The need for manuscript writing may continue throughout life, when students label maps and posters, adolescents complete job or college applications, and adults complete federal income tax forms. By middle school, many students blend manuscript and cursive to form their own style of handwriting. To date, no research has decisively indicated the superiority of one script style over the other.

Both manuscript and cursive possess complementary features, and these should be considered when the occupational therapist, child, child's parent, and educational team are collaboratively deciding which style might best serve the child.

Manuscript is endorsed for the following reasons:

1. Manuscript letterforms are simpler, easier to visually discriminate, and hence easier to learn.
2. It closely resembles the print of textbooks and school manuals.
3. It is needed throughout adult life for documents and applications.
4. It is more readable than cursive.
5. The traditional vertical alphabet is more developmentally appropriate, easier to read, and easier to write for young children, as well as easier for educators to teach, than the slanted alphabet.

Advocates of cursive writing point out the following:

1. Cursive movement patterns allow for faster and more automatic writing.
2. Reversal of individual letters and transpositions of words are more difficult than in manuscript.
3. One continuous, connected line enables child to form words as units.

Handwriting Intervention

In school settings, if the referred student's educational team decides that functional written communication is a priority for the student's individualized educational program (IEP), the occupational therapist may be instrumental in directing and guiding this aspect of the program. Typically, the team uses either a remedial or a compensatory intervention approach, or both, to improve the child's written communication. Compensatory strategies improve a student's participation in school with accommodations, adaptations, and modifications for certain tasks, routines, and settings,^{6,66,107} whereas remedial approaches improve or establish a student's functional skills in a specific area.

When the team focuses on the occupation of written communication, generally both remedial and compensatory techniques are concurrently used. For example, Hunter, a second-grader, has manuscript handwriting that is unreadable; about 60% of his written letters are not legible; and his writing speed is at the bottom of his class. Although he participates in an intensive handwriting remediation program, he needs accommodations and strategies that help him achieve functional written communication in the classroom. Consequently his teacher decided to adjust the time required to complete

assignments, allow him to use oral reporting for certain class assignments, or require a lower volume of work to be accomplished than that of his peers. The teacher and the occupational therapist select specific techniques to assist him with legibility, such as spacing between words, sizing letters, and placing text on lines. Readiness activities that are easy to incorporate into the classroom can be embedded in his daily routine. Providing varied and interesting writing materials in the classroom and home allow the opportunity to embed meaningful writing experiences into activities.⁸⁵

When a child's handwriting is both illegible and slow, team members may occasionally decide to incorporate assistive technology, such as a computer, tablet, or portable word processor. E-mail and texting are increasingly important methods for personal communication.⁴² The student and the team, particularly the occupational therapy practitioner, must work to find a technologic system that allows the student proficiency in text generation.¹⁰⁶ As in handwriting, computer use requires adequate attention, motor control, sensory processing, visual functioning, and self-regulation from the student. Small studies show that word processing with word prediction can improve the legibility and spelling of written assignments.⁵⁶ However, the computer is not a magical tool but one that allows the child to acquire keyboarding and word processing skills through planning, routine instruction, and practice. In this age of technology, it is important for all students to develop keyboarding skills for computer use in the classroom, workplace, and home. However, handwriting skills continue to be needed throughout student and adult life. Table 18-4 lists the assistive technology features and the potential benefits of word processing for the student who struggles with handwriting. Table 18-3c on the Evolve website lists forums that occupational therapists can access to learn about specific applications and programs.

Models of Practice to Guide Collaborative Service Delivery

Models of practice and strategies used by occupational therapists may be unfamiliar to children, educators, parents, and other school personnel. Therefore the occupational therapist must be able (1) to clearly articulate intervention techniques, activity modifications, and classroom accommodations being used; (2) to collaborate with the teacher and others to provide service in the least restrictive environment; (3) to implement therapeutic strategies for improving written communication; (4) to train others to work with children with handwriting problems; and (5) to closely monitor the progress of the child and change aspects of the program to continue improvement.

The overall focus of the educational program is the improvement of student performance in a particular area (e.g., written communication). Occupational therapy models of practice that guide services to improve handwriting include (1) acquisitional/motor learning, (2) sensorimotor, (3) biomechanical, (4) cognitive, and (5) psychosocial. Surveys of occupational therapists in the United States¹²¹ and Canada⁴⁰ indicate that the most frequently applied theoretical approaches to children's handwriting intervention are multisensory (92%, United States) and sensorimotor (90%, Canada). However, occupational therapists most often combine various theoretical approaches for handwriting intervention,⁴⁰ and this use of multiple approaches is advocated in the pediatric occupational

TABLE 18-4 Assistive Technology to Support Handwriting Skills

Assistive Technology	Description
Text to speech	Speaks as the student types letters, words, and sentences. Speaks if text is selected and text-to-speech is then activated. May highlight word and/or sentence as it speaks. Voice (e.g., male/female) can be selected as well as speed of speech.
Electronic spell check	Provides immediate feedback about what has been typed and allows opportunities for self-correction. Spell check after production of writing. In-line spell check with visual supports. In-line spell check with visual and auditory cues. Phonetic spell check. Talking spelling suggestions for misspelled words.
Picture-supported text or picture library	Pictures appear as the students type words for building a sentence or story with pictures only. Pictures can be sized and location can often be selected (above or below text). Some programs will allow a choice of picture libraries used with the text including GIFs (animated pictures). Picture-supported text often has text-to-speech feature.
Abbreviated expansion	Freestanding or embedded software that allows users to create their own shortened abbreviations for commonly used words or phrases. The abbreviation is often expanded by using a modifier key after the abbreviation is typed into the document. The purpose of abbreviation expansion is to reduce the number of keystrokes needed to create a typed document.
Word prediction	Software-embedded word prediction. Independent word prediction. Frequency-weighting word prediction. Grammatically based word prediction (use of syntactic rules). Phonetic word prediction. Content-specific word prediction (e.g., custom dictionaries, extraction of text from digital reading materials). Adjustable number of word prediction choices displayed. Auditory preview of words predicted before selection. In-line versus stationary word prediction. Picture-supported word prediction.
Electronic word and sentence banks	When selected, pictures, words, or sentences contained in a cell/button can be placed in a word processing document. Cells/buttons can be combined together to create a grid/toolbar. Cells/buttons/toolbars/grids can be linked so they can be dynamically displayed onscreen at different times. Cells/buttons/toolbars/grids can be scanned so that switch users can have alternate access for writing activities. Some programs will allow “drag and drop” features of words within the word processor so that cells/buttons/grids/toolbars are not needed.
Voice recognition software	The user speaks into a microphone and the words are converted by the computer into text. Users must “train” and “correct” the system for their unique speaking style. Training and correction can be time consuming, but has improved in the last 5 years. Users need to be able to remember specific commands to direct the computer. Environmental noise can be an issue for reliable detection of text. It is a hands-free text entry system.

therapy literature.^{23,89} Current research suggests that motor learning approaches using task-oriented interventions appear to have efficacy.^{27,121}

The occupational therapist must be skillful in the use of one or several models of practice concurrently and in teaching others to implement strategies originating from these models of practice. By remaining focused on the child’s occupational outcome related to writing and applying various models of practice in the child’s educational program, the occupational therapy practitioner can provide appropriate opportunities for the child to learn and master the skill of written communication. A systematic review of handwriting interventions that are considered within the domain of occupational therapy practice concluded that handwriting intervention is effective only if

it includes handwriting instruction and practice.⁶¹ Further research to identify effective components of handwriting instruction and efficient means of delivering sufficiently intensive intervention is warranted. Table 18-3 describes the evidence for handwriting intervention effectiveness.

Acquisitional and Motor Learning Approaches

Handwriting may be viewed as a complex motor skill that “can be improved through practice, repetition, feedback, and reinforcement” (p. 70).⁵⁹ Researchers have demonstrated that children develop functional handwriting skills when direct handwriting instruction is (1) individualized to the child, (2) planned and changed based on evaluation and performance

data, and (3) overlearned and used in a meaningful manner by the child. When therapists and educators employ these conditions in a positive, interesting, and dynamic learning environment, children are more likely to become efficient, legible writers.⁸ Therapeutic practice was more effective at improving handwriting performance than sensorimotor-based intervention.³³

For occupational therapy practitioners, motor learning theories apply to handwriting instruction. Learning a new motor skill has been described as progressing through three phases: cognitive, associative, and autonomous. First, in the *cognitive phase*, the child is attempting to understand the demands of the handwriting task and develop a cognitive strategy for performing the necessary motor movements. Visual control of fine motor movements is thought to be important at this phase. A child learning handwriting in this phase may have developed strategies for writing some of the easier manuscript letters, such as *o*, *l*, or *t*, but may have more difficulty writing complicated letters, such as *b*, *q*, or *g*.

In the *associative phase*, the child has learned the fundamentals of performing handwriting and continues to adjust and refine the skill. Proprioceptive and kinesthetic feedback becomes increasingly important during this phase, whereas reliance on visual cues declines. For example, in the associative phase a child may have mastered the formation of letters but is engaged in improving the handwriting product by learning to space words correctly, to write letters within guidelines, or to maintain consistent letter slant. Children continue to need practice, instructional guidance, and self-monitoring strategies of handwriting performance.

In the *autonomous phase*, the child can perform handwriting automatically with minimal conscious attention. Variability of performance is slight from day to day and the child is able to detect and adjust for any small errors that may occur.¹⁰⁰ Once the child has reached this level of handwriting, his or her attention can be expended on other higher-order elements of writing⁴⁶ or it can be saved to alleviate fatigue.¹⁰⁰ Repetition and practice are important elements enhancing children's handwriting skills. Students in an intensive practice group improved significantly more than students in the visual-perceptual-motor activity group.⁶⁰

Implications and strategies for handwriting instruction and remediation evolve from reviews of handwriting studies⁶² as well as motor learning theory.⁷² Many handwriting intervention programs are commercially available. (See Table 19-4e on the Evolve website for brief descriptions of and ordering information for these programs and a list of Internet resources.) Each should contain a scope and sequence of letter and numeral formations along with successive instructional techniques. To date, no empiric evidence reveals one commercial handwriting program to be more effective than another.

The scope and sequence of the handwriting intervention program should focus on a structured progression of introducing and teaching letter and numeral forms. Frequently, letters with common formational features are introduced as a family, such as the lowercase letters *e*, *i*, *t*, and *l*. After the child has mastered these letters, he or she can use them immediately to write the words *eel*, *tile*, and *little*. Whether the chosen handwriting intervention method is a commercially available or a teacher- or therapist-prepared method, each child's program should be individualized with focus on the child's specific delays. Thus, the focus of the child's program is to sequentially

introduce new letters and use them with mastered letters. The therapist also guides, reinforces, and monitors the child in relearning letters formed incorrectly.²⁴ Combining newly acquired letters with already mastered letters allows the child to write in a meaningful context (i.e., the formation of words and sentences). This immediate reinforcement of writing words is more powerful and purposeful for the child than writing strings of letters repeatedly.²⁵

Instructional approaches of handwriting intervention programs vary but tend to comprise a combination of sequential techniques including modeling, copying, stimulus fading, composing, and self-monitoring.^{48,52} When acquiring new letterforms, initially the child often needs many visual and auditory cues. However, the service provider fades out the cues as soon as the child can successfully form the letter without them. Next, the child proceeds to copying letters and words from a model and then to writing letters and words from memory as they are dictated. Finally, the child advances to generating words and sentences for practice. In each phase, the child is encouraged to correct his or her own work, also known as self-monitoring. Students can identify their best letters or words, can read what they have written to identify words difficult to read, and can share their self-reflection with peers or the therapist.^{27,57}

Acquiring handwriting skills and applying them in school means the educational team focuses not only on letter formation but also on the legibility and speed of the student's handwriting. In addition to correct letterforms, other components of legibility include spacing, size, slant, and alignment. Spacing between letters and words, text placement on lines, and sizing letters often need direct modeling and instruction.

Sensorimotor Interventions

The parameters for this model of practice, when applied by the occupational therapist with children with handwriting problems, include providing multisensory input through selected activities to reinforce learning. When given various meaningful sensory opportunities at a level that permits assimilation, the child's nervous system can integrate information more efficiently to produce a satisfactory motor output (e.g., legible letters in a timely manner). All sensory systems, including the proprioceptive, tactile, visual, and auditory, can be accessed and reinforced within a handwriting intervention program. For example, providing novel and interesting materials for children to practice letterforms may keep students motivated, excited, and challenged, thereby enhancing student success and learning. Children with handwriting difficulties who have experienced frustration with commonly used paper-and-pencil drills may respond more favorably to handwriting instruction using a multisensory format. Although, fundamentally, multisensory approaches provide students with more information for learning and can increase motivation, a study that compared sensorimotor interventions with therapeutic practice of handwriting found that children received handwriting practice improved more in handwriting performance.³³

Writing tools, writing surfaces, and positions for writing are all integral parts of a sensorimotor approach. Examples of writing tools to be used are felt-tip pens (regular, overwriter, changeable-color), crayons (scented, glittered, glow-in-the-dark), paintbrushes, grease pencils or china markers, weighted pens, mechanical pencils, wooden dowels, vibratory pens, and chalk. Children's interest in and feelings about writing might

TABLE 18-5 Strategies for Handwriting Problems

Handwriting Problems	Potential Solutions
Spacing between letters	Use finger spacing with index finger. Use fingerprint spacing by pressing on an inkpad before finger spacing. Teach the "no touching rule" of letters.
Spacing between words	Use adhesive strips (e.g., Post-It Notes) as spacers between words. Make spaces with a rubber stamp. Use a dot or a dash (Morse code) between words.
Spacing on paper	Use grid paper. Write on every other line of the paper. Draw colored lines to mark (e.g., green is left, red is right).
Placing text on lines	Use pictorial schemes on writing guidelines. Provide raised writing lines as tactile cues for letter placement. Remind students that unevenly placed letters are "popcorn letters."
Sizing letters and words	Use individualized boxes for each letter. Name letters with ascending stems, no stems, and descending stems, "birds," "skunks," and "snakes," respectively.
Near-point copying	Highlight the text on the worksheet to be copied. Teach the students to copy two or three letters at a time.
Far-point copying	Enlarge print for better viewing. Start with copying from nearby vertical models. Position the student to face the chalkboard.
Dictation	Attach an alphabet strip to the desktop for the student who cannot remember letterforms. Dictated spelling words can contain several but not all letters.
Composition	Be certain that students can form letters from memory. Provide magnetic words to write short poems or stories.
Speed	Allow students to begin projects early to finish with peers. Photocopy math problems from textbook to reduce copying. Preselect volume of work to be done that may be different from that of peers.

Modified from Amundson, S. J. (1998). *TRICS for written communication: Techniques for rebuilding and improving children's school skills*. Homer, AK: O.T. KIDS.

improve when allowed to use a variety of writing tools. Writing with chalk, grease pencils, or a resistive tool also provides additional proprioceptive input to children, because more pressure for writing is required than with the traditional tools of paper and pencil. Unconventional writing tools and writing on textured surfaces can be easily incorporated into classroom assignments.

Colored lines on the paper or paper with raised lines can be helpful for the child who has difficulty knowing where to place the letters on the page. In addition, green lines drawn to symbolize *go* on the left side of the paper and red lines to symbolize *stop* on the right side may help a child know which direction to write his or her letters and words. Upright orientation of the writing surface may also lessen directional confusion of letter formation (*up* means up and *down* means down) versus orientation at a desk on a horizontal surface, where *up* means away from oneself and *down* means toward oneself.¹⁰¹

Biomechanical Approaches

Ergonomic factors such as sitting posture, paper position, pencil grasp, writing instruments, and type of paper influence handwriting quality and speed. Therapists implement compensatory strategies, including adaptive devices, procedural adaptations, and environmental modifications, to improve the interaction and fit between a child's capabilities and the demands of the handwriting task. This model emphasizes modifications to the

student's context to improve handwriting and written production. Various strategies for addressing handwriting problems that combine sensorimotor, biomechanical, and compensatory approaches are listed in Table 18-5.

Sitting Posture

Although standing and lying prone may be encouraged as alternative writing positions, students continue to spend much of the school day seated at a desk. Therefore the occupational therapist should immediately address the student's seated position in the classroom. An optimal writing posture includes the student sitting with the feet planted firmly on the floor, providing support for postural shifts and adjustments.¹⁴ The table surface should be 2 inches above the flexed elbows when the child is seated in the chair. In this position, the student can experience both symmetry and stability while performing written work. To facilitate appropriate seating for students, the occupational therapy practitioner may recommend adjusting heights of desks and chairs, providing footrests for children, adding seat cushions and inserts, or repositioning a child's desk to face the chalkboard in the classroom. Compared with standard school furniture, the use of specialty school furniture did not lead to immediate gains in printing legibility for children with cerebral palsy.⁹⁹

Paper Position/Writing Surface

Paper should be slanted on the desktop so that it is parallel to the forearm of the writing hand when the child's forearms are

resting on the desk with hands clasped.⁷⁰ This angle of the paper enables the student to see his or her written work and to avoid smearing his or her writing. Right-handed students may slant the top of their paper approximately 25 to 30 degrees to the left with the paper just right of the body's midline. Conversely, a slant of 30 to 35 degrees to the right and paper placement to the left of midline are needed for students using a left-handed tripod grasp. For the student with a left-handed "hooked" pencil grasp lacking lateral wrist movements, slanting the paper to the left is appropriate. The writing instrument should be held below the baseline, and the nonpreferred hand should hold the writing paper.

Writing on slanted surface (20- to 30-degree slant) can improve the child's pencil grasp. The slant automatically positions the hand in wrist extension and tends to angle the hand into some supination. A wrist-extended position facilitates finger flexion and grasp. In addition, the hand on a slanted surface is positioned closer to the eyes, which can facilitate the eyes' tracking of the hand's movement. Use of a vertical or semi-vertical surface can also promote more upright posture. Figure 18-6 shows an example of a slant board used in a first grade classroom.

Pencil Grip

Benbow¹⁴ defined the ideal grasp as a dynamic tripod with an open web space. With the web space open (forming a circle), the thumb and index and middle fingers make the longest flexion, extension, and rotary excursions with a pencil during handwriting. Current researchers agree common grasp patterns include the lateral quadripod, dynamic quadripod, and lateral tripod.^{32,103} Educational team members may consider encouraging a student to modify the pencil grasp when he or she (1) experiences muscular tension and fatigue, also known as writer's cramp; (2) demonstrates poor letter formation or writing speed; (3) demonstrates a tightly closed web space that limits controlled precision finger and thumb movements; or (4) holds the pencil with too much pressure or exerts too much pencil point pressure on the paper.

FIGURE 18-6 A slant board can be helpful when a student is first learning handwriting because it promotes wrist extension and an efficient pencil grasp. Eye-hand coordination may be easier with the hand closer to the child's eyes.

A variety of prosthetic devices and therapeutic strategies are available to assist the child in positioning the digits for better manipulation of the writing instrument.⁶ The occupational therapist should be knowledgeable about hand functions to determine which adaptive devices and techniques are most appropriate for each individual child. Stetro grips, triangular pencils, moldable grips, and the pencil grip may facilitate tripod grasps. Writing muscle tension and fatigue may be reduced for some children by using a wide-barreled pencil. To gain more mobility of the radial digits, children may hold a small eraser against the palm with the ulnar digits, allowing for more dynamic movement of the pencil. Older children with hand hypotonicity may achieve a viable pencil grasp by holding the pencil shaft between the web space of the index and middle fingers with thumb opposition.¹⁴ Other techniques to encourage the delicate stability-mobility balance of a functional pencil grasp include the use of external supports such as microfoam surgical tape, ring splints, and neoprene splints and should be used with a working knowledge of hand anatomy and kinesiology. A rubber band sling that encourages the student to use a slanted and relaxed pencil position for writing is shown in Figure 18-7.

In attempting to modify a grip pattern, the educational team needs to carefully consider a child's age, cooperation, and motivation along with the child's acceptance of a new grip pattern or prosthetic device before attempting to reposition the child's fingers. Modifying a grasp pattern may be more successful with younger children, and once grip positions have been established, they are very difficult to change.¹⁴

Writing Tools

The type of writing instruments children use in the classroom also warrants consideration. Bralecki and Rice¹⁸ found that the diameter of a pencil does not have an effect on legibility of a child's handwriting when compared with the size of his or her hand. In general, children should be allowed to choose among a variety of writing tools; parents and teachers may help the individual child determine which writing utensil

FIGURE 18-7 A rubber band sling allows for a slanted, relaxed pencil position.

is most efficient and comfortable. Traditionally, kindergarten and primary grade classroom teachers have promoted the use of a wide primary pencil for beginning writers. Carlson and Cunningham²² examined tool usage among preschool children performing drawing, tracing, and writing tasks. They found that the readability of their written work was not enhanced by the use of a wider diameter pencil. This study suggests that the pervasive use of the primary pencil is probably not warranted for all kindergarten children because some children perform better with a no. 2 pencil, whereas others do well with a primary pencil.

Cognitive Interventions

Cognitive interventions for handwriting are based on learning theories that involve self-instruction and verbal mediation,⁸⁰ as well as strategies of imitation, practice, self-evaluation, and feedback.^{53,90} One top-down cognitive approach is the Cognitive Orientation to (daily) Occupational Performance (CO-OP).^{81,91} The therapist uses verbally based, highly individualized problem-solving techniques to facilitate motor skill acquisition (see Chapter 11). In this approach the child, facilitated by the therapist, generates his or her own solutions to resolve problematic aspects of task performance using a combination of strategies.⁹¹ The global strategy Goal-Plan-Do-Check provides a problem-solving framework that can be generalized to any task. Within this framework, the child applies domain-specific cognitive strategies to master occupational performance goals.⁹²

For students with cognitive limitations that affect attention, activities to compensate include (1) placing a black mat that is larger than the worksheet underneath it to increase high contrast, thereby assisting visual attention to the worksheet; (2) drawing lines to group materials; and (3) reorganizing worksheets.¹¹⁰ Visual stimuli on a worksheet or in a book can be reduced by covering the entire page except the activity on which the student is working or by using a mask that uncovers one line at a time (Figure 18-8). Reducing competing sensory input in both the auditory and visual modalities can be helpful for some students with poor visual attention. For example, headphones can be worn when working on a visual task. Good lighting and use of pastel-colored paper helps reduce glare. Practice of visual searching techniques, such as using *Where's Waldo?* and similar books, can encourage development of search strategies and visual attention.

Other suggestions include cueing the child to important visual information by using a finger to point, a marker to underline, or therapist verbalization to help the child maintain visual attention. For example, children tend to look at a picture when it is named. Visual work should be presented when the student's energy is highest and not when he or she is fatigued.⁹⁷ In addition the teacher can devise and teach the student time-pressure management strategies.

Strategy training can be used to control distractibility, impulsivity, or a tendency to lose track or to overfocus.¹¹¹ Intervention strategies that are taught to the student may include the following³⁹:

- Attending to the whole situation before attending to parts
- Taking timeouts from a task
- Monitoring the tendency to become distracted
- Searching the whole scene before responding

A handwriting program should support the student's learning style. The student whose preferred learning style is based

FIGURE 18-8 Student uses a mask to uncover one line at a time.

on an auditory system can benefit from verbal cues or self-talk when writing. A student who is a visual learner can benefit from a writing strip on the desk, “word walls,” modeling, and visual cues on the paper for start points. In addition, the therapist can develop cue cards for the student to place on his or her desk with common reversals. Directional cues can be paired with verbal cues for the child who commonly reverses letters and numbers. These cognitive cues rely on visual images for distinguishing letters and include the following:

1. With palms facing the chest and thumbs up, the student makes two fists. The left hand will form a *b* and the right hand will form a *d*.
2. Lower case *b* is like *B*, only without the top loop.
3. To make a lower case *d*, remember that *c* comes first, and then add a line to make a *d*.

Children with visual-cognitive problems often overspace or underspace words. The correct space should be slightly more than the width of a single lowercase letter. When a child has handwriting spacing problems, the occupational therapist may recommend using a decorated tongue depressor or a pencil to space words, or simply have the child use his or her finger as a guide. The child can also imagine a letter in the space to aid in judging the distance.

An effective writing surface for assisting students with text placement and size is a color-coded, laminated sheet. When accompanied by verbal cues from the service provider, this sheet provides immediate visual cues to the child learning letterforms. Beneath the solid, red writing baseline, the color brown represents the “soil” or “ground”; the space above the

FIGURE 18-9 Lined paper with diagrams helps with letter size and the placement of text.

solid baseline and dashed black middle guideline are green for the “grass”; and the space above the dashed guideline to the top solid writing line is blue for the “sky.” For example, the letter *h* would start at the top of the sky, head downward, and end in the grass. This same pictorial scheme can be applied to lined paper for classroom assignments, allowing students strong cues for learning letter placement and size (Figure 18-9).⁶

When students need additional help to stop at lines, templates with windows can be used in teaching handwriting. These templates can be made out of cardboard with three windows; one for one-line letters (*a, c, e, i, m, and n*), one for two-line letters (*b, d, k, l, and t*), and the third for three-line letters (*f, g, j, p, q, z, and y*). It is important to consider that visual memory is used to recognize the letters or words to be written, and motor memory starts the engram for producing the written product. Therefore it may be that motor memory, not visual memory, is the basis for the problem.

Various types of writing paper are available in the educational setting. Unlined paper and lined paper with a dashed middle guideline between the lower baseline and upper line are both commonly used in the early elementary grades. Studies of handwriting suggest kindergartners who use paper with lines and those who use paper without lines do not differ in legibility.^{30,118} Children typically first practice writing letters using wide-spaced (1-inch) lines. As handwriting proficiency improves, usually in third or fourth grade, children use paper with narrow-spaced ($\frac{3}{8}$ -inch) lines.⁸ The occupational therapist and educator can allow the student the opportunity to experiment with paper with different lines and line spacing to determine which supports optimal handwriting.

Psychosocial Approaches

Psychosocial approaches used for children’s handwriting intervention typically focus on improving the student’s self-control and coping skills. Psychosocial approaches also create social contexts for practicing and learning handwriting, recognizing the importance of peer supports, peer modeling, and social interaction to student learning. Occupational therapists reinforce the importance of handwriting for communicating with others, sharing written stories, and sharing personal messages. The therapist uses social communication as a context for

practicing handwriting (e.g., writing a note to parents and addressing an envelope to his or her residence). Sharing with children the importance of readable handwriting and the rationale for intervention, as well as providing positive, meaningful, everyday experiences using handwriting, helps children value the act of handwriting and increases motivation to produce good handwriting. When a child presents a neatly drawn and written (relative to the child’s ability) Thanksgiving Day card at home, the parents can provide social reinforcement. In addition, teachers might reward the child with typically poor handwriting with a special certificate for improved handwriting on receipt of a readable spelling paper or written class assignment. By offering children choices, success, responsibility, and encouragement within the natural setting, therapists teach children to view handwriting as a functional and socially valid skill.

Occupational therapy practitioners also use small groups as a context for handwriting interventions. In Case-Smith et al.,²⁵ students practiced handwriting in small groups, then shared their papers with each other to “circle the best letter.” Peer evaluation appeared to motivate the students and reinforce their best handwriting. By using integrated groups of students with high and low level handwriting, the therapist encouraged peer modeling and natural peer supports (e.g., peer-to-peer encouragement). Occupational therapists have also created handwriting clubs to motivate students and to support handwriting practice by encouraging fun and positive social interactions.⁶⁰

Service Delivery

According to the research, children with disabilities have less instructional time with literacy. The quantity and quality of literacy experiences are dramatically different from those of their peers.⁸³ Providing occupational therapy services to children with handwriting difficulties should be based primarily on the needs of the individual child as determined by the educational or clinical team. Currently many educational teams use a continuum of service delivery that allows for more flexibility, fluidity, and responsiveness to an individual child’s needs (see Chapter 24). Case Study 18-3 illustrates a continuum of services to promote written expression.

Some children are good candidates for improving their manuscript or cursive handwriting through remediation. However, other children are not. The occupational therapist and the child’s clinical and educational teams need to consider compensatory strategies that allow the child with poor handwriting the greatest opportunity for functional written communication. Alternatives to handwriting include keyboarding and word prediction, adapting and reducing the amount of written assignments, dictating assignments, and having study buddies to assist with written expression. In school settings, the educational team, along with the parent(s), determines which type of written communication is or will be most functional for the child and develop a short-term plan (e.g., learning essential manuscript words) and a long-term plan (e.g., learning word processing).

Consultation and training others to implement intervention strategies are often the most appropriate service delivery models to improve children’s handwriting. Alternative service providers (e.g., educators, educational assistants, volunteers, high school students, and parents) can implement techniques and programs when the occupational therapist assumes responsibility for

CASE STUDY 18-3 Continuum of Occupational Therapy Services for Tara

At the beginning of second grade, Tara, a girl with a learning disability, was assessed by the occupational therapist for poor handling of classroom materials and tools (e.g., glue stick, scissors, computer mouse) and illegible handwriting. After a comprehensive occupational therapy evaluation, Tara's parents and the educational team decided to focus on assisting her to become a more proficient writer, with the occupational therapist and the regular education teacher spearheading the intervention program.

The therapist and the teacher met to develop classroom strategies to be implemented. These strategies included positioning Tara's desk directly in front of the chalkboard, reducing the length of her written assignments, and providing her with an alphabet strip attached to her desktop and placed at the recommended angle of her writing paper.

The educator also requested the help of the occupational therapist in implementing motivating exercises to prepare the entire class for their daily creative writing period. The occupational therapist scheduled a time with the teacher and spent 10 to 15 minutes per week (for 4 weeks) teaching the entire class hand-dexterity games before a classroom writing activity. She also provided the teacher with a written handout of games, so the teacher could ask questions and have a later reference.

Because of the extremely poor legibility of Tara's writing, the team chose to have her join an ongoing handwriting

intervention group in the classroom. This group held 25-minute sessions twice a week for three consecutive weeks. During this direct service time, the occupational therapist further assessed individual children. She trained the teacher's assistant to coordinate the handwriting group and address some of the individual problems. The occupational therapist returned to the handwriting intervention session once every 2 weeks to supervise the service provider, monitor the children's progress, and modify the programs when needed. A regular consultation time was established with the educator to evaluate Tara's progress in class, strategize regarding new situations affecting her handwriting performance, and write a progress note to her parents.

In Tara's case, during the first 4 weeks after the initial team meeting, the occupational therapist implemented direct service, training of a teaching assistant, and consulting with the teacher. However, the provision of services was not locked into a set schedule (e.g., two 25-minute sessions per week of direct therapy). By using a continuum of service provision, the occupational therapist initially worked with the teacher, orchestrated an ongoing intervention program that another service provider could implement after training, and continued to make regular contact with Tara and the educational team members, including Tara's parents.

organizing, modeling, and teaching the methods. When intervention methods are implemented by others, the occupational therapist regularly monitors, provides feedback, and adjusts techniques as needed. Practicing through homework should be used on an individual basis, after consideration of how this fits with the child's interests, ability, and occupational engagement.⁶¹ Consultation appears most successful when the occupational therapist models the strategies for the services provider, clearly articulates the rationale for the methods and approaches used in the program, and designs a well-organized program that can be applied easily.

A user-friendly program that the teacher or aide can easily implement within the classroom is more likely to be followed. For example, by supplying (1) specific written and oral directions of the program; (2) a container, such as a basket, full of materials for the handwriting intervention program (e.g., Thera-Band, in-hand manipulation games, sequenced writing lessons, clay trays, different writing tools); (3) data management sheets; and (4) a system to provide reinforcement and rewards, the program can be administered easily. Handwriting interventions for one student can also benefit other children in the classroom who may be struggling with handwriting. For students to benefit, therapists must give teachers guidance and instruction in how to appropriately use these tools and should monitor how they are used.

In addition, meaningful writing activities that enhance handwriting can be embedded throughout the school day. For example, teachers can emphasize good handwriting when students use interesting paper and writing tools in writing centers, write shopping lists in the kitchen center, create class books,

survey peers about their favorite ice cream and graph the results, or write letters to peers and family. "Capitalizing on the meaning that is the heart of all writing" is essential to promote writers who want to share their thoughts through writing.⁴²

Summary

Handwriting is an important academic occupation for children. Children with neuromuscular impairments, learning disabilities, and developmental delays are often referred to occupational therapy for handwriting problems.

- The role of the occupational therapist includes evaluating the child's functional performance of prewriting and handwriting skills, along with the related client factors, task demands, and environmental features.
- The occupational therapist assists the educational or clinical team in planning an integrated approach to promote a functional written communication means for the child.
- Handwriting intervention programs should be comprehensive, incorporating activities and therapeutic techniques from the acquisitional/motor learning, sensorimotor, biomechanical, cognitive, and psychosocial models of practice.
- Handwriting programs and interventions should be provided in the child's natural setting and should be explicitly linked to the writing curriculum.
- For many children with handwriting difficulties, compensatory strategies and computer keyboarding can augment handwriting and enable success in functional written communication.

CHAPTER

19

Influencing Participation Through Assistive Technology and Universal Access

Judith W. Schoonover • Rebecca E. Argabrite Grove

KEY TERMS

Assistive technology service	Self-determination
Universal design	Electronic books
Universal Design for Learning (UDL)	Computer-based communication system
Input	Electronic communication aids
Output	Non-electronic communication aids
Alternative and augmentative communication	Self-advocacy
Electronic aids for daily living	Positioning and ergonomics
Learned helplessness	Digitized speech
	Synthesized speech

GUIDING QUESTIONS

1. What are the purposes of assistive devices and services and their relevance to the practice of occupational therapy?
2. How do legal mandates influence assistive technology service delivery?
3. Which guiding frameworks/models influence decisions about assistive technology?
4. How do teams collaborate to provide assistive technology services?
5. How can assistive technology enhance childhood occupations?
6. Which assessments are used to evaluate the need for, selection of, and effects of assistive technology?
7. How do sociocultural differences influence the acceptance of assistive technology?
8. What is the continuum of and interrelationship between no-tech and high-tech solutions?
9. How are evidence-based practices used throughout the service delivery process?
10. What are resources for continued competence in the evaluation, selection, and implementation of assistive technology?

“Not every child has an equal talent or an equal ability or equal motivation; but children have the equal right to develop their talent, their ability, and their motivation.”

—John F. Kennedy

Introduction

Assistive technology (AT) has been an important tool since the origins of the occupational therapy profession, as well as throughout its history, to improve function and participation. Traditionally, occupational therapists have used different types of adaptive equipment, such as reachers, buttonhooks, and pencil grips, to promote functional independence in their clients. However, the explosion of technology into everyday life has changed the way (and offers possibilities for where) children receive, interact with, and apply information. Technology provides new and exciting options for people in general, but for children with disabilities it is often a necessity. Judiciously selected AT affords users creative solutions, which allows them greater independence and opportunities for participation at home, at school, in the workforce, in the community, and in society. Occupational therapy practitioners (OTPs) use a wide range of electronic devices, from simple switches to tablets to complex robotics, to support meaningful occupational engagement. Stoller described AT as “special devices or structural changes that promote a sense of self-competence, the further acquisition of developmental skills into occupational behaviors, and/or an improved balance of time spent between the occupational roles in an individual’s life as determined by the individual’s goals and interests and the external demands of the environment” (p. 6).¹⁰⁵

“Occupational therapy practitioners’ understanding of their clients’ daily occupational needs, abilities, and contexts make them ideal collaborators in the design, development, and clinical application of new or customized technological devices” (p. 678).³ Assistive technologies may unlock human potential and optimize human performance throughout the life span and across contexts, and allow individuals to assume or regain valued life roles. The selection of the “right tool for the job” bridges the gap between what people *want* to do and what they *can* do to participate in activities that are meaningful and life sustaining. Assistive technologies can serve a variety of needs

and can be part of the educational, habilitative, and/or rehabilitative process depending on the environments in which services are provided.

Congress enacted legislation designed to support the procurement and use of AT for individuals with disabilities. This expansion in the use of AT opens new doors, creates opportunities, and enables individuals with disabilities to realize functional goals that were previously unattainable. Although the materials, structure, and form of devices used continue to evolve over time, above all other considerations the primary emphasis of AT across the life span continues to be on functional outcomes for AT users.³²

Ideas about disability are shifting. The practice of occupational therapy acknowledges the impact of the environment in intervention, recognizing its effect on performance and participation. Assistive devices and services are only as effective as the environment in which they are implemented. The World Health Organization¹¹⁶ states that disability is a condition that is based on the interaction between persons with health conditions and their environment. Emphasis is placed on the removal of environmental barriers preventing inclusion and participation rather than trying to change the individual. If children with disabilities are to enjoy their right to participate at school, work, play, and in the community and to have the opportunity to realize their full potential, creating and maintaining an accessible environment are essential. Occupational therapy practitioners “make recommendations to structure, modify, or adapt the environment and context to enhance and support performance” (p. 357).⁴ With the influx of technology into the daily lives of all individuals comes the increased responsibility for OTPs to keep abreast of current trends so that the tools they recommend and implement can produce the best outcomes for the clients they serve.

Influencing Children’s Growth and Development with Assistive Technology

Children have an “inborn drive to discover and learn” (p. 1)²¹ that motivates them to understand the world around them, strive for independence, establish a sense of self, and connect socially with others. When a disabling condition is present, children may have difficulty with accessing play, learning, or self-care activities. Burkhart offered four “secrets” to support children’s successful engagement: (1) create motivating activities, (2) develop opportunities for active participation, (3) present information and materials using multiple modalities, and (4) use authentic learning scenarios in natural contexts.²¹ Research indicates that AT can be instrumental in helping young children with disabilities learn valuable life skills such as social skills, including sharing and taking turns, communication skills, attending, fine and gross motor skills, self-confidence, and independence.^{9,63,85,109,111} As children grow they may use technology to develop independence in many activities of daily living and instrumental activities of daily living, complete school assignments, develop prevocational and vocational skills, increase opportunities for social participation, and play games or participate in leisure activities. The use of AT can create novel opportunities for children to explore, interact, and function in their environments.

For children with disabilities, introducing the appropriate types of technology systems as early as possible may enable

the child to participate in important learning situations that otherwise, because of his or her disabilities, may not be possible. For more than 20 years, researchers and clinicians have documented and discussed the unique opportunities that all types of AT offer for teaching and for advancing the life choices of children with disabilities.^{11,12,39,51,63,70,93,106,109}

Because technology is constantly changing, this chapter presents problem-solving approaches, principles, and frameworks for decision making versus in-depth descriptions of specific devices or systems. The frameworks and guidelines for decision making that are presented should not be viewed as limiting strategies. Rather, they are meant to be a starting point. Each practitioner needs to adjust the concepts, given the individual needs of the client and family, other team members involved, availability of resources, and factors unique to each situation.

Definition and Legal Aspects of Assistive Technology

Assistive technology comprises a broad range of devices, services, strategies, and practices used to address functional problems encountered by individuals who have disabilities.²⁷ *Assistive technology* is legally defined by Public Law (PL) 108-364, The Assistive Technology Act of 2004, as “any item, piece of equipment or product system whether acquired commercially off the shelf, modified, or customized that is used to increase, maintain or improve functional capabilities of individuals with disabilities.”

Public Law PL 108-364 further defined an AT service as any service that directly assists an individual with a disability in the selection, acquisition, or use of an AT device. The law includes several clarifications to enhance the definition of AT service: (1) evaluating needs and skills for AT; (2) acquiring assistive technologies; (3) selecting, designing, repairing, and fabricating AT; (4) coordinating services with other therapies; and (5) training both individuals with disabilities and those working with them to use the technologies effectively.

In a similar manner, the Individuals with Disabilities Education Improvement Act (IDEA) (PL 108-446) defines both AT devices and services as a means of providing a free and appropriate public education. IDEA 2004 requires that individualized education program (IEP) and individualized family service plan (IFSP) teams consider a child’s need for AT devices and services at least annually during the development of the IEP/IFSP. Additional information regarding other legislation related to AT can be found in [Table 19-1e](#) on the Evolve website.

In practice and research, *assistive technology* is used as a broad term that encompasses devices ranging from low technology to high technology. Low-tech devices (e.g., pencil-and-paper communication boards and built-up foam handles) are inexpensive, simple to make, and easy to obtain. High-tech devices (e.g., wheelchairs, augmentative communication devices, and specialized computer software and peripherals) are generally expensive, more difficult to make, and may take longer to obtain. Mid-tech devices fall somewhere in between and may consist of hand-made or commercially available items. Other descriptors of AT include “soft” and “hard” technologies, representing the human components (decision making, strategizing, training) involved in the provision of AT and the actual, tangible devices.³²

This chapter discusses general information regarding the use of AT with children, followed by specific examples of application. Many of the principles and decision-making strategies discussed in this chapter can be generalized to all areas of AT.

Models for Assistive Technology Assessment and Decision Making

“When matching person and technology, you become an investigator, a detective. You find out what the different alternatives are within the constraints.”

—From Living in the State of Stuck: How Technology Impacts the Lives of People with Disabilities

The OTP uses a variety of theories and principles to guide the occupational therapy process (evaluation, intervention, and outcome monitoring). Models specifically related to AT help OTPs make decisions regarding its use and facilitate the integration of AT within the practice of occupational therapy.

Assessment tools and models to guide AT evaluation and service delivery have been developed by a number of professionals.^{9,32,98,113,117} Each of these models provides a framework for evaluating needs, making decisions, and implementing intervention. Using a model for service delivery helps to ensure that the evaluation process is systematic and complete. Three models are described in this chapter. The Human Activity Assistive Technology (HAAT) model,³² the Student Environment Task Tool (SETT) framework,¹¹⁷ and the Matching Person and Technology assessment process⁹⁷ follow the person-environment-occupation model⁷⁵ and emphasize an occupation-based approach to AT practice. These models provide frameworks for decision making regarding the selection, implementation, and evaluation of AT.³²

Human Activity Assistive Technology

The HAAT model (Figure 19-1) is a dynamic and interactive model in which three factors—the human, activity, and

FIGURE 19-1 The Human Activity Assistive Technology (HAAT) model. (From Cook, A., & Polgar, J. [2008]. *Cook & Hussey's assistive technologies: Principles and practice* [3rd ed.]. St. Louis: Elsevier.)

AT—form a collective whole that is then placed within the context of participation.³² The human component includes physical, cognitive, and emotional elements. Activities are synonymous with occupations (e.g., self-care, productivity, leisure), and AT refers to a device and/or service. The context is strongly emphasized as a determining factor for outcomes.³²

Student Environment Task Tool

A framework developed specifically for school settings is referred to as the SETT framework: student, environment, task, and tools. It is designed to be used by educational teams to develop good decision making that promotes collaboration, communication, sharing of knowledge and perspectives, flexibility, and ongoing processes among educational team members,¹¹⁷ resulting in student-centered, environmentally specific, and task-focused tool systems to support a student's participation in curricular and extracurricular activities throughout the school day. SETT includes a series of questions that are designed to guide discussion, evaluation, and intervention. Teams may choose to use a few or all of the questions, depending on the needs of the student. Table 19-1 outlines the SETT

TABLE 19-1 SETT Framework Questions

Context	Questions
Student	What does the student need to do? What are the student's special needs and current abilities?
Environments	What are the instructional and physical arrangements? Are there special concerns? What materials and equipment are currently available in the environments? What supports are available to the student and the people working with the student on a daily basis? How are the attitudes and expectations of the people in the environment likely to affect the student's performance?
Tasks	What activities occur in the student's natural environments that enable progress toward mastery of identified goals? What is everyone else doing? What are the critical elements of the activities? How might the activities be modified to accommodate the student's special needs?
Tools	What no-tech, low-tech, and high-tech options should be considered for inclusion in an AT system for a student with these needs and abilities doing these tasks in these environments? What strategies might be used to invite increased student performance? How might the student try out the proposed system of tools in the customary environments in which they will be used?

questions. Many of these questions are consistent with the type of information that an OTP gathers as part of the occupational profile and occupational performance analysis, and they are applicable to a variety of settings. The Wisconsin Assistive Technology Initiative publication, *Assessing Students' Needs for Assistive Technology (ASNAT)*, 5th Edition,⁵⁵ is a comprehensive, process-based, systematic approach to providing a functional evaluation of the student's need for assistive technology in his or her environment using the SETT format.

Matching Person and Technology

The Matching Person and Technology model and assessment process are designed to help individualize the process of matching each person with the most appropriate AT. This model and process consider three factors: milieu (i.e., characteristics of the environment and psychosocial setting in which the person uses the technology), personality (i.e., personality, temperament, and preferences), and technology (i.e., functions and features).⁹⁷

Occupational therapy practitioners consider the dynamic and constant interaction of the person with the environment through engagement in occupation during all aspects of AT service delivery.⁶⁷ Environmental interventions and modifications should be considered first or in tandem with any devices or services required to ensure engagement and participation. Additionally, social, spiritual, and cultural factors should be examined as potential contributors to outcomes of AT intervention.

Child- and Family-Centered Approach

The social context of AT use can be considered the most influential and important, because it is often the social environment, including the attitude of others, that creates a disability more than the physical barriers in the environment.³² Any person (e.g., parent, sibling, teacher) who interacts with an individual using AT, either directly or indirectly, is considered part of the social context. The simple presence of a disability can be socially stigmatizing, and the introduction of AT can add an additional burden, particularly when individuals within the social environment do not support use of the technology. When consistent individuals support the child in using AT across environments (e.g., home, school, work), the use of the technology is likely to be more effective and more linked to enhanced participation. Each person's unique culture influences the manner in which he or she interacts with others and the importance of participation and engagement in various activities and life roles.³² Some cultures do not value the independence that AT provides individuals with disabilities, or an AT device may be abandoned if it replaces an important life function of another family member. For example, the grandmother who views communicating for a child with cerebral palsy as one of her roles may resist the child's use of an augmentative communication system. Cultural factors must be considered in providing AT devices and services. [Box 19-1](#) summarizes some sociocultural factors that the occupational therapist may need to consider when evaluating, designing, and selecting AT systems for children.

In addition to recognizing the impact of the social and cultural environment from the standpoint of AT acceptance, it is important to communicate the purpose of the AT and to

BOX 19-1 Cultural Factors That Affect Assistive Technology Delivery

- Use of time
- Balance of work and play
- Sense of personal space
- Values regarding finance
- Roles assumed in the family
- Knowledge of disabilities and sources of information
- Beliefs about causality
- View of the inner workings of the body
- Sources of social support
- Acceptable amount of assistance from others
- Degree of importance attributed to physical appearance
- Degree of importance attributed to independence
- Sense of control over things that happen
- Typical or preferred coping strategies
- Style of expressing emotions

From Cook, A., & Polgar, J. (2008). *Cook and Hussey's assistive technologies: Principles and practice* (3rd ed.). St. Louis: Elsevier.

provide training and support to those in the environment who will facilitate implementation. A study of caregiver perspectives of AT use with young children on the autism spectrum revealed that caregivers had misconceptions about what AT is and received little support from early intervention providers in understanding the function of AT.¹⁸ Assistive technology service includes teaching caregivers how to use AT devices in naturally occurring activities. Effective training begins by determining factors that need to be considered during the planning stage of the training, moves to strategies and techniques to use during the training, and concludes with strategies for follow-up after the training has ended ([Research Note 19-1](#)).⁴⁵

Competent AT service provision involves communicating the intent of the device, how it will assist the child, and why it is important to use it via demonstration, modeling, and practice. Even when AT devices are intuitive and easy to understand, additional training assists teachers, related service providers, paraprofessionals, administrators, parents, and/or other caregivers in determining appropriate times and places to use the technology and strategies to increase both use and *usefulness*.

Technology Abandonment

"We are fascinated with technology. We expect it to make a difference in our lives, and particularly in education. We see its effects as beneficial. We look for it to change and improve what has come before. We await technological improvements in our lives, from better toaster ovens to improved, more efficient schools..." (p. 3).⁶⁶

Despite the many promises of technology, one third or more of individuals discontinue use of their AT devices.⁹⁷ Abandonment can mean the device is no longer needed, but more often it signifies a mismatch between the user and the device. When a device fails to live up to its promise of potential, freedom, and independence, disillusionment with the idea of AT may result. Failure to take into consideration the user's preferences, ideas, and desires for an AT device is a primary reason for abandonment.^{86,97} Users of AT, their families, and/

RESEARCH NOTE 19-1

Dunst, C. J., Trivette, C. M., Meter, D., & Hamby, D. W. (2012). *Influences of contrasting types of training on practitioners' and parents' use of assistive technology and adaptations with infants, toddlers and preschoolers with disabilities*. Research Brief, 6(1). Tots-n-Tech Institute: <http://www.tnt.asu.edu>.

Abstract

This systematic review included 35 studies examining adult learning methods and practices relative to the provision of assistive technology (AT) training for children between the ages of 0 and 8.75 years. Six operationally defined adult learning characteristics were used to code and analyze results for practitioner, parent, and child outcomes. Results indicate that greater positive benefits were gained by adult learners and children when AT devices were described, explained, and demonstrated by trainers; learners had input and direct practice with the devices; trainer feedback and strategies for real life application were provided; and learners engaged in a standards-based self-assessment for mastery.

Implications for Practice

- Acceptance and sustained use of AT is likely to be most effective when recipients of AT training are involved in all phases of the learning process, including planning, application, reflection, and self-assessment.
- Effective methods for AT training should include trainer and learner joint engagement in activities with real-life application, learner input, guided practice and feedback, and standards-based self-assessment for mastery of use.
- AT training should be focused and concentrated with a small number of learners (<15) and child AT users (<10) during initial learning phases.

or educational staff may have high expectations for an AT device and can be devastated when expectations are not fully met. Assistive technology is abandoned for many reasons. According to Copley and Ziviani,³⁴ barriers to AT implementation and integration in the educational setting include lack of appropriate staff training and support, negative staff attitudes, inadequate assessment and planning processes, insufficient funding, difficulties with procuring and managing equipment, and time constraints. Lauer, Longnecker Rust, & Smith⁷³ propose replacing the term “abandonment” with the term “discontinuance,” suggesting that it provides a more accurate reflection of the AT utilization process. When service providers have more insight into AT discontinuance, they do a better job of updating, revising, and improving AT services for users and their family members, which in some cases results in the device no longer being necessary as the individual’s health, function, and well-being improve.

Learned Helplessness and Self-Determination

When children perceive that they have little control over outcomes within their environments, the phenomenon of learned helplessness can result. Learned helplessness is a secondary

disability and is the belief that one cannot exert personal control over outcomes experienced when interacting with the environment.^{2,79} Children with learned helplessness exhibit low self-esteem, directly affecting how they interact and perform functional skills. They may demonstrate a lack of initiation and an inability to cope with the events around them. In addition, when opportunities for integrating basic cognitive and perceptual skills are missed in early childhood, these children do not develop a foundation for learning higher-level concepts. Therefore it is essential to create an environment that provides guided practice, strategies, and adaptations to allow children to become independent as early as possible.

The opposite of learned helplessness is self-determination. Self-determination is defined as “acting as the primary causal agent in one’s life and making choices and decisions regarding one’s quality of life free from undue external influence or interference” (p. 24).¹¹⁴ Self-determination encompasses self-efficacy (outcome and efficacy expectations) and self-advocacy. Efficacy expectations are personal beliefs regarding one’s capability to realize a desired behavior in a specific context (judgment of what one can do with the skills one has). Outcome expectations are personal beliefs about whether a particular behavior will lead to a particular consequence (being able to determine if one’s goals are realistic). Self-advocacy refers to an individual’s ability to speak for him- or herself, make decisions for him- or herself, and voice his or her rights, particularly when those rights have been violated or diminished. The individual is able to take ownership of his or her needs, rather than expecting someone else to take responsibility for them.^{108,114} Appreciating and being able to function with a sense of interdependence are crucial parts of self-determination.

Self-determination is a set of skills that can be taught and learned. Key characteristics and components include autonomy, self-awareness, choice making, decision making, problem solving, goal setting and attainment, internal locus of control, positive attributions of efficacy and outcome expectations, and self-knowledge.¹¹⁴ OTPs promote the development of self-determination, providing services that develop skills of interdependence and independence, enhancing the participation and productivity of children, and recognizing that self-determination can mean different things to different people and strongly influences quality of life. AT devices can help with the development, practice, and effective use of self-determining behaviors for children with disabilities.

Self-determination has been identified as a critical component of successful transition from cradle to college and/or career, as well as for supporting the continued use of assistive technology after transition out of high school.²⁵ Several online resources support the users of assistive technology in determining and articulating their needs. (See [Box 19-1e](#) on the Evolve website for transition portfolios and materials.)

Setting the Stage for Assistive Technology Service Provision

Practice Settings

“The institutional context refers to larger organizations within a society that are responsible for policies, decision-making processes, and procedures” (p. 43).³² The International Classification of Functioning, Disability and Health categorizes

TABLE 19-2 Practice Settings in Which Assistive Technology Services Are Provided

Setting	Services Provided
Hospital or medical center	Primary role is evaluation that is typically provided on an outpatient basis for a series of assessments (1-2 visits); may require an inpatient stay of 2-3 weeks Referrals and recommendations made directly to agencies or third party payers Limited access to child for follow-up and training; limited opportunities to consult with parents and teachers May provide direct treatment, particularly for children under the age of 3 years or those who have an acquired disability (e.g., spinal cord injury)
Regional center	Developed in response to legislation, funded by the Department of Education or other agencies for individuals with disabilities Often has AT lending library for borrowing equipment on a short-term basis Team has broad-based experience with various diagnoses, resources for obtaining equipment, types of AT, and adapted methods of use Also involved in advocacy, consumer awareness, focus groups Limited follow-up care and minimal input into training the child, family, and educational team
Public school	Most children receive AT services at a school Daily problem solving related to AT use can occur and child receives support in the natural environment in which AT is to be used School-based team has easy access to child and understands educational curriculum but may lack expertise or experience with more complex AT systems
Home and community setting	May provide direct treatment, especially for children under the age of 3 years Direct training available to child and family Problem solving related to AT use can occur and child receives support in the natural environment in which AT is to be used Can provide carryover to other practice settings such as school or work May have limited opportunities to consult with others

Adapted from Beukelman, D. R., & Mirenda, P. (1992). *Augmentative and alternative communication: Management of severe communication disorders in children and adults*. Baltimore: Brookes.¹³

economic, legal, and political components as services, systems, and policies.¹¹⁶ This institutional overlay has major implications for both the acquisition and use of AT with regard to funding, legislation related to environmental and community access, as well as standards that govern product design, function, and safety.³²

Differences in practice settings in which OTPs who provide AT may be employed are outlined in Table 19-2. The role of the OTP in each of these settings is governed by a combination of professional scope of practice, the expertise of other members of the team, and the agency or funding source.

Occupational Therapy Process and Assistive Technology in the Schools

According to the most recent statistics published by the U.S. Department of Education, Office of Special Education Programs,¹¹² as required under the IDEA, an estimated 6.5 million children from birth to 21 years of age receive special education services. Most children who need AT receive those services in school. AT devices and services are provided if necessary for a child to receive free and appropriate public education in the least restrictive environment. The need for AT must be considered, at least annually, for all children who receive services under IDEA. When AT is a necessary part of the student's program, the school district is responsible to make sure that it is available to the child. It is not uncommon for the expertise of an OTP to be requested when the team is considering AT for a student. Guides and models for considering AT for

students in special education are available online (see Appendix 19-A on the Evolve website for Internet resources).

Baush, Ault, and Hasselbring indicated that appropriate AT devices and services can help a student improve, increase, or maintain performance of functional skills (e.g., self-help, mobility, or communication), access curriculum (e.g., multimedia presentations or books on tape), become a more efficient learner (e.g., pencil grips and raised lined paper to improve writing legibility), or compensate for lack of skills (e.g., word prediction software to assist with spelling or reduce key-strokes).¹⁰ The roles and responsibilities of IEP team members, including the OTP, providing AT services within a school setting are listed in Box 19-2.

The Interprofessional Team

The provision of AT services occurs across disciplines, and the training and experience of the service providers has not been widely studied (see Research Note 19-1).¹¹⁵ Several universities offer certificate programs and advanced degrees in AT. In addition, the Rehabilitation Engineering and Assistive Technological Society of North America (RESNA) has established a mechanism for verifying a minimum level of competence for individuals serving as AT providers through an examination process that provides credentialing for persons working as assistive technology professionals. The assistive technology professional usually has a background in a rehabilitation discipline such as occupational therapy, physical therapy, speech-language pathology, or engineering.

BOX 19-2 Roles and Responsibilities of School Assistive Technology Teams

1. Consider AT devices and services as an integral and necessary part of the IEP process as outlined by IDEA 2004.
2. Become familiar with different types of AT and a variety of tools that support student needs.
3. Assess each student's need for devices and services to support educational performance and access to curricular and extracurricular activities.
4. Seek additional resources and assistance from other educational professionals such as the members of an IEP.
5. Gather and analyze data about a student and his or her customary educational environments, goals, and tasks when considering AT needs. Student performance in core academic areas, social skills and behavior, communication, independent living, and organizational skills, along with demands of the task and environmental features, exist in a dynamic relationship and may all be considered in combination during the AT assessment process.
6. Consider a range of AT options from no-tech to high-tech and use of existing resources, the procurement of new devices, or both.
7. Organize the physical space where AT is used, establish routines that support use of AT, and support consistent use of AT in all appropriate environments.
8. Communicate and document the AT process in the IEP, with rationale for the decisions made and scientific evidence to support devices and services. Supporting evidence may include AT assessments, device trials, student achievement with and without AT, student-based preferences, and teacher observations.

From Baush, M. E., Ault, M. J., & Hasselbring, T. S. (2006). QIAT Consortium (2007). Quality indicators for assistive technology services. Retrieved August 2008 from http://natri.uky.edu/assoc_projects/qiat.

As with many other specialty areas in pediatrics, the successful implementation of AT requires a cohesive and effective team that emphasizes shared vision and ownership. The team's input is critical to making decisions regarding AT because devices are used across the child's environments and address multiple performance goals that cross professional boundaries. See [Research Note 19-2](#).

Collaboration among children, parents, teachers, and occupational therapists enables the team to determine the best match of AT to strengths and needs and provides a supportive environment for measuring, learning, and reviewing the use of the AT. Decisions that the interprofessional team and the family make together are most likely to meet the multifaceted needs of the child.

The specific members of the team may vary depending on the type of device being introduced to the child, the expertise of the individuals involved, and the specific setting. For example, in a clinical setting the team may include the child and family, occupational therapist, physical therapist, speech-language pathologist, doctor, nurse, rehabilitation engineer, and social worker. In school-based practice the team may include the child and family, occupational therapist, physical therapist, speech-language pathologist, educator, administrator, and psychologist.

In some settings, occupational therapy assistants and aides provide some of the AT services. Assistants are particularly

**RESEARCH NOTE 19-2**

Watson, A. H., Ito, M., Smith, R. O., & Andersen, L. T. (2010). *Effect of assistive technology in a public school setting*. *American Journal of Occupational Therapy*, 64, 18–29.

Abstract

Given the lack of outcomes research in assistive technology (AT), as provided in the public school setting and required by the Individuals with Disabilities Education Act (IDEA), this quasi-experimental repeated-measures study examined the effectiveness of AT as a result of a specific service delivery model utilizing a multidisciplinary team approach. Thirteen students with varied educational disabilities were provided with AT to target academic and communication goals over the course of a school year within a special education setting. Results indicate that a multidisciplinary approach may have a significant effect on individualized education program (IEP) goals. These findings support the use of AT by occupational therapists to achieve students' individualized educational goals.

Implications for Practice

- AT provided by a multidisciplinary team may be helpful in promoting attainment of IEP goals and objectives in a public school setting.
- The Student Performance Profile has potential as an effective tool for collecting AT outcomes.
- Data collection and analysis of student outcome measures may improve service delivery and provide justification for AT services.

helpful in training a child to use a system once the occupational therapist has planned and established the program. Assistants and aides may also be involved in practicing use of the device with the child and helping others use the systems. Occupational therapists working in AT service delivery must determine which activities are appropriate to delegate and which activities are specialized and require the training and skills of a therapist.⁵

Assistive Technology Evaluation and Intervention: A Dynamic Process

The OTP has a key role on the AT evaluation team. The unique perspective on occupation and engagement in meaningful activities offered to the team is helpful in determining needs, problem-solving potential solutions, and evaluating outcomes. The assessment of client satisfaction is a key factor in determining the effective implementation and usefulness of AT in the lives of individuals with disabilities.^{36,37,97,99,108}

In addition to evaluation and intervention services, AT services may also include device procurement, training, skill acquisition, monitoring, and other services that support and enable the child's participation in home, school, and community activities. Because of the complexity of many AT systems, specifically those that are high-tech, the OTP needs a systematic procedure for follow-up and adjustments to help ensure the viability of the system over time. These steps of the process are dynamic

rather than linear and sequential. For example, intervention may begin by addressing prerequisite skills for AT use before completing the AT evaluation and procuring a specific device. Once a system has been chosen and purchased, evaluation, monitoring, and decision-making processes continue throughout intervention.

Evaluation

According to IDEA (1997; 2004), school divisions are required to provide assistive technology evaluations and services; however, the Federal Register (July 10, 1993) distinguishes between assessment and evaluation as follows: Evaluation: A group of activities conducted to determine a child's *eligibility* for special education. Assessment: A group of activities conducted to determine a child's *specific needs*. The implication of this language is that an evaluation might be a one-time event, whereas an assessment is an ongoing event.

When considering AT needs, the OTP closely examines the child's abilities and difficulties, demands of the environment and task, and the child's goals. The first step of the assessment is to identify key activities that the child or family needs or wants him or her to do. The Canadian Occupational Performance Measure is a useful tool to assist with the identification of client-centered goals and the importance of the goals.⁷⁴ The importance that an individual assigns to an activity helps predict whether he or she will accept technology that enables participation in that activity.¹⁰³

A number of inventories, checklists, and processes have been developed to assist with assessment. When an assessment is requested, observation should occur in the student's natural environment, which might include home, school (e.g., classroom, playground, lunchroom, bathroom, extracurricular areas), and community settings (e.g., work settings or other relevant locations). When conducting the evaluation, practitioners consider all factors influencing a child's participation in given activities, including how often and for how long the child engages in them (Box 19-3). During the assessment, existing technology used by the child and its effectiveness in the customary environment are documented. A complete occupational therapy evaluation may or may not be a component of the AT process, depending on the practice setting in which it occurs. Formal and informal evaluation tools that may be used during the assessment process are described in Table 19-3.

The AT assessment may be completed by the team who will also provide the intervention (e.g., fitting and training of the device) or a team that has been formed specifically for the purpose of completing AT assessments. Many hospitals, clinics, and some community agencies and schools have a designated AT team because of the complexity of many AT systems. The OTP who does not work with AT on a regular basis may have difficulty maintaining expertise on all the systems and devices available because of the number of devices and the rapid development of new systems. When separate teams are responsible for evaluation and intervention, ideally these teams collaborate to make decisions and recommendations.

In addition to a comprehensive assessment, a trial period with different types of AT is needed to achieve a good match between the AT device or system and the child and family. The trial period may be one of the most important aspects of the AT evaluation. These trials can help prevent the costly

BOX 19-3 Guiding Questions in Evaluating a Child for Assistive Technology

Motor

- Which body parts are capable of reliable, accurate, and controlled movement?
- Can the child be positioned adequately in and maintain an upright sitting posture?
- Does the child have sufficient range of motion, finger dexterity, strength, and endurance?
- What is the child's overall endurance and strength?
- What is the child's level of independence in daily living skills?

Sensory and Perceptual

- Can the child attend to visual feedback on the monitor?
- Can the child respond to auditory feedback?
- What are the child's strengths and limitations in visual perception and visual motor skills?
- Is the child easily distracted by visual stimuli?

Cognitive and Communication

- What is the child's cognitive level?
- What is the child's attention span?
- What are the child's receptive and expressive language skills and potential?
- What are the child's face-to-face and written communication needs?
- Can the child sequence multiple-step directions?

Psychosocial

- Does the child seem motivated to use AT?
- Which activities does the child enjoy?
- Does the child see AT use as meaningful and rewarding?
- Will the child and family tolerate the influence of this AT device?

Context

- Where will the child use the AT device?
- How can the AT device or interface be positioned for optimal use?
- Do classroom or home environments allow for safe and easy access to educational materials and use of the AT devices?
- Does the child have any previous experience with AT?
- Are the individuals who work with the child (family and professionals) willing to use AT?
- What are the short- and long-term goals with the AT device?

procurement of an incorrect device. The cost of AT includes not only the purchase of the device but also the ongoing expenses for maintenance, upgrades to the system, and repairs. Throughout assessment and intervention, consideration should be given to the family's financial resources, access to repair services, whether the AT device significantly increases the child's level of participation, whether the AT device will "grow" with the child, and whether a less complex device will meet the same needs.¹⁰⁹

The team discusses these issues and others unique to each family in deciding whether the system is a reasonable and appropriate investment for the family that will result in increasing the child's functional independence. The team presents the

TABLE 19-3 Assistive Technology Assessments

Assessment	Description
Assessing Students' Needs for Assistive Technology: A resource manual for school district teams from the Wisconsin Assistive Technology Initiative (WATI), updated June 2009; http://www.wati.org/?pageLoad=content/supports/free/index.php Georgia Project for Assistive Technology (GPAT), http://www.gpat.org/	Not designed as a test protocol but provides a comprehensive process-based systematic approach to assessment. Package includes WATI Assessment forms together with the <i>Consideration Guide</i> , <i>Student Information Guide</i> , <i>Environmental Observation Guide</i> , <i>Decision Making Guide</i> , <i>AT Checklist</i> , and <i>Trial Use Guide</i> . GPAT has developed lists of assistive technology devices by attribute (e.g., writing support) and resources pertaining to legal mandates for assistive technology, considering assistive technology for students with disabilities, documenting need for assistive technology, implementation and integration, and evaluation of effectiveness of assistive technology.
MPT Assessment Instruments, http://www.matchingpersonandtechnology.com/mptdesc.html	Each instrument is actually a pair of instruments: one designed for the provider of technologies (counselor, occupational therapist, teacher, employer, trainer, etc.) and the other designed for the technology user. <i>Survey of Technology Use (SOTU)</i> —helps identify technologies an individual feels comfortable with or successful in using so new technology can be built around existing comfort or success <i>Assistive Technology Device Predisposition Assessment (ATD PA)</i> —helps people select AT <i>Educational Technology Predisposition Assessment (ET PA)</i> —helps students use AT to attain educational goals
Functional Evaluation for Assistive Technology, http://www.nprinc.com/assist_tech/feat.htm	Five scales are completed by various members of the AT team to allow for an ecologic assessment of needs: Contextual Matching Inventory; Checklist of Strengths and Limitations; Checklist of Technology Experiences; Technology Characteristics Inventory; and Individual-Technology Evaluation Scale.

BOX 19-4 Criteria for Evaluating Assistive Technology Devices

- Effectiveness.** How much the device improves the user's living situation and enhances functional capability and independence
- Affordability.** The extent to which a person can purchase, maintain, and repair a device without financial hardship
- Reliability.** The degree to which a device is dependable, consistent, and predictable in its performance and levels of accuracy for a reasonable amount of time
- Portability.** The influence of the device's size and weight on the user's ability to move, carry, relocate, and operate it in varied locations
- Durability.** The extent to which a device delivers continued operation for an extended period of time
- Securability.** How well a consumer believes that a device affords physical control and is secure from theft or vandalism
- Safety.** How well a device protects the user, care provider, or family member from potential harm, bodily injury, or infection
- Learnability.** The ease of assembly, initial learning requirements, and time and effort to master use
- Comfort and acceptance.** The extent to which a user feels physically comfortable with the device and does not experience pain or discomfort with use; how aesthetically appealing the user finds the device and the user's psychologic comfort when using it in private or public
- Maintenance and repairability.** The degree to which the device is easy to maintain and repair (by the consumer, a local repair shop, or a supplier)
- Operability.** The extent to which the device is easy to use, is adaptable and flexible, and affords easy access to controls and displays

From Scherer, M. J., & Lane, J. P. (1997). Assessing consumer profiles of "ideal" assistive technologies in ten categories: An integration of quantitative and qualitative methods. *Disability and Rehabilitation*, 19, 528-535.

child and family with objective and realistic information regarding investment in and use of AT.

Given a complete description of the options and alternatives, the family and the team make the final decision as to which AT is implemented and how it is incorporated into the child's routines. Box 19-4 presents 11 criteria, developed by more than 700 AT consumers, that the team should use to evaluate different AT devices. In summary, AT evaluations should be conducted (1) as part of an ongoing process linked to

educational and/or therapeutic planning, (2) by a team within the natural setting where the child needs to engage in his or her occupations, (3) with trials with potential AT devices, and (4) with meaningful follow-through involving all team members.⁹²

Decision Making

Occupational therapy practitioners use problem solving and clinical reasoning skills throughout the process of procurement,

implementation, and follow-up with AT. Problem solving involves defining the situation or problem, determining the short- and long-term goals, and brainstorming potential processes to reach the determined goals. In addition to the assessment tools described in Table 19-4, see Box 19-2e on the Evolve website for resources that support AT decision making. When working with children, the team, including the occupational therapy practitioner, considers short- and long-term goals in terms of what the child's needs are at present, 1 year later, 3 to 5 years later, and 7 to 10 years later. This can be difficult when working with young children, but the information can facilitate decision making, especially in addressing AT needs. In working with an adolescent, the focus becomes a successful transition plan, independence in the community, and participation in work roles. The procurement and use of the AT can be a critical part of a successful transition into future life roles for an adolescent.^{20,72,104} The team revisits and rewrites goals systematically as the child grows and matures, as contexts change, as child and family needs and desires change, and if the child's medical condition changes.

Lahm and Sizemore interviewed AT teams to identify factors that influenced decision making in selecting AT.⁷¹ Important factors included client goals, environmental demands, family/client demands, and client diagnosis. Funding was considered but was lower in importance. Because an awareness of environmental demands was another important factor, evaluations should include strategies for gathering information about the environmental demands (e.g., site visits, checklists, photos, interviews) to facilitate the best decision making.

Device Procurement

It can take up to several months to procure an AT device. When funding issues stall the process, members of the team may be involved in writing letters of justification to insurance companies and other third-party payers. Careful documentation during the trial periods with different devices can help with this process. Documentation can include videos or pictures of the child using the system that demonstrate how the system helps improve his or her function.

Once the system has arrived, the team works to put the system together, test the system, and begin training. Some companies provide representatives who can help with the process, and others have videos that come with the system. However, it is not uncommon for a system to be delivered with minimal instructions. This can be daunting to the family and other support providers. Comprehensive intervention and education help the child and family incorporate the device into their daily lives.

Funding

Occupational therapy practitioners working in the area of AT are often involved in helping procure the appropriate devices. In particular, they often provide the documentation used in applying for funding. Funding can come from various sources, including Medicaid, grants, private insurance, nonprofit agencies such as United Cerebral Palsy, private foundations, schools, and individual payment. In some states, funds are available through the Department of Developmental Disabilities, the

Department of Health, or the Department of Social Services to help purchase AT devices. As students enter high school and begin the transition to work and career sites, the state's vocational rehabilitation agency may also assist with the funding of devices. In addition, the team can consider alternative sources of funding.²³ Community service organizations, equipment loan programs, used and recycled equipment, and technical assistance projects can provide funds for AT. Often these alternative sources can take additional time and effort to research and contact. However, when a family or system has limited resources, pursuing creative funding options can result in the successful procurement of a device. When families cannot afford new devices or secure funding, they may explore AT reuse programs such as the *Pass It On Center* coordinated by the U.S. Department of Education's Office of Special Education and Rehabilitative Services, because these programs often do not have eligibility requirements.⁸⁴ OTPs should learn about the different funding options available within their state and region to contribute to the team's effort to obtain funding for AT devices. See [Research Note 19-3](#).

Funding of AT in school districts raises unique issues. The school district is the payer of last resort, but it is ultimately

responsible for AT devices that the child needs to learn in the school environment.^{23,110} Public or private insurance can be applied to obtain AT devices and services when they are determined to be medically necessary.¹⁰² The use of these funds must be voluntary on the part of the parents and with their written consent. School districts can also work with community service organizations or associations (e.g., the Muscular Dystrophy Association) to purchase AT devices or pay for services. If the AT device is purchased with the parents' funds or insurance, then the device belongs to the child and the child's family. However, if the school district purchases the device, then the school district owns the device.^{82,113}

The occupational therapist may write or assist with writing a letter of justification to support the funding of an AT device. Strong supporting documentation is based on the assessment data gathered by the team and takes into consideration the language and priorities of the funding agency that clearly demonstrates the necessity of the device to strengthen the child's engagement in occupation is an important part of the process.²³ If the letter is written to a health insurance agency, then medical necessity must be emphasized; if it is directed to an education-related funding source, then it must address the child's ability to access and participate in educational programming. Requests to vocational agencies must address employment potential and work skills.^{23,100,113} Other key elements in the letter may include information about the child, the device, the assessment procedures including results of any trials conducted, and the environment(s) in which it will be used; how the child will benefit from the device; alternatives to or potential outcomes of not being provided with the device; supporting photos or measurements; and information about the cost of the device and other options considered.

RESEARCH NOTE 19-3

Long, T. M., Woolverton, M., Perry, D. F., & Thomas, M.J. (2007). *Training needs of pediatric occupational therapists in assistive technology*. *American Journal of Occupational Therapy*, 61, 345–354.

Abstract

The training of providers working with children who need AT devices or services has not kept pace with the variety and complexity of AT devices available. This article reports on a survey of pediatric occupational therapists who responded to questions about their training needs in the area of AT and delivering AT services. A large number of respondents reported less-than-adequate training in policies governing AT services and the organization and function of the service delivery system. Therapists reported a need for and interest in accessible and affordable training in the areas of funding of technology and services; collaborating with families and other service providers; and accessing reliable, knowledgeable vendors.

Implications for Practice

- Policy and practice context for providing AT services has become more complex, and practitioners are faced with, or unaware of, new and more sophisticated devices that might promote more opportunities for meaningful participation in their clients with disabilities.
- A majority of pediatric occupational therapists in this national sample rated their preparation in the area of AT as being less than adequate and rated their confidence in terms of delivering AT and AT services as low.
- Training in identification of funding sources and use of high-tech devices is among the most pressing training needs.

Implementation of Assistive Technology Services

An AT implementation plan is part of the service aspect of AT delivery and should include person(s) responsible, conditions of use, frequency of use, and duration of use. The team considers all of the tasks and contexts in which the AT will be used. For example, if a student requires a voice output communication system, it should be readily available at all times throughout his or her day (e.g., at lunch or recess to socialize, during instruction to ask or answer questions, during independent work to indicate needs and wants, and at home to interact with his or her family).

The introduction of an AT device, especially a complex device, can change the focus of a child's program. Time must be spent on training and practice within the child's natural environments (i.e., school, home) as the family and professionals make efforts to integrate use of the device into the child's everyday activities. Thus the development of skills needed to use the device often becomes the focus of intervention. Involvement by every member of the team encourages skill generalization to various settings and situations of the child. When staff are encouraged to work as a team and time is provided for them to communicate, the effectiveness of AT is likely to increase. AT devices should be readily accessible; if the device or strategy takes longer than 60 seconds to access and set up, it is less likely to be used. Examples of forms used to document an implementation plan (e.g., the NATRI Assistive Technology

Implementation Plan and the QIAT Plan for Evaluation of Effectiveness of AT Use) can be accessed in Appendix 19-B on the Evolve website.

Bowser and Reed¹⁷ identified key points to assist educational teams in making decisions regarding the use of AT services and identifying resources that can be written into the child's IEP. Implementation and periodic review of the plan will help avoid the potential discontinuance of recommended AT devices and services.

Measuring Progress and Outcomes

Not only does good AT decision making require an eye on the future, but evaluating the outcomes of AT takes a long-term commitment³⁸ to ensure that it continues to support the child's engagement and participation in purposeful activities. Often it is difficult to operationalize and define global outcomes specific to AT.⁵² The goal of outcome measurement is to determine the efficacy and utility of AT devices and implications for discontinued use. It is important that occupational therapists as members of AT teams select appropriate outcome measures to determine whether devices and services have the intended effect.

Data collection is critical to evaluating AT's success. The team should be involved in a collaborative discussion regarding how data will be collected. Data collection should be simple and straightforward enough for all team members including family members to understand and complete with ease. Outcome measures should be individualized to how the child will access and use the equipment. For example, when designing a data sheet for switch use, one considers which part of the body will be used to activate the switch, how much wait time will be allowed before a prompt is given, the type of prompt to be given (e.g., visual, verbal, hand-over-hand), and objectively what constitutes success for the given task (e.g., single switch activation, activation or deactivation of an electronic device, holding a switch for a specified amount of time). The occupational therapist can guide the team in a discussion of how to measure the child's performance.

Data collected over time can support the continued use of AT devices or justify the need for follow-up assessment. Often data are collected on targeted goals and objectives and are dependent on the service settings in which the device is used. Possible factors to measure include changes in the child's performance or level of function, change in level of participation, how often the device is used and under what circumstances, overall consumer satisfaction, goal achievement, quality of life, and cost analysis/savings. Table 19-4 outlines a number of assessments that may be used to evaluate outcome measures for AT.⁷

Once the child and family have a basic understanding of the AT system and begin to use it independently, the child may be discharged from direct services. However, discharge from a regular routine of intervention should include a follow-up plan. Follow-up can occur in several ways, from a telephone call to an extended clinic visit or simple review and analysis of data collected. The type of follow-up and when it should occur depends on the complexity of the system and the skills of the child, family, and other professionals working with the child. A predetermined schedule for follow-up (e.g., at intervals of 6 months or less or sometimes 1 year or more) is a component

of effective service delivery. Problems and delays in service can be prevented with planned periodic review.

In addition to outcomes for individual users of AT, instruments are available to assist AT teams in conducting quality assurance studies for the services that they provide. Quality Indicators for Assistive Technology (QIAT)⁸⁹ and the School Profile of Assistive Technology Services⁹⁰ are both used in school settings to support the development and delivery of AT services. Use of these indicators as guidelines can support outcomes for the child, the family, the classroom, and the system.

Universal Design and Access

Because it encompasses such a broad spectrum of services, the definition of AT is elusive; therefore, some OTPs fail to recognize that the familiar tools in their "toolboxes" are really AT devices (Figure 19-2). Occupational therapy practitioners working with children with special needs, their families, and educators often create, individualize, or adapt devices to enable independent participation for students with physical, communication, or developmental challenges to learning.¹⁰⁵

Professionals and consumers have a common misconception that AT is complicated and expensive. Often, simple low-tech solutions are overlooked. Mistrett found that given a range of low- to high-tech solutions, families generally choose to use low-tech solutions more often, perhaps because their appearance is similar to typically found toys and materials and calls less attention to the disability.⁸⁰ Assistive technology can be viewed as a barrier rather than a bridge, or "just one more thing to do," unless it is intuitive and its value is revealed in everyday successes. Assistive technology can help to level the playing field for children with disabilities, enhancing physical, instructional, and social inclusion opportunities.

Access

Providing physical access to homes and schools may include both devices and services.⁶⁵ Modifications to buildings, rooms, and other facilities allow children with physical or sensory

FIGURE 19-2 Examples of readily available, universally designed low-tech tools. (Photo courtesy Judith Schoonover.)

impairments to navigate both inside and outside of buildings using curb cuts, ramps, and door openers; labeling of key areas with pictures, text, and Braille; the provision of accommodations for individuals of varying sizes or those who use wheelchairs to access restrooms, water fountains, or elevators. Occupational therapy practitioners are trained to identify ways to improve performance and safety in the natural context to arrange resources and to modify the environment to decrease or eliminate barriers.

Bus modifications for entry and exit and safe and appropriate seating can help with transportation to and from school or community and school-related activities including field trips, sports, and recreation. Within the building, doors, walkways, handles, light switches, and stairs can be modified to provide equal access to all students. Outside the building, seating and playground modifications can allow or enhance safe mobility and participation in recreational activities.⁵⁴

Schools and clinics have established guidelines for ensuring universal access as they update and expand their computer systems. When all children, including those with disabilities, have equal access to technology, costly modifications for individuals can be avoided. Often the complexity of AT is not considered when general technology is purchased, so that computers do not support some of the software programs or adaptive peripherals needed by children with disabilities. A team of professionals, consumers, technology developers, and standards organizations must plan together to ensure that technology is accessible to all.

Universal Design

"We must create spaces at all times that all can use, no matter their abilities, age or size."

—Ron Mace, architect, founder and program director of the Center for Universal Design²⁹

Ron Mace was a visionary who used the term *universal design* (UD) to describe the concept of making all products and the built environment physically pleasing and usable to the greatest extent possible by everyone, regardless of their age, ability, or status in life. His work on accessible design was instrumental in the passage of national legislation prohibiting discrimination against people with disabilities, the Fair Housing Amendments Act of 1988, and the Americans with Disabilities Act of 1990. The principles of universal design are outlined in [Box 19-5](#).

According to the Center for Universal Design, "the intent of UD is to simplify life for everyone by making products, communications, and the built environment more usable by as many people as possible at little or no extra cost."²⁹ Universal design is a proactive approach that can eliminate many barriers but does not replace the need for individualized AT. Although typical furnishings, toys, and instructional materials found in homes and classrooms may meet the needs of many, items that are "easier to handle, larger, less slippery, color coded, or in some ways more inviting and functional" (p. 5)⁹¹ may be required for others.

Positioning and Ergonomics

Positioning and ergonomics include the physical positioning of the child for comfort, function, and work; location of the child

BOX 19-5 Principles of Universal Design

Principle One: Equitable Use

The design is useful and marketable to people with diverse abilities.

Principle Two: Flexibility in Use

The design accommodates a wide range of individual preferences and abilities.

Principle Three: Simple and Intuitive Use

Use of the design is easy to understand, regardless of the user's experience, knowledge, language skills, or current concentration level.

Principle Four: Perceptible Information

The design communicates necessary information effectively to the user, regardless of ambient conditions or the user's sensory abilities.

Principle Five: Tolerance for Error

The design minimizes hazards and the adverse consequences of accidental or unintended actions.

Principle Six: Low Physical Effort

The design can be used efficiently and comfortably and with a minimum of fatigue.

Principle Seven: Size and Space for Approach and Use

Appropriate size and space are provided for approach, reach, manipulation, and use regardless of user's body size, posture, or mobility.

Connell, B. R., Jones, M., Mace, R., Muller, J., Mullick, A., Ostroff, E., Sanford, J., Steinfeld, E., Story, M., & Vanderheiden, G. The Center for Universal Design (1997). The Principles of Universal Design, Version 2.0. Raleigh, NC: North Carolina State University. Retrieved September 2014 from http://www.ncsu.edu/ncsu/design/cud/about_ud/udprinciples.htm.

within the environment; and location of supports in relationship to the child. Seating, positioning, and mobility devices are often the foundation for successful use of AT, and they may be used to improve body stability, provide proximal trunk and head support, allow for exploration of the environment, and reduce localized skin pressure.⁸⁷

Positioning should never be static in nature. The right seating and positioning equipment allow users to interact with their environment and perform tasks that are meaningful and life sustaining. "A task performance position is one that the person must be able to assume and maintain and in which the person can move" (p. 3).⁶⁴

The environment cannot and should not come to the child; the child should be able to enter into and interact within the environment. One size does not fit all ([Figure 19-3](#)). With variances in physical size and stature, standard furniture can make it a challenge to provide adjustability to fit everyone comfortably. Individually designed seating and positioning allows users of AT to work in neutral, relaxed positions that

FIGURE 19-3 One size does not fit all. It is important to adjust learning environments to promote health and productivity. (Photo courtesy Judith Schoonover.)

consider energy conservation, which is important to maximize productivity while protecting health and minimizing the risk of injury. As technology becomes a more important part of children's lives, so does the need to pay attention to the health aspects of using computers, tablets, and mobile devices. American children typically spend between 1 and 3 hours a day at a computer, putting them at high risk for wrist, neck, and back problems.³⁵ If children, or those advocating on their behalf, learn at an early age how to adjust a workstation, they will make similar adjustments later in life. These habits and skills can be established as early as the preschool years. Many schools have chosen not to include ergonomics programs because of the costs often associated with implementation. **Box 19-6** outlines some minor changes that have minimal or no costs associated with them.

Participation: Supporting Life Skills with Assistive Technology

Occupational therapy practitioners work with children with significant disabilities. Although prerequisite skills may be necessary for successful use of certain devices, many children use a range of AT to address life skills such as communication, mobility, self-help, play and leisure, and work.¹¹⁸

BOX 19-6 Ergonomics: Budget-Minded Solutions/Tips for Home and School

Evaluate current equipment to determine whether it can be adjusted at all. If adjustable equipment is available, ensure that all users understand the need for it and how to adjust it. Educate and empower students to make their own workstation modifications by providing them with the tools and materials they require.

Recognize that lighting, glare, and proximity of the computer monitor to the user can all have negative impact on vision. The computer monitor should be at or slightly below eye level and approximately 24 inches away. Provide document holders at eye level to minimize eyestrain when copying.

Good ergonomic habits are best learned when modeled.

One size does not fit all. Provide a number of seating options and footrests for the user to choose from.

Never use the "legs" that many keyboards have attached on the bottom surface of the keyboard because they place the keyboard at a positive slope (slant the keyboard toward the operator). This position forces the user to bend wrists to touch the keys rather than maintaining a neutral position. If a slanted plane is desirable for visibility purpose, place keyboard on binder so that user's wrists are supported.

Obtain or make footrests—investigate whether your school or a local high school can make footrests as part of their woodworking program.

Make adjustments to the equipment as needed—providing several heights of work surfaces or sizes of chairs may be warranted.

If a mouse tray is unavailable, make sure that the mouse is close to the side of the user's body. This is necessary to ensure that the upper arm can remain relaxed and posture can remain as neutral as possible. In some cases, a lap tray can be used.

Costs can be minimized by involving school maintenance staff, woodworking classes, parent organizations, or service clubs to make adjustments to equipment.

Stretching programs (i.e., to stretch neck, spine, shoulders) can be downloaded from many reputable websites at no charge. If no changes can be made to the workstation, ensure that all students are educated on taking appropriate breaks and are given stretches.

Modified from Office ergonomics reminder sheet (2003). *Options Quarterly Online Newsletters*. Available at <http://www.oiwweb.com/pages/newsarchive03.html>.

Switch Use to Operate Toys and Appliances

Low technology, such as the use of simple switches and cause and effect toys/appliances or software, may be the initial AT system of choice. Occupational therapists may use these devices to help a child learn cause and build foundational skills for future AT systems. For some children with significant disabilities, simple devices that provide sensory input (e.g., fans, vibrators, music, lights) may be more motivating than some of the cause-effect toys or software. These devices can be hooked into an electronic aid to daily living (EADL) and then a switch can be used to turn them on and off. The EADL can run electronically operated toys or appliances and has functions that allow the child to control how the switch is used (e.g., a timer can be used so the child has to hit the switch every 30 seconds).

FIGURE 19-4 **A**, An example of a touch switch: the jelly bean switch. **B**, An example of a switch that is activated by pulling on the multicolored ball. (**A**, Photo courtesy Enabling Devices. **B**, Photo courtesy Judith Schoonover.)

Often, low-tech solutions are controlled through a single switch. Typically, a touch switch that requires a press and release is used (Figure 19-4A). However, for some children this type of switch may not be motivating, or the student may not have the physical skills needed to access the switch. Figure 19-4B shows an example of a switch that helps a student learn cause-effect relationships. Some children may not have the physical skills to press or pull against resistance and may use a switch that is activated through a light touch (Figure 19-5A). Switches can be mounted so that the position can be easily adjusted to improve access for a student (Figure 19-5B). Although this switch requires minimal controlled movement, its cognitive demand is greater than that for the switches pictured. The touch-free switch may be too abstract for students with low cognitive skills.³¹

Through the use of low-tech tools, switches, and simple cause-effect activities, all children can participate in a variety of learning activities at home and in the classroom. Figure 19-6A shows an option for participation in a water play activity through a switch toy. Figure 19-6B shows an option

FIGURE 19-5 **A**, The Sensitrac flat pad switch. Switch is activated by a simple touch. **B**, The Sensitrac flat pad switch can be easily positioned for a child to access. (Photos courtesy AbleNet.)

for participation in a gardening activity, and Figure 19-6C illustrates an option for game play with peers. Switches may allow partial participation, in which the student uses a switch to complete one step of the task. For example in Figure 19-6B, the student pressed the switch to turn on the Waterpik; then another student used the Waterpik to water the flowers.

Switch Use with Computers

Many of the switches that can be used to access low-tech solutions (see Figures 19-4 and 19-5) can also be used to access the computer. More complex switch systems use indirect selection. In deciding on a switch-driven system, consideration should be given to the motoric and cognitive requirements of the system.³¹ For example, a child who is able to accurately and reliably hit a switch at 9 months of age does not have the cognitive skills to understand the concept of scanning. In addition, research suggests that the placement of the switch (e.g., a head switch versus a switch that is struck with the hand) may have a cognitive component that affects a child's accuracy.⁵⁶ A single (or dual) switch can be used to run systems such as scanning.

FIGURE 19-6 A, The child uses the switch to play with the water toy. B, The child uses the switches to participate in a gardening activity with her peers. C, The child uses the switch to turn on the Bed Bugs game. (A and C, Photo courtesy Ablenet; B, Photo courtesy Enabling Devices.)

Alternative and Augmentative Communication

"If all my possessions were taken from me with one exception, I would choose to keep the power of communication, for by it I would soon regain all the rest."

—Daniel Webster, 1822

Verbal communication is an inherent function of human beings and lends quality and detail to social interactions with others. Communication is not designed to be a solitary activity, because the purpose of communication is to exchange and share information with another individual. Children with disabilities may present with a range of performance levels related to receptive and expressive language. The National Joint Committee for the Communications of Persons with Severe Disabilities states, "all persons, regardless of the extent or severity of their disabilities, have a basic right to affect, through communication, the

conditions of their own existence."⁸¹ In addition to this basic right, the committee has outlined specific communication rights that should be ensured during all daily communication acts with persons with disabilities (Box 19-7).

Alternative and augmentative communication (AAC) is defined as communication that does not require speech and that can be individualized to the unique needs of the child. An AAC system uses a combination of all the methods of communication available to a child. This can include "any residual speech, vocalizations, gestures, and communicative behaviors in addition to specific communication strategies and communication aids" (p. 7).⁴⁰ The overall purpose of AAC is to enable the transmission of a message to another individual. Research indicates that individuals with complex communication needs who do not gain successful access to AAC are at high risk for abuse, crime, unemployment, and limited social networks.^{19,26}

Alternative and augmentative communication interventions should be dynamic and include not only the individual child, but also his or her primary communication partners. Beyond

BOX 19-7 Basic Communication Rights

1. The right to request desired objects, actions, events, and persons and to express personal preferences or feelings
2. The right to be offered choices and alternatives
3. The right to reject or refuse undesired objects, events, or actions, including the right to decline or reject all proffered choices
4. The right to request and be given attention from and interaction with another person
5. The right to request feedback or information about a state, object, person, or event of interest
6. The right to active treatment and intervention efforts to enable people with severe disabilities to communicate messages in whatever modes and as effectively and efficiently as their specific abilities will allow
7. The right to have communication acts acknowledged and responded to, even when the responder cannot fulfill the intent of these acts
8. The right to have access at all times to any needed augmentative and alternative communication devices and other assistive devices and to have those devices in good working order
9. The right to environmental contexts, interactions, and opportunities that expect and encourage persons with disabilities to participate as full communicative partners with other people, including peers
10. The right to be informed about the people, things, and events in one's immediate environment
11. The right to be communicated with in a manner that recognizes and acknowledges the inherent dignity of the person being addressed, including the right to be a part of communication exchanges about individuals that are conducted in his or her presence
12. The right to be communicated with in ways that are meaningful, understandable, and culturally and linguistically appropriate

From National Joint Committee for the Communication Needs of Persons with Severe Disabilities. (1992). Guidelines for meeting the communication needs of persons with severe disabilities. *ASHA*, 34 (Suppl. 7), 1–8.

the obvious function of self-expression, AAC supports the development of language and emerging literacy skills, enhances participation in educational settings, facilitates friendships, and supports interactions with family members and people in the greater community.³² When one family member relies on AAC, it always has an impact on the entire family unit.⁵⁷ For this reason, it is imperative to use a collaborative approach when evaluating and implementing AAC supports. Various members of the team will bring different levels of expertise to share: child and parents will have the best knowledge of daily communication needs and routines; teachers will have knowledge related to literacy and instruction; speech-language pathologists are experts in language development; and occupational and physical therapists provide services related to positioning, accessing, and physically using the AAC system.

Attitude and acceptance of AAC play a role in its impact on the quality and function of interactions. AAC systems are designed with layout and components that match the desires, preferences, abilities, skills, and environmental contexts of the child. Many parents are fearful that AAC will interfere with speech development, when in fact it has been found to enhance

BOX 19-8 Strategies to Facilitate Communicative Interaction

1. Structure the environment to foster interaction.
2. Attend to the child. Solicit a shared focus.
3. Provide meaningful opportunities for communication.
4. Have realistic expectations for the child.
5. Provide appropriate language input.
6. Avoid yes/no questions and “test” questions.
7. Pace the interaction. Give the student time to communicate. WAIT.
8. Follow the child's lead. Respond to his or her attempts to communicate.
9. Provide models for the child's expressive modes of communication. Coach the child as needed.
10. Prompt if necessary. Remember to fade out prompts to natural cues. Enjoy communication.

Adapted from Special Education Technology Center, Ellensburg, WA.

it.¹⁶ A family-centered approach should be used when AAC is integrated into the child's daily experiences and interactions, to ensure caregiver support of its use.⁷⁸

Communicative interaction has four purposes⁷⁷: expression of wants and needs, information transfer, social closeness, and social etiquette. There are three types of AAC communicators³⁸: emergent communicators who have no reliable method of symbolic expression, context-dependent communicators who do have symbolic communication but are limited to specific contexts because they are intelligible only to familiar partners or may have insufficient vocabulary, and independent communicators who can communicate with anyone on any topic. Children who use AAC are most frequently identified as “responders,” whereas typically developing peers consistently act as the “initiators” of communication.³⁰ These classifications can serve as a foundation for identifying and establishing an AAC system in conjunction with the use of strategies that facilitate communication (Box 19-8).

Types of Alternative and Augmentative Communication Devices

AAC devices can be viewed on at least two continua, including no-tech to high-tech systems and aided or unaided communication methods. Depending on their age, contexts, and skills, children may use a combination of aided and unaided communication and a combination of low- and high-tech devices. Unaided or body-based communication is no-tech and consists of vocalizations, gestures, facial expressions, sign language, pantomime, eye gaze, and/or pointing. All people use some combination of unaided communication. Children with disabilities often use gestures, facial expressions, and body language as allowed by their functional skills.

Aided communication systems are distinguished as either nonelectronic or electronic communication aids and require the child to be able to use a symbol system.³² Nonelectronic aids are considered low-tech and include communication boards or books, picture-based systems, or paper and pencil. Picture-based systems are used increasingly with children in preschool, children with significant disabilities, and children with autism (Figure 19-7). Some children may find it easier to

FIGURE 19-7 Example of a low-tech communication board. (Photo courtesy Judith Schoonover.)

use visual-based systems of communication and to process content delivered using such systems.

Picture Exchange Communication System (PECS) is a form of ACC often used with individuals with a variety of communicative, cognitive, and physical difficulties, including pre-schoolers, adolescents, and adults who have little or no verbal ability. Visual representation such as objects, photographs, realistic drawings, line drawings, and written words can be used to increase understanding, communication, and social connectedness and can take many forms depending on the environment and the circumstances under which they are used. Visual bridges⁶² can be designed to assist students to communicate about themselves using a combination of written words, objects, photos, computer-generated picture symbols, clip art, or other visual cues. Visual bridges can also be used during reading and writing activities. Emergent readers benefit from graphics paired with text to reinforce the meaning of print.

For individuals who have difficulty understanding two-dimensional visual representation systems such as photos, drawings, and graphics, PECS can be useful. For example, a True Object Based Icon (TOBI)—a drawing, picture, or photo cut out in the actual shape or outline of the item that is represented (Figure 19-8)—can be used with these individuals. Another example of providing symbolic representation of language, allowing communicators to relate to objects and experiences, are tangible symbols,⁹⁵ two- and three-dimensional manipulatives that can be objects, parts of an object, or an associated object that conveys meaningful information to the user or represents their communicative intent. For example, a small bit of chain might indicate time to swing, or a circle formed from a pipe cleaner may indicate “morning circle” (Figure 19-9).

Electronic communication aids or devices are generally considered more high-tech and may include speech generating devices (SGDs), talking frames, cell or smart phones, tablets, or computers. Speech-generating devices may produce digitized or synthesized speech output.³² Digitized speech records a person’s actual voice and allows flexibility in selecting a child, male, or female voice; however, it requires a lot of memory for storage and is limited to only what is recorded and stored. Synthesized speech is generated electronically but has the

FIGURE 19-8 Multiple means of representation clockwise from left: an object, a TOBI, a photo, a picture symbol, and a word. (Photo courtesy of Judith Schoonover.)

FIGURE 19-9 Example of a tactile symbol communication board. (Photo courtesy Judith Schoonover.)

advantage of text-to-speech capabilities. The intelligibility of synthesized speech can vary depending on the type of system.

Different types of simple AAC devices are available. One example can be seen in Figure 19-10A. This device can be used for communication, by containing a recorded message that is activated each time the user presses the switch (Figure 19-10B). Another simple AAC device for individuals who are ambulatory is shown in Figure 19-10C; it is worn like a watch and can have several prerecorded messages. These messages are easy to change and symbols can be used to help the user remember the messages. Using symbols when shopping can help users remember items (Figure 19-10D). Devices like those in Figure 19-10E benefit children who may eventually use more high-tech AAC.

High-tech electronic communication aids generally are either computer-based systems or dedicated systems. Computer-based systems are often considered in addition to a communication system. Computer-based systems are made up of computers that can perform as a communication system through the use

FIGURE 19-10 AAC devices. **A**, BIGMack communication device. **B**, Using a continuum of communication supports to participate in storytime. **C**, Talk Trac communication device. **D**, Using symbols while shopping to help the user remember. **E**, Supertalker to retell story. (Photos courtesy Judith Schoonover.)

of specialized software and other modifications, but can also carry out other functions such as environmental control. Ideally, computer-based systems should be able to be mounted on wheelchairs or easily portable in some other manner. Dedicated systems operate primarily as electronic communication

aids ([Figure 19-11](#)) with hardware and software features specifically designed for communication purposes. These systems are available in various sizes and weights and provide auditory, visual, or printed output. All electronic communication devices are programmed with individualized overlays. The board's

FIGURE 19-11 Example of a dedicated, dynamic display augmentative and alternative communication device. (Photo courtesy of Judith Schoonover.)

overlays can provide as few as two and as many as 128 choices to the child.

In recent years, relatively inexpensive mobile technology from touch-screen phones to tablet devices has become a popular and sometimes controversial alternative to more traditional and often more expensive speech-generating devices. Mobile apps provide many of the vocabulary building and text-to-speech features of other AAC devices and some have features that allow programming “on the fly.” Although mobile technology may be smaller and more portable, work faster, and have a more socially acceptable appearance, customizability, learnability, durability, and supports for training may be compromised.¹ Access considerations include turning on the device, navigation between programs or screens, and icon selection. Because of their mainstream popularity, many people are aware of mobile devices as possible systems to be considered to deliver communication-related systems. Caution must be exercised to avoid making the user fit the device as opposed to determining the right device for the individual. With new technologies come new approaches to providing communication devices, including one developed by a speech-language pathologist and an occupational therapist that tries to integrate and use multisensory convergence (motor, auditory, visual) to promote the development of language.⁵⁸

Selecting an Alternative and Augmentative Communication System

A number of factors are considered in designing a high-tech AAC system, the first of which is to assess understanding of symbolic representation.¹⁴ Receptive understanding of functional objects, visual matching, and spelling and literacy skills related to word recognition are all cognitive skills that help define the symbol system that is necessary. Examples of symbol systems include real objects, photographs, symbols, and traditional orthography (use of letters and words).

The control interface or manner in which the device is accessed may include use of a keyboard; single, dual, or multiple switch arrays; and joystick, mouse, or other alternative

FIGURE 19-12 Visual scene display versus grid. (From Blackstone, S. [2004]. Visual scene displays. *Augmentative Communications News*, 16, 1–5.)

pointing devices.³² Selections can be made directly by pointing or touching or via an indirect method such as auditory or visual scanning, directed scanning, or coded access. To allow communication faster than the rate of keying in text, encoding (or symbol) systems are used. This language uses sequenced multiple-meaning icons to retrieve words, phrases, or sentences. Like word prediction, many communication systems come with message prediction. Some of the more advanced systems can learn the communication “style” of the user and begin to predict with greater accuracy.

In addition to the input method, AAC devices use two visual display types (screens). A dynamic communication display offers thousands of graphics (some that are electronically animated) and text options. The display changes (using the same message-formation process that produces natural speech) based on the choices of the user. They are often accessed via a touch screen; however, alternatives are available. Dynamic displays, such as the one in Figure 19-11, are helpful for children who may have difficulties with memory, but they do require a high level of visual attention, constant decision making, and the need for mastery of object permanence. The second type, visual scene displays, offer “hot spots” that are contextually embedded within graphics that provide more meaningful and individualized interactive displays (Figure 19-12). Drager⁴⁴ made a comparison of visual scene displays and more traditional grid layouts used by typically developing 2½-year-old children during communicative tasks during a birthday party. Findings indicated that performance was better using the visual scene display.

Once a device has been obtained, programming of the device and training of the child and all communication partners are essential for success. Collaborative efforts should be taken to identify vocabulary that includes conversational messages (greetings, information sharing, and requests), core vocabulary (for literate or preliterate children to encourage language and cognitive development), and fringe vocabulary (unique to the individual child’s activities, preferences, family, environments, favorite expressions, etc.).³² Vocabulary needs will vary by context, communication mode, and individual characteristics.¹⁵ Specific functions of communication, such as requesting; rejecting/protesting; gaining attention; engaging in greetings, farewells, and other social niceties; commenting; achieving social closeness; asking for information; and confirming/denying,⁴³ must be taught to optimize communication competence (Box 19-9).⁷⁷ As with all other AT, communication systems are constantly being upgraded and changed. Continuing education courses and additional training can help

BOX 19-9 Communication Competence

Linguistic Competence: adequate mastery of the native language (i.e., vocabulary and grammar) plus mastery of the code (e.g., signs or symbols) required to operate the AAC system.

Operational Competence: mastery of technical skills required to operate the system, i.e., the motor and cognitive skills required to signal a message or to operate specific device features (e.g., pointing, signing, visual scanning, operating switches, controlling cursors, editing).

Social Competence: knowledge and skill in the social rules of communication (e.g., making appropriate eye contact, sharing the balance of talking and listening), and using communication for a range of different purposes (e.g., social chatting, requesting items, responding to others, contradicting people).

Strategic Competence: flexibility to adapt communicative style to suit the receiver (e.g., signing more slowly to strangers, turning up the volume on the communication aid).

From Light, J. (1989). Toward a definition of communicative competence for individuals using augmentative and alternative communication systems. *Augmentative and Alternative Communication*, 5, 137–144.

therapists become familiarized with the terminology, communication strategies, and available hardware and software.

Computers

Use of personal computers is becoming more prevalent in school, home, and work settings. The computer is a flexible, motivating, and powerful instructional tool that can facilitate individualized teaching and learning. Computers with or without specialized software provide multiple means of communicating, playing, exploring, self-expression, interacting with the environment, learning cause and effect, and completing school and work-related tasks with greater degrees of independence. Most children with and without disabilities have had some exposure to a computer system by the time they enter school. At home, the computer might be used for recreation, entertainment, communication, work, and study. Social connections with others can be formed through e-mail, instant messaging, and social networking sites. For example, some adolescents with disabilities describe social networks and friendships that they have been able to develop using the computer, Internet access, and appropriate software programs.¹⁰⁸

A computer can motivate children to learn and develop a large repertoire of skills. It provides simulations of experiences that some cannot otherwise experience. The computer is also infinitely patient with drill and practice and can provide the repetition needed for some children to learn. An almost endless variety of software programs, input devices, and output devices are available to customize computers to meet individual needs.⁶ Young children can be introduced to a progression of systems that follows their developmental and functional needs. Success using simple systems precedes the use of more complex systems. Table 19-5 outlines benefits of computer use for children.

At school, children typically use word processing programs, the Internet, e-mail, and virtual classrooms in some aspect of their education. Software programs cover most academic subjects as well as recreational and competitive activities. The

multimedia features of the computer can support learning rules, turn taking, and social skills. Math software and Internet sites include features such as virtual manipulatives or drills; creative writing software has recording features, sound, graphics, and animations; and keyboarding software teaches typing, as software and website designers continue to add features that make their products and sites accessible to a growing range of people and abilities.

The judicious use of computers and software can help develop literacy or strengthen skills through the use of games, screen readers, and online books. “Virtual field trips” make it possible to visit and explore environments that might otherwise be inaccessible, and computer simulations can provide preparation for social situations, academic tasks, prevocational training, and driver education. For children who are unable to recognize print in traditional formats, modifications to access the same text as that for their peers can decrease their dependence on the support of others in the environment to read or write for them. When, as a result of motor, emotional, or attention difficulties, children are challenged to produce art products or written work, the computer can assist in generating digital artwork or text that is neat and uniform in appearance. Producing more accurate, legible, or attractive work can increase self-esteem and self-expression and decrease frustration. As with any tool, the user must be aware of its features and trained in its applications and maintenance to receive full benefits. Successful computer access requires a means to provide input into the system, receive output (or information) from the computer, and process that information to use it in a functional, meaningful manner. Various types of computers (e.g., Macintosh or personal computer [PC]) are available in the home, school, clinical, and work settings. Before recommending the purchase of software programs or adapted access devices, the memory and technology of the system must be evaluated to determine its compatibility with the program. Now, many software programs are both PC and Mac compatible. For example, alternative keyboards can be used on either machine without significant reconfiguration. However, because certain hardware and access devices remain specific to either the PC or the Mac, therapists should attend to these specifications. Competencies that school-based occupational therapists should possess include the ability to operate major computing systems used in public schools and troubleshoot system problems, establish networks using telecommunications systems, operate general application programs, apply teacher utility tools, and provide computer-based instruction.⁵⁹

Input

In considering different input systems for accessing computers or tablets, the “least change” principle should be applied. This means that a standard keyboard and standard workstation with some modifications are preferred over an expanded keyboard or other type of input device if the child can use them (Figure 19-13), exemplifying the concept of least restrictive environment (Table 19-6). Interventions to enable computer access are listed in Table 19-7.

Output Systems and Information Processing

Output is the product or outcome that is produced when using a computer. Like input, output can also accommodate the needs of individuals with disabilities. Information (output)

TABLE 19-5 Benefits of Computers for Young Children

Benefit	Examples
Put child in control	Use child-directed software Allow child to move at his or her own pace Are accessible to children with limited motor control
Engage the child cognitively	Use two-switch step scanning for simple cognitive interface Use two-switch software whereby each switch has a distinct function Provide trial-and-error learning Provide logical consequences to the child's efforts Use of patterns and use of surprise Provide experiences with familiar objects and tasks Allow for active versus passive learning
Provide opportunities for choice making	Sustain attention—increase opportunity for control and cognitive engagement Further expand awareness of consequences Provide error-free learning environment
Provide language immersion	Provide voice-output feedback describing child's actions Use simple but functional language Provide opportunities for sound play Offer predictable repeated lines with periodic surprise lines to go along with the action Relate three-dimensional experiences with objects and toys to two-dimensional screen
Provide opportunities for joint attention and shared interaction	Give opportunity for adult-child interaction Encourage pointing, showing, and shared enjoyment Provide opportunity for the child to take the lead and the adult to follow along and support Provide opportunities for child-child interaction
Facilitate communicative interaction	Allow the child to express ideas Provide voice-output and visual information that may be used to communicate to someone else
Provide multisensory feedback with consistency and repetition of language and cognitive concepts	Allow virtual manipulation of objects to develop cognitive skills Provide immediate feedback to child Allow child to control repetition as desired Reinforce emerging literacy skills Reinforce emerging mathematical skills or sequence, numbers, and patterns within a play context—not adult directed
Ensure cognitive simplicity	Present concepts in small steps Help child maintain attention by providing immediate success Help child stay out of a random "guessing mode" or "trying to please mode," which could lead to inaccurate or confusing consequences

From Burkhart, L. J. *Effective use of computers with young children*. Available at <http://www.lburkhart.com/handcomp.html>.

FIGURE 19-13 Example of low-tech keyboard modifications including color-coding and enlarging letters on keys. (Photo courtesy Judith Schoonover.)

from the computer is displayed visually on the monitor or printed from the printer. For a child with visual, perceptual, or cognitive impairment, adaptations to the monitor may need to be considered. Some printers provide braille output, and several software programs provide voice output. Some of these programs read text, whereas others provide output regarding all the functions of the computer. Voice output systems can help support learning and computer use and exploration for students with learning disabilities, cognitive delays, autism, and visual impairments.

The computer's output and the user's successful processing of information are often closely related. If the user cannot successfully process and use the information received from the computer in a meaningful and functional manner, he or she will abandon the system. With the increased screen resolution and the complexity of graphics now available in computers, some users with visual-perceptual difficulties find the visual information they receive distracting or overwhelming. For example, a child who has poor figure-ground skills may have difficulty with graphics that are cluttered and complex.

TABLE 19-6 Problem Solving for Computer Access (Starting with a Standard Computer Workstation)

Problem	Potential Solutions
Difficulty pressing one or more keys	Change height of table or chair Change position of keyboard Change sensitivity of key or active delayed acceptance Use a keyguard Use an expanded keyboard with larger keys Use a stylus, mouthstick, or headstick Change size of letters on keyboard
Tendency to produce multiple characters rather than one	Change height of table or chair Change position of keyboard Change sensitivity of key or active delayed acceptance Deactivate auto-repeat
Difficulty holding down more than one key simultaneously	Use Sticky Keys feature or utility Use a mechanical key latch
Ability to use only one hand	Teach student to use one-handed typing techniques for standard keyboard Use a chord keyboard Reconfigure the keyboard to use one-handed pattern Use onscreen keyboard and mouse for typing
Difficulty with the standard mouse	Use a trackball Use a trackpad Create a mouse track template Use MouseKeys feature of operating system
Slow or inefficient input	Increase keyboarding practice so that motor patterns are more automatic Set up templates for standard formats Use macros and abbreviation expansion for repeated words and phrases Use word prediction software programs
Drooling	Use a keyboard cover (Safe Skin) Use alternative keyboards that are not moisture sensitive
Difficulty seeing the screen or highlights	Ensure that the monitor is not facing a window or that the blinds are drawn Use an antiglare filter Reduce glare by turning down overhead lights Change size of font Change font (serif fonts are better for reading text; sans serif fonts are better for letter recognition) Change attributes of font (bold) Change color of background or text for greater contrast Set screen to monochrome Use a large screen or lower screen resolution Use a screen magnifier (hardware or software)
Difficulty reading text	Ensure that the monitor is not facing a window or that the blinds are drawn Use an antiglare filter Reduce glare by turning down overhead lights Change size of font Change font (serif fonts are better for reading text; sans serif fonts are better for letter recognition) Change attributes of font (bold) Change color of background or text for greater contrast Set screen to monochrome Use a large screen or lower screen resolution Use a screen magnifier (hardware or software) Use a voice output tool (screen reader)
Tendency to be distracted by sound	Turn off sound features of application Turn down volume from system control panel
Difficulty hearing feedback	Use hearing protectors or noise-canceling ear protectors Turn up volume (can use headphones) Use amplified speakers
Difficulty finding correct key on the keyboard	Use stickers or enlarged key letters to highlight correct keys Increase size or contrast of keyboard caps Use color coding for "landmark" keys Use Kids Keys Keyboard (for younger students) Mask nonapplicable keys

TABLE 19-6 Problem Solving for Computer Access (Starting with a Standard Computer Workstation)—cont'd

Problem	Potential Solutions
Difficulty shifting between information on the screen, the keyboard, and the desktop	Use document clip to suspend printed page next to monitor Change position of keyboard Change position of monitor Use a touch screen and on-screen keyboard
Difficulty remembering keyboard functions	Develop a “cheat sheet” of keyboard shortcuts to keep close by Develop keyboard mnemonics to aid memory of keyboard functions
Decreased motivation	Recheck student goals to ensure student involvement in goal-making process Try a different software program to address goal Change the purpose for which the computer is being used Change the access method Decrease the amount of time on the computer Scale the activity to the student's skills (up or down)

From Swinth, Y. L., & Anson, D. (1998). Alternatives to handwriting: Keyboarding and text-generation techniques for schools. In J. Case-Smith (Ed.), *AOTA self-paced clinical course: Occupational therapy: Making a difference in school system practice*. Rockville, MD: AOTA.

TABLE 19-7 Computer Access

Input	Ergonomic keyboard Disabling auto-repeat function Keyboard adaptations (color-coded, alphabetic, keyguards) Direct (expanded) and indirect (letter scanning, switch) selection
Alternate keyboards	Membrane: require less pressure to activate and allow customization of overlays Miniature: smaller and lighter; designed for users with decreased strength and range of motion Chord: designed to minimize finger travel; require multiple simultaneous keystrokes to produce letters and phrases Onscreen keyboards: provide image of keyboard that can be accessed via mouse, touch, trackball, joystick, eyegaze
Mouse emulators	Devices that simulate mouse movement and selection, including arrow keys, touch pads, trackballs, head pointers, interactive whiteboards, and touch windows and screens
Voice recognition	The computer or tablet recognizes and translates voice sounds into text or commands (refer to Evolve website for more information)
Other input	Other types of input systems used with children include eye-gaze systems, braille, TouchFree Switch, and a Tongue Touch Keypad. Once the user activates the keys, a signal is sent to an interface box connected to the computer

Software

Careful decisions must be made to find programs that match interests and skills. With the burgeoning number of software programs available, from simple to highly complex, many with disabilities can use common software programs that are available to everyone. Often software programs require that the user make specific, discrete responses to visual, auditory, or tactile stimuli. The user must be able to attend briefly and have the interest and motivation to activate a toy or a computer purposefully. Computer activities and programs, including public domain software, can be used to teach basic skills, such as object permanence, sustained attention, and cause-and-effect relationships. Other computer programs teach skills in discrimination, matching, and directionality. The OTP can determine whether and how the software customizes the video and audio display to meet students' individualized needs.

Because computers operate using different input and output methods and a large variety of software programs are available, they are useful tools to promote children's functional independence in life roles. Children can have opportunities to use

computers throughout their school years and into their work settings; they can also use computers as environmental control devices and for play and leisure exploration.

Electronic Aids for Daily Living

Originally EADLs were known as environmental control units (ECUs). These are systems that allow the child to interact with and manipulate one or more electronic appliances, such as a television, radio, CD player, lights, telephone, or fan, using voice activation, switch access, a computer interface, or adaptations such as X-10 units (transmitters and receivers) that use a communications “language,” allowing compatible products to interact with each other using the existing electrical wiring. The EADL should meet primary needs as well as any long-range goals. The system should also be fairly easy to assemble, learn to use, and maintain. As mentioned previously, EADLs can be integrated into a computer system. They also can be stand-alone systems. Some of these systems have a discrete control interface (an electronic device is turned either on or off, such

FIGURE 19-14 Schematic of an EADL setup with the Powerlink. (Drawing courtesy Ablenet.)

as a light, fan, or television), and others are capable of continuous control interface (devices that operate in successively greater or smaller degrees of control). Lowering and raising the volume on a television and dimming a light are examples of continuous control. A common EADL setup used with children is shown in Figure 19-14. Many EADL options are available for a variety of settings.

Changing the Landscape in Education: Planning for Every Student in the Twenty-First Century

Universal Design for Learning

One aspect of universal access that is gaining increased attention in the schools is universal design for learning (UDL).⁹⁴ UDL is defined in the Higher Education Opportunity Act (P.L.110-315) as:

A research-based framework for designing curriculum—including goals, methods, materials, and assessments—that enables all individuals to gain knowledge, skills, and enthusiasm for learning. Universal design for learning provides curricular flexibility (in activities, in the ways information is presented, in the ways students respond or demonstrate knowledge, and in the ways students are engaged) to reduce barriers, provide appropriate supports and challenges, and maintain high achievement standards for all students, including those with disabilities (HEOA, P.L. 110-315, §103[a][24]).

The concept of universal design (UD) was referred to by the Center for Applied Special Technology²⁸ as a framework for educational reform based on decades of brain research and focused on providing curriculum and materials to support learners with diverse needs in today's schools. Principles of UD in the educational environment assume that students with a variety of skills and needs will be participants in learning and that the goals, curriculum, instructional materials, and assessments need to proactively anticipate and address this diversity through alternatives, options, and adaptations. School administrators have placed increased emphasis on the development and implementation of a universally designed curriculum that allows all children equal opportunity to learn and demonstrate what they have learned. UDL advocates for more than one way to represent content (the “what” of learning), plan and execute learning activities (the “how” of learning), and achieve and maintain learner engagement (the “why” of learning). It involves developing and improving learning environments where all children are included.

Three principles form the framework of UDL²⁷:

1. Multiple means of representation to give learners various ways to acquire information and knowledge (e.g., more than one example, critical features highlighted, use of media and formats, use of background context)
2. Multiple means of actions and expression to provide learners with options to demonstrate what they know (e.g., flexible models of skilled performance, opportunities to practice with supports, ongoing, relevant feedback, flexible opportunities for demonstrating skill)
3. Multiple means of engagement to tap into learners' interests, offer appropriate challenges, and increase motivation (e.g., choices of content and tools, adjustable levels of challenge, choices of rewards, choices of learning context).

Assistive technology and accessible software are important elements of a universally designed curriculum.⁶¹ Through their professional assessment and unique understanding of the relationship between the environment, the person, and demands of occupational engagement, OTPs in school settings have practiced UDL principles and provided interventions that include multiple means of representing what they want the student to learn or do, accommodating for differences in perception; engaging the student to maintain that “just-right” challenge of attention motivation and self-regulation; and allowing students to “show what they know,” as well as assessing the effectiveness of their intervention.¹⁰¹ UD, UDL, and AT share the goal of reducing barriers and facilitating participation, yet UD and UDL do not replace the need to provide AT *devices* and particularly AT *services*. Assistive

technology is based on an individual need, whereas UDL is approached from an educational environment standpoint in which instructional design meets a diverse population of learning style and needs. Students may require individually selected AT devices in the form of communication devices, visual aids, mobility supports, particular software, and adapted toys and tools in order to meaningfully participate in their roles as learners.

Instructional Technology

The influx of technology into our daily lives has resulted in dynamic and continuously changing tools altering the way we work, play, and socialize. The National Technology Plan for Education 2010 calls for schools to infuse curriculum and teaching methodology with technology skills. One of the many goals (and benefits) of the National Educational Technology Standards is designing student-centered, project-based, and online learning environments to meet the learning styles and needs of a wide range of students.

Schools use many kinds of instructional technology, providing software in most academic areas and for students of all ages. Examples include literacy software to develop letter-to-sound correspondence, math software for drill and practice of math facts, keyboarding software, and content-area software to reinforce concepts of science and social studies. Student assignments may include copying or producing written work using a word processor, research using the Internet, and e-mail. The inherent flexibility of technology offers opportunities for differentiation and scaffolding consistent with educational initiatives such as UDL and Response to Intervention with potential for improving the learning and achievement of all students. For example, use of a technology-based graphic organizer can provide nonreaders and readers with visual representation of a concept with text, images, and/or graphics and sound recordings. Educators can embed recorded directions and specific details to further enhance the graphics and support student learning.

This same technology plays an additional role for persons with disabilities by providing access to the learning environment. Features in software applications including adjustable user settings and alternate keyboard access can help reduce barriers and positively influence participation. Occupational therapy practitioners who are aware of the accessibility needs of their clients can advocate for the purchase of accessible instructional software. The National Center on Accessible Information Technology in Education promotes the use of electronic and information technology for individuals with disabilities in educational institutions at all academic levels and features a searchable database of questions and answers regarding accessible educational and instructional technology on its website (<http://www.washington.edu/accessit/>). Features to consider in evaluating accessibility of instructional software are outlined in [Box 19-10](#).

Sometimes students with disabilities *require* technology that is helpful or sometimes used by students without disabilities such as calculators and word processors. Students with disabilities might *need* to use calculators or word processors or use them with modifications to participate in math or writing activities. This need redefines common classroom tools as AT that may be a required service in the IEP; therefore it is important

BOX 19-10 Key Features to Consider In Evaluating Accessibility of Instructional Software

- Does the documentation describe accessibility features such as keyboard access to functions and features, options to change display settings such as size and font, options to turn off animation or blinking, and information about how to turn on captioning for video content of the software program?
- Is documentation available in electronic text so that it can be converted easily to braille or audio formats and can be read easily by people who use a screen reader or screen magnification program?
- Are all commands and functions available from the keyboard? Keyboard commands or shortcuts provide a simplified method for navigating through menus and dialogues and making selections. These features are important for individuals who may not see the cursor on screen or who have difficulty with mouse control.
- If information is conveyed in color, is it also conveyed using text?
- Can users select features such as size, color, font, and contrast to aid those with visual or perceptual difficulties?
- If the software uses animation such as flashing, rotating, or moving displays, is all information available when animation is turned off to support users who might become distracted or visually overwhelmed?
- Is information that is conveyed with sound such as music, narration, or tones also conveyed in another way?
- If a software program uses video to convey important information, is that information available in other formats such as a transcript or audio version? If the software program requires timed responses, can the response times be adjusted or disabled to meet user needs?
- Does the software program allow and support use of AT such as screen reading software, screen magnification software, voice recognition software, word prediction software, alternative keyboards or computer mice, and software that helps people who have difficulties reading and writing?

National Center on Accessible Information Technology in Education (AccessIT). (2004). Accessible Instructional Software in Education (Publication #6). University of Washington. Retrieved September 2014 from http://adasoutheast.org/ed/edpublications/itseries/6_Instructional_Software.pdf.

to consider how important the tool is to the student's learning and participation.

Occupational therapy practitioners should have knowledge of the accessibility features of computer operating systems and networked software; an awareness of the attributes available in instructional tools such as overhead projectors, interactive whiteboards, digital cameras, and tablet computing; an ability to use the Internet; and programs or software to connect with others electronically.

Assistive Technology for Literacy Skills

Literacy skills include the complicated processes of reading, writing, and spelling as forms of communication; reading is the communication process of constructing meaning from written text, and writing is the communication process of composing meaningful text.

The primary goals of IDEA 2004 and the No Child Left Behind Act of 2001 are improving student achievement and providing students who have disabilities with access to the general education curriculum; however, providing access does not guarantee increased participation, especially for children who have reading and writing difficulties. Public educational institutions must ensure that communications with persons with disabilities “are as effective as communications with others” as mandated by Title II of the ADA by the federal Office of Civil Rights (OCR) (28 C.F.R. § 35.160[a]). In this context “communication” means: “The transfer of information, including (but not limited to) the verbal presentation of a lecture, the printed text of a book, and the resources of the Internet.”

Children who struggle with learning to read and write need to be supported by individuals who can accurately assess their strengths and weaknesses and select and apply AT tools and strategies effectively. Assistive technology can help children with disabilities in language acquisition by learning to attend to words and enhancing their interest in listening to stories. Most important, they can increase their opportunities for social engagement. Koenig and Holbrook define functional literacy as “the application of literacy skills and the use of a variety of literacy tools to accomplish daily tasks in the home school, community, and work setting” (p. 265).⁶⁹ A multitude of software, word processors, text readers, and electronic books are available on the Internet to support children’s literacy. An essential element related to the effectiveness of technology in supporting literacy is its interactive quality, which allows children to get involved with the content as they manipulate the media.⁵⁰ Literacy software programs interact with children, similar to a parent’s reading to children and involving them in the book by turning the pages, looking at pictures, and asking questions. Technology allows children to control the process by “hooking” their interest. Koenig reiterates the importance of starting early with children “regardless of the severity” of their disability.⁶⁸ For additional information, refer to the Literacy Support Software Comparison Chart from Spec-tronics Inclusive Learning Technologies available on the Evolve website.

Reading Skills

Children most at risk for reading difficulties are those with less verbal skill, phonologic awareness, letter knowledge, and familiarity with the basic purposes of and mechanisms for reading.²² Research on early reading development emphasizes the pairing of written words and sounds for helping children’s decoding skills. For children with physical, visual, communication, or cognitive delays, traditional books may restrict their abilities to interact with and access books. One of the methods that can be used to provide successful literacy experiences is through adapting books.³³ Adapted books provide print access that follows the UDL framework. Adaptations can include making books easier to use (turning pages or holding) and text easier to read (simplified, changed) and remember. The original story or subject is maintained but may contain modified language, clear visual representations, and manageable page layouts to increase the potential for participation. Adapted books can be prop- or paper-based or created electronically with software or apps. Adapted books can be used by themselves or with AT

FIGURE 19-15 Example of an adapted book with tactile and rebus symbol support. (Photo courtesy Judith Schoonover.)

ranging from low-tech homemade devices to switches, voice output communication aids, braille or large print materials, sign language, or adapted props. For more information on how to create, publish, and share free e-books, see [Box 19-3e](#) on the Evolve website.

Copyright laws allow the creation and use of books in an alternate format solely for the purpose of making the book accessible to persons with disabilities; however, it is important to review copyright laws and how they pertain to each situation in which an adapted book is being contemplated. A copy of the original book is required when using an adapted book. Books can be adapted to provide physical access to text by creating space between pages with page “fluffers” (foam, weather stripping, sponges, giant paper clips, clothespins), using book holders for stabilization (recipe book holders, card holders, acrylic display frames, easels), or reproducing them so that they can be listened to or viewed with technology ([Figure 19-15](#)). Accommodations for print difficulties include change in font size and color, magnification, contrast, audio output, tactile display, icon-enhanced text, scaffolded information, and multimedia. Altering the spacing between characters, words, lines of text, and in margins can affect a reader’s ability to more easily view and interpret print. Electronic books combine reading, writing, listening, and speaking and provide a multi-sensory approach with related pictures, sound, and video, and appeal to different learning styles. The ability to read is essential for many daily life activities and participation in varied environments at home, school, work, and in the community. Reading contributes to play and leisure, academics and world knowledge, communication and social awareness, following directions and schedules, shopping and meal preparation, and work-related tasks. Edyburn proposed a process of scaffolding digital text to meet the varied reading and cognitive needs of children by reducing the amount of text, as well as adding additional visual cues in the form of pictures or symbols. He used the term *cognitive rescaling* to describe “a process of altering the cognitive difficulty of information” (p. 10).⁴⁷ (See Evolve website for resources on cognitive rescaling.) Print materials can be designed or transformed with supports

embedded to ensure that all learners have access to information through the use of common software features such as evaluating readability level, summary tools, voice recordings, and autocorrect in novel ways. Comprehension can be aided by inserting graphic organizers, photos, and video. Students can also be taught to alter the amount, cognitive challenge, and appearance of digital text.⁸³ Other accommodations for print disabilities include the use of commercially available talking photo albums, specific reading software, e-books, audio recordings, screen readers, and multimedia.

Although trends in education are changing, and more school districts are turning toward digital textbooks, many resources and texts written and published primarily for use in elementary and secondary school instruction and required by the state education agency or local education agency for use by students in the classroom are print-based. Some students may have difficulty accessing these materials, such as those with low vision or blindness or those with physical challenges who are unable to hold a book or turn pages. Provisions within the IDEA require state and local education agencies to provide the same information found in textbooks or handouts in specialized formats called “accessible instructional materials” (“AIM”) such as braille, large print, audio, and digital text to students with disabilities who require them in a timely manner (Section 300.172, Final Regulations of IDEA 2004). The website of the National Center on Accessible Instructional Materials (<http://aim.cast.org/>) serves as a resource to educators, parents, publishers, conversion houses, accessible media producers, and others interested in learning more about implementing AIM and National Instructional Materials Accessibility Standards. Occupational therapy practitioners working as a part of a team can assist in the identification of needed learning opportunities for students with print disabilities, assist students in using the materials provided in alternative formats, and collect data on the effectiveness of the provided supports. Based on their ability to assess motor, cognition, language/processing, and sensory strengths and weaknesses, OTPs can assist with selection of the appropriate technology (interface/input, processing, output, properties), instruction, training, accommodations, and/or modifications associated with AIM.

Assistive Technology for Writing

The act of writing not only requires motor and sensory skills but also includes cognitive processes in the form of recognizable language and vocabulary; generation of ideas; organization of ideas; expression of ideas; and use of correct grammar, punctuation, and spelling. With handwriting as the most common reason for referrals to occupational therapy in school-based practice, practitioners are well aware that writing skills can be enhanced with no-tech or low-tech aids and devices. Simple adaptations, like smooth-writing pens that are comfortable to hold or adapted paper, can make the difference between needing physical assistance and working independently. Service delivery in the natural context, using tools that are intuitive, may mean borrowing or adapting tools that already exist in the classroom.

For individuals who may have motor difficulties that affect the ability to write for function, alternatives to written production should be explored such as the use of a keyboard and mouse (or alternative mouse), portable word processor, or

notebook computer. Technology competencies should not be limited to teaching keyboarding as an alternative to handwriting, but rather encompass the accessibility features of computer operating systems and networked software; an awareness of the attributes available in instructional tools such as overhead projectors, interactive whiteboards, digital cameras, and tablet computing; and an ability to use the Internet or connect with others electronically. Beyond the physical components, writing can be conceptualized as a cognitive process that includes the following steps: prewriting/brainstorming ideas, drafting/composing and organizing initial ideas, editing, and, finally, publishing the final product.³²

Standard word processing and multimedia software, often available in the classroom, features sizable and colored fonts, margin and line spacing options, spell and grammar checking, opportunities for outlining and highlighting, use of tables to organize information, use of macros and abbreviation expansion, general accessibility features, and incorporation of multimedia to represent ideas. More specifically, concept-mapping software allows the user to conceptualize information graphically using a combination of pictures and/or text. It is helpful for planning, organizing, and drafting and frequently offers templates for getting started.

Other software products allow the child to complete a written assignment with visual and/or auditory feedback. Word prediction and word completion can reduce the number of keystrokes necessary and as a result may increase overall speed.³² After a child types in the first few letters of a word, the program will attempt to predict whole words and presents a list of choices for the child to scan and select (Figure 19-16). Many word prediction programs include customizable dictionaries that suggest alternative word selections, which can facilitate improvement in the quality of a child’s written work. These features are beneficial to support spelling for children who have good word recognition skills. Spell-checking programs have proved to be helpful editing tools, specifically when integrated into a word processing program; however, grammar checkers have not.⁷⁶ Other options may include use of a traditional or electronic dictionary or thesaurus for children who have word retrieval deficits.

In combination with visual supports, some children benefit from the use of auditory feedback. Text-to-speech software converts printed digital text to synthetic speech and is available in a number of software applications, free Internet downloads, and in Windows and Macintosh operating systems. Synthesized text-to-speech screen readers support drafting and editing, which can help detect errors by reviewing what is written and listening to individual letters, words, or sentences. Most

FIGURE 19-16 Example of word prediction software.

text-to-speech applications feature highlighting functions providing audio as well as visual support. They also reduce the visual load for individuals with visual processing deficits and are a valuable alternative for auditory learners. Users with print disabilities can also access contents of web pages, e-mail, e-books, or printed documents when paired with digital speech output, which is available in a number of applications. The age and gender of the “voice,” reading rate, dynamic highlighting, and color of font and background can be manipulated to address the individual needs or preferences of the user. In addition, word processing applications often include a voice recording feature to support the writing process. Ideas can be captured through recording, then listened to in order to transcribe, or an educator can relay directions or offer instructional prompts within the text document.

Some children require speech-to-text (or voice recognition) options that allow them to dictate thoughts and commands to a program that produces written text for them. Speech input technology responds to the human voice by producing text or executing verbally dictated commands to navigate through computer applications.³² Speech recognition presents words through speech, so to produce accurate dictation the user must have appropriate breath support and oral mechanisms.⁶⁰ The process results in a multisensory written language experience. Voice quality, pitch, volume, and articulation have a direct impact on the quality of the product generated, as well as set up and positioning of the user. In addition to specific dictation software products and apps, Windows and Macintosh operating systems include speech recognition features. A substantial training component is required to use this type of technology, and the environmental context in which it is used must be examined closely. Speech input can be accomplished by dictating to another individual or to a tape recorder or by using the record feature in various operating systems or applications as a less costly alternative. This allows individuals with intelligible speech to express themselves, even when writing is problematic for attention, motoric, or cognitive reasons.²⁶

Assistive Technology for Math

Mathematics is a part of typical school curriculum and is considered a functional life skill. Mathematical concepts include sorting, numbers, differences in attributes (color, shape, size), patterns, counting, sequence, graphing, and numeration. Ideally, a combination of individualized instructional strategies and numerous opportunities to use and manipulate concrete objects to count, sort, compare, and combine is used to reinforce concepts of same/different and greater than/less than/equal to. Additional support (e.g., grippers, nonskid materials), access to a calculator (Figure 19-17), or alternatives to hands-on manipulation such as “virtual manipulation” (<http://nlvm.usu.edu/en/NAV/vlibrary.html>) allows active participation in math exploration for all.⁸

To determine whether a child needs AT in the area of mathematics, the IEP team should consider whether the child can effectively participate in math instruction and complete math requirements of the curriculum or work setting without the use of aids/devices. If not, then a determination must be made regarding which tools would most effectively reduce barriers to accessing the curriculum. Refer to Table 19-8 for a description of math supports.

FIGURE 19-17 Examples of no-tech, low-tech math supports including TouchMath, number lines and counters, coin calculators, a calculator with enlarged buttons, a Time Timer, and a standard Judy Clock math manipulative. (Photo courtesy Judith Schoonover.)

TABLE 19-8

Assistive Technology Supports for Math

Number line/ruler	Provides visual support for writing numbers correctly as well as basic computation
TouchMath	Multisensory teaching approach that links manipulation with memorization of math facts
Enlarged or masked math worksheets	Reduces visual clutter and provides additional space for showing work
Graph or grid paper	Supports alignment of problems
Alternative response methods	Number stamps, stamps for drawing graphs, clocks, and number lines
Handheld calculator	Provides visual support for writing numbers correctly or in sequential order as well as computation
Talking calculator	Vocalizes data and resulting computations through speech synthesis
Special features calculator	Options to speak and simultaneously display numbers, functions, entire equations, and results
On-screen calculator	Features such as speech synthesis and adjustment to display including size and color of keys and numbers
Specialized calculator	Realistic money bill and coin buttons to count money or teach value of different coins

Assistive Technology as a “Cognitive Prosthetic”

Assistive technologies for overcoming challenges associated with focus, memory deficits, ability to organize, and task completion is an important emerging field. Portable organizers can

be used as cognitive aids and assist in organization and self-regulation by providing self-directed electronic task management support for vocational and nonvocational activities.⁵³ Tablet-based computing devices and their associated applications enhance the lives of students with cognitive challenges by providing them with academic, communication, leisure, employment, and transition support and access to vital information in a socially acceptable format. Edyburn⁴⁹ defines cognitive prosthetics as assistive technology that helps a person use compensatory strategies to perform daily activities.

Typically electronic in nature, cognitive prosthetics include personal digital assistants, pocket personal computers, watches with alarm features, mobile devices including cell phones with reminder features, etc. Personal digital assistants and other mobile devices have touch screens that allow a person to input, save, and retrieve information. These devices offer a portable solution for keeping track of assignments, appointments, reminders, and contact information, as well as deliver prompts or access preferred stimuli, and may include microphones, forward- and backward-facing cameras, and touch-screen capabilities. Pictures and videos can be used to provide social cues, step-by-step directions, and more. Personal calendars and daily planners can be used to manage time and complete tasks. Global positioning system receivers can help with independent navigation within the community. The multiple function capabilities of mobile device platforms may permit a consolidation of tools. Apps, software, and free Internet sites can help organize daily and monthly activities. Online tutorials and apps can deliver training that can be repeated many times. Software that is multisensory, can be personalized, is reinforcing, and can motivate is preferable. It is important to consider the limitations of mobile devices, including the need for technical competencies in order use them independently, and the possibility of disruption owing to damage, malfunction, or theft.

Not all cognitive supports are high tech in nature. Structuring the environment can also enhance performance. For example, shields or color codes on equipment can help with focus and sequencing; using carrels around work areas can reduce visual distractions; and earphones can help block out sound distractions. Other simple solutions include portable timers, alarm clocks, social scripts, and watches with alarms.

Assistive Technology and Transition

Transition planning is essential to pave the way to successful change. Transitions are an inevitable part of life, yet the passages from preschool to elementary school, elementary school to high school, and high school into early adulthood can result in a loss of continuity. For an individual with disabilities, transitions can be especially challenging if the supports that provide access to participation are not available or prove unsuitable in the new environment. Critical information, as well as competencies, can be lost if positioning, teaching methodologies, and information regarding specialized technology are not passed along from one stage and setting to the next. IDEA mandates the provision of both AT services and transition services for students with disabilities. When a student with a disability requires AT to accomplish one or more functional skills, the use of that AT must be included in effective transition planning. Transition plans for AT users address the ways the student's use of devices and services are transferred from one setting to

BOX 19-11 Components of Effective Transition Plans for Assistive Technology Users

- Address the AT needs of the student, including roles and training needs of team members, subsequent steps in AT use, and follow-up after transition takes place.
- Empower the student using AT to participate in the transition planning at a level appropriate to age and ability.
- Recognize advocacy, as related to AT use, as critical to the plan's success.
- Identify the AT requirements in the receiving environment.
- Proceed according to an individualized timeline.
- Address specific equipment, training, and funding issues such as transfer or acquisition of AT, manuals, and support documents.

The QIAT Community (Revised, 2012). Quality Indicators for Assistive Technology Transition. Retrieved September 2014 from <http://indicators.knowbility.org/indicators.html>.

another. AT transition involves people from different classrooms, programs, buildings, or agencies working together to ensure continuity. In addition to ensuring that AT devices and support services accompany students during transitions, service providers should assist clients and their families in becoming responsible users of AT. The goal of self-management and independent use should begin the first time a child uses AT, steering him or her onto a path of optimal independence as an adult. Competencies should be developed in the area for which the AT device was chosen (e.g., communication, writing) as well as in how to use and care for the device, when to use it, and the social implications and responsibilities of using the device.²⁴ Development of self-determination skills to ensure that AT becomes an integrated part of typical routines will aid in successful transitions from home to school and from school to the community.²⁴

For individuals beginning or ending their public school education, transition planning is included in legal mandates; therefore transition plans should contain a statement of needed AT devices and services and indicate agency responsibilities and linkages, if appropriate. Various agencies may be involved, and the decision regarding who is responsible for providing the AT services needed for successful postgraduation activities should be determined in advance by the transition team.

The QIAT Consortium has identified areas of best practice for AT transition⁸⁸ (Box 19-11), and although their guidelines focus mainly on the late high school transition to postsecondary and work placement, they serve as a reminder of the goals of the transition process and help identify key elements that need to be addressed in a transition plan. The FCTD Family Information Guide to Assistive Technology and Transition Planning, available online and in printable (pdf) format, was last updated in 2009 and includes sections on transition planning and AT, laws governing accommodations and transition in birth to 12 years, postsecondary settings, resources, and more.

Evidence-Based Practice and Assistive Technology

Research of AT services and outcomes is limited.^{46,48,96,107} Because of the ever-changing nature of this field, the

CASE STUDY 19-1 Assistive Technology Problem Solving

Jeremy

Jeremy is a 2-year-old with Down syndrome. His family wants to provide every opportunity for him to develop cognitive skills. They plan for him to attend general education classrooms as he gets older. They were recently at a conference and heard about tablet technologies as tools for supporting learning and educational performance for some children with Down syndrome. They asked the early intervention team to recommend a tablet and apps to use with Jeremy. Would you recommend a tablet for 2-year-old Jeremy? If so, what criterion would you use to determine which apps to recommend?

Linnea

Linnea is a third grade student with spinal muscular atrophy. She is fully included in her neighborhood school with support from related services as needed. Recently she has been complaining to her parents and therapists that her hand gets tired when writing and that her handwriting looks “sloppy.” Her teacher also has noticed that she seems irritable and lacks concentration during class. Linnea, her family, and her therapists have discussed using computers for written communication in the past, but Linnea and her family have always been reluctant to explore this at length because she does not want to “look different.” Linnea has had experience with

computers since kindergarten. Her class goes to the computer lab three times a week, and she began learning basic keyboarding skills in second grade. Her classroom has two computers that students use for drill, practice, and special projects. How would you address written language requirements in the context of Linnea’s classroom using a UDL approach?

Margy

Margy is 17 years old and has cognitive impairments and attention-deficit/hyperactivity disorder (ADHD). During her last individualized transition plan, her family expressed the desire for Margy to get a job in the family carpet cleaning business. Margy enjoys greeting people, and others enjoy her bubbly and outgoing personality, so her parents felt it would be good if she could work with the receptionist in the front office of their business. Her father felt that she should have more responsibility than simply greeting customers. Challenges reported by her teacher include being on time to class, remaining focused on tasks, and organizing herself and materials. In addition, Margy has a difficult time communicating when she gets nervous, which can affect her intelligibility. After further discussion, the team agreed that this could be a reasonable expectation for Margy and worked to develop a plan to reach this goal. Which AT and/or environmental modifications might you consider for Margy?

complexity of the devices, and the need for individualized decisions, it is difficult to build a large evidence base in this area of practice that is consistent with the available technology.⁴⁸ Some AT companies are adding research information regarding their products and AT outcomes to their websites; however, research published in peer-reviewed journals may be of higher quality and avoids the bias often found in research used to promote products to consumers. Whenever possible, AT research should guide and support decision making and provide further foundational knowledge about AT devices and services. When evidence is not available, OTPs working in this area must engage in data-based decision making with each client to document whether the use of the device results in increased participation and engagement across environments. Occupational therapy practitioners should be good consumers of AT research and should also measure and document AT outcomes as part of best practice services. Ongoing research examining the effectiveness of AT as an intervention is needed.

Summary

Assistive technologies can diminish the impact of disabilities and allow children improved alternatives to participate.⁸⁰ Occupational therapy practitioners who work with children and youth are ideally suited to evaluate and determine an appropriate match of AT tools to the child and should become familiar with the continuum of AT options available on the Evolve website (see [Table 19-8e](#)). Recent advances in AT allow many devices to grow and expand with the child during the

developmental years and into adolescence and adulthood as they undergo transition into higher education and community work experiences. With the current pace of progress and research, future AT will offer greater ease of use, wider application, assistance in additional areas of function, and more availability as a result of lower costs ([Case Study 19-1](#)). The responsibility of those who implement AT intervention is to provide a health-promoting balance between occupational roles and activities consistent with the individual’s valued goals and interests, as well as the demands of society.¹⁰⁵

Most people could not escape technology if they tried. Cell phones, tablets, and social media affect all aspects and contexts of everyday life, including work, leisure, self-help, and interpersonal relationships. Most important, *assistive* technology changes and reshapes attitudes about what people *do* and *can do*. With this influx of new tools, it is crucial to determine the “right tool for the job.” Occupational therapy practitioners have the opportunity, challenge, and responsibility to educate themselves and others about the possibilities offered by new technologies, while not forgetting that the best solution might be the easiest and least complex.

Collaboration among team members and professional development are necessary practice components of AT that require both time and commitment. Barriers to collaboration include finding time and a place to meet. Technology can be used by practitioners to bridge time and distance gaps such as use of an electronic survey to schedule meetings or to post planning documents online in order for all shareholders to contribute thoughts and ideas. Although meeting in real time may be preferable, use of conference calls, multimedia, video

conferencing, e-mail, “cloud storage” of documents, and chat rooms can support productivity on behalf of the children and families served. Care should be taken that the modalities chosen meet the learning style and comfort level of the participants.

The direct connection between occupational therapy and AT allows us to unlock human potential and optimize human performance through the promotion of participation in activities that are personally meaningful, relevant, and life sustaining. The challenge is to increase collaborative practices, insist on opportunities for professional development, advocate for the provision of appropriate AT, and continue to define the role of occupational therapy in the provision of AT.

- Children who use AT at an early age have the advantage of developing with and using it to benefit them throughout their lives.
- Occupational therapy practitioners should become familiar with the continuum of AT options and engage in ongoing professional development to maintain competency.
- The combination of occupational therapy and AT services together can promote success across all areas of occupation.
- It is important to recognize how the physical, academic, social, and virtual environments contribute to functional performance.
- AT is both a device and a service and must be matched appropriately to the child and family’s needs.
- Collaboration with other team members is essential.
- UDL allows access for all while simultaneously meeting the needs of children with disabilities, thus creating an inclusive climate for social participation.

Manual wheelchairs	Positioning

GUIDING QUESTIONS

1. How is mobility important to a young child's development?
2. What factors should be considered during an evaluation for seating and mobility equipment?
3. How is mobility assessed and categorized for different levels of motor function?
4. What are alternative methods of mobility appropriate to meet the child's developmental and functional needs?
5. What are wheelchair features and designs that meet the needs of children with various levels of motor control?
6. What power mobility devices are currently available?
7. How do occupational therapists and family determine the most appropriate device?
8. How is technology used to assess seating and positioning?
9. What devices are available to children with unique seating and position needs?
10. How do positioning and seating affect function and successful use of a mobility device?
11. How are biomechanical principles applied to position and seating?

This chapter presents an overview of the importance of mobility for growth and development and the implications of impaired mobility. Responsibilities of the occupational therapist for evaluating and recommending appropriate mobility devices are emphasized. Guidelines and criteria for selecting mobility equipment are defined, and descriptions of mobility devices are provided. This chapter also describes the importance of positioning and other factors that influence successful use of assistive devices.

Mobility is fundamental to an individual's overall development and functioning in the occupations of self-care, work, and play and is essential to quality of life. The definition of *functional mobility* includes moving from one position or place to another (e.g., bed mobility, wheelchair mobility, and transfers [wheelchair, bed, car, tub or shower, toilet, or chair]), performing functional ambulation, and transporting objects. *Community mobility* is defined as moving oneself in the community and using public or private transportation (e.g., driving or accessing buses, taxicabs, or other public transportation systems). This chapter addresses primarily mobility as a means of locomotion, with an emphasis on evaluation and intervention principles.

Developmental Theory of Mobility

The newborn has little independent control of any part of the body. Motor and sensory symmetry and midline orientation develop gradually, followed by controlled purposeful movements and the beginning of alternating coordinated movements. The first form of mobility that the infant experiences is rolling, first from side to supine, then prone to supine, and finally in either direction. The 6-month-old infant achieves mobility by pivoting in the prone position. The infant continually becomes more active against gravity ([Figure 20-1](#)). Most 8-month-old infants creep and move from sitting to quadruped positioning and back. By the ninth to tenth month, the infant has a strong desire to move upward. First, infants pull to stand and cruise along furniture, such as a coffee table; then they hold onto someone or something as they take their first steps. The average age at independent walking is 11.2 months, and most children achieve independent upright ambulation between 9 and 15 months of age.^{11,18}

Developmental theorists accept that physical and psychological developments are interrelated and that early experiences influence subsequent behavior. "Through their motor interactions infants and toddlers learn about things and people in their world and also discover they can cause things to happen" (p. 18).¹⁵ During the first months of life, children seek physical control of their environment and continue to do so by building and enhancing their motor skills day by day.

Children gain various learning experiences as they move about.³⁶ Locomotion and other motor skills, which develop rapidly during the first 3 years of life, become the primary vehicles for learning and socialization and for the growth of a healthy sense of independence and competence. A typical

FIGURE 20-1, cont'd

toddler travels more than 39 football fields per day and accumulates an average of 15 falls an hour.² Piaget viewed self-produced movement as a crucial building block of knowledge. He theorized that the intercoordination of vision and audition with movements, including locomotion, laid the basis for the child's understanding of space, objects, causality, and self.⁶⁵ The ability of children to influence their environment and to affect or alter it through their own actions is intrinsically motivating. Early experiences are believed to foster curiosity, exploration, mastery, and persistence, and are therefore important for later intellectual functioning.

Impaired Mobility

Children with physical disabilities who have difficulty achieving independent motor control are often deprived of opportunities for self-initiated or self-produced mobility. Palisano found that very few children with severe cerebral palsy between ages 4 and 12 years have a means for self-initiated mobility.⁶² When these children do experience mobility, it is of a passive nature, as in being held or pushed in a stroller. Children with cerebral palsy spend more time sitting than their peers.⁶⁶ Because they lack the necessary movements to explore and act on their environment, important learning opportunities are hindered. Mobility-impaired toddlers who cannot move across a room to reach out and touch an object or interact with a person are at a great disadvantage. They cannot experience the sensorimotor and developmental activities of their peers who have achieved upright mobility, such as pushing and pulling toys, opening and closing drawers, or moving around and under objects. Psychologists who have studied typical development have observed improvements in social-emotional, cognitive, and visual spatial development in infants when they first gain mobility.^{1,8,17,19} Self-initiated mobility also affects motor functioning and the ability to develop mature reach and grasp and postural control.^{49,50} Researchers who have studied the impact of early exploration on a child's development have also suggested that self-produced locomotion and active choice are important for the development of perception and cognition.^{16,31,60,72,81} Young children who at 3 years old were high stimulation-seeking demonstrated increased cognitive, scholastic, and neuropsychological test performance at 11 years.⁶⁹

"When development along any line is restricted, delayed, or distorted, other lines of development are adversely affected as well" (p. 66).¹⁴ Restricted experiences and mobility during early childhood can have a diffuse and lasting influence. Long-term physical restriction during infancy or early childhood can significantly alter and disrupt the entire subsequent course of emotional or psychological development in the involved child.⁴⁵ Such deprivation of physical and social contingencies can lead to secondary developmental problems, including limiting motivation to explore the environment. Infants born with significant motor impairments quickly "begin to lose interest in a world which they do not expect to control" (p. 113).¹² This motivational effect is termed *learned helplessness*, a condition in which the child gives up trying to control his or her own world because of motor disability and diminished expectations of caregivers.^{29,72} Butler found that children whose mobility is limited during early childhood develop a pattern of apathetic behavior—specifically, a lack of curiosity and initiative.¹⁴ These character traits are believed to have a critical influence on intellectual performance and social interaction. The detrimental effects of limited early exploration were identified in a study comparing shortcut choices in a simulated maze of able-bodied teenagers with those of teenagers who had varying histories of mobility impairment. Despite equivalent levels of mobility, participants whose mobility was more limited early in development were poorer in the task than those whose mobility had deteriorated with age. The results suggest that early independent exploration is important in the development of spatial knowledge and that the detrimental effects of limited early exploratory experience may persist into the teenage years.⁷⁴

In children with severe physical disabilities, newly gained independent mobility can have a positive effect on emotional, social, and intellectual states.^{26,35} Paulsson and Christoffersen found that children with disabilities using mobility devices became less dependent on controlling their environment through verbal commands, more interested in all mobility skills, and more active in peer activities.⁶³ Butler found that children who had some means of ambulation could and would make choices, but those who did not ambulate were much less likely to exercise available options.¹³ The lack of ambulation appeared to severely restrict the child's opportunities to practice decision making and express an opinion or desire. Guerette et al. found that powered mobility can positively influence cognitive and psychosocial development of young children who are unable to move independently.⁴⁰ They also suggest that self-initiated powered mobility for a young child has a positive impact on the family.⁸⁰

Self-Initiated Mobility

Intervention for young children with physical disabilities often includes the provision of adapted equipment: supported chairs, standers, bath seats, and adapted strollers. This equipment provides a means for properly and safely positioning a child, but it does not provide a means for accessing the environment or experiencing the stages of development that occur with self-initiated mobility. Children who have a means for self-initiated mobility decide where, when, and how to move. It is the responsibility of the occupational and physical therapist to

FIGURE 20-2 The FCI Walker Mini allows an 18-month-old child with a developmental delay to explore his environment. (Courtesy Freedom Concepts Inc.)

determine how young children with disabilities can access their environment, explore their surroundings, and experience developmentally appropriate activities. Mobility devices, which provide a physically disabled child with a means to access and explore the environment, not only provide a means for mobility but also facilitate psychosocial, visual spatial, language, and cognitive development. Such devices include prone scooters, handheld walkers, support walkers, manual and power wheelchairs, and alternative powered mobility devices.

The current trend is for mobility devices to be recommended at young ages, when typical children are first ambulating (Figure 20-2). Many professionals believe that if self-initiated mobility does not occur in the first year, the use of devices for mobility should be considered. Mobility is often a priority issue for children with disabilities and others in their environment. When researchers surveyed the occupational performance needs of school-age children with physical disabilities in the school system and community, most teachers, parents, and children identified mobility as their greatest area of concern.⁶⁸ However, professionals lack agreement when and if mobility devices for very young children, particularly support walkers and powered mobility devices, are appropriate.

A support walker differs from a handheld walker in that it typically includes a seat with postural supports for the pelvis, trunk, and sometimes the head. In the past, occupational therapists were reluctant to recommend support walkers for children with cerebral palsy because they would often use undesirable postures during ambulation, and they believed it might increase the child's spasticity. However, many support walkers are now designed with features that complement the child's therapeutic goals.^{58,60,91} In addition, several studies have demonstrated that resistive exercise does not increase spasticity in individuals with cerebral palsy.^{10,27,32,53} Although further study is needed, several studies of persons with cerebral palsy concluded that a progressive strength-training program can improve muscle strength and walking ability without increasing spasticity.^{4,10}

Professionals and third-party payers may resist providing a powered mobility device to a young child with physical disabilities, particularly before the age of 5 years. Indeed, most

children born with congenital mobility impairments are not given their first wheelchair until the age of at least 3 years, and most of these do not receive a chair they can propel independently until age 5.^{33,35} Children with a physical disability under the age of 5 years are often denied the opportunity for using a powered mobility device because they are considered too young to have the cognitive skills to understand how to use it. However, "Clinical experience and research projects have established that powered mobility devices offer children at least as young as 17 months of age a safe and efficient method of independent locomotion" (p. 18).^{15,37} Galloway studied the ability of infants as young as 7 months to use a motorized robotic device for self-generated mobility.³⁷ Research continues to substantiate the fact that children as young as 18 months can achieve independent skills in powered mobility.^{33,35}

However, it can be a challenging task for an occupational therapist to suggest consideration of a mobility device, particularly a power wheelchair, to the family of a young mobility-impaired child. Many caregivers consider the suggestion as a symbol of giving up hope for independent ambulation. For this reason, use of a walker, support walker, or alternative powered mobility device may be more accepted by the families of very young children. The occupational therapist must convey to the family the concept that all children need a means of mobility to access the environment for exploration to encourage development in the visual, perceptual, language, social, and cognitive domains. The mobility device is intended to assist the child in achieving independence in exploration until and if another method is acquired.

Caregivers may believe that use of a power wheelchair will reduce the likelihood of their child's achieving independent mobility through ambulation. Research has not demonstrated that use of a powered mobility device prevents or delays the child's acquisition of motor skills. On the contrary, researchers find positive changes in children's development after the introduction of a powered mobility device.^{55,63,88} During mobility training, children with severe motor disabilities demonstrated improved head control and trunk stability, increased motivation, and greater self-confidence in movement.¹³ Deitz, Swinth, and White concluded that for some young children with severe motor impairments and developmental delay, use of a powered mobility device may potentially increase self-initiated movement occurrences during free play.²⁵ Nilsson and Nyberg analyzed case studies of preschool children with profound cognitive disabilities participating in power wheelchair training experiences.⁵⁵ They concluded that the training experiences increased wakefulness and alertness, stimulated a limited use of arms and hands, and promoted the understanding of very simple cause-and-effect relationships.

In another study, children 15 months to 5 years of age with physical disabilities who participated in a 2-week mobility exploration day camp demonstrated a variety of positive behavioral changes.⁸⁸ The children experienced mobility by using the Mini-Bot, a standing powered mobility device, to explore the environment (Figure 20-3). They participated in daily 1½ hour sessions for 2 weeks. Behavioral changes that caregivers and occupational therapists observed in some children included increased eye contact, increased verbalization and communication, improved sleeping patterns, increased active arm use, and a more positive disposition.

FIGURE 20-3 A 2-year-old child with arthrogryposis experiences self-initiated mobility while standing and moving in the powered Mini-Bot, with the option to drive it with a joystick or switches. (Courtesy Innovative Products, Inc.)

Augmentative Mobility

Butler introduced the term *augmentative mobility* to describe all types of mobility that supplement or augment ambulation. “Given augmentative mobility, disabled children can experience more success in directly controlling their environment, thereby reducing or avoiding secondary social, emotional and intellectual handicaps” (p. 18).¹⁵

The concept of augmentative mobility for functional mobility can be expanded to include transitional mobility. Transitional mobility allows the child to use a mobility device to have self-initiated movement without the expectation that it must be functional. The child may not consistently move the mobility device in a desired direction but uses it as a means for exploring the effects of movement and learning how to move. The occupational therapist can best provide transitional mobility by allowing the child to move the device in a large room with open space in which the child is free to explore. These experiences can then help the child make the transition to a more functional level of purposeful mobility. Not all children are able to achieve functional mobility; in these instances transitional mobility remains an important means for the child to explore the environment.

Ideally, a mobility-impaired child should have more than one type of mobility device for use in indoor and outdoor environments. Any methods that are chosen for mobility require close cooperation among all professionals working with the child and family.

Assessment and Intervention

Classification of Mobility Skills

Children’s mastery of functional mobility skills has been classified and categorized in several ways. Hays examined current existing diagnostic conditions of children without locomotion and divided them into four functional groups⁴³:

1. *Children who will never ambulate.* This category includes children with cerebral palsy with severe involvement and spinal muscular atrophy types I and II. Generally, these children have no opportunity for independent mobility.
2. *Children with inefficient mobility who ambulate but are unable to do so at a reasonable rate of speed or with acceptable endurance.* This category includes children with cerebral palsy with less involvement and myelomeningocele with upper-extremity involvement. For these children, assisted mobility may provide an efficient means of mobility above that which they are capable of producing themselves. Warren uses the term *marginal ambulators* for this group.⁸⁶
3. *Children who have lost their independent mobility.* This category includes victims of trauma and children with progressive neuromuscular disorders. The developmental implications may be less critical than in the first two groups, and the issue is acceptance of assisted mobility as an adaptation to the acquired disability.
4. *Children who temporarily require assisted mobility and often progress to independent mobility with age.* This category includes many children with osteogenesis imperfecta and arthrogryposis. Functional considerations in this group are both developmental and practical.

There are significant differences among these groups that may have implications for mobility and its integration into the child’s overall concept of disability, as well as for evaluation and intervention. Group I children may achieve independent mobility through the use of a support walker and power wheelchair. Group II children may be able to independently propel a manual wheelchair, ambulate in a support walker indoors, and use a power wheelchair for community mobility. Children in groups III and IV will use a variety of mobility methods during the transition period.

Mobility Assessments

Evaluation of children has traditionally focused on the achievement of developmental milestones. Occupational therapists have discussed the limitation of such evaluations because underlying impairments (e.g., motor control deficits) cannot fully explain the extent and form of functional difficulties seen in children with disabilities.²² Furthermore, the tasks that are most relevant for daily independence in mobility function have not been well defined in traditional developmental milestone tests. The team considers several factors before selecting the type of mobility device that is appropriate for a child. These factors include:

- Purpose and goals for using the device
- Environments for intended use
- Child’s physical and psychosocial abilities and limitations.
- Advantages and disadvantages of the device across environments
- Modifications that may be needed for comfort and control

- Congruence to intervention goals
- Cost-benefit ratio

Using a top-down evaluation process, the occupational therapist focuses on what the child needs or wants to do, the context in which he or she typically engages in occupations, and the limitations that he or she may experience.^{22,30} Therapists assess underlying performance abilities only to the extent that is needed to help clarify the possible sources of limitations in occupational performance. In mobility evaluation, occupational therapists focus on the child's overall pattern of locomotion and transfer skills in relation to a particular performance context.

Occupational therapy models of practice, such as the Person, Environment, Occupation, and Performance model of human occupation or the Canadian Occupational Performance Model, may provide the overarching framework to view the child's performance in daily living and mobility. These models provide the framework for semi-structured interviews to identify the child's strengths and weaknesses within their family and environment. After understanding the child, practitioners may decide to examine mobility more specifically.

Three instruments that evaluate children's functional abilities, including mobility, are the Pediatric Evaluation of Disability Inventory Computer Adaptive Test (PEDI-CAT),⁴¹ the Functional Independence Measure for Children (WeeFIM),⁸⁴ and the School Function Assessment.²²

- The PEDI-CAT assesses daily activities, mobility, social/cognitive, and responsibility domains. The functional mobility subscale measures basic transfer skills (e.g., getting in and out of a car) and body transportation activities (e.g., walking up and down stairs).
- WeeFIM is based on the Functional Independence Measure and is for children from 6 months to 7 years of age. This scale measures the child's independence in mobility—transfers, locomotion, and stairs—and provides useful information for progress assessment, program planning, and communication with caregivers.
- The School Function Assessment identifies the adaptations that benefit a student to perform functional tasks in the school environment K-6. It is a criterion-based instrument intended to facilitate collaborative program planning as it relates to elementary school students with disabilities. Part I measures the student's participation levels during six school activities: regular or special education classroom, recess or playground, transportation to and from school, bathroom and toileting activities, transitions to and from the classroom, and mealtime or snack time. Part II measures the types of task supports provided to the student (assistance from adult) or adaptation (e.g., a wheelchair); Part III examines how the student performs during specific school-related tasks in the areas of Physical Activity Performance and Cognitive Behavioral Activity Performance.

The Pediatric Powered Wheelchair Screening Test (PPWST) and the Powered Mobility Program (PMP) were developed as a cognitive assessment battery and a wheelchair mobility training and assessment program to help clinicians determine a young child's readiness to drive a power wheelchair.^{77,78} The PPWST and PMP were validated for children ages 20 to 36 months with orthopedic disabilities who used a joystick to control the wheelchair.^{38,39} The cognitive domains of spatial

relations and problem solving were found to be significant predictors of power wheelchair mobility performance.

Occupational therapists evaluate client factors (e.g., motor, perceptual, and cognitive factors) that influence mobility. Human functions important to mobility include neuromotor status (vision, hearing, and seizure disorders), orthopedic conditions, and psychosocial variables. Occupational therapists also consider both chronologic and developmental age and the child's environments. The therapist must make potential mobility devices and positioning systems available during the evaluation process so that the child and the caregivers have an opportunity to gain experience using potential mobility devices. These trials provide the caregivers and the child with information and experience that will assist them in becoming informed consumers and full participants in deciding which mobility device best meets their needs.

Mobility Evaluation Teams

Selection of the most appropriate positioning and mobility device requires the skills of a therapy team working in close collaboration with the school team, prescribing physician, child, parent or caregiver, and assistive technology professional (ATP). The ATP is "a service provider who analyzes the needs of individuals with disabilities, assists in the selection of the appropriate equipment, and trains the consumer on how to properly use the specific equipment. This equipment may include manual and power wheelchairs, alternate computer access, augmentative and alternative communication devices and other technology to improve the function and quality of life for an individual with a disability" (<http://resna.org>). The ATP is credentialed through the Rehabilitation Engineering and Assistive Technology Society of North America (RESNA). Occupational and physical therapists who make recommendations for assistive technology equipment often seek an ATP credential. An ATP may also be certified as a Seating Mobility Specialist through RESNA, which recognizes and identifies rehabilitation professionals with advanced knowledge and experience in the field of seating and mobility. RESNA also provides certification for a Rehabilitation Engineering Technologist, who designs, customizes, and modifies assistive technology (AT). The ATP is responsible for maintaining updated knowledge of available equipment and assisting in identifying choices of mobility devices according to the features that the child requires to use it optimally.

The physical or occupational therapist, together with the child, family, and school team, determine the needs of the child and establish goals to identify the features and options in a mobility device or devices that will meet the desired outcomes and assist the family in setting appropriate functional goals and expectations for using the mobility device. The child's school team should be included in the evaluation process to determine the needs of the child for accessing the school environment, the physical space, the curriculum, communication technology, and educational materials. Once the needs are identified, the purpose for using the device is determined, and the environments in which it will be used are considered, the therapist or family requests a local supplier of durable medical equipment or ATP to bring the mobility devices under consideration to the therapy session. The ATP offers input about what features and options are available on the device and how to adjust it

properly. The ATP provides a variety of mobility devices during the evaluation with features that meet the mobility needs of the child, family, and school team.

Some medical equipment suppliers may have a limited selection of devices available for demonstration, so only one device may be evaluated at each session. Therefore the occupational therapist may not have the opportunity to compare the child's performance in various types of mobility devices. Without direct comparison of the mobility devices, decisions about which devices are optimal for the child are difficult for the occupational therapist to make. The decision is less risky when side-by-side comparisons of different devices are available during the evaluation. This method enables evaluation of performance with each mobility device under consistent child and environmental conditions. If a supplier is not able to bring the requested devices, the manufacturer's representative may be able to provide the device and expertise for the evaluation.

Once the mobility device and options are recommended in a written report and justified to the funding agency for authorization, actual delivery may take 3 to 9 months. It is imperative that the ATP and occupational therapist work together during the delivery and fitting of the equipment, which typically takes up to an hour, to assure that the mobility device meets the needs of the child and expectations of the team. Most funding agencies do not approve replacement of a mobility device, such as a wheelchair, within 3 to 5 years of the purchase date. If the equipment is not appropriate, the child and family may not have another option for several years. The limitations in reimbursement become critical when a misunderstanding during the evaluation or ordering process results in a device that does not meet the predetermined outcomes. It is imperative that the occupational therapist, ATP, and family immediately decide how to best resolve these issues. The therapist is responsible for periodically (every 4-6 months) reevaluating the fit and function of the device to determine if it meets the stated goals and growth of the child.

Mobility Devices

Selection of a specific type of a mobility device depends on several factors. The therapy team first decides on the purpose for using the mobility device or devices. Does the child need a means for exploring and accessing the environment (self-propelled manual, power wheelchair, or hands-free support walker) or do the caregivers need a convenient way to transport the child (stroller or manual wheelchair)? The next, most critical aspect of evaluating a mobility device is to consider the environments in which it is to be used by the child and caregivers. If the child's home has high pile carpet, propelling a manual wheelchair or using a walker with wheels smaller than 5 inches in diameter will be quite difficult. The force needed to move a wheelchair over various surfaces has been measured. Using concrete as the baseline, the increase in force needed to cross each surface is 3% for linoleum, 20% for low-pile carpet, and 62% for high-pile carpet.³ The effort required by the individual to use the device will affect functional performance. If the mobility device is too complicated or the child must exert too much effort, it will not be used.

The occupational therapist must consider the features, adaptations, and hardware options needed for optimal use across all environments such as school, home, and community; the system must not reduce performance in functional activities such as eating, personal hygiene, transfers, and augmentative communication. The needs and concerns of the caregivers and school personnel who will be transferring the child into and out of the device, transporting it, and maintaining the equipment must be considered. The cost/benefit ratio is considered in decision making.

The occupational therapist must use his or her skills as an investigator during the mobility assessment process. Thoughtful planning and careful analysis of person-device-environment fit are necessary for the therapist to ensure that the child and family receive the optimal device. When a device is ordered without a comprehensive team mobility evaluation, the child may end up with a wheelchair that will not fit into the family van with the user in it, tips over when the speech-generating device is mounted on it, cannot be self-propelled outside because the family lives in a hilly area, is too large to maneuver efficiently in the classroom environment, or is too tall to fit under the tables and desks. [Case Study 20-1](#) provides an example of a child whose need for a mobility device—a support walker—was not evaluated properly.

Alternative Mobility Devices

Tricycles

Tricycles ([Figure 20-4](#)) are a means for mobility, although third-party funding is typically not available because tricycles are not considered a medical necessity. However, they can provide community mobility outdoors and on playgrounds.

FIGURE 20-4 The Discovery Trike can fit a child as young as 12 months. An adult can assist the child by steering the front wheel with the push handle. (Courtesy Freedom Concepts.)

CASE STUDY 20-1 Brian

Brian is 5 years old and has severe spastic cerebral palsy. He is dependent on others for mobility in his manual wheelchair. He is fully included in a kindergarten classroom. His mother believes Brian will have more peer interaction if he can use a support walker in the classroom, which places him at his peer's height. She also believes he had better digestive function when he previously used a walker at a younger age. Brian was evaluated at his medical therapy session to determine what type of walker would provide him with mobility in the classroom. His parents expressed interest in a particular walker, and the occupational therapist borrowed one from a medical equipment provider for Brian to use during the evaluation at the medical therapy unit. The family was excited when they observed Brian slowly propelling the walker forward. The therapist recommended the walker for purchase with custom modifications, which included a headrest and a custom thigh-length seat to reduce adduction. The family

ordered the walker and Brian began to use it in his classroom.

After 5 months of trying to use the support walker in the classroom, he could not take more than three steps in it. The occupational therapist determined that he did not have the ability to maneuver the walker in the classroom because of a high degree of resistance from the carpeted surface. The therapist initially evaluated Brian in a room with linoleum, without consideration of the classroom environment. The therapist reevaluated Brian in another walker that had large 20-inch wheels, which made it easier for him to maneuver over carpet. At this time, additional funding to purchase another walker is not available. He would have benefited from a side-by-side evaluation of several types of walkers with consideration of the characteristics of all the environments in which he would use the walker and consultation with all team members.

FIGURE 20-5 Prone scooter mobility devices.

Many types of tricycles are available with adaptations, such as trunk supports, and hand-propelled models are available for children who do not have the ability to pedal with their legs (e.g., children with spina bifida). A unique and helpful feature for both the child and the care provider is a handle at the back of the Freedom Concepts tricycle, which enables the adult to steer the front wheel while the child pedals. This assists a child with limited upper extremity function who may not have the ability to hold onto the handle bars to steer the tricycle.

Prone Scooters

Prone scooters (Figure 20-5) require use of the arms and the ability to lift the head while moving. The advantages of using a prone scooter include access for participating in play activities on the floor, the ability to get on and off independently, and the ability to change direction more easily than with other types of manual mobility devices. Disadvantages include fatigue from maintaining neck and back extension, vulnerability of the head to hitting objects, the possibility of the hands getting caught in the casters or rubbed on rough surfaces, and difficulty viewing the environment above the ground level. Children with

spina bifida may find the prone scooter functional because they have the upper extremity function and strength to propel it and the scooter can support their legs.

Caster Carts

Caster carts offer another means of mobility to children with upper-extremity function (e.g., those with spina bifida) (Figure 20-6A). Children can use caster carts indoors or on flat outdoor surfaces. Some children may be able to transfer on and off independently because of the close proximity to the floor. The device requires a considerable amount of energy expenditure for propelling long distances because of the small diameter of the wheels. Children with lower-extremity muscle contractures or tightness, such as in the hamstring muscles, may find it difficult to sit comfortably and securely because they are often unable to tolerate long-leg sitting. These children may feel more comfortable with a triangular-shaped wedge placed under the knees to support their legs in knee flexion. A battery-powered multidirectional scooter board from Enabling Devices allows a child to move either in a circular motion with one switch input or in all directions using several switches or a joystick (Figure 20-6B).

A

B

FIGURE 20-6 A, Caster cart mobility device. B, Joystick- or switch-controlled multi-directional scooter board. (Courtesy Enabling Devices, Hastings-on-Hudson, NY.)

Aeroplane Mobility Device

The aeroplane mobility device was designed by an occupational therapist for children with cerebral palsy who can move their legs but need support of the upper body ([Figure 20-7A](#)). The device provides developmentally appropriate positioning, particularly for children with spasticity, because the child is positioned with hip abduction and extension with knee flexion, and the upper extremities are in a weight-bearing position. This position often assists in reducing undesirable posturing in children who have spastic cerebral palsy, especially for children who exhibit extensor posturing in standing. Other advantages include ease in viewing the environment, the handmade nature of the device, and acceptance by parents because it looks like a toy rather than an assistive device. The aeroplane mobility device is not available commercially but can be fabricated from wood. Disadvantages include lack of adjustability for growth, difficulty turning and moving backward, and heaviness.

Mobile Stander

If a child has upper extremity function to push and maneuver wheels, a mobile stander may provide another means for

A

B

FIGURE 20-7 A, The aeroplane mobility device can be handmade and is designed for children younger than 3 years of age. B, The Rifton Dynamic Stander provides standing mobility in prone which clients can self-propel with their upper extremities. (Courtesy Rifton Equipment.)

mobility. These devices allow the child to experience lower extremity weight bearing in a standing position while achieving mobility by using large hand-held wheels for self-propulsion ([Figure 20-7B](#)).

Walkers

Children who have the ability to pull to a standing position, maintain a grip on a handle, and steer with their arms may be

FIGURE 20-8 A, The Crocodile walker is a hand-held walker designed for children who can hold onto the frame without pelvic or trunk supports (Snug Seat). B, A preschooler plays ball in his WalkAbout. C, A young child accesses his favorite race car toy at home by walking up to it in his KidWalk.

able to use a hand-held walker. These walkers are designed for use either in front of (anterior walker) or behind (posterior walker) the child (Figure 20-8A). Children with mild to moderate cerebral palsy or lower levels of spina bifida with leg bracing most commonly use hand-held walkers. Walkers can have three or four wheels and are available in various wheel sizes. The smaller the caster, the more difficult it is for use outdoors and over uneven surfaces. Posterior walkers are available with a feature in which the casters lock when the walker is pushed backward. This feature enables the child to stand and lean against the walker or the seat during rest periods. However, this feature makes maneuvering the walker more

difficult because the child cannot move the walker in a reverse direction, which is needed when backing away and turning, without lifting it up to overcome the anti-rollback mechanism. Casters can be fixed rather than swiveled, which allows movement only in the forward direction so the user must lift the walker to turn it. Swivel casters allow the child to turn the walker without lifting it, but this feature requires more postural control from the child to direct the walker. The advantages of hand-held walkers are their low cost and convenient transportability. The disadvantages for some users include poor body alignment when pushing a walker and the fact that the hands are not free for performing tasks.

Support walkers are designed for children who have some ability to move their legs reciprocally but need support at the pelvis, chest, and possibly the upper extremities and head. It is critical to identify the purpose for using the support walker and the environments where it will be used, to achieve maximum benefit for the child. If the purpose of the support walker is to provide self-initiated mobility for a child to access the indoor home environment, allowing the child to reach objects and people, then features should include wheels that are a minimum of 5 inches in diameter, which move more efficiently over carpets and thresholds than smaller wheels, and a design that does not include hardware, arm troughs, or a tray in front of the child, which would limit the ability to reach during exploratory activities (Figure 20-8C). However, children with limited arm and hand function as a result of hypotonia or spasticity may require modifications to the support walker such as a tray, which limits getting close to objects and people but encourages spatial awareness through movement.

Decisions regarding available options and features on a walker are made based on the child's physical function and the environment. Selection of appropriate features and adjustments that provide optimal positioning will increase functional use of these types of walkers. Children who adduct or scissor their legs as a result of spasticity may propel the walker more efficiently if a wider and longer padded seat is provided to reduce adduction and maintain leg alignment during ambulation. A young child with hypotonia or weakness may be more successful using a lightweight walker with all swivel casters over smooth flat surfaces such as linoleum (see Figure 20-2). Adjustable posterior tilt, a feature that positions the child slightly behind vertical, may also assist a weak child in maintaining an upright trunk and head position. Children with spastic cerebral palsy may need to be tilted in a slightly forward lean position, which along with a properly positioned pelvis (in neutral or anteriorly tilted position) assists in placing the feet behind the pelvis and trunk, thereby making it easier for the child to initiate movement in a forward direction. However, forward tilt can also make it significantly more difficult for the child to keep the head upright.

Support walkers can provide children with the opportunity to explore their environment in an upright, hands-free position while providing capability for active range of motion. Therapists are encouraged to promote more activity in children with cerebral palsy by using mobility-enhancing devices.²³ However, many support walkers have limitations in maneuverability, particularly indoors, because they require a large turning radius. The KidWalk was designed by an occupational therapist to promote use of the upper extremities during exploration.⁶⁰ It has minimal hardware in front of the child so the child can use self-initiated mobility to be within arm's reach of people and objects to access and explore the environment and perform developmental activities such as pushing, pulling, opening and closing drawers, reaching, and carrying objects to achieve occupational therapy goals. The KidWalk allows a high degree of maneuverability, particularly over carpeted surfaces and thresholds, because of the placement of a large wheel located at the vector of the child's body, which also encourages rotation of the upper body over the pelvis, a more desirable movement. It incorporates a mechanism for weight shifting during ambulation and a dynamic swivel seat to encourage reciprocal leg movements and does not depend

on upper body function to maneuver it. The upper body supports can be removed as the child develops balance and control. Because of its large mid-wheel design, it works well outdoors and over uneven surfaces such as playgrounds. Benefits of using a support walker for school-aged children include the ability to exercise and participate in recess by running and chasing or kicking, throwing, and catching balls while interacting with peers.

Alternative Powered Mobility Devices for Young Children

A variety of alternative powered mobility devices are available for children who cannot achieve self-initiated mobility using reciprocal leg movements or by pushing large wheels. Motorized toy vehicles are available for children to provide early mobility experiences using a joystick; adapted models with special electronics for using up to four switches are also available. From the caregiver's perspective, the greatest advantage for use of these toy vehicles is that they look like a toy that any other child would use, rather than an assistive device. They are also an option for providing a child with the opportunity to learn how to drive a motorized device in preparation for using a power wheelchair. Disadvantages include difficulty using these vehicles indoors because of limited maneuverability; large size, which prevents the child from getting close to objects in the environment for reaching, exploring, and interacting with others; and sometimes noisy operation.

The MiniBot and the GoBot were developed by an occupational therapist (see Figure 20-3).^{89,90} Each is a powered mobility device designed to enable physically challenged preschool children from 12 months to about 8 years of age to move in an upright position and explore the environment by getting close enough to objects and peers to reach and touch. It is intended for transitional mobility indoors or for use outdoors on flat surfaces. The child can be positioned in either a standing, semi-standing, or seated position. A joystick or multiple switches can be positioned at any location at which the child can reach the controls for driving the device. The MiniBot is not a power wheelchair; it is a therapeutic and educational tool intended to provide developmental opportunities equivalent to those experienced by able-bodied peers, such as pushing or pulling toys, kicking balls, moving quickly, moving slowly, and problem solving. The MiniBot can increase the child's opportunities for hands-free exploration and provide new sensory experiences (particularly vestibular, visual motor, and spatial relations). It is intended for children who would otherwise spend their early developmental years passively sitting in a stroller or manual wheelchair.

Wheeled Mobility Systems

Wheeled mobility systems include dependent mobility systems or transit wheelchairs, independent manual mobility systems such as self-propelling wheelchairs, and independent powered mobility systems that are battery powered. The first mobility system most children acquire is a stroller, which is considered to be a transit dependent mobility system because the user is depending on others for mobility. Parents often prefer the ease of use of a stroller and feel the appearance is more acceptable than that of a wheelchair when the child is very young.²⁰

FIGURE 20-9 Strollers. **A**, The Zippie Voyage Stroller™ provides tilt, recline, and seating components in a foldable base. **B**, The Convaid Rodeo chair is a light weight, crash tested transit model with tilt-in-space, size-adjustable frame, and optional thoracic lateral supports. (**A**, Courtesy Sunrise Medical; **B**, Courtesy Convaid, Inc.)

However, a stroller may not provide supportive seating for a child with moderate to severe disabilities. Mobile positioning systems, which provide more support than a stroller, while still being lightweight and easily foldable, are available through medical equipment providers. Some of these models include bus or van anchors for transporting the child in a vehicle, such as the Convaid Rodeo (Figure 20-9B), and lightweight foldable strollers with a seating system, like the Zippie Voyage by Sunrise Medical (Figure 20-9A).

Other dependent seating and positioning systems offer an adjustable height chassis to position the child close to the floor or up to various table heights (Figure 20-10A). The seating system is fully adjustable by the occupational therapist to accommodate the needs of a variety of users so a custom seating system is not necessary, but modifications may be required to meet individual needs. These types of adjustable positioning chairs are meant to primarily be used indoors and are not designed for transporting because they are quite heavy. Dependent mobility systems can provide convenience for care providers and teachers, as well as optimal positioning for function. The seating system can also be removed on some models and transferred to another type of base such as an outdoor or stroller base. The greatest disadvantage of a dependent mobility

system is that the child must depend solely on others for mobility and has no means for self-initiated mobility and exploration. Peers may also perceive an older child with a disability who uses a dependent mobility system such as a stroller as being less able and less approachable than a child of similar age who sits in a wheelchair. Dependent mobility systems that can be retrofitted into a larger wheel base should be considered if the team believes that the child will be able to self-propel within the next few years. However, if the child appears to have some ability to eventually propel the wheels but does not have repeated opportunities early in development to learn how to reach and push, then the likelihood of doing so may be lessened.

Manual Wheelchairs

Manual mobility systems are either independent manual wheelchairs that allow the user to self-propel by pushing two large wheels or dependent manual wheelchairs with small wheeled bases that do not provide opportunities for independent mobility (Figure 20-11F). A manual wheelchair is appropriate for a child who has the ability to functionally and efficiently propel it. It is also used as a means of transportation by caregivers or as a backup wheelchair when the child's power wheelchair is

FIGURE 20-10 The Leckey Contoured Advance Seat in the highest position (A) and lowest position (B). (Distributed by Ottobock USA.)

not working. Great strides in design and material selection have resulted in lighter frames than the standard 35-pound wheelchair such as the TiLite Twist (Figure 20-11A). Weights can range as low as 14 pounds for lightweight, ultra-lightweight, and high-performance manual wheelchairs.⁵¹ Manual wheelchairs for playing court sports such as tennis and basketball or racing are designed specifically for the sport.²¹ These wheelchairs have a rigid frame and a high degree of camber in the rear wheels and use small rollerblade-type casters in front.

Wheelchairs with large rear tires are most common but models with large front tires and small back casters are available (Figure 20-11B). Propelling a wheelchair with large front tires may be more efficient for the child because more surface area of the tire is exposed for gripping the wheel and pushing. However, the large front tires can limit access to the environment, such as when transferring and sitting at tables. The wheelchair with large front tires is also more difficult to push over curbs and uneven surfaces because of interference from the rear casters.

If the user has a single functional arm for wheelchair propulsion, such as a child with hemiplegia, an adapted manual wheelchair with a one-arm drive feature can provide independent mobility. The wheelchair is designed with two rims on the wheel the child uses to propel. One of the rims is connected through an axle to the other wheel. If either rim is pushed separately, it turns the wheelchair. If both rims are pushed simultaneously, the wheelchair moves forward or backward. A manual wheelchair can also be propelled with the feet if the wheelchair has a low seat-to-floor height, known as *hemi-height*.

A power assist unit, designed into the hub of a special wheel attached to a manual wheelchair, provides the convenience of a manual wheelchair without the extra effort involved with propulsion (Figure 20-11C). The LEVO Kid wheelchair includes a powered sit-to-stand feature, which can provide peer height interaction and the benefits of convenient standing throughout the day (Figure 20-11D).

A new concept in mobility systems is the Kids ROCK2 Reaction™ Dynamic Seating wheelchair, which allows the child to move into trunk flexion or extension in the wheelchair while maintaining proper pelvic positioning. When the child moves using hip and knee extension, the backrest reclines and the footrests move in an upward direction extending in a 35-degree range. When the child relaxes, the compressed springs move the backrest and footrests to the starting position (Figure 20-11E).

Power Wheelchairs

Powered mobility wheelchairs have a battery-operated motorized unit that the user drives by means of a joystick or alternative controls such as pneumatic sip-and-puff, ultrasonic head controls, proximity switches that operate by the user moving close to the switch but not touching it, or multiple push switches. If a child cannot propel a wheelchair long distances at the same speed and efficiency as demonstrated by the average person walking, then the occupational therapist should consider recommending a power wheelchair to increase the child's independence and function. The advantages of a power wheelchair over a manual one are increased speed capability, ease

of maneuvering, and less energy expenditure required for moving, particularly for long distances. Some children who use a power wheelchair also have a manual wheelchair for use in environments that are not accessible to a power wheelchair or when the power wheelchair is being repaired.

Power wheelchairs are available in several styles with various options and are differentiated by the electronics, control systems, and placement of the drive wheel, which may be rear-wheel drive (Figure 20-12A), mid-wheel (Figure 20-12B), or front-wheel (Figure 20-13A). Attributes that are affected by the drive wheel position include maneuverability, stability, traction, and performance (speed, efficiency, obstacle climbing, and crossing a side slope). Maneuverability depends on the turning radius.

- Rear-wheel drive wheelchairs are designed with the drive wheels located at the rear of the wheelchair and caster wheels in front. It tracks straighter than other wheel

configurations, making it easier to steer if using alternative controls such as switches. It works well over rough terrain and has less hardware extending in back of the wheelchair than the mid-wheel drive configuration.

- Mid-wheel drive wheelchairs tend to have greater maneuverability because of the smaller turning radius.⁴⁶ Some mid-wheel power wheelchair manufacturers claim to have a 19-inch turning radius, versus a minimum 33-inch radius with a rear-wheel drive. However, mid-wheel drive wheelchairs require a third set of stabilizing caster wheels, which may extend up to 17 inches behind the user. This feature may make it difficult for users to turn around without catching the casters on objects, particularly if spatial awareness is not optimal.
- Front-wheel drive works well over various types of terrain, uphill and downhill, because power in the front wheels pulls

FIGURE 20-12 **A**, The Power Tiger is a rear wheel drive pediatric power wheelchair. **B**, The Q610, a mid-wheel drive power wheelchair with tilt-in-space. **C**, Skippi power wheelchair. (A, manufactured by Invacare; B, by Quantum Rehab; C, manufactured by Otto Bock.)

the user over obstacles. Children who have used a rear-wheel drive wheelchair may find maneuvering a front-wheel drive wheelchair more challenging because the back end of the wheelchair may fishtail at higher speeds.

The recent trend in power wheelchair design is to provide a full suspension system in the front and rear casters or tires. This allows the user to move over a variety of terrains and drive up 3-inch curbs, even at slow speeds. Standard rear-wheel drive wheelchairs are optimal for children who have limited vision and spatial awareness difficulty, because most of the wheelchair

hardware is within their field of vision. Most wheelchair manufacturers provide a choice of several models that are intended for joystick operation and models that include sophisticated microcomputer electronics for alternative input methods for driving and for remotely operating environmental devices. Features of power wheelchair electronics can accommodate the needs of various users. Such features include adjustments for torque, tremor dampening for children having difficulty directing the joystick, a short-throw joystick option for users with muscle weakness who do not have the strength to push the

(A-C, Courtesy Permobil, Lebanon, TN; D by Body Point.)

joystick to its end range, speed adjustments, and acceleration settings so that the wheelchair can be set to increase speed rapidly or gradually. Some manufacturers now offer electronics, such as the True Track Technology (Invacare Corp.), that enable the wheelchair to track straight on slopes and uneven surfaces. Speeds can be as high as 15 mph, but typically range

from 3 to 10 mph. Distance traveled on one battery charge can be as far as 25 miles.

Several features can be made available on power wheelchairs to increase a child's function and level of independence. Technology-dependent children who require oxygen support can become mobile by using portable ventilator carts attached

to the wheelchair.⁷ Another useful feature for accessing the environment enables the child to independently move from a sitting to a standing position and drive around while standing (see Figure 20-13A). A seat that lowers to the floor may assist children to independently transfer into the wheelchair and play with peers (Figure 20-13B). A powered elevating seat, which raises the child to various heights for greater accessibility in the environment, is also available (Figure 20-13C). Additional features include power tilt-in-space, which tilts the seat backward to about 45 degrees while maintaining the same seat-to-back angle (see Figure 20-12B), and power recline, which places the child in the supine position by reclining the back of the chair. These two features are useful for individuals who need frequent relief of pressure under their buttocks, such as those with spinal cord injury and muscle weakness or for those with hip, back, and neck pain.

Power wheelchairs are typically controlled with a joystick. A proportional joystick allows the driver to increase acceleration and speed of the wheelchair in relation to the distance the joystick is moved. The farther the user pushes the proportional joystick, the more rapidly the wheelchair moves. A nonproportional joystick (digital or microswitch) does not affect the wheelchair's speed; any amount of force used to push the joystick results in the same speed. An attendant joystick is another option for a power wheelchair. It is typically a small joystick mounted to the back of the wheelchair and is accessed by the caregivers who need to drive the power wheelchair when accuracy is required, such as moving up a narrow ramp.

Power wheelchairs do not typically fold for transporting in a vehicle. Accessible vans that have been modified with a lift are required for transporting the user and power wheelchair in a vehicle. However, there is a pediatric power wheelchair, the Skippi from Ottobock Kids, that can be disassembled so that it can be transported in a vehicle without the need for a van (Figure 20-12C). If the child can be transferred to a car seat, a covered trailer can be hitched to the back of a vehicle for transporting a power wheelchair.

Powered mobility scooters are another option for powered mobility. The individual who uses a scooter typically has good sitting balance, requires minimal positioning adaptation, and can understand and physically operate the tiller handle bar controls.

A manual wheelchair can be converted to a power wheelchair by purchasing an add-on unit such as the E-Fix by Frank Mobility Systems Inc. The unit includes two motors that are placed inside the hub to rotate the tires, an electronic control unit, and a joystick. The manual wheelchair can still remain foldable. The electronic controls for the add-on units are not as sophisticated or adjustable as those found on standard power wheelchairs. This makes it more difficult for some children with impaired motor responses to accurately operate the chair. Add-on units are also not highly recommended for individuals who use their wheelchairs outdoors and over rough terrain because they are not designed to withstand the forces that a power wheelchair must endure.

The power wheelchairs today offer sophisticated electronics that provide opportunities to integrate mobility with speech-generating devices and electronic aids to daily living so the child can use the power from the wheelchair to continuously charge the speech-generating device, turn on lights, operate the

television, and wirelessly access a computer through the power wheelchair electronics.

Selection of Wheelchair Features

If the child's goal is to independently propel a manual wheelchair, it is critical that the wheelchair and seating be designed to allow proper biomechanics for efficient propulsion. The occupational therapist achieves this by recommending the proper size of wheelchair frame and an appropriate seating system. Most wheelchair manufacturers include wheelchair growth kits, which accommodate the need to widen or lengthen the frame without entirely replacing the wheelchair. It is critical to select a wheelchair that fits the child's present needs, rather than a wheelchair that is too large with the goal that the child will "grow into" it. A wheelchair that is too wide is more difficult for the child to propel. If the seat is too long, the child's pelvis cannot achieve a neutral position; it will be pulled into a posterior tilt, reducing upper extremity function and causing the child to sit on the sacrum with a rounded back, which contributes to the risk of sliding out of the seat. If the backrest is too tall, it will be difficult to position a headrest at the occipital area behind the neck or use shoulder straps.

The occupational therapist simultaneously considers what type of seating or positioning system is needed and how it will interface with the mobility base for optimal function and performance. For example, in ordering a seat cushion, the child's functional mobility skills, the frame size of the manual wheelchair, and the desirable seat to floor height must be considered. If the cushion is placed on top of the wheelchair frame, the child may be positioned too far from the wheels for reaching and propelling them efficiently. To prevent this situation, the occupational therapist considers the height of the wheelchair seat when ordering the cushion; a workable alternative in this instance is a narrower cushion that can be recessed into the wheelchair frame.

Another common situation that reinforces the need to assess seating and wheelchair mobility simultaneously is recommending a backrest cushion for a child without considering the features of the wheelchair. The cushion may position the child too far forward of the axle's wheel. If the child's center of gravity is forward of the rear wheels instead of directly over the rear wheel axle, propulsion is more difficult and inefficient. Many wheelchairs have a standard axle plate whereby the hub of the wheel is mounted to the frame and the wheels cannot be relocated within the child's reach. However, if the occupational therapist recommends an adjustable axle plate for the wheelchair in combination with the appropriate front caster size, the wheels can be relocated and mounted in the best location for the child to reach the wheels for propulsion.

Wheelchair features are recommended based on needs in the areas of mobility (being able to reach and propel the wheels of a manual wheelchair or reach the floor to propel with the feet), accessibility (moving through doorways, maneuvering in small spaces, and fitting under tables), transfer techniques (dependent or independent), seating and positioning, communication (which may include mounting a speech-generating device to the wheelchair), and transportation (if the child will be transported while sitting in the wheelchair in a motor vehicle, certain options such as transport tie-downs need to be included on the wheelchair). The features available in a manual wheelchair that

may affect the child's posture and function include the ability to mount an appropriate seating system; the frame's diameter size for attaching a mounting bracket to position a speech-generating device; and options such as tilt-in-space, recline, and capability for multiple axle positions for adjusting the wheel location.

Wheelchairs are available in standard or custom sizes as measured by the seat width and depth, height of the seat from the floor, and backrest height. The occupational therapist must consider seating systems and wheelchairs that will accommodate the child's growth, physical changes, and functional needs while also considering the needs of the caregivers. The therapist should begin selection of a wheelchair by evaluating and documenting the child's current physical and functional abilities, with consideration of physical changes that may occur and the positioning and mobility goals for the child. Wheelchair selection depends on the type of seating and positioning system the individual requires. For example, if a child needs to sit with a medial thigh pad or abductor to keep the knees apart, then a wider space between the leg rest hangers will be required. Wheelchairs are typically designed with equal distance between the footrest hangers, but some models have a footrest hanger that flares out to accommodate wider foot placement. The occupational therapist must also consider the environments in which the child will use the wheelchair, which method the child will use for propelling the wheelchair, how the caregivers will transport it, and which sources of funding are available. The therapist is often responsible for providing a medical justification for the seating and mobility system.

Once the child's needs have been identified, the occupational therapist matches them to the specific features available in a wheelchair:

- *Style of frame:* Folding manual wheelchair (has lots of flexibility; folds side to side or forward onto the seat), non-folding or rigid manual wheelchair (lightest weight, has "tightest" responsive ride, back folds down, and wheels are removable), modular folding (frames come apart, separating the seating system from the base, which folds for manual and power wheelchairs), modular nonfolding (can be disassembled into several parts for manual and power wheelchairs).
- *Tilt-in-space:* Tilt is when the seat orientation to the ground can be changed while the seat-to-back angle remains constant.²⁴ This allows the seat to be tilted backward or forward as an entire unit while maintaining the same seat-to-back angle. It can be manual or powered for independent operation by the user. Tilt ranges are 45 to 65 degrees. Tilt can accommodate users with insufficient head and trunk control, individuals who require pressure relief under the pelvis, or those with back or hip pain. The greater the degree of tilt, the more weight is distributed from the pelvis to the back (see Figure 20-12B). The occupational therapist must be aware that the tilt-in-space position may restrict the child's field of vision. When tilted backward, the child's visual field is directed upward toward the ceiling. In this position the child must flex the head forward to view the surroundings. This tilted position may also stimulate the sleep mechanism and limit the development of head control. A tilt-in-space feature can also provide a few degrees of anterior tilt to position the child slightly forward, which may encourage trunk and neck extension for a more work-ready position.
- Manufacturers offer a traditional tilt-in-space wheelchair, with tilt occurring at a fixed pivot point (see Figure 20-11F) or a rotation-in-space wheelchair (Figure 20-11G).
- *Recline:* Recline is when the angle between the seat and the back can be changed while the angle between seat and ground remains the same.²⁴ This feature positions the user in a reclined position in which the seat-to-back angle opens from the seated angle to about 170 degrees. It can be operated manually by a caregiver or operated with power by the user. Some children with gastrointestinal issues may need to recline after a meal. This feature may also assist the care provider by allowing a reclined position for diaper changes.
- *Footrest style:* Footrests support the user's feet and may act as a step for transfer in and out. Features include single plate or double plate, fixed, pull-up, swing-in or swing-out, and manual and powered elevating leg rests. The typical angle of footrests is 70 or 90 degrees to accommodate fixed positions of the legs and feet. Many children sit more upright with 90-degree footrest hangers to accommodate tight hamstring muscles. If footplates are too far in front, placing a stretch on tight hamstrings, the pelvis will be pulled into a sacral sit position, thereby promoting a rounded trunk, which will adversely affect the child's head position. Footrest hangers that are angled less than 90 degrees make the length of the wheelchair frame longer, thereby decreasing maneuverability in tight places. Foot positioning options include shoe cups, ankle straps, or toe straps to secure the feet onto the foot rest, which may be necessary for added stability or when an extended leg position interferes during transport of the child.
- *Armrest style:* Armrest styles can be full length, which makes it difficult to get close to a table or desk, or arm length, which incorporates a notched area in the frame of the armrest for getting under surfaces. Armrests can be height adjustable, fixed, or removable, with pull-out or swing-away options. Some users may benefit from wider, contoured armrest pads for more arm support, particularly when using a joystick for driving a power wheelchair. Tubular style swing-up armrests, which are narrow, are often recommended for individuals who can reach the wheels for propelling.
- *Backrest height:* A high backrest may be needed to support the seating and positioning needs of a client with a severe disability or for tilt and recline. A low backrest may be more functional for a client with good upper body function. A backrest that ends at the top of the shoulders is preferred so an adjustable height-contoured headrest can be positioned under the child's occiput.
- *Backrest adjustability:* An angle-adjustable back provides the ability to set the seat-to-back angle to accommodate the child's position. A child who extends or pushes backward may benefit from a decreased back angle, whereas a child who is hypotonic and has difficulty maintaining a vertical head position may benefit from a greater than 90-degree seat-to-back angle. A biangular backrest is comprised of two back cushions hinged together: a pelvic pad that ends just below the posterior superior iliac spine is attached by a hinge to the upper back cushion. This allows the pelvic pad to be angled forward to encourage an anterior or neutral pelvic position while the upper back cushion is tilted rearward to allow the upper back to be positioned slightly behind the

FIGURE 20-14 **A**, The Freedom Designs Inc. Ergo Adjustable Bi-Angular Back Cushion. **B**, Ride Designs cushion can be custom molded for an individual.

pelvis to accommodate the natural curves of the spine (Figure 20-14A). This is in contrast to a flat back rest cushion, which does not accommodate the natural spinal curves.

- *Height and adjustability features* of push handles for the adult pushing the wheelchair. If a manual wheelchair will be pushed primarily by a tall caregiver, then the push handle height will need to be adjustable or extended.
- *Floor-to-seat height*: Seat height is important for transfers and getting under surfaces such as tables. A lower seat height is typically preferred for younger children, particularly if a seating system will be integrated into the chair, which may raise the user higher. A lower seat height may facilitate self-transfers. A high seat height may place the child closer to peer height.

- *Style and location of wheel locks or brakes*. If the child has the strength and understanding to lock the brakes independently, then they need to be within reach. Some brakes are under the wheelchair and operated by pushing a lever with the foot. A push button brake can be positioned on the back of the wheelchair frame behind the push handles, a convenience for the caregivers and an option for a child who should not be releasing the brake intentionally.
- *Type, size, and placement of wheels and casters* on a manual wheelchair for maximum efficiency during propulsion and to accommodate weight distribution: An adjustable axle plate can provide individualized wheel placement for the child to reach the tires. This may also assist children who are positioned forward of the push wheel because of a short seat depth, which places too much weight over the forward casters, thereby increasing resistance during propulsion. Tires can be pneumatic (air filled for a cushioned ride), semi-pneumatic (gel insert for flat-free maintenance), or solid (no maintenance but provides the stiffest ride and may add extra weight).
- *Additional features* include sit-to-stand in a manual wheelchair (see Figure 20-11D) or a power wheelchair, whereby the child can move independently from a seated position to standing (see Figure 20-13A). The advantage of this feature is the ability to reach various heights, bear weight, and stretch throughout the day, and for some boys, the efficiency of standing without needing to transfer for toileting needs, as when using a urinal.

Powered Mobility Evaluation and Intervention

To determine which power mobility device is appropriate for a child, the occupational therapist, teacher, child, and caregivers must first define the goals for using powered mobility (Box 20-1). The team also considers how the child will access or drive the power wheelchair, and which power wheelchairs provide the control interface methods that the child needs now and may need in the near future, if change in motor performance is expected. The occupational therapist begins an evaluation of the child's ability to drive a power wheelchair by assessing the child's position, to determine how to optimize motor function for efficient and accurate access of the controls. It may be necessary to use an evaluation seating system or interim modifications to the child's own seating system during the powered mobility evaluation. The child must feel secure, comfortable, and stable, particularly in the pelvis, trunk, and head, before attempting to operate a power wheelchair.

Selecting the Control Device

A joystick is the standard and often the preferred method for the individual who can maneuver it efficiently and accurately. The user can operate a joystick using a hand, foot, forearm, chin, head pointer, or even the back of the head, by using an adaptation that connects the joystick to a bracket that is attached to a movable headrest. Some children may find it difficult to accurately use a joystick placed in its traditional location at the front end of the armrest. These children may have

CASE STUDY 20-2 Trevor

Trevor, a 4-year-old child who is unable to communicate, was having difficulty driving the power wheelchair using a joystick placed at the end of his right armrest. The teacher questioned Trevor's ability to drive safely and accurately, believing that his bumping into objects was purposeful. The occupational therapist observed Trevor's arm and hand movements and noted that he seemed to have difficulty pushing the joystick forward and to the right side. He tended to

internally rotate his arm and pull it toward his body. The joystick was then mounted on an adjustable bracket that positioned it in midline, close to his chest. The midline position also enabled the joystick box to be rotated about 30 degrees toward his body. After several more attempts at driving, Trevor's accuracy improved immediately. Once the most reliable placement was located, he became a functional driver.

BOX 20-1 Questions to Guide Mobility Device Selection

- Are the goals to provide functional and independent home, school, and community mobility, or are the goals to provide transitional mobility experiences so that the child can have new opportunities to learn how to move, explore, and interact within the environment?
- Which maneuverability features of the powered device are important in considering the various environments in which the device will be used (such as indoors in limited spaces in a classroom or home, outdoors over rough terrain, or on a playground)?
- What are the table heights the wheelchair must fit under at school, the home, and community?
- Is it necessary for the child to reach various heights in the wheelchair? Should a powered lift seat be considered?
- Will the child need the ability to tilt-in-space or recline?
- How will the child transfer into and out of the wheelchair?
- How will the mobility device be transported? Will it need to be disassembled to fit inside the trunk of a vehicle?
- If the wheelchair is to be transported in a van, is head clearance sufficient for the child when entering the vehicle and can the wheelchair be secured to the van for transport?
- Will the environments need to be made accessible with ramps into doorways or powered lifts into vehicles?
- Will the child need an environmental control option included in the power wheelchair electronics for using the joystick or alternative access method to wirelessly access an alternative electronic device such as a speech-generating device or computer?

better motor control if the joystick is placed inside the armrest, in midline, or rotated several degrees toward the body ([Case Study 20-2](#)). A micro joystick, or attendant joystick, which is smaller in size than a standard joystick, may be necessary for these types of situations and are available for most power wheelchairs. The small joystick is easier to position in midline or under the chin. Another feature that can assist in improving control or efficiency during joystick use is a support (such as a wide armrest or trough) under the elbow, forearm, or wrist. If the child has difficulty moving the joystick in the desired direction, the occupational therapist can place a template with a cross shape cut out inside the control box to limit deviation of the joystick to the desired directions. The therapist can also

position the joystick with proper hardware to another location in which control will be enhanced. During the evaluation for joystick operation, the therapist not only must evaluate the positioning needs of the child and placement of the joystick, but must consider the type of joystick, type of joystick knob, and desired location of the on-off switch for either independent access or to avoid unintentional access by the user.

Joystick knobs are available in various styles, shapes, and sizes to accommodate various hand and wrist positions. The most common shapes are round, T-shaped, and U-shaped like a goal post ([Figure 20-13D](#)). A child with weakness of the upper extremities may find it more efficient to use a U-shaped joystick so that the hand is supported in the palm and at the sides. Another access method is the use of an interface tablet device that senses finger movement on a tablet device to navigate a power wheelchair.⁵⁹

Selection of the most appropriate style of joystick and its placement directly affects the ability to accurately and efficiently drive a power wheelchair. [Case Study 20-3](#) provides an example of a child whose position is evaluated for more accurate use of a powered mobility device.

Children with severe physical disabilities may be able to operate a power wheelchair but often are not given the opportunity because they are physically unable to operate a joystick. Alternative control interfaces or access methods are available for these individuals.

If a child does not have the physical ability to control a joystick, the occupational therapist should consider alternative control interfaces or access methods such as switch operation, particularly for individuals with cerebral palsy. Multiple switch access is available in which switches are placed around the body part that is able to reach the switches, typically using three or four switches. The wheelchair is driven in one of four directions, depending on which switch is activated. Many types of switches are available, for example, battery-powered electronic and proximity sensors, activated by getting near the switch, and mechanical switches that require different levels of pressure to activate, that vary in size, or that include auditory feedback. Switches can be placed at the head, hand, elbows, knees, or feet, where the child has the ability to make contact with the switches and release them or move close to the switches if they are in proximity. An adjustable mounting bracket, such as that available through AbleNet Inc., is extremely helpful for positioning a switch consistently in multiple locations.

Before selecting the type of switch, the occupational therapist first identifies the most reliable movements the child can voluntarily use to access a switch, utilizing the least amount of

CASE STUDY 20-3 Amanda

Amanda is a 9-year-old girl who has a diagnosis of cerebral palsy quadriplegia with athetosis (see [Figure 20-15](#)). Her trunk stability is limited such that she cannot sit independently; she extends her hips and back, causing her to slide forward in her seat; she has minimal control of arm and hand movements but can voluntarily move her arms toward her side; she has fair to good head movements when her pelvis and trunk are stable. Efficient and reliable operation of a power wheelchair is not possible because the positioning seat belt slips, causing her to slide forward on the seat, adversely affecting motor control of her arms and head.

She now sits in a custom seating system comprised of a contoured seat cushion, which is soft under the pelvis and moderately firm under her thighs to reduce extensor thrust posturing; a biangular back cushion with lateral hip and trunk pads; an occipital neck rest; and a sub-ASIS (defined below) padded bar.⁵² The seat belt alone did not provide a stable pelvis that she needed to reduce extraneous body and head movements. The sub-ASIS bar is placed across the lap where the seat belt would be placed. It is hinged on one end of the seat cushion and connects to a bracket on the other end, which provides consistent but comfortable hip placement. It is positioned just below (sub) the anterior superior iliac spine (ASIS) of her pelvis, which provides a consistent pelvic

position and, therefore, upper body position, rather than depending solely on a positioning belt, which loosens and allows her pelvis to slide forward on the seat, decreasing stability and increasing extraneous movements. The positioning belt remains in place for her to use instead of the sub-ASIS bar when stability of the pelvis is not necessary.

These seating components have increased her stability such that she can move her head accurately to activate three proximity switches from Adaptive Switch Labs (ASL) to drive a power wheelchair. She independently accesses two switches placed on the side of her armrest to change modes of operation for speed and moving in reverse. A third switch placed on the right side of her armrest allows her to turn her wheelchair on and off independently. She accesses her speech generating device, a Vmax by DynaVox mounted to her power wheelchair, by using a head tracking-mouse emulation method that uses a camera to track her head movements. She wears a reflective dot on her forehead, which the camera tracks while she moves her head to position the cursor on the screen over a letter or symbol. Her communication device can also be programmed to work remotely with electronic devices around her house. She can use it as a universal remote for her television and DVD player and to operate light switches in a room. She also has access to a telephone with an additional accessory on her Vmax.

active range and therefore energy expenditure. Children may have experience using a switch to operate a modified battery-operated toy or single-switch computer game, which requires one activation of the switch with a quick release.⁸⁷ The child may be able to use the same movements for switch access to drive a power wheelchair, but most children will use an access method that requires them to maintain contact and activation on the switch during the time they are driving the power wheelchair and move off the switch in time for stopping.

If the child can nod “yes” and “no,” then he or she may have the ability to use the same movements for activating switches placed in back and to the sides of the head. The head-switch sensing array from Adapted Switch Labs (ASL) consists of proximity switches embedded into a headrest that detect head movements for driving the wheelchair ([Figure 20-15](#)). Users may have more optimal control of the head array if they also use a suboccipital neck support to increase stability. These switches are operated not by making contact on the switch, but rather by getting close or proximal to the switch. The head array can also be mounted near the hand or foot for use with movements of the arm or leg. An array of fiber optic switches from ASL can be embedded in a lap tray so the child can wave an arm above each switch to operate the wheelchair or other electronic device.

Switches can be used in a momentary or latched mode through the wheelchair electronics. Momentary switches require the user to maintain contact on the switch to activate it. The child needs to be able to maintain contact on the switch long enough to move the wheelchair in a desired direction. A latching mode allows the user to press the switch one time to activate it, rather than holding it in the “on” position. A second

FIGURE 20-15 A 9-year-old girl in Power Tiger from Inva-care using an ASL head array for driving and for mouse emulation on her computer.

activation turns the switch “off.” If the child needs to use switches to drive a power wheelchair, at least three switch sites are preferred: for driving forward and turning both directions. Reverse can be operated by a fourth switch or the adult. If the child can operate only one or two switches, the occupational therapist may need to consider a scanning method, which the child uses through a scanning menu on a display; however, the scanning method requires a higher degree of concentration requiring visual and cognitive function because of the complexity of the task.

An input method used frequently by individuals with spinal cord injuries is pneumatic sip ‘n’ puff, which the user activates by gently inhaling or exhaling into a straw-like device held in the mouth. This method requires oral motor control and the ability to build pressure in the mouth.

The Tongue Drive System uses sensors imbedded in a dental retainer and a magnet pierced onto the tongue that makes contact with the sensors to drive the power wheelchair. The Rolltalk Nova is an interface for driving a power wheelchair using eye gaze, which is intended for individuals with very little active movement.

Once the occupational therapist has determined a preferred motor response, the child can assess the switch on a powered mobility device. However, the quality of motor control and accuracy is directly dependent on the child’s body position and the extent to which the position influences stability, mobility, muscle tone, and energy expenditure. Therefore, an evaluation of power wheelchair mobility control must simultaneously include a seating evaluation to determine how the child’s motor control is influenced by body position.

Assessing Driving Performance

Several factors can interfere with a person’s ability to drive a powered mobility device. If a child has difficulty, the occupational therapist should first consider if the wheelchair, electronics, and interface, such as switches, are working properly. The brakes must be released and the wheels must be engaged. If the child continues to have difficulty, the type and placement of the controls should be re-evaluated. Simultaneously, the therapist evaluates the child’s position to determine whether changes in the child’s posture influence motor control. Other considerations include undetected visual and perceptual difficulties, impairment in hearing, processing and response time, seizures, motivation, and behavior. Children with visual impairment often find it difficult to drive a power wheelchair outdoors in bright sun, preferring to do so indoors in large areas such as a clinic or classroom.

Many children may not initially be successful using a power wheelchair because of the overwhelming amount and degree of sensory input that is required. Imagine being a child with a severe disability who has difficulty with motor planning, coordination, visual perception, and communication, and is experiencing movement in a powered device for the first time. It would be overwhelming to experience the excitement and vestibular sensation of moving while trying to view the surroundings, which are quickly passing by, and simultaneously listen to an adult telling you how and where to move.

The occupational therapist should assess a young child for powered mobility, whenever feasible, by providing a method that promotes exploration, problem solving, and self-learning

for the child. Such a method requires an open space with activities and toys strategically placed around the room to facilitate experiences in movement and exploration.

The most common method for evaluating a person’s ability to use a powered mobility device is to have the device available for trial use during the evaluation. A facility typically cannot afford to purchase power wheelchairs for evaluation purposes. Fortunately, ATPs often lend power wheelchairs to a clinical therapy unit for short-term evaluation purposes. The positioning and mobility equipment with the specific features that the child will need to operate the device should be available during the evaluation. Equipment used during an evaluation should be in optimal working condition. The occupational therapist should begin the evaluation by test-driving the equipment to learn the forces and movements required to drive it, select the best speed for the client, and set any other adjustments, such as sensitivity of the controls. If a powered mobility device is not actually available, the switches can be mounted on the child’s manual wheelchair and when the switch is pressed by the child, the therapist can move the wheelchair accordingly, as if the child is in control of driving.

It may also be beneficial to lend or rent a power wheelchair to children and their families for an extended evaluation. This allows more time for the child to learn how to use the controls and for the family to become familiar with the features of a power wheelchair to assist them in becoming more informed consumers. It provides an opportunity for the family to experience the responsibilities of maintaining and transporting a power wheelchair.

Power Mobility Training

Children may initially prefer spinning in circles seeking the vestibular and sensory input rather than listening to directions or driving to a target. This should be part of the training as it provides sensory input they would otherwise not experience. Learning to drive a power wheelchair, particularly with alternative controls, takes practice, and those children who can be exposed to the experiences on a daily basis in a natural environment will have an advantage over children who can only receive training once a week in a clinical setting.

The occupational therapist should “limit physical and verbal commands as much as possible to avoid sensory overload on the part of the child” (p. 85).⁷⁶ If a child is trying to move toward an object, the therapist should state the desired outcome, such as “come closer,” rather than specific commands, such as “push the joystick left” or “push the red switch and come over here.” Feedback should also be positive, such as “You found the wall,” rather than “Oops, you crashed again.”⁸⁸ If further assistance is needed to help the child understand the operation of the control, the therapist can facilitate the proper response by physically guiding the child’s movements for the desired response. The therapist must understand that children respond to visual, auditory, and sensory demands at different rates. A child with spastic cerebral palsy or quadriplegia may require much longer to make a visual motor response than a child with athetoid cerebral palsy, a spinal cord injury, or muscle disease.

Computer programs are available for powered mobility assessment and training.⁷⁵ R. J. Cooper and Associates has developed a power wheelchair simulation program as well as

software for joystick and mouse training. The program displays a power wheelchair on the screen that the user must navigate through a maze or room. Hasdai, Jessel, and Weiss studied whether a driving simulator would help a child master skills that are comparable with those required to drive a power wheelchair.⁴² Their results indicated benefits from using such a program to prepare children for powered mobility.

Seating and Positioning

Positioning is critical to the successful use of any mobility device because posture and task performance are inter-related.²¹ How an individual is positioned in a mobility device, whether it be standing or sitting, can have an effect on several physiologic factors, including visual and motor performance, postural control,⁵⁴ ranges of movement, muscle tone,⁵⁶ endurance, comfort, respiration, and digestion. These factors can affect functional performance activities such as hand function,⁵⁷ levels of independence in mobility, self-care, activities of daily living such as transfers, and social interaction with others.⁴⁴

Understanding the Biomechanics of Seating

To identify the positioning needs of a child, the occupational therapist must first have a thorough understanding of the biomechanical forces and neurophysiologic factors that can influence posture and movement. Biomechanical considerations are critical to obtaining proper alignment of the pelvis, spine, and head when postures are flexible or when accommodating individuals who have fixed postures and no longer have active or passive range of motion as a result of contractures. The position and stability of the pelvis provide a foundation for movements that occur above and below the pelvis. **Box 20-2** presents exercises that stress the importance of good alignment in sitting. Neurophysiologic factors include the child's reaction to tactile input, body reactions to orientation in space, and movement.

Seating Guidelines

The goals of seating are to provide alignment (in the presence of flexible postures) or accommodation (in the presence of fixed or static postures); stability to improve distal motor function while minimizing undesirable tone and reflexes that interfere with alignment and stability; distribute seated pressures to maintain skin integrity; improve physiologic function such as breathing, swallowing, and digestion; increase independence in electronic activities of daily living and activities of daily living; increase seating tolerance; decrease fatigue; and provide comfort.

There are basically three types of seating system cushion surfaces: planar, contoured, and custom molded. *Planar seating* consists of flat surfaces with no contours. This type of seating may be more appropriate for individuals with mildly affected development who require only minimal body contact with the support surfaces of the seat. *Contoured seating* systems allow the body to have more contact with the support surface because its shape conforms to the curves of the spine, buttocks, and thighs. A contoured seat can be fabricated by layering various densities of foam that respond to the shape and weight of the

BOX 20-2 Exercises to Understand the Biomechanics of Seating

Sitting in Posterior Pelvic Tilt

While in a sitting position, place your hands on the anterior crest of your pelvis (the two hip bones). Bend forward by rounding your back. You will feel your pelvis rolling backward into a posteriorly tilted position. Hold your pelvis in this position and try to sit upright by extending your back. You may be able to move your head upright, but moving your trunk into a vertical position is dependent on placing your pelvis in a neutral or anteriorly tilted position. To view your environment with your pelvis in the posteriorly tilted position, you would need to either hyperextend your neck (an undesirable position) or slide your pelvis forward in the seat until your head achieves an upright position. Try maintaining a rounded or kyphotic back position and slide your pelvis forward in the seat. Feel the excessive pressure at the cervical and upper thoracic levels and the coccyx. Imagine being positioned like this for hours at a time and experiencing the discomfort, fatigue, and limited range of your upper extremities if you were in a wheelchair without a proper positioning system to improve or accommodate your posture.

Pelvic Position Stability

Place your buttocks at the edge of your seat, lean only onto one side of your pelvis, and lift your feet so they are unsupported. Hold your pencil at its top edge and try to write. It is difficult to perform accurate and efficient movements of your arm and hands because you do not have a stable base for the movements to occur. Imagine trying to accurately and safely operate the joystick of a power wheelchair in this position.

person, thereby contouring around the bony prominences and other body curves (**Figure 20-16A**). A molded seating system is custom made for an individual who has fixed contractures and asymmetries of the pelvis and spine, such as scoliosis. The seating specialist uses a seat simulator to take an impression of the individual in the preferred seated posture which accommodates the asymmetrical position of the legs, pelvis, and spine. The impression is either electronically scanned or actually sent to the manufacturer for fabrication of the cushions (**Figure 20-16B**).

Cushions can also be custom molded using foam-in-bag technology, in which liquid foam is poured into a plastic bag that is positioned around the person's body and, once formed, provides a molded cushion that is then upholstered. This technique is more difficult to fabricate, because the individual's position must be held in place while the foam is being formed. If the child moves, the quality of the foam mold is negatively affected.

Optimal seating provides a stable place for the child's pelvis and spine, from which a range of movements for achieving functional tasks can occur. Seating is not static. Rather, it is a series of active movements or postures an individual uses to accomplish a series of motor tasks, such as maintaining the pelvis, trunk, and head upright against gravity while using the movements of the eyes, arms, and hands to access the controls of a power wheelchair or push the wheels of a manual wheelchair. For this reason, a series of postures must be made available to the child, not by restraining the child with straps and harnesses, but rather by supporting and guiding the child's

FIGURE 20-16 **A**, A custom seating system includes a biangular back cushion, contoured seat cushion, lateral hip and trunk pads, a Subasis bar, an occipital ring headrest and custom padding around the frame of the tilt-in-space wheelchair for a child with athetoid cerebral palsy. **B**, A custom molded seating system accommodates an individual's asymmetrical fixed position. (By Prairie Seating Corporation.)

movements with an appropriate seating and mobility system. The occupational therapist needs to consider the biomechanical forces of an individual's movements to determine what may be contributing to undesirable postures and, therefore, limited function.

The key points in achieving functional seating are the position and stability of the pelvis. A pelvis in a slight anterior tilt or neutral position is preferred. The angle of hip flexion can also affect postural control in sitting. Some children with extensor posturing may have a reduction of muscle tone with less than 90 degrees of hip flexion combined with hip abduction,

FIGURE 20-17 Hip Grip, a dynamic pelvic stabilization device.

whereas others may prefer an anteriorly tilted seat with the knees lower than the hips and weight over the feet. Stability at the pelvis can be achieved through contact points around the pelvis. These include the surfaces under and at the sides and the forces on top of the pelvis. The occupational therapist must determine how a child responds to various types of seat surfaces and contours under the pelvis such as a flat seat surface or a contoured seat (a seat cushion that provides a recessed pocket for the pelvis and blocks forward movement of the ischial tuberosities).

The occupational therapist can also improve stability of the pelvis and trunk by ensuring that the femur is properly supported along its entire length, from the back of the pelvis to approximately 1 inch from the popliteal area under the knee. One exception to this is to use a much shorter seat depth for a client who can propel a wheelchair using the legs and feet. In this situation, a shorter seat with a slight anterior tilt would be preferred. Contoured lateral hip pads placed on the seat cushion in contact with the pelvis can assist in maintaining a symmetrical position and reduce pelvic shift to either side. Stability can be provided above the pelvis to reduce sliding in an upward and forward direction. This is typically accomplished by placing a positioning belt at a 45-degree angle to the seat or closer to the thighs. Positioning belts come in several styles and include a standard 2-point attachment as well as a 4-point attachment belt, which provides support on top of the thighs as well as a 45-degree angle around the pelvis. A new device for dynamically positioning the pelvis while allowing for functional pelvic movements is the Hip Grip pelvic stabilization device from Body Point (Figure 20-17). Made of a contoured padded harness, the Hip Grip attaches to the lower part of the wheelchair backrest and around the sacral area of the pelvis. A positioning belt with sub-ASIS pads is secured in front of the pelvis. A rotational mechanism at the sides of the Hip Grip maintains postural stability while allowing the user to move the pelvis in the anterior and posterior directions, as when reaching

or propelling the wheelchair. For children who consistently slide and push out of the seat and may have skin irritation from the position belt slipping, the Subasis bar is another seating component for providing a consistent pelvic position. It consists of a padded contoured positioning bar that is mounted on the seat cushion in front of the pelvis just below the individual's anterior superior iliac spine (ASIS), in front of the pelvis. It is hinged on one side, allowing it to swing into place over the pelvis where it is snapped into place with hardware mounted to the other side of the seat (Figure 20-16A). Lateral contoured hip pads are also used in conjunction with the sub-ASIS bar to assure that the pelvis is positioned in midline, and it is most frequently used in conjunction with a biangular backrest. Fit and function must be checked weekly when using a sub-ASIS bar to assure an optimal fit (placed snugly under the ASIS but can be rotated when in place), which is critical for successful implementation.

Other components, such as footplates, lap trays, arm rests or arm troughs, a contoured backrest, and headrests, can provide additional support to the pelvis and trunk. Proper support of the head is as important as supporting the pelvis. A headrest that completely supports the entire head may limit the child's ability to see and hear. A lower profile head rest that provides support in the suboccipital area of the head may allow for greater range of head movements to accommodate vision, hearing, and use of switches around the head for accessing devices for communication and mobility.

The use of orthotics, or devices for bracing the extremities or body, may also assist in achieving optimal positioning in the seated and standing positions. Ankle-foot orthoses are most commonly recommended to align the foot and ankle and assist in either reducing muscle tone or supporting a weak limb. For a child who uses an ankle-foot orthosis when ambulating in a support walker, a hinged orthosis that allows for ankle movement may provide more function than a static design. A thoracic-lumbar-sacral orthosis, or body jacket, may be another alternative for individuals with scoliosis to use for support in the seated position.

Young children who exhibit an increase in extensor movements and asymmetry when being evaluated for a seating system may benefit from using a "barrier" vest as proposed by Kangas.⁴⁸ The vest is made from Plastazote foam, which is not strong enough to totally support the child and allows the child to have some movement. It is worn to decrease the child's sensitivity to individual points of contact from hands touching the body during handling or from pads on a seating system, which can set off the extensor body reaction. The child wears the vest for up to 6 months while developing greater postural stability.

Seating Evaluation

The therapist should begin the initial assessment by observing the child using any existing seating and mobility systems to note posture, movements, comfort, satisfaction with the equipment, and other factors that may affect function. During the seating evaluation, the occupational therapist will need to consider:

1. The angle between the seat and the back surfaces
2. The tilt of the system in space (orientation)
3. The type of surface on which the child will be seated

4. The seating components that will provide stability and affect postures⁹

The occupational therapist should begin the evaluation by positioning the child on a low mat table so that he or she can complete a postural assessment to determine whether any limitations in ranges of movement exist that may interfere with the upright and seated positions. The therapist obtains further information by positioning the child in a sitting position while using the hands to support the child to identify key points of control and positions that provide a desirable change in posture, muscle tone, and movements. These key points become the necessary components of the seating system. The positions, such as the angle of hip flexion and the orientation in space of the child, become the pitches and angles of the components necessary in the seating system and wheelchair hardware.²¹

Once the occupational therapist gathers information from the postural assessment, other methods are also available that use evaluation equipment for assessment of the child's position to determine which components, angles, and sizes are needed in a seating system. Simulators are self-contained, with chairs that the therapist can adjust to fit a child or an adult to determine which type of seating components and angles are appropriate.⁸² The simulator allows the therapist to "evaluate the client in the system, alter angles of the seat to the back, try varying positions in space, and determine component sizes and accessories that are required before making recommendations for a particular system" (p. 73).⁸³

The occupational therapist and the ATP can use simulators to evaluate planar, contoured, and molded seating (see Figure 20-18). The therapist first completes a postural evaluation of the individual to determine which seating components are necessary and then adjusts the simulator to the individual's size. The therapist selects angles, which include seat-to-back and tilt. Further adjustments can be made to determine how position influences movement and function. The advantages of using a seating simulator include (1) use as a single evaluation tool for various ages, sizes, and diagnoses; (2) source of information about the various types of seating systems, such as planar versus molded; and (3) options to motorize simulators to evaluate powered mobility access and the effect of positioning on motor control. The problem that the assessment team often encounters when using simulators is difficulty in transferring the information from the simulator into an actual seating system and knowing how that system will integrate into a mobility base. Children may also respond negatively to the simulator evaluation because its mechanical appearance and large size may intimidate them.

Another method for evaluating seating and positioning is use of a modular mockup or adjustable evaluation seat system that can be placed in a mobility base. These are typically available in planar or contoured seating devices rather than in custom-molded devices. The main advantage of using this method is that the child can use the actual mobility device while seated in the mockup seat. A trial using an adjustable evaluation seat system is particularly important because positioning can influence body movements and therefore functional outcomes. The disadvantages are that more equipment must be available to fit a range of individuals, and pitches and angles cannot always be accurately assessed.

Children with hypotonia, such as those with muscle disease or cerebral palsy, have specific needs. A useful positioning

FIGURE 20-18 Prairie Seat Simulator. A clinician can use the fully adjustable Prairie Seat Simulator to evaluate a client for wheelchair seating components, pitches, and angles.

system includes a biangular back design that supports the sacrum in a neutral position but angles the remaining backrest about 15 degrees away from the back at the posterior superior iliac spine. This provides a resting position of the trunk behind the pelvis and accommodates the forces of gravity in the upright position (see Figure 20-16A). Consideration of a tilt-in-space feature in the mobility base and an adjustable seat-to-back angle may also provide the hypotonic or weak child with greater tolerance for sitting upright.

Children with increased muscle tone and spasticity who adduct their legs and extend their hips and spine are often more difficult to position. The occupational therapist must identify key points of control for positioning these children. For example, the therapist determines the desired degree of hip and knee flexion or extension, hip abduction, and reduction of asymmetrical positioning that positively influences muscle tone and control of extremity movement. The critical factor for reducing the degree and frequency of extensor posturing is to determine which factors contribute to these movements. Kangas observed that certain children become more asymmetrical as hypertonus increases and that this increase in muscle tone is stimulated when they feel pressure behind their head or neck from a headrest.⁴⁸ These children may also have better postural control in the upright position rather than reclined or tilted.⁵⁶ In other children who extend forcibly in combination with rotation of one side of the body forward, the resulting pelvic obliquity may place strain on the soft tissue when the child is positioned symmetrically with both legs forward. These

BOX 20-3 Gross Motor Function Classification System

- LEVEL I**—Walks without Limitations
- LEVEL II**—Walks with Limitations
- LEVEL III**—Walks Using a Hand-Held Mobility Device
- LEVEL IV**—Self-Mobility with Limitations; May Use Powered Mobility
- LEVEL V**—Transported in a Manual Wheelchair

For additional description of the levels, see: http://www.canchild.ca/en/measures/gmfcs_expanded_revised.asp.

children often prefer to have one leg abducted (almost off the seat cushion) and one leg forward. This often reduces the strength and frequency of hip extension and rotation of the upper body as the child extends.

The occupational therapist must frequently re-evaluate a child's position, particularly in a seated mobility device, to accommodate postural, developmental, and physiologic changes. Once a child receives a seating mobility system, the therapist should re-evaluate its fit and function every 4 to 6 months. Positioning and mobility literature and support materials are available,^{20,28,82,83} and more specific information and techniques on positioning are available through additional reading and workshops.

Mobility Devices and Diagnoses

Children with cerebral palsy achieve most of their gross motor abilities before the age of 5 years and peak in their motor performance by adolescence.⁷¹ Children in Level III of the Gross Motor Function Classification System (GMFCS)⁶¹ may walk with aids, but like children in Levels IV and V they will depend on wheelchair mobility for most of their mobility needs. See GMFCS levels defined in Box 20-3. To achieve a high level of independent mobility, both manual and power wheelchairs should be considered at an early age for children with impaired walking ability.⁷⁰ Children at GMFCS Levels III-V benefit from using a support walker at an early age to explore their surroundings, exercise, and access physical education and recess activities, such as running, and interactive games like chase and soccer.

Children with spina bifida are provided with mobility devices such as a caster cart at a very early age. Because it is low to the ground, young children's use of caster carts for indoor mobility on smooth surfaces allows peer interaction and self-transfers. Many of these children may achieve ambulation with assistive devices including braces and hand-held walkers, depending on the level of the lesion, ability to stand upright, and their support systems.⁶⁴ Because children can propel a manual wheelchair independently, their functional performance and self-determination can increase. Appropriate wheelchairs for preschool children include small sizes that are low to the ground and have large wheels in front for greater access to push. As the child gets older, rigid lightweight or ultralightweight manual wheelchairs are appropriate. It is important to include a pressure-relief seat cushion, particularly for older children. Some children may need to depend on powered mobility to keep up with their peers for long distances. A power

wheelchair that lowers the young child to the floor and back up to seat height may be appropriate for independent transfers (see [Figure 20-13B](#)).

Children with neuromuscular disorders such as spinal muscular atrophy (SMA) and muscular dystrophy typically need powered mobility from an early age. Children as young as 20 months old with SMA can learn to drive a power wheelchair independently.⁴⁷ Most children can initially operate a joystick, but options for alternative access should be built into the electronics when initially recommending the power wheelchair to accommodate changes in physical ability if the child is no longer able to independently operate the joystick. A tilt-in-space feature on the wheelchair and a pressure-relief cushion are often needed for later stages during the course of the disease.

Children with a mid to high level spinal cord injury require a power wheelchair, some with a ventilator attached to the back of the wheelchair. The occupational therapist considers weight-relieving features of a wheelchair, such as tilt-in-space, reclining back, and pressure-relief cushions. Alternative controls such as sip 'n' puff or switch arrays may be needed if upper extremities are immobile. Electronic aids for daily living and computer access strategies can be integrated into the electronics of the power wheelchair. Children with lower level spinal cord injuries may be able to propel an ultralight wheelchair.

Transportation of Mobility Systems

Manufacturers of wheelchair mobility systems do not recommend using them as a seat in a motor vehicle. However, most families do not recognize this warning and allow the child to travel while seated in the wheelchair in a motor vehicle or school bus. Manufacturers are now providing safer options for transporting a wheelchair with the child in it because of a voluntary ANSI/RESNA standard called WC-19, *Wheelchairs Used as Seats in Motor Vehicles*.⁵ Wheelchairs are considered WC-19 compliant if they have four accessible and identifiable points to secure the chair to the vehicle, as well as seating, a frame, and other components designed to allow better fit of a lap and shoulder belt. The standard requires wheelchairs to be dynamically crash-tested at 30 miles per hour and 20g crash conditions, which are the standards used to test child safety seats.

It is important that occupational therapists recommend wheelchairs that are WC-19 compliant and educate clients and families on safe methods for transporting a wheelchair in a motor vehicle. Standards have also been developed to recognize the safety of a specialized seating system that may be used in another manufacturer's wheelchair bases. The ANSI/RESNA WC-20 standards are for seating devices for use in motor vehicles.⁶ One standard requires that all students being transported in a wheelchair on a bus must face forward. Wheelchairs that are transported in a side-facing position are more likely to deform and collapse in a crash, and the shoulder belt is ineffective.⁷³ School-based occupational therapists must work with transportation personnel to educate them on the importance of forward-facing positions for wheelchair riders, as well as the proper use of tie-downs. The lap belt must be snug and low on the pelvis and the shoulder belt positioned over the middle of the clavicle and across the sternum, where it connects to the pelvic belt over the hip. Any device such as an

augmentative communication device or computer and lap tray must be removed and tied down separately.

Factors That Influence the Successful Use of Mobility Devices

Successful use of mobility devices depends on the fit of the child to the device, the features of the device, and the physical and social environments. Specific functional performance tasks correlate with the ability to use a power wheelchair. Preliminary findings indicate a relationship between specific cognitive scales and readiness for powered mobility, particularly in the areas of spatial relations and problem solving.^{34,79,85}

Another factor that influences a child's ability to use a powered device is the ability of the professional or the caregiver to determine the most accurate and efficient means for the child to access the device. If a child is having significant difficulty in maneuvering a powered mobility device successfully, the occupational therapist must first re-evaluate the position of the child and the access method to determine whether it is the most effective means. The longer it takes a child to successfully demonstrate use of a control, the more likely it is that either the access method is inappropriate or the child's seating needs have not been met. [Case Study 20-4](#) describes this type of situation.

The occupational therapist must consider changes that the child will have in the future, both expected and unexpected, when recommending equipment. For example, the therapist must determine whether the system can be easily changed as the child gains new skills, grows, or changes physically. This is particularly important for the therapist to consider when ordering a power wheelchair. For example, a child with a progressive disability may be able to operate a joystick at the time the chair is ordered. However, electronic options need to be included, such as the ability to readily change the input method, if the child's functional status changes and use of a joystick is no longer feasible. It is more economical in most cases to initially order options on equipment rather than retrofit the equipment at a later date.

The occupational therapist may also need to determine where and how a speech-generating device can be mounted to the child's wheelchair. Selection of the appropriate mounting bracket depends on the tube size of the wheelchair frame and locations on the wheelchair where it can be attached. A problem that therapists often encounter with manual wheelchairs is positioning the child or rear wheels too far forward of the wheelchair's center of gravity, which often causes the wheelchair to tip forward when the communication device is mounted. The most frequent problem encountered with mounting a speech-generating device on power wheelchairs is finding a place to mount the bracket on the frame and making certain it does not interfere with moving through doorways.

The therapy team and ATP have a responsibility to assist the family and child in becoming informed consumers by identifying seating and mobility issues and needs, then presenting several alternatives during the evaluation. The family should make the final decision on the specific type of mobility device after considering the options that the team presents. The most important and significant contribution that the occupational therapist can make is to evaluate access methods and help

CASE STUDY 20-4 Stephanie

Stephanie is a 15-month-old girl with cerebral palsy who successfully used a switch-operated GoBot to maneuver and explore her surroundings. It took her about 5 hours to become proficient at using a set of four press switches with her hand and to understand the relationship to directionality. However, when she entered another therapy program, the occupational therapist did not consider information on her ability to use switches for driving. Instead, the therapist placed her in a wheelchair training program using the only equipment available, a joystick-operated power wheelchair. After 6 months of training for 3 hours each week, Stephanie demonstrated no improvement in her ability to drive the power

wheelchair. Upon re-evaluation of her access method, the therapist provided her with four switches at her hand and evaluated a switch array behind her head. She was able to use both access methods but when questioned, preferred using switches behind her head. The head switch array provided her with immediate success in driving the power wheelchair. Had the therapist provided her with the appropriate control method (switch access instead of a joystick, which she could not operate because of her impaired motor function), she might have demonstrated the ability to use the power wheelchair in significantly less time.

caregivers develop and implement strategies to meet identified goals. The therapist must re-evaluate the outcome as the child progresses. This includes providing periodic evaluations of fit and function of the equipment.

Summary

The literature indicates that independent mobility plays a facilitative role in cognitive, language, and social development.⁴⁷ Therefore when mobility is severely delayed or restricted, emotional and psychosocial development are affected. Augmentative mobility devices can provide young children with functional or transitional mobility. They allow children with physical disabilities greater opportunities to become initiators and active participants in daily occupations and experiences. Occupational therapists emphasize methods of adapting the child's environments to maximize his or her functional mobility. The occupational therapist is responsible for ensuring that children with physical receive opportunities for mobility at the earliest age possible to promote participation and development more equal to their able-bodied peers.

Case Studies 20-5, 20-6, and 20-7 include comprehensive information about the children's equipment and adapted environments. These descriptions demonstrate how mobility equipment is integrated with other AT and environmental adaptations to best meet the children's functional needs.

Summary Points

- Self-initiated mobility allows young children with physical disabilities the opportunity to access and explore their surroundings, significantly contributing to visual spatial, sensory motor, social, emotional, and cognitive development.
- Several factors must be considered during an evaluation for seating and mobility equipment, including the purpose or goals for using the device, environments in which the device will be used, features and adaptations that will meet the desired outcomes across all environments, factors that might reduce function in other areas (hardware that interferes with transfers, eating, personal hygiene, or communication), needs and concerns of the care providers and school personnel, options for transporting the device, and cost versus benefits.
- Occupational therapists consider features and options on a mobility device to allow the child's optimal function given his or her abilities and limitations in everyday environments.
- If a child cannot propel a manual wheelchair at the same speed and efficiency as ambulatory peers, then a power wheelchair should be considered to increase independence and function.
- Self-propelling manual wheelchairs are typically recommended over dependent mobility bases, because they offer large wheels for self-propulsion, a frame that can be adapted for growth, more options for mounting speech-generating devices, more adjustments for posture, a range of tilt and seat-to-back angles, and a variety of seating components for postural support.
- Power wheelchairs are designed with a front-wheel, mid-wheel, or rear-wheel configuration and each has advantages and disadvantages.
- The evaluation team should select a wheelchair that fits the child's present body size and needs but also take into account the potential for growth.
- The occupational therapist must consider the features of a seating and positioning system that meet the needs of the client before considering the wheelchair base. Because posture and task performance are inter-related, positioning is critical to the successful use of any mobility device. The therapist must consider positioning components, pitches, angles, and surface contours that affect posture and movement.
- For a child who is prone to pressure-related problems when sitting in a wheelchair, pressure-relief cushions, tilt-in-space, and or recline should be considered. A tilt-in-space feature of a wheelchair functions by maintaining the same seat-to-back angle while tilting the seat backward or forward, and a reclining feature reclines the seat back, increasing the seat-to-back angle and allowing for hip extension.
- Manufacturers of power wheelchairs offer electronic options to adapt joystick functions and to remotely access other devices such as a computer, speech-generating device, telephone, or television through the electronic controls of the wheelchair.
- Occupational therapists need to be aware of wheelchair transportation safety and WC-19 compliant mobility equipment, which indicates that the manufacturer has designed the wheelchair for use as a seat in a moving vehicle.

CASE STUDY 20-5 David and Eric

David

David is an 11-year-old boy diagnosed with Duchenne's muscular dystrophy at 4 years of age. Shortly afterward, his little brother, Eric, was diagnosed with the same condition at 5 months of age. The two brothers and an older sister live with their parents in a small town.

Duchenne's muscular dystrophy is an inherited X-linked disease that affects the voluntary skeletal musculature, with progressive weakness and degeneration of the muscles that control movement. The muscle weakness begins in the proximal and axial musculature and slowly progresses distally. Frequently, children with Duchenne's muscular dystrophy require a wheelchair by 12 years of age. Breathing becomes affected during the later stages of the disease, leading to severe respiratory problems. Respiratory infections commonly cause death during the person's early twenties.

When receiving David's diagnosis, the family was introduced to a team of professionals who specialize in different aspects of musculoskeletal weaknesses. The family received support to help them deal with the initial shock and necessary information about the disease. Twice a year, the family continued to meet with the team for medical and orthopedic evaluations. They also received counseling services to support their social and psychological well-being.

Last year, David had an Achilles tendon lengthening to release a tight heel cord, and shortly thereafter began to use a long-leg orthosis. It is important to lengthen the walking phase in boys with Duchenne's muscular dystrophy to delay hip and knee flexion deformities and equinovarus deformity of the foot and ankle. For 2 years David used a standard lightweight manual wheelchair for traveling long distances or when he was fatigued. Currently the therapy team and David's family are considering a power wheelchair for David, to allow him to conserve energy for social and educational activities. The team plans on spinal stabilization when David's scoliosis

exceeds 25 degrees and normal forced vital capacity pulmonary function drops below 50%.

Eric

Eric is now 7 years of age. The progression of his disease is following the same course as David's, although somewhat slower. The early signs of Duchenne's muscular dystrophy are becoming prominent, such as the waddling gait, tendency to fall, and difficulty rising from a sitting or lying position.

At the time of Eric's diagnosis, the family lived in an apartment but soon decided to build a house. The occupational therapist provided recommendations for designing the house for wheelchair accessibility to maximize function and independence.

The family has been living in the house for 2 years, and they are pleased with the features that enable the boys to be independent. The outdoor surfaces (sidewalks and ramps) are firm, stable, and slip resistant. The floor plan is spacious, doorways are wide, and there are no thresholds. A few sliding doors have been installed to allow maximum door width and to eliminate floor swing space requirements. Controls, levers, and switches are placed low to be within reach from a wheelchair. The windows' lower edges are only 20 inches above the floor for the same reason. The bathrooms are spacious, with both a bathtub and a shower. The boys love taking baths because they stay warmer and move more freely in the water. The sink is freestanding so the boys can get close to it. An automatic faucet has been installed, which turns on when the hands are placed under the faucet. A full-length mirror is on the wall.

The family continues to need extensive support and assistance to adjust to new challenges. In addition to direct service to the family, the occupational therapist continues to work closely with the schools to ensure that accessibility is available.

CASE STUDY 20-6 Jason

Jason is a 7-year-old boy with cerebral palsy, which has affected his ability to speak, move his body with control, and eat. Although he demonstrates severe delays in his motor skills, he is alert and attentive and understands what is said to him. From his early days, his family was motivated to ensure that Jason have a childhood as normal as possible. They were creative in designing simple devices and tools to accomplish these goals. His grandfather designed the first mobility device for him. Using a pushcart to hold golf clubs, he mounted a car seat to the frame with foam pieces in the seat to help align Jason's body and prevent him from leaning over. His mother used it to push him around the neighborhood during her daily jogging routine. He also used a standard stroller but required a positioning system to assist him in sitting upright by providing support at the pelvis, trunk, and head. The first seating system was made of Tri-Wall, a three-layer-thick cardboard that can be used to fabricate temporary seat inserts for

children. Another seat insert was fabricated from Tri-Wall and placed on a dining room chair so that he could eat at the family table instead of in a high chair.

By the time he was 12 months of age, Jason's family built him an aeroplane mobility device (see [Figure 20-7A](#)) to use at home. When he outgrew this by 2 years of age, his occupational therapist evaluated him for a support walker and found that he could effectively use the KidWalk by Prime Engineering (see [Figure 20-8C](#)). He continued to use this device for indoor mobility and for playing in Little League for special needs children when he was 5 years of age. He and his teammates used an automatic device to hit the ball, and Jason ran around the field using his walker.

When Jason was 3 years old, his family decided that the walker alone did not adequately meet his community mobility needs. His occupational therapist evaluated him for a power wheelchair and found that he could operate the joystick once

Continued

CASE STUDY 20-6 Jason—cont'd

he was positioned with maximal support at his feet, pelvis, trunk, and head. His therapist and family determined the features he would need to operate a power wheelchair. He needed a molded seating system for support and alignment, and, to increase independence, the system needed to include the capability to elevate the seat from the floor to various heights. The therapist identified a power wheelchair with these features and recommended a custom-molded seating system.

The family made the home environment accessible to Jason in many ways. When he was 2 years of age, they decided that it was important for him to roll out of bed in the morning and try to roll on the floor. They placed a low-height mattress on the floor in the corner of his bedroom and made it his bed. They lined the sides of it with his stuffed toys to protect him from unintentionally hitting his arms against the walls. This arrangement allowed him to get out of bed on his own. They also lowered the light switch in his room so that he could reach it from his walker or wheelchair.

Positioning him in the bathtub when he was a toddler was a challenge, but his mother made a bath seat for him from a

milk crate. She placed foam around the edges and the seat for comfort. When he outgrew this, his family acquired a bath seat designed for children with disabilities. His occupational therapist recommended an adapted toilet seat with a high backrest. It provided Jason with the ability to begin toilet training at 2 years of age. His family also installed a flip-down bar in front of the toilet so Jason could stand at the toilet “like his dad.”

During these early years, Jason’s occupational therapist introduced him to augmentative communication symbols and aids. By the time he was 12 months of age, he could point to symbols in his communication book using his fist and soon progressed to using a speech-generating device with voice output by accessing it with a head tracking system. The speech-generating device was mounted on his power wheelchair. Today Jason is fully included in a second grade class. He uses AT to do his schoolwork and has an attendant with him throughout the day. Both simple and sophisticated AT devices have enabled him to function within a regular education classroom and to participate in most of the activities of his peers.

CASE STUDY 20-7 Jet

Jet is an inquisitive, happy and interactive 6-year-old boy who has cerebral palsy. He began attending preschool seated in his first wheelchair, a Zippie TS, a tilt-in-space dependent base, which he had outgrown. His therapy and preschool team, understanding the benefits of self-initiated mobility, recommended an evaluation to include a lightweight manual wheelchair he might learn to propel himself with optimal seating and positioning. The wheelchair had to easily disassemble to fit into the family car and be light enough to help him learn to propel it in spite of his hypotonia. He also required seating options that would stabilize his pelvis to prevent it from sliding forward into hip extension when he would use his arms and hands. He used a speech-generating device (SGD) with a key guard for communication and accessed it by pointing with either hand. It would need to be mounted to the frame of the new wheelchair. Seating options were evaluated first by having him borrow a wheelchair for several weeks with a seating system temporarily designed for him. The trial system allowed him some experience with new seating components so he could be part of the decision-making process and allowed the team to observe his function to determine how the components contributed to or interfered with functional tasks. After the trials, Jet, his family, school, and therapy team with the ATP decided that the most appropriate seating components for him would include a Jay backrest with lateral trunk pads, a contoured custom seat cushion with contoured lateral hip pads, a Subasis bar to provide hip stability, and a HAWC headrest to provide occipital and lateral support of his neck to assist in separating shoulder movements from body and head movements (Figure 20-19). Without the HAWC headrest, he leaned to either side when he tried to use his hands, which affected his visual field, endurance, and accuracy when selecting targets on his SGD. The headrest also provided midline support during feeding and allowed him to feed himself finger foods and drink from a straw more efficiently. The ATP

FIGURE 20-19 A 6 year old boy wears wrist splints to access his speech generating device mounted to his wheelchair while seated in his TiLite manual wheelchair and positioned in a Jay back, HAWC headrest, a custom seat cushion and subbasis bar at his pelvis.

CASE STUDY 20-7 Jet—cont'd

presented several lightweight manual wheelchairs at the evaluation and the family/team decided that the features of the TiLite Twist best met his needs because of the accessible wheels he could learn to propel, 1-inch tubing (which made it easier to mount his SGD), ability to adjust pitch through the caster, flip-back footrest, and foldable backrest for transport and growth adjustments.

Jet also had to access his environments in preschool, at home, and in the community as well as to have a means for

dynamic weight bearing and exercise. After evaluating several dynamic standing mobility devices, he was able to most efficiently maneuver a KidWalk owing to its ability to allow for weight shift, its compact turning radius, and large wheels for independent mobility on the playground turf surface. It was recommended and authorized. The KidWalk provides him with the opportunity to independently choose center time activities in preschool, run at recess with his peers, and begin learning how to jump. His family acquired the KidWalk for home use and Jet learned to walk to his local park, surprising his family by learning how to open the gate, drink from a fountain independently for the first time (Figure 20-20), and help with activities such as washing the family car (Figure 20-21). He is learning to self-propel the wheels of his manual wheelchair across a room and recently self-propelled outdoors over his backyard deck to pick a flower. His most efficient means for mobility is walking in his KidWalk. His next mobility goal is to learn to access a powered mobility wheelchair for distance mobility, which he is learning to do in weekly therapy sessions.

FIGURE 20-20 Jet walks up to a drinking fountain in his KidWalk standing mobility device and learns how to take a drink for the first time.

FIGURE 20-21 Jet washes his family's car while standing and moving in the KidWalk.

CHAPTER

21

Neonatal Intensive Care Unit

Jan Hunter • Anjanette Lee • Leslie Altimier

KEY TERMS

Neonatal intensive care unit	Neuroprotective core measures
Nursery classifications (levels of care)	Epigenetics
Neonatal developmental specialist	Sleep and brain development
Mastery skill levels, novice to expert	Preterm infant neurobehavioral organization
Preterm infants	Synactive theory of development
Very-low-birth-weight infants	States of arousal
NICU models of care	Neuromotor development
Healing environment (physical and sensory)	Therapeutic positioning
Individualized, family-centered, developmentally supportive care	Nutritive sucking
Neuroprotection	Non-nutritive sucking
	Cue-based, infant-driven feeding
	Kangaroo care and skin-to-skin holding

GUIDING QUESTIONS

1. What is the scope of knowledge and what are the various roles required for competent practice in the neonatal intensive care unit (NICU)?
2. What is meant by “potentially better practices (PBPs) to support neurodevelopment in the NICU,” as developed by the collaborative Vermont Oxford Network project?
3. How do the intrauterine and NICU extrauterine environments differ?
4. What are protective interventions to reduce avoidable stimulation from excessive or inappropriate light, sound, and caregiving practices in the NICU?
5. Why is protected sleep so important to an infant in the third trimester, whether in the womb or the NICU?
6. What factors are considered in evaluating an infant in the NICU?
7. What are the six neurobehavioral states, as defined by Brazelton and Als?
8. How and why do posture and movement patterns differ between term and extremely preterm infants?
9. What are common positional deformities of preterm infants, and how do these iatrogenic deformities potentially influence future development?
10. What factors are considered in therapeutic positioning?
11. What key factors facilitate successful breastfeeding in the NICU?
12. Why is non-nutritive sucking beneficial to preterm infants?
13. What are the primary differences between a traditional feeding approach and a cue-based, infant-driven feeding approach with NICU infants?
14. What are challenges in parenting a preterm infant in the NICU?

Kimberly underwent an emergency cesarean delivery at 25 weeks' gestation when intrauterine circulation problems developed in two of her three triplets. Adyson was born prematurely to a 15-year-old student who concealed her pregnancy from her parents. Tonya, with a history of three previous miscarriages, had a cerclage (a surgical procedure to help keep the cervix closed during pregnancy), and was able to carry Darren until 32 weeks' gestation. Brittney was born at 28 weeks to a mother being treated with methadone. Dylan, born at term to a febrile mother, became critically ill with pneumonia and developed respiratory failure during his first day of life. Myesha was delivered by an emergency cesarean section following a motor vehicle accident in which the placenta was partially torn from the uterine wall. Maria's prenatal ultrasound revealed an infant with multiple congenital anomalies.

These real-life examples represent the urgency and wide range of skilled medical care necessary to optimize survival and functional outcome in preterm and high-risk infants. Each of these infants was admitted to a neonatal intensive care unit (NICU) following delivery; all but one baby survived.

Overview of the NICU and Developmental Care

A neonatal intensive care unit is a stimulating and rewarding practice area for therapists with a passion for at-risk infants.

Experienced NICU clinicians are convinced that many long-term functional problems can be minimized or eliminated with appropriate developmental support from birth, a very motivating concept.

Because the NICU is a complex setting, with the most vulnerable patients and little or no room for error, it can also be overwhelming and intimidating for someone new to the NICU. Everything is relevant and interrelated—just where does one start to build knowledge and skills? A NICU primer, a short illustrated introduction to the world of the NICU, is available on the Evolve website.

This chapter includes a basic medical foundation, the changing role of a neonatal developmental specialist, the scope of knowledge and skills required, basic fetal development and the impact of birth requiring neonatal intensive care, environmental considerations, neuroprotective developmentally supportive care applications, neuromotor development, feeding in the NICU, and partnering with families. The final section discusses practical suggestions and approaches to becoming an essential member of the NICU team and attaining proficiency as a neonatal developmental specialist.

Nursery Classification and Regionalization of Care

While the NICU primer (available on the Evolve website) provides a historical overview of the NICU; this section describes the current status. The spiraling expense and complexity of medical care created a growing discrepancy between newborn death rates at major medical centers and those at smaller hospitals. In the early 1970s, regionalization of perinatal care emerged to provide advanced levels of health care to any mother or infant within an identified perinatal care region while avoiding unnecessary duplication of services. Patient care was generally provided at the nearest hospital, with transfer to a higher level facility as needed for more complex problems. Initially three levels of neonatal care were identified: level I (routine newborn care), level II (intermediate care), and level III (neonatal intensive care). Subcategories were added in 2004 but not consistently used. The latest revision in 2012 includes four levels of neonatal care, as described in Box 21-1.^{13,129}

Developmental Specialists Emerge as Integral Members of the NICU Team

Infant survival was the original indicator of NICU success. As the survival rate increased for younger, smaller, and sicker infants, an increased awareness of environmental and caregiving influences on the vulnerable newborn has enlarged the scope of NICU care to encompass infant development and family issues, in addition to primary medical concerns.⁷¹ Consequently, a unique neonatal developmental specialist role has emerged, which transcends traditional discipline boundaries. Neonatal developmental specialists in a specific NICU may variably be an occupational therapist, physical therapist, speech pathologist, nurse, and/or child life specialist with advanced training and a passion to help babies and their families function at an optimal level in the NICU and beyond. A neonatal developmental specialist can be expected to provide direct patient care, collaborative consultation with families and the medical

BOX 21-1 Nursery Classifications (2012)

- **Level I:** A hospital nursery that is able to provide neonatal resuscitation and postnatal care of healthy newborn infants and stable late-preterm infants born at 35 to 37 weeks' gestation. Sufficient expertise and experience to stabilize ill newborns or infants born at less than 35 weeks' gestation prior to transfer to a higher level facility are also necessary.
- **Level II:** This hospital special care nursery provides care to infants born at or less than 32 weeks' gestation with birth weight ≤ 1500 g who have physiologic immaturity issues that are expected to resolve rapidly with continued maturation (e.g., apnea of prematurity, inability to maintain body temperature, inability to take oral feedings) or who are convalescing from a higher level of care. A level II NICU can provide continuous positive airway pressure and may provide mechanical ventilation for brief periods (e.g., 24 hours).
- **Level III:** This is a hospital NICU able to provide continuous life support and comprehensive care for extremely high-risk newborn infants and those with critical illness, including infants born extremely preterm. Level III units can provide critical medical and surgical care and ongoing assisted ventilation (e.g., high-frequency ventilation, inhaled nitric oxide). Level III units have ready access to a full range of pediatric medical subspecialists; advanced imaging with interpretation on an urgent basis; access to pediatric ophthalmologic services for the monitoring, treatment, and follow-up of retinopathy of prematurity; and pediatric surgical specialists and pediatric anesthesiologists on site or at a closely related institution to perform major surgery. Level III units can facilitate transfer to higher level facilities or children's hospitals, as well as back-transport recovering infants to lower level facilities.
- **Level IV:** These units have the capabilities of a level III NICU and are located in institutions that can provide on-site surgical repair of serious congenital or acquired malformations. Level IV units can facilitate transport systems and often provide outreach education to other area NICUs.

Adapted from American Academy of Pediatrics, Committee on the Fetus and Newborn. (2012). Levels of neonatal intensive care. *Pediatrics*, 130, 587–597; and Stokowski, L. A. (2012). Noteworthy professional news: Four levels of neonatal care. *Advances in Neonatal Care*, 12, 326–328.

team, staff and family support and education, facilitation of system changes in the NICU environment, and/or caregiving practices that are neuroprotective to the infant and supportive of family as partners in care.^{10,115}

Traditional neonatal therapy in the 1980s (and still persisting in some NICUs) consists solely of rehabilitation and developmental stimulation for infants identified with developmental risk factors (e.g., extreme prematurity, prenatal drug exposure, genetic syndrome), pathology with inherent neurodevelopmental risks (e.g., central nervous system [CNS] abnormalities), and atypical performance (e.g., abnormal tone, poor feeding, chronic illness with developmental delay). Traditional therapy targets specific problems such as limited range of motion, atypical muscle tone, extreme irritability, poor feeding, and developmental delay. Remediation and rehabilitation continue to be appropriate for NICU infants with pathology affecting development and function.

FIGURE 21-1 A critically ill extremely preterm newborn (A) and an infant with multiple congenital anomalies (B; hydrocephalus, a large myelomeningocele, and lower extremity arthrogryposis) illustrate the range of infants cared for in a neonatal intensive care unit. (Courtesy Infant Special Care Unit, University of Texas Medical Branch, Galveston, TX. Photographs by Jan Hunter.)

Currently, state-of-the-art developmentally supportive care is neuroprotective and begins at birth to help promote physiologic stability and optimal neurodevelopment, rather than waiting for a baby to first become medically stable.⁸¹ This approach acknowledges that any infant who requires neonatal intensive care has inherent developmental risks and vulnerabilities, parenting an infant in the NICU is stressful and difficult, environmental and caregiving factors interact and affect each baby's evolving status, and both the infant and family must receive individualized support throughout the NICU hospitalization for optimal outcomes (Figure 21-1).

The early neuroprotective and preventive component of developmental support is not necessarily inherent in the traditional rehabilitation model. In contrast with the rehabilitation emphasis of direct hands-on contact, the current practice of protecting the fragile newborn from excessive or inappropriate sleep disruption and sensory input is often a more urgent priority than direct interventions or interactions with the infant.

Becoming a Developmental Specialist

The advanced practice area of the NICU requires specialized knowledge and skills that take time and intentional effort to acquire. These include the following: familiarity with relevant neonatal medical conditions, procedures, and equipment; understanding the unique developmental abilities and vulnerabilities of term, preterm, and ill infants; familiarity with evolving neonatal behavioral organization, family systems, NICU ecology; current models of practice; and appreciation of the manner in which these factors interact to influence infant and family behavior and development.^{15,132,133,136}

Despite the degree of experience in other practice areas, everyone initially enters the NICU as a novice. Trust, acceptance, and respect are gradually earned from protective NICU staff as each neonatal developmental specialist achieves and consistently demonstrates competency in knowledge, skills, and interpersonal professional relationships. It helps to understand the progression from novice to expert, with the traditional Dreyfuss definitions that were operationalized by Hunt^{42,63} (see Table 21-1e on the Evolve website).

Developing a Medical Foundation

Abbreviations and Terminology

Learning the language of the NICU is essential for the neonatal developmental specialist. Although changing documentation requirements specify that practitioners eliminate abbreviations and spell out terms, NICU language continues to contain many abbreviations, as illustrated by the following medical summary:

Cody is a 39 wk pma wm born at 25 WBD, 24 WBE by SVD to a 19 y/o now G2P1Ab1, A+, VDRL-mom with h/o of IVDA, smoked 1 PPD, PIH, PTL, PPROM 72° PTD. Pt. had TCAN ×1 (reduced PTD), AGA at 545 gms, Apgars 1¹, 3⁵, 6.⁷ Significant medical complications have included RDS, CLD, PIE, AOP, PDA (ligated), hyperbilirubinemia, anemia, MRSE and CONS sepsis, medical NEC, BIH (repaired), R gr. 3 and L gr. 4 IVH with frontal and temporal lobe PVL, ROP stage III OD (regressing) and stage III with plus disease OS (s/p Avastin injection OS). Pt. required HFOV with iNO, for 22 days, SIMV for 8 days, BiPAP for 14 days, NCPAP for 9 days, and remains on HFNC with FiO2 0.5 at 0.5L.

Understanding abbreviations and the terms they represent is a prerequisite to beginning a neonatal practice. See Box 21-2 for a list of some common NICU abbreviations.

Classifications for Age

For consistency, the American Academy of Pediatrics' Committee on the Fetus and Newborn (2004) has established the following definitions.¹²

Gestational age (or menstrual age) refers to the total time elapsed between the first day of the last normal menstrual period and the day of birth. Gestational age (GA) is calculated as completed weeks; a 26-week and 5-day fetus is considered 26 weeks GA. The range used for a full-term pregnancy in the United States is generally 38 to 42 weeks. Any infant born before 38 weeks is considered preterm; an infant born between 34 and 37 weeks is called late-preterm, with increasing recognition that such infants are still immature and vulnerable; and an

BOX 21-2 Common Medical Abbreviations in the Neonatal Intensive Care Unit**A**

A—apnea
 AAP—American Academy of Pediatrics
 Ab—abortions (includes spontaneous)
 ABG—arterial blood gas
 ABR—auditory brainstem response
 AD—right ear
 AEP—auditory evoked potential
 AGA—appropriate for gestational age
 A-line—arterial line
 AOP—apnea of prematurity
 APIB—Assessment of Preterm Infant Behavior (AIs)
 AROM—assisted rupture of membranes
 AS—left ear
 As & Bs—apnea and bradycardia
 ASD—atrial septal defect
 AU—both ears

B

B—bilateral; bradycardia
 BAEP—brainstem auditory evoked potential
 BAER—brainstem auditory evoked response
 BIH—bilateral inguinal hernia
 BPD—bronchopulmonary dysplasia
 bpm—beats/min (pulse)
 BSER—brainstem evoked response (same as ABR, AEP, BAER, or BAEP)
 BW—birth weight

C

CAN—cord around neck (nuchal cord)
 CBC—complete blood count
 CDH—congenitally dislocated hip
 CHD—congenital heart disease
 CHF—congestive heart failure
 CLD—chronic lung disease
 CMV—cytomegalovirus
 CNGF—continuous nasogastric feeding
 CNS—central nervous system
 COGF—continuous orogastric feeding
 CPAP—continuous positive airway pressure
 CPT—chest physical therapy
 C/S—cesarean section
 CSF—cerebrospinal fluid
 CTF—continuous tube feeding
 CXR—chest x-ray

D

dB—decibels
 DIC—disseminated intravascular coagulation
 DTGV—transposition of the great vessels
 D₅W—5% glucose solution
 D₁₀W—10% glucose solution

E

ECMO—extracorporeal membrane oxygenation
 ELBW—extremely low birth weight (<1000 g)

F

FC—foot-candle
 FEN—fluids, electrolytes, nutrition
 FHR—fetal heart rate
 Fio₂—fraction of inspired oxygen (percentage of oxygen concentration)
 FT—full term

G

G—gravida (pregnancies)
 GA—gestational age
 GBS—group B streptococcus

GER—gastroesophageal reflux
 GERD—gastroesophageal reflux disease

H

HAL—hyperalimentation (same as TPN)
 HC—head circumference
 HFJV—high-frequency jet ventilation
 HFV—high-frequency ventilation
 HFOV—high-frequency oscillating ventilation
 HIE—hypoxic-ischemic encephalopathy
 HMD—hyaline membrane disease
 HR—heart rate
 HSV—herpes simplex virus
 HTN—hypertension
 HUSG—head ultrasound

I

ICH—intracranial hemorrhage
 ICN—intensive care nursery
 IDC—Integrative Developmental Care model
 IDM (or IODM)—infant of a diabetic mother
 IDV—intermittent demand ventilation
 IH—inguinal hernia
 IMV—intermittent mandatory ventilation
 iNO—inhaled nitric oxide
 I/O—intake/output
 IPPB—intermittent positive pressure breathing
 IRV—inspiratory reserve volume
 IUGR—intrauterine growth retardation
 IV—intravenous
 IVDA—intravenous drug abuse
 IVF—in vitro fertilization; intravenous feeding
 IVH—intraventricular hemorrhage

K

kcal—kilocalories
 KMC—kangaroo mother care

L

L (or LC)—living children
 LA—left atrium
 LBW—low birth weight (<2500 g)
 LGA—large for gestational age
 LMP—last menstrual period
 L/S ratio—lecithin-to-sphingomyelin ratio
 LTGV—physiologically corrected transposition of the great vessels
 LV—left ventricle

M

MAP—mean airway pressure
 MAS—meconium aspiration syndrome
 MCA—multiple congenital anomalies
 MDU—maternal drug use
 MRSA—methicillin-resistant *Staphylococcus aureus*
 MRSE—methicillin-resistant *Staphylococcus epidermidis*

N

NB—newborn
 NBAS—Neonatal Behavioral Assessment Scale (Brazelton)
 NC—nasal cannula
 NCPAP—nasal continuous positive airway pressure
 ND—nasoduodenal
 NEC—necrotizing enterocolitis
 NG—nasogastric
 NGT—nasogastric tube
 NICU—neonatal intensive care unit
 NIDCAP—Neonatal Individualized Developmental Care and Assessment Program (AIs)
 NNNS—NICU Network Neurobehavioral Scale

BOX 21-2 Common Medical Abbreviations in the Neonatal Intensive Care Unit—cont'd

NNS—non-nutritive sucking	RDS—respiratory distress syndrome
NO—nitric oxide	REM—rapid eye movement
NP—nasopharyngeal	ROM—rupture of membranes
NPA—National Perinatal Association	ROP—retinopathy of prematurity (formerly called retrolental fibroplasia, RLF)
NPCAP—nasopharyngeal continuous positive airway pressure	RPR—rapid plasma reagin (test for syphilis)
NPO—nothing by mouth	RRR—rate, rhythm, respiration
NREM—non-rapid eye movement	RV—right ventricle
NS—nutritive sucking	S
NTE—neutral thermal environment	SA—substance abuse
O	Sao ₂ —oxygen saturation
O ₂ sats—oxygen saturation	sats—oxygen saturation levels
OD—oral-duodenal; right eye	SCN—special care nursery
OG—oral gastric	SGA—small for gestational age
OGT—oral gastric tube	SIMV—synchronized intermittent mandatory ventilation
OS—left eye	s/p—status post
OU—both eyes	SROM—spontaneous rupture of membranes
P	SSC—skin-to-skin care
P—pulse; para (births)	SVD—spontaneous vaginal delivery
P ₁ —primipara (first birth)	T
Paco ₂ —arterial partial pressure of CO ₂ (concentration of CO ₂ in peripheral arteries)	TA—truncus arteriosus
PAL—peripheral arterial line	TAPVR—total anomalous pulmonary venous return
Pao ₂ —arterial partial pressure of O ₂ (concentration of O ₂ in peripheral arteries)	TCAN—tight cord around neck
PBPs—potentially better practices	TCM—transcutaneous monitor
PCA—postconceptional age (old term; now PMA, postmenstrual age)	TcPO ₂ —transcutaneous oxygen pressure
PDA—patent ductus arteriosus	TLC—total lung capacity
PEEP—positive end-expiratory pressure	TOF—tetralogy of Fallot
PFC—persistent fetal circulation (old term; now PPHN, persistent pulmonary hypertension of the newborn)	TORCH—congenital viral infections (<i>toxoplasmosis, rubella, cytomegalovirus, and herpes</i>)
PICC—percutaneously inserted central catheter	TPF—toxoplasmosis fetalis
PIE—pulmonary interstitial emphysema	TPN—total parenteral nutrition
PIH—pregnancy-induced hypertension (preeclampsia, eclampsia)	TPR—temperature, pulse, respiration
PIP—pulmonary insufficiency of the preterm; peak inspiratory pressure	TRDN—transient respiratory distress of the newborn
PMA—postmenstrual age	TTN—transient tachypnea of the newborn
PO—by mouth	U
PPD—packs per day (refers to smoking)	UAC—umbilical artery catheter
PPHN—persistent pulmonary hypertension of the newborn (previously called persistent fetal circulation, PFC)	UAL—umbilical artery line
PPROM—prolonged premature rupture of membranes	UDC—Universe of developmental care model
PPS—peripheral pulmonic stenosis	ULBW—ultralow birth weight (<750 g)
PROM—passive range of motion	URI—upper respiratory infection
PROM—premature rupture of membranes	USG—ultrasound
PS—pulmonic stenosis	UTI—urinary tract infection
PT—preterm	UVC—umbilical venous catheter
PTL—preterm labor	V
PVL—periventricular leukomalacia	VDRL—Venereal Disease Research Laboratory
Q	VEP (VER)—vision evoked potential (response)
q—every	VLBW—very low birth weight (<1500 g)
qh—every hour	VSD—ventricular septal defect
qid—four times a day	W
R	WBC—white blood cell
RA—right atrium	WBD—weeks by dates (for gestational age assessment)
RBC—red blood cell	WBE—weeks by examination (gestational age assessment)
	WBU—weeks by ultrasound (gestational age assessment)

infant born after 42 weeks is post-term. Once the infant is born, the GA remains the same.

Postmenstrual age (PMA) refers to the infant's increasing age in relation to the first day of the last menstrual period, and thus continually changes over time. PMA is obtained by adding

the weeks since birth to the infant's gestational age. When the infant born at 27 weeks reaches his or her expected due date, the PMA is 40 weeks (27 weeks of gestation plus 13 weeks since birth). PMA is commonly used until 40 to 44 weeks, equivalent to term or 1-month corrected age, respectively.

Chronologic age refers to the infant's actual age since birth. Chronologically, the infant born at 27 weeks' gestation is 3 months old on the expected due date and 12 months old on the first birthday. Chronologic age of preterm infants is usually corrected for prematurity to correlate better with developmental expectations and performance (e.g., the infant born at 27 weeks' gestation will not developmentally look the same at 3 months' chronologic age as the infant born at term).

Corrected age refers to how old the infant would be if born at term rather than prematurely. The number of weeks of prematurity is first determined (GA is subtracted from the term equivalent of 40 weeks) and then subtracted from the chronologic age. The infant born at 27 weeks' gestation was born 13 weeks prematurely (40 weeks – 27 weeks GA = 13 weeks early). The corrected age of this infant on the first birthday is 9 months because the actual birth was 3 months earlier than the expected due date. Corrected age is variably used for 1 to 3 years in children born preterm when assessing developmental status.

Classifications by Birth Weight

Infants born weighing more than 2500 g (5.5 pounds) are considered average in size. A birth weight of 1500 to 2500 g is termed *low birth weight* (LBW). A very-low-birth-weight (VLBW) infant is 1000 to 1500 g, extremely low birth weight (ELBW) is less than 1000 g, and ultralow birth weight (ULBW) is less than 750 g.

Birth weight between the 10th and 90th percentiles on a standardized growth chart is appropriate for gestational age (AGA). Birth weight below the 10th percentile is small for gestational age (SGA), and birth weight above the 90th percentile is large for gestational age (LGA). These categories apply equally to preterm, term, and post-term infants. Any infant growing normally in utero will be AGA. An infant of a mother with severe pregnancy-induced hypertension (PIH) who experienced intrauterine growth restriction (IUGR) may be born SGA, whereas the infant of a mother with diabetes is often LGA.

Medical Conditions and Equipment

Medical complications and technology both have profound effects on preterm and high-risk infants, with subsequent implications and precautions for neonatal therapists. Developing a basic medical foundation and learning NICU medical terminology is an ongoing process that progresses from a general familiarity with terms and definitions to gradually understanding the pathophysiology of diseases and biomechanics of equipment. Recognizing that medical technology and interventions are constantly evolving, Table 21-1 lists common medical equipment in the NICU.

Models of Care in the NICU

Developmentally supportive care is a philosophy and approach to caregiving intended to improve neurodevelopmental outcomes in preterm and sick infants who lack the maturity, health, or competence necessary to cope with life in the NICU easily. Incorporating rapidly growing scientific knowledge from

multiple disciplines, *developmental care* is an inclusive term applied to environmental modifications, changes in caregiving practices, and efforts to increase family involvement.

Developmentally supportive care has historical roots. In the nineteenth century, Florence Nightingale emphasized the importance of nurturing healing environments for patient recovery and improved outcomes.⁹⁸ With the survival of increasingly preterm infants and the creation of neonatal intensive care as a medical specialty, conceptual frameworks have emerged to guide understanding and provision of neuroprotective developmentally supportive care with this uniquely vulnerable population.^{3,5,89}

Universe of Developmental Care Model

The universe of developmental care (UDC) model reformulated neonatal developmental care theory to portray a patient- and family-centered environment within the health care universe.⁴⁶ Because the skin and brain both develop from the embryonic ectoderm, in the UDC model, the skin acts as a shared sensory interface between the infant's brain and the current environment. This approach recognizes the interactive link between all developing systems and the caregiver and family while simultaneously providing a practical basis for formulating individualized patient care plans within the NICU's complex technologic environment.

With its inclusion of assessment and documentation, this approach also can address the increasing emphasis on core measures of quality control required by regulatory organizations (e.g., Centers for Medicare and Medicaid Services and the Joint Commission). The UDC model includes five developmental care core measures focused on care actions essential to promoting healthy growth and development of the preterm infant and family. These developmental care core measures include the following: (1) protected sleep, (2) pain and stress assessment and management, (3) activities of daily living (positioning, feeding, and skin care), (4) family-centered care, and (5) healing environment.⁴¹

Neonatal Integrative Developmental Care Model

The neonatal integrative developmental care (IDC) model expanded the five core measures described above into seven distinct family-centered developmental core measures for neuroprotective neonatal care. This expansion enables additional focus on developmentally appropriate positioning and handling, optimizing nutrition and feeding, and protecting skin, all areas that are fundamental to neonatal developmental care.⁹ The seven neuroprotective core measures for family-centered developmental care described in the IDC model include the following: (1) healing environment, (2) partnering with families, (3) positioning and handling, (4) safeguarding sleep, (5) minimizing stress and pain, (6) protecting skin, and (7) optimizing nutrition. The simplified neonatal IDC model depicts the seven core measures as overlapping petals of a lotus demonstrating the integrative nature of developmental care⁶ (Figure 21-2).

The IDC is the most current and comprehensive model for NICU developmental care. Most of the remaining chapter content can be placed within this framework; the reader is

TABLE 21-1 Common Medical Equipment in the NICU

Equipment	Description	Purpose
Thermoregulation Equipment		
Radiant warmer	Open bed with overhead heat source	Typically used during medical workup of new admission or for critically ill infants requiring easy access for frequent or complicated medical care
Incubator (Isolette)	Clear plastic heated box enclosing mattress and infant	Used to provide warmth (and sometimes humidity); allows calories to be used for growth and healing Preferred location for attempting to reduce environmental stimuli, discourage unnecessary handling, and protect sleep. Infant may or may not be dressed and swaddled, depending on specific NICU protocol. Depending on design, access is through portholes or a door on the front, or the entire top of the Isolette raises up.
Open crib	Bassinet-style bed; no external heat source provided; infant dressed in clothes and swaddled in blankets	Used for larger and more stable infants; caregivers (including occupational therapist) must be careful to avoid cold stress during baths, assessments, and procedures.
Oxygen Therapy with Assisted Ventilation		
Bag and mask ventilation	Bag attached to face mask is rhythmically squeezed to deliver positive pressure and oxygen.	Used for resuscitation of an infant at delivery or during acute deterioration or to increase oxygenation if necessary after an apneic spell.
CPAP	Steady stream of pressurized air given through an endotracheal tube, nasopharyngeal tube, nasal prongs, or small nasal mask; supplemental oxygen may or may not be used.	Positive pressure is used to keep the alveoli and airways from collapsing (to keep them open) in an infant who is breathing spontaneously but has a disorder such as RDS, pulmonary edema, or apnea. CPAP is now commonly used from birth (when effective) to reduce potential problems from mechanical ventilation.
Mechanical ventilation (CMV, HFOV, HFJV)	Machine controls or assists breathing by mechanically inflating the lungs, increasing alveolar ventilation, and improving gas exchange. Conventional mechanical ventilation forces can contribute to lung damage; high-frequency ventilation (oscillators and jets) use different mechanics to cause less barotrauma to the lungs.	Used for infants with depressed respiratory drive, pulmonary disease with increased work of breathing and suboptimal oxygenation and ventilation (e.g., MAS, RDS), and frequent apnea despite CPAP; infant is usually orally or nasally intubated but may have a tracheostomy if ventilator dependence will be prolonged.
ECMO	Sophisticated life support system that uses a modified heart-lung bypass to provide nearly total lung rest and minimize barotrauma (lung damage that can occur with prolonged high ventilator settings)	Used as a rescue technology for qualifying infants in critical respiratory failure who are unresponsive to conventional medical management or sometimes for preoperative support during cardiac surgery. Use of ECMO has decreased with the advent of therapies such as high-frequency ventilation and inhaled nitric oxide (pulmonary vasodilator drug).
Oxygen Therapy without Assisted Ventilation		
High-flow nasal cannula (HFNC)	Warmed and humidified oxygen or room air (21% oxygen) delivered at higher flow rates (>1 L/min) by flexible NC with small prongs that fit into the nares; a HFNC can be set up from ventilators or many CPAP machines; Vapotherm (Vapotherm, Exeter, NH) is a separate respiratory therapy device attached to a nasal cannula that allows very high nasal flows of supersaturated (saturated without condensation) air-oxygen blends.	Used to improve gas exchange or reduce work of breathing. High flow rates may reduce the need for intubation and mechanical ventilation or replace less well-tolerated nasal CPAP. Very high humidity allows higher flow rates (compared with those possible with nasal cannula) without drying nasal mucosa.
Nasal cannula	Humidified oxygen delivered by flexible nasal cannula with small prongs that fit into the nares	Used for infants requiring supplemental oxygen without positive pressure support, generally for prolonged periods. Handling and portability are easier with a nasal cannula than with an oxyhood.
Oxygen hood (oxyhood)	Plastic hood with flow of warm humidified oxygen placed over infant's head and possibly upper trunk	Used for infants who are breathing independently but need a higher concentration of oxygen than 21% room air; higher humidification allows oxygen delivery that is less drying to nasal mucosa than oxygen by a nasal cannula (not as commonly used since HFNCs became available).

CPAP, Continuous positive airway pressure; ECMO, extracorporeal membrane oxygenation; HFJV, high-frequency jet ventilation; HFOV, high-frequency oscillating ventilation; MAS, meconium aspiration syndrome; RDS, respiratory distress syndrome.

FIGURE 21-2 A simplified schematic diagram of the neonatal integrative developmental care model depicts the seven core measures as overlapping petals of a lotus, demonstrating the integrative nature of developmental care. (Courtesy Leslie Altimier.)

encouraged to refer often to the schematic diagram of the IDC model to help organize information.

NICU Environment and Caregiving

Evidence-Based Practice and Potentially Better Practices to Support Neurodevelopment in the NICU

The scientific method is a cyclic process of inquiry based on observations, synthesis, hypothesis, and predictions that lead to more observations. Evidence-based practice (EBP) traditionally rests on the gold standard of randomized controlled trials (RCTs). However, not all aspects of NICU neuroprotective developmental care can be methodologically or ethically captured in RCTs, and EBP is not intended to rely only on RCTs to the exclusion of other potentially innovative strategies gained from practice.¹⁰⁵ Browne²⁹ noted that EBP integrates clinical expertise and systematic clinical research; external clinical evidence informs but does not replace individual clinical expertise.

A collaborative hospital project by the Vermont Oxford Network (VON) conducted a comprehensive review of relevant neonatal literature.^{76,81} The researchers reviewed a vast amount of literature and synthesized the information to identify 16 potentially better practices (PBPs), with an emphasis on potential (rather than definitive) benefit. The group concluded PBP's that are known to be safe but have limited clinical evidence for

long-term benefit become more compelling when compared with existing practices with uncertain safety and no evidence of benefit.

The VON group divided the identified PBPs into two bundles, with the first cluster of interventions to be implemented for all infants on admission and the second bundle of interventions to be added by 31 to 32 weeks. Caregiving interventions were bundled because they are all necessary and more effective as a group than if implemented separately, and omission of any one of these practices may lessen the ultimate benefit. The extensive literature review, application to brain development and sensory systems, evidence-based conclusions, and implementation strategies make these two articles valuable developmentally supportive care resources for the NICU developmental specialist or caregiver. These 16 PBPs are summarized in [Table 21-2](#).

"Mismatch" of an Immature Infant in the High-Tech Environment

Sensory components of the typical intrauterine and NICU extrauterine environments are significantly different ([Table 21-3](#)). Barring complications, the fetus develops in a warm, snug, darkened environment in which basic needs are met and a normal sequence of development is supported.

The intrauterine environment of the maternal womb protects a developing fetus against harsh outside stimulation while

TABLE 21-2 Potentially Better Practices to Support Neurodevelopment in the NICU

System	Potentially Better Practice	Benefits
Cluster I		
	Full implementation recommended for all NICU admissions beginning at 23 weeks' gestation	
T-1	Containment and body flexion	T, S
T-2	Positive oral stimulation, non-nutritive suck	T
T-3a	Gentle touch, hand grasping, facial stimulation	T, S
T-4	Decrease painful and negative stimulation	T, S
C-1	Exposure to mother's scent	C, S
C-2	Minimizing exposure to noxious odors	C, S
A-1	Noise abatement	A, S
V-1	Minimizing ambient light exposure	V, S
V-2	Avoiding direct light exposure	V, S
S-1	Developing strategies that preserve normal infant sleep cycles	S
	Supporting family involvement in care practices that promote sleep	
	Nonemergent care provided at appropriate times; minimizes disruption of sleep (with diurnal implementation, as possible, after 30-wk gestation)	
S-2	Minimizing exposure to narcotics and other medications that may disrupt or disturb sleep cycles	S
Cluster II		
	Full implementation recommended for all NICU admissions beginning at 31-32 wk	
T-3b	Infant massage, diurnal implementation	T
T-3c	Skin-to-skin care	T, C, S
A-2	Exposure to audible maternal voice, diurnal implementation	A
V-3	Cycled lighting: minimum of 1-2 hr	A, V, S
V-4	Provide more complex visual stimulation after 37 wk (term gestation)	V

A, Auditory development; C, chemosensory development; S, preservation of sleep; T, somatesthetic-kinesthetic-proprioceptive development; V, visual development.

NOTE: A potentially better practice may affect multiple developing sensory systems (T, C, A, V, S).

Data from Laudert, S., Liu, W. F., Blackington, S., Perkins, B., Martin, S., MacMillan-York, E., et al.; NIC/Q 2005 Physical Environment Exploratory Group. (2007). TABLE 21-3 Comparison of Intrauterine and Extrauterine Sensory Environments

System	Intrauterine	Extrauterine
Tactile	Constant proprioceptive input; smooth, wet, usually safe and comfortable; circumferential boundaries	Often painful and invasive; dry, cool air; predominance of medical touching, with relative paucity of social touching
Vestibular	Maternal movements, diurnal cycles, amniotic fluid create gently oscillating environment, flexed posture with boundaries to movements	Horizontal, flat postures; rapid position changes; influence of gravity, restraints, and equipment
Auditory	Maternal biologic sounds, muffled environmental sounds	Loud, noncontingent, mechanical, frequent (sometimes constant), harsh intermittent impulse noise
Visual	Dark; may occasionally have very dim red spectrum light	Bright lights, eyes unprotected Often no diurnal rhythm
Thermal	Constant warmth, consistent temperature	Environmental temperature variations, high risk of neonatal heat loss

providing a variety of tactile, vestibular, chemical, visual, and auditory sensory stimuli in a controlled and integrated fashion.⁷⁹ The intrauterine environment of a developing fetus is characterized by limited light exposure, muted noise through fluid, sleep cycle preservation, and unrestricted access to the mother via somatosensory auditory and chemosensory pathways.¹⁰ The uterine wall provides secure yet flexible boundaries with generalized extremity flexion and containment for the developing fetus. Vestibular and tactile stimuli come from maternal and

fetal movements, immersion in warm amniotic fluid, and contact with the fetus's own body parts and the uterine wall. Hormonal cycles of the mother provide rhythmic stimulation and cyclic organization. Nutritional and oxygenation needs of the fetus are met by the placenta. Auditory inputs include the maternal voice, bowel sounds, blood flow through the placenta and umbilical cord, and filtered sounds from the extrauterine environment, transmitted through amniotic fluid and maternal body tissues.⁹⁵

After birth, demands are suddenly made on the preterm newborn to breathe, regulate body temperature, move against the effects of gravity, activate immature gastrointestinal (GI) function, adjust to bright light and unmuffled noise, cope with invasive or painful procedures, and endure frequent sleep disruptions and deprivation. The preterm infant's immature CNS is generally competent for protected intrauterine life but not sufficiently developed to adjust to and organize the overwhelming stimuli and demands of the NICU. Negative and random sensory inputs replace meaningful positive sensory inputs into the developing brain and can permanently alter normal brain development. This creates a so-called mismatch of the neonate with the high-tech world now necessary for survival.

The *animate* environment refers to the presence and activities of people in the NICU, both medical (hospital staff and caregiving practices) and social (primarily family and friends). The *inanimate* environment usually refers to the physical properties of light and sound in the NICU, although other factors such as gravity and temperature are also significant. Continual overwhelming stimuli in the NICU may stress the highly sensitive preterm infant's already vulnerable CNS, cause repeated hypoxic episodes, contribute to abnormal structural and functional changes of the brain, and create maladaptive behaviors that contribute to later poor developmental outcome.^{48,110} Events, stimuli, and environmental factors can support the processes of organized sensory development or create significant interference. Sensory interference may occur when immature sensory systems are stimulated with inappropriate stimuli or out of turn—because sensory systems develop in a predetermined order, sensory stimulation that is excessive or disrupts this order may cause sensory interference (interference with expected normal sensory system development).⁷⁹ The healing environment referred to in the IDC model addresses physical and sensory components of the NICU.

Physical Environment

A multidisciplinary NICU committee, under the auspices of the Physical and Developmental Environment of the High-Risk Infant Project, regularly updates and publishes a consensus on recommended standards for NICU design. This comprehensive set of minimum design standards is based on clinical experience and an evolving scientific database. The intent is to optimize NICU design within the constraints of available resources, facilitate excellent neuroprotective developmental health care for the infant in a setting that provides adequate space and facilities to support the central role of the family, and meet the needs of the NICU staff.¹²⁸ The latest recommendations are used worldwide and are available online (www.nd.edu/~nicudes).¹⁴³

Sensory Environment

Creating and monitoring a healing sensory environment involves issues related to tactile (touch and thermoregulation), vestibular, olfactory, gustatory, auditory, and visual sensory systems of the neonate. The proficient neonatal developmental specialist understands emerging strengths and vulnerabilities of early sensory system development and the impact of direct and indirect sensory stimulation on the vulnerable NICU infant.

Development of fetal sensory systems occurs in a chronological but overlapping order. The limbic system (emotions) and systems of touch (somatosensory), movement (kinesthetic, proprioceptive, vestibular), smell (olfactory), and hearing (auditory) are structurally complete but functionally immature at the earliest age of viability. They all respond to external stimuli by 25 to 28 weeks' gestation and exhibit in utero learning; developmentally supportive care will respond to the developmental needs of each of these systems.⁴⁹ Visual system structures and function are not complete because their earliest use is ideally at term gestation.

Because the sick preterm infant experiences significant stress (e.g., agitation, autonomic instability, excessive use of calories) when incoming stimuli exceed the ability of the immature CNS to respond and adapt, reducing avoidable stressors (including unnecessary therapy interventions) to help the infant remain calm, organized, and asleep becomes a priority.⁸¹ Examples of developmental interventions that support neonatal physiologic stability and brain development include practices such as preservation of sleep, NICU light and sound modifications, therapeutic positioning, nurturing touch, non-nutritive sucking, alteration of caregiver timing and handling techniques, and increased family involvement.^{10,64,76,81}

Temperature (Thermoregulation)

As the newborn moves from a warm, fluid-filled, floating intrauterine environment with flexible constraints to a dry, cool environment influenced by gravity and loss of consistent boundaries, a major goal of neonatal care is to provide a neutral thermal environment in which the infant is neither gaining nor losing heat at the expense of energy expenditure.⁷ Preterm infants are predisposed to excessive heat loss and are vulnerable to cold stress from several causes. Extended postures, thin skin, immature thermoregulation, and reduced insulating subcutaneous fat in very premature infants allow heat to transfer from the body to the air. A specialized brown fat used by newborns to metabolize heat is not produced until the last trimester of gestation. Pulmonary dysfunction, CNS immaturity, and frequent caregiving interventions may also contribute to heat loss. The infant may lose heat by convection (heat loss to surrounding air), conduction (body contact with cooler solid surface), radiation (heat loss to cooler solid object not in direct contact with the infant, such as incubator walls), and evaporation (heat lost as liquid from the respiratory tract and permeable skin, which is converted into a vapor).

The optimal environment for any newborn, especially a preterm infant, is kangaroo care, or skin-to-skin holding on the bare chest of mother (or father; [Figure 21-3](#)). The term *thermosynchrony* refers to a process during skin-to-skin contact in which the temperature of a mother's chest has been shown to increase by 2°C to warm a cool infant and decrease by 1°C to cool an overheated infant. Skin-to-skin contact with the mother meets the premature infant's needs for touch in the most natural environment possible outside the womb and also supplies needed proprioceptive sensory input to the infant's developing brain. When the parents are unavailable for skin-to-skin holding, or it is not possible, attention should focus on thermoregulation of the infant's individual bed space. To maintain a constant central temperature within narrow limits (36.5°–37.5°C), VLBW or premature infants should be cared for in incubators or radiant warmers.⁷

FIGURE 21-3 Skin-to-skin holding (kangaroo care) involves placing the unclothed baby (except for diaper) against the bare chest of the mother or father. Numerous benefits have been documented for infant and parent (specifically the mother), and an international initiative is under way to increase the initiation and frequency of this practice. (Courtesy NICU, Memorial Hermann Hospital Southwest, Houston. Photograph by Beverly Edwards.)

Positioning an infant in a midline, flexed, and contained position with the assistance of therapeutic positioning aids and swaddling decreases the surface area of the infant exposed to environmental air, thus reducing radiant and convective heat losses. This flexed and contained position offers additional temperature stability for the infant by minimizing extraneous movement and energy expenditure. Fluidized positioners magnify these benefits by allowing the infant to be immersed in a three-dimensional conformational positioner that assumes the same ambient temperature as the incubator or radiant warmer⁶⁴ (Figure 21-4).

The developmental specialist must diligently protect NICU infants from heat destabilization during each and every contact. Cold stress and overheating can cause complications in NICU infants.

Touch and Proprioception

The percentage of human touch in the NICU is overwhelmingly medical, and even noninvasive touch can be perceived as painful when it follows another painful procedure. Physical support of the infant during caregiving handling and procedures, kangaroo care (described briefly earlier), holding by a parent, and infant massage attempt to balance medical with nurturing touch.

Massage is an art and a science, best performed by a caregiver specifically trained in infant massage techniques, precautions, and warning signs. Massage is an active engagement between the infant and the caregiver; it is done with (rather than to) the baby. As with any type of stimulation, the developmental specialist should closely monitor the infant's physiologic and neurobehavioral responses, with handling modified accordingly. Specialized training, such as the Neonatal Touch and Massage Certification (<http://www.neonatalcertification.com>) is recommended to ensure that the developmental specialist adapts well-baby massage techniques to the unique medical and neurobehavioral sensitivities of the NICU infant.

FIGURE 21-4 Three-dimensional nesting in a fluidized positioner that conforms to each infant reduces body exposure and heat loss mechanics in this extremely preterm infant born at 22 weeks' gestation, now 24 weeks' PMA. (Courtesy Infant Special Care Unit, University of Texas Medical Branch, Galveston, TX. Photograph by Jan Hunter).

Traditional infant massage can be physiologically stressful and behaviorally disorganizing to preterm infants younger than about 32 weeks' postconception and those who are not yet medically stable. These younger or medically fragile infants may benefit more from the gentle human touch of a static hand swaddle (facilitative tuck). Preterm infants with the prerequisite degree of medical stability for more traditional infant massage are often approaching hospital discharge; developmental specialists can teach parents infant massage techniques for home use (Figure 21-5). Studies have shown that massage is associated with multiple physiologic, neurologic, behavioral, and neuromuscular benefits for infants; parents report decreased stress, increased attachment, improved self-esteem, and a more active role in caregiving.¹⁴⁴

Massage is increasingly recommended as an intervention to promote growth and development of preterm and low-birth weight infants in the NICU. However, some have raised concerns as to whether infant massage can produce overstimulation and therefore cause adverse effects. Further research through controlled trials is recommended to determine the benefits, risks, and optimal application of this nurturing human touch.⁷⁰ As with all interventions, precautions are needed to carefully guard against cold stress.

Sound and Noise in the NICU

Early auditory development involves the structural parts of the ears that develop in the first 20 weeks of gestation and the neurosensory part of the auditory system that is in a critical period of development from 25 weeks' gestation to approximately 5 to 6 months post-term.⁵⁰ An infant's ear structures (outer, middle, and inner ear) and cortical auditory center are formed and functioning by 25 weeks' gestation, although they remain functionally immature and continue to develop during the last trimester.

FIGURE 21-5 Mother using a static hand swaddle to provide nurturing touch to her NICU infant prior to adding selected massage strokes as tolerated. (Courtesy Kara Ann Waitzman, Creative Therapy Consultant, Neonatal Touch and Massage Certification.)

Neurosensory auditory development is sensitive to extra-uterine differences in the NICU environment.⁵² In the womb, sounds are muted through a fluid-filled environment. In contrast, NICU infants have historically been bombarded with noise (undesirable sound) that may be relatively constant throughout the day and night, predominantly mechanical rather than social, and often noncontingent to individual infants. Sound inside the incubator is characterized by continuous white noise and nonspeech sounds; harsh mechanical noises penetrate clearly and reverberate, whereas speech sounds are indistinct. NICU infants are exposed to vibration and noise during transport and when on high-frequency ventilation; noise and vibration combined may have a synergistic effect.

An infant born prematurely is exposed to low- and high-frequency sound without the protective noise attenuation of the mother's body. The hearing threshold of the infant has been reported as 40 decibels (dB) at 28 to 34 weeks' gestation, 30 dB at 35 to 38 weeks' gestation, and less than 20 dB at term; these thresholds are greatly exceeded in the NICU.⁷³ Loud or prolonged sounds may damage the delicate hair cells in the developing cochlea, with resultant hearing loss in the same frequency range as that of the damaging sound; preterm infants are at risk for hearing loss in low-frequency (speech) and high-frequency ranges.⁵²

Sensory interference may occur when immature sensory systems are stimulated out of order or bombarded with inappropriate stimuli. Background noise in the NICU may also interfere with the infant's ability to discriminate speech of parents and other caregivers.^{52,92} Long-term difficulties in auditory processing can occur in the presence of normal intelligence and hearing sensitivity; behaviors associated with disturbed auditory processing have been noted in NICU graduates. Auditory processing problems may manifest as poor listening skills,

difficulty following multistep directions, poor discrimination of specific auditory signals amid other background or impulse noise, distractibility, short attention span, and/or poor reading and spelling skills.⁶⁷

Infant stress from environmental noise may be observed as a decrease in oxygenation and an increase in vasoconstriction, blood pressure, intracranial pressure, heart rate, respiratory rate, apnea, and bradycardia.¹⁴⁰ Sound is registered by the brain even during sleep, and intense impulse noise is known to increase visible arousals and arousals detected by changes in sleep brain wave patterns. Sleep disruption is a major concern in the NICU,⁴⁸ with major negative impacts on the neural circuitry formation essential to early brain and sensory system development. Sleep deprivation also impedes the infant's medical recovery.⁴⁸

Sound Recommendations for the NICU Infant

Early auditory system development occurs when nerve cells in the brain, sensory organs, and peripheral nerves fire independently of outside stimulation; this spontaneous endogenous stimulation can be blocked by exposure to drugs, alcohol, and toxic chemicals. Unlike the visual system, however, the auditory system also requires outside auditory stimulation (voice, music, and meaningful environmental sounds) during the last trimester.⁵² Auditory learning and memory requires the following: (1) a low background noise level (see NICU design standards¹⁴³) for the infant to (2) hear and recognize differences in pitch, pattern, intensity, and rhythm within (3) protected sleep cycles, with emphasis on rapid eye movement (REM) sleep, especially after 32 weeks' gestation.⁵⁰

The NICU staff needs to be diligent to provide an appropriate supportive environment for early auditory environment. Single-patient room designs reduce noise overflow. The staff in NICUs with pods or larger rooms can move bed spaces of sensitive infants away from loud or high-traffic areas and hold conversations, including medical rounds, away from the bedside. Auditory alarms can be reduced in volume and silenced quickly to reduce infant exposure to piercing impulse noise; remote control devices to silence alarms and visual alarms are also available. Respiratory tubing and water traps can be positioned to promote drainage; accumulated water should be emptied frequently to prevent bubbling (60-70 dB). Incubator covers can significantly reduce the noise level in an incubator.

In addition to controlling background noise, staff should arrange the timing of caregiving to support and protect sleep cycles and REM sleep. Neonatal developmental specialists can model appropriate voice and interaction for parents. Parents who understand the value and benefits of sleep are less likely to frequently awaken and overstimulate their infant. Emotional memories, comfort, and attachment are linked to auditory learning in even young infants; this is another incentive for educating and including parents in infant care. In contrast, an environment with loud low-frequency noise, unusual vibration and motion, and frequent sleep disruptions can interfere with optimal auditory development.

High noise levels in NICUs affect staff and families as well as infants, elevating the stress level in an already stressful environment. Goals of a quieter NICU include prolonged periods of undisturbed sleep for the infant, providing an environment for discernment of an audible maternal voice at 31 to 32 weeks' gestation and beyond, and providing a more comfortable and safe work environment for staff.⁸¹

Music therapy is a current NICU ‘hot topic’, and initial research shows benefit to infants. Music therapy intervention has been shown to “deepen infant sleep-state, support infant self-regulation, assist in the stabilization of breathing and heart rates, enhance parent/infant bonding, sooth irritability, re-enforce feeding/sucking rhythms and weight gain, and promote a sense of safety during painful procedures” (<http://nicumusictherapy.com/Nicumusictherapy/Welcome.html>).

Evidence continues to be gathered about what source, type, intensity, or duration of music can be beneficial to preterm infants. Any intervention must consider the infant’s state and stability, timing in relation to other demands on the infant, potential disruption to (or enhancement of) infant sleep (best tested with sleep electroencephalography), and impact on any nearby infants. Musical toys and tape recordings, which can reverberate inside the incubator and continue playing regardless of infant cues, do not qualify as controlled and sensitive music therapy and are not recommended in the NICU. Headphones are also not recommended because of variable decibel levels and the noncontingent obligatory nature of the stimulation.

Light in the NICU

Lighting requirements in the NICU are very different for NICU infants and their adult caregivers.¹¹⁴ The NICU staff needs variable light levels and sources for personal biorhythms (e.g., arousal and alertness, mood, temperature, hormone levels, sleep cycles) and for work-related tasks such as charting, infant assessments, and intricate procedures. Lighting needs generally increase with caregiver age.

Conversely, the fragile immature infants generally need protection from NICU light sources. The visual system of the preterm infant is functionally and structurally incomplete before term birth and requires dimness and sleep for continued optimal development.^{48,49} The growth of the eye in utero is genetically coded and needs no light prior to 40 weeks; the infant’s visual system continues to develop normally without external stimuli during the last trimester of gestation, with significant maturation and differentiation occurring in the retina and visual cortex.^{48,49}

In infants born early, the eyelids remain fused until 24 to 26 weeks’ gestation, with little spontaneous eye opening until after 29 weeks, emphasizing that the eyes of the preterm infant are not yet ready to process visual input at this stage of development. Preterm infants are unable to protect themselves from room light because they cannot close their eyelids tightly until after 30 weeks; their thin eyelids do not adequately filter light; and the iris does not significantly constrict until 30 to 34 weeks.⁴⁴

Sensory interference can occur when one developing sensory system is stimulated out of turn or bombarded with inappropriate stimuli. For example, auditory system maturation typically occurs without strong competing sensory stimuli during the last trimester. Early birth with premature exposure to light may precipitate earlier visual system function, but preterm infants exposed to light in the NICU during the last trimester have an increased incidence of auditory processing dysfunction at school age. Premature stimulation of the visual system appears to compete and interfere with optimal development of the auditory sensory system during this critical period.⁴⁸ Although early light exposure has not been shown to increase

the incidence of retinopathy of prematurity,¹¹¹ ambient NICU illumination may be implicated in subtle visual pathway sequelae and visual processing problems.^{44,49,79}

Increased light intensity has been shown to increase heart rate and respiratory rate and decrease oxygen saturation for preterm infants in the NICU. Light levels and abrupt fluctuations can disrupt sleep of the premature infant, an important consideration because vast sensory system and early brain developments occur during sleep.⁵⁰

Environmental Modifications of Light in the NICU

In contrast with the darkened womb, many NICUs have chaotic and unpredictable lighting patterns. Neither continuous dim or bright light has been demonstrated to be optimal for the development of preterm babies, and often the youngest and sickest infants are exposed to the highest levels of light for monitoring and medical procedures. Guidelines for appropriate NICU lighting are available from the regularly updated recommended standards for newborn ICU design.¹⁴³ Light intensity (illuminance) is measured with the metric unit lux (preferred term) or the English unit, foot-candle. One foot-candle equals approximately 10 lux (more precisely, 1 foot-candle = 10.764 lux).

Flexibility in lighting options accommodates the variable needs of caregivers and babies at differing stages of development and at various times throughout the day. Combinations of direct and indirect deflected lighting, adjustable ambient lighting at each bedside, no light source in an infant’s direct line of sight, focused adjustable task lighting, and separate, well-lit areas for tasks such as charting or medication preparation are beneficial.¹⁴³ At least one source of natural daylight visible from each patient care area provides psychological benefits to NICU families and staff and assists with day-night cycled lighting.²

Circadian cycles are individual biorhythms over a period of approximately 24 hours. A third-trimester fetus has a functioning biologic clock (suprachiasmatic nuclei in the hypothalamus) capable of generating circadian rhythms, such as hormone secretion, activity patterns, and feeding cycles, in response to maternal day-night cues. These maternal circadian signals are disrupted in the infant who is born prematurely.⁸¹ Light influences the infant’s circadian system by a different neuronal pathway from that used for vision and becomes important for regulating circadian biorhythms after preterm birth. It has been suggested that the circadian system of a preterm infant is responsive to light very early (perhaps by 25–28 weeks’ gestation) and that low-intensity light can entrain the developing circadian clock.^{113,120} Cycled lighting in neonatal care has been shown to establish circadian cycles with beneficial effects on infant’s fussing and crying behavior and growth in the first weeks of life.⁵⁶

Because bright lights can disrupt sleep, current recommendations suggest a baseline (ambient) level for the patient care area of 10 to 20 lux.⁸⁷ This continuous dim lighting is probably best for infants younger than 28 weeks’ gestation.⁴⁸ After 28 weeks’ gestation, diurnally cycled lighting (dim lighting at night, with daytime levels increased to 250–500 lux) shows evidence of potential benefits for the infant (e.g., longer sleep, improved growth, more stable breathing, decreased levels of stress hormones), and cycled lighting in the NICU shows no evidence of harm.^{81,113} A recent Cochrane review compared the effectiveness of cycled lighting (CL; ≈12 hours of light on and

BOX 21-3 Guidelines for Supporting Visual Development in the NICU

The infant's visual system is designed to develop in utero in darkness until term birth, devoid of external images or light stimulation. NICU care practices need to protect the endogenous processes needed for visual development carefully and prevent interference with the development of the other sensory systems

22-28 Weeks

The eyes of a very preterm infant (22-28 weeks' gestation) should always be protected from bright and direct light. Only low-level indirect ambient lighting should be used for preterm infants who cannot block out light through their thin eyelids, may not be able to turn away from light, and cannot communicate their needs. The developmental specialist should also be aware that some sedative and CNS depressant drugs can interfere with the endogenous neuronal activity necessary for early visual development; nonpharmacologic pain management and secure supportive positioning may decrease the need for high doses or frequency of these drugs.

28-36 Weeks

Care of the 28- to 36-weeks'-gestation preterm infants should focus on protecting sleep cycles, especially REM sleep. During this time, intense stimulation from NICU noises, vibrations, and other disturbing stimuli of other sensory systems can greatly interfere with the processes of visual system development and also disrupt sleep cycles and necessary REM sleep.⁷⁹ Because the infant's circadian clock can respond to light by 28 weeks, some daily exposure to shorter wavelength light can help entrain a circadian rhythm.

The ability to attend visually emerges at 32-34 weeks PMA and is enhanced in low ambient light. Although we cannot prevent an infant from using emerging visual skills, this does not mean that we should encourage it at this young age. Sensory interference and unnecessary competition with auditory development remains a concern. In addition, attempts by parents and caregivers to stimulate visual engagement and interaction at this age often create stress and disturb sleep cycles and endogenous brain activity.

36-40 Weeks

At 40 weeks' gestation, the human visual system has intact retinal development and pathways to the visual cortex and now requires regular external and interactive visual stimulation. Visual experiences for healthy visual development requires ambient light (not direct light), focus, attention, novelty, movement, and, after 2 to 3 months, color.

State Organization

State organization prior to term age equivalency does not require vision, but instead develops in response to gentle nurturing input (e.g., warmth, skin-to-skin holding, soft voice or music, pleasant and familiar taste and smell, gentle motion). For infants in this age range, social and emotional context and atmosphere are just as important as the visual experience; parents need to be involved and trained to understand the type and content of interaction necessary for continued development in these early post-term months.

Adapted from Graven, S. N. (2011). Early visual development: Implications for the neonatal intensive care unit and care. *Clinics in Perinatology*, 38, 693–706.

12 hours of light off) with irregularly dimmed light (DL) or near-darkness (ND) and with continuous bright light (CBL) on growth in preterm infants at 3 and 6 months of age. Trends for many outcomes favored CL compared with ND and CBL.⁹³

Graven⁴⁹ has emphasized three primary areas of care in the NICU that can adversely affect visual development in the preterm infant. These include interference with endogenous brain cell activity, sleep deprivation, and intense light exposure. **Box 21-3** summarizes implications for supporting visual development in the NICU.

Supplemental Sensory and Developmental Stimulation

Much of the early research on supplemental stimulation with preterm infants was based on the sensory deprivation theory and the subsequent desire to provide additional stimuli. This research has been criticized because of the use of small samples, exclusive application to healthy preterm infants, wide age span of infants treated as a homogenous group, failure to take into account individual differences of infants, and methodologic discrepancies that preclude comparisons among studies.

Although much remains unknown, sleep protection remains a top priority. Concerns exist about the immediate and long-term impact of sensory stimuli in the NICU on the preterm infant's still-developing sensory systems. When considering sensory stimulation in the NICU, protecting the fragile newborn from excessive or inappropriate sensory input is a more

compelling priority than direct intervention or interaction with the infant. Stimulation is not therapeutic if it disrupts sleep or stresses the infant; an infant may respond to stimuli, but at a physiologic cost, with no sum benefit. Developmental specialists must continually modify sensory stimulation in the NICU according to each infant's postconceptional age, medical status, current state of readiness and responsiveness, ongoing cues of stress or stability, and current sleep cycle. In other words, the developmental specialist provides graded sensory input when the infant is ready and seeking, not because it is time for therapy.

Early stimulation for these younger preterm infants may be safest if it replicates normal parenting activities, such as being held, listening to the caregiver's soft voice, and looking at the caregiver's face. Young infants tolerate stimulation best if it is unimodal (one sensory input at a time). Ideally, family members provide this contact (**Figure 21-6**).

Stable infants approaching or exceeding term age equivalency often become bored or uncomfortable and demand more attention. Fluidized positioners (Sundance Solutions, White Plains, NY) allow increased positioning comfort and variability in bed and with developmental equipment. The developmental specialist may provide mobiles, mirrors, and/or musical toys for auditory and visual stimulation. Baby swings or vibrating, bouncy infant seats can provide gentle vestibular input and a different view of the world. Even the variety of being placed in a standard infant seat may calm some infants. Portable infant carriers may be options for stable infants who can be

FIGURE 21-6 The support provided by containment, suckling, and grasping helps this preterm infant establish eye contact with her mother for a time of quality interaction.

temporarily separated from (or have portable) medical equipment. Supporting families to be available, involved, and knowledgeable is the best way to meet the infant's developmental and emotional needs both in the NICU and after discharge.

Potential Impact of the NICU Environment on Brain Development in the Preterm Infant

The brain and sensory systems of the neonate are intimately inter-related. Every sensory experience is recorded in the brain, creating a behavioral response and thereby leading to yet another sensory experience. This cyclic interdependent action and reaction is the basis for neurobehavioral and neurosensory development.

The developing brain forms three distinctive structural layers: the brainstem, limbic system, and cerebral cortex.⁸³ The brainstem (medulla, cerebellum, pons) is nearly complete around the seventh month of gestation.^{19,43,112} The brainstem receives sensory messages and relays sensory information to the cerebral cortex. An example is the processing of vestibular sensations necessary for hearing, balance, vision, and focusing attention.⁸³ The brainstem also regulates autonomic functions of internal organs, such as breathing, heartbeat, and digestion.¹⁹

The limbic system is located by the thalamus, under the cerebrum. In addition to involvement in smell, the multiple structures comprising the brain's limbic system are directly involved with emotion, behavior, motivation, and formation of long-term memory.

With continued maturation (to adulthood), the highly specialized cerebral cortex (cerebrum, or cognitive brain) performs complex organization of sensory input, contains specific areas to control volitional function, and develops plasticity to adapt throughout the life span.^{19,43}

Nervous system basic functions include autonomic, sensory, motor, and state regulation. Autonomic function includes self-regulation of respirations, heart rate, blood pressure, temperature, and nutritional intake. The infant must adapt and respond to many changes simultaneously to survive and thrive in the extrauterine environment after birth.^{25,138} Although autonomic regulation is usually sufficiently mature for the full-term infant

to adapt successfully after birth, the preterm infant often requires assistance.

Multiple factors interact to influence both structural and functional brain development. The development of early brain architecture and function before the youngest age of viability (cell differentiation and migration, initial cell location, primitive neuronal pathways, response to early stimulation) is primarily guided by a genetic blueprint and influenced by spontaneous internal (endogenous) or maternal hormonal stimulation. After birth, at any viable age, external (exogenous) experiences from the environment now stimulate sensory organs of variable maturity. The resulting interaction when external environmental stimulation influences are sufficient to alter gene expression (not gene sequence) is a process termed *epigenetics*.^{35,88} Alterations in gene expression following maternal exposure to stress, environmental toxins, and nutritional modifications have been associated with physiologic and behavioral changes in offspring.⁹⁴

The interaction among low birth weight, prenatal adversity, and postnatal environmental conditions has been associated with low cognitive function, behavioral disorders, and psychiatric disorders.¹²¹ The impact of preterm birth on the developing brain, along with associated painful and unpredictable procedures, environmental stress, and maternal separation, may contribute not only to injury but also to lasting epigenetic consequences.⁸⁸ The field of epigenetics may provide critical information about how early experiences, prenatal and postnatal, may affect long-term development.

The fetal neurologic system is in a highly active stage of development during the third trimester of gestation. Young children and adolescents who were VLBW infants have pronounced structural abnormalities demonstrated as smaller volumes of cerebral white matter and neocortical grey matter, smaller surface area of the corpus callosum, larger lateral ventricles, and smaller cerebellar and brainstem volumes.¹³⁵ Focal injuries such as periventricular hemorrhagic infarction and cystic periventricular leukomalacia are highly correlated with motor impairment; however, an apparently normal cranial ultrasound does not imply a reduced risk for major neurosensory deficits.^{21,22,65,74,139} Subtle alterations in the volume or architecture of brain wiring (neuronal pathways and connections) may not be visible on radiologic imaging but can still lead to neurodevelopmental or learning differences.⁷²

The statistics of survival and of long-term neurodevelopmental problems are generally correlated with the degree of prematurity, although exceptions exist on both ends of the spectrum. Last-trimester brain and neurosensory development outside the protective development of the womb increase the risk for motor impairments, cerebral palsy, visual impairment, auditory dysfunction, learning difficulties, and behavioral disorders.^{4,57,130,134} Additionally, preterm infants demonstrate increased risk for language delays, visual processing difficulties, and executive dysfunction.^{20,66}

Extremely preterm (<26 weeks' gestation) and LBW infants are also at increased risk for a variety of behavioral problems, such as attention deficit, attention-deficit/hyperactivity disorder, autism spectrum disorders, anxiety, and other emotional disorders.^{24,68,80,119} Of growing concern is the prevalence of neurodevelopmental impairments in preterm survivors, which include a constellation of cognitive, language, and behavioral outcomes without major neurosensory deficits.^{1,2,18} Although

the causes of these impairments remain unclear, it is thought that early stressful environmental influences on the brain during critically sensitive developmental periods may contribute to these adverse outcomes,³⁰ a concept that is well supported by animal research.

With research documenting increased risk for subtle and significant long-term sequelae in children born prematurely, efforts to support the preterm infant's fragile neurologic system become essential to decrease the negative effects of continuing development within the extrauterine environment of the NICU.^{76,81} This goal is the basis of neuroprotective developmentally supportive care, with the hope and promise of improved outcomes for future infants.

Box 21-4 summarizes the highlights of fetal brain and sensory system development at advancing gestational ages, with corresponding implications for environmental and caregiving modifications.

Safeguarding Sleep

Medical literature is unequivocal on the divergent and profound effects of sleep deprivation and improved sleep on NICU infants.^{50,81} At 23 weeks' gestation, the fetal brain is smooth, with undeveloped synaptic connections, which subsequently develop within the context of the NICU experience for the prematurely born infant. A last-trimester fetus has undisturbed

BOX 21-4 Fetal Sensory System Development: Implications for Environmental and Caregiving Modifications

Basic Brain Development

First trimester: Formation of neural tube and prosencephalon.

Disruption of normal development during this period can cause major malformations, such as neural tube defects and agenesis of corpus callosum.

2-4 months' gestation: Proliferation of neuronal and glial cells, which are stored in the germinal matrix.

3-8 months' gestation: Migration of cells from germinal matrix to cerebral cortex.

5 months' gestation through childhood: Organization (alignment, orientation, layering) of cortical neurons, arborization (differentiation and branching of axons and dendrites to increase cell connection possibilities), increased complexity in brain surface convolutions (sulci) as different areas develop for specific functions.

8 months' gestation (peak time): Myelination.

Most Fetal Sensory Systems (Tactile, Vestibular, Taste, Smell) Are Functioning at the Age of Viability

Tactile: Even the youngest NICU infant has sophisticated perioral sensation and perceives pressure, pain, and temperature. The back and legs are very sensitive to touch, especially prior to 32 weeks, when modulation improves.

Vestibular: System structurally complete but still functionally immature. Movement and position changes can be overstimulating and stressful.

Taste: Withdraws from bitter taste at 26-28 weeks. Calms to sweet taste at 35 weeks. Taste can be affected by sense of smell.

Smell: Responds to odors with approach or avoidance. Noxious odors can prompt physiologic instability and behavioral stress. He or she can recognize mother via smell.

NICU Implications

Coordinate care among disciplines to reduce handling, minimize sleep disturbances, and accommodate feedings. Help support the infant during examinations and procedures:

- Contain extremities (use hands, blanket, positioning aid).
- Encourage sucking on pacifier or on own hand.
- Brace feet against boundaries or palm of caregiver hand.
- Have baby grasp tubing, strap, adult finger.
- Shield infant's eyes from room or procedure light.
- Observe for signs of overstimulation. Can you pause and help infant reorganize before proceeding?

- Contain infant's extremities flexed against his or her body during smooth, slow position changes.
- Use soft fluid boundaries; amount of support needed will vary but is greater for younger, sicker infants.
- Firm steady touch (containment) is better tolerated than light moving touch (stroking).
- Young infants may tolerate holding better skin-to-skin (versus swaddled) and without vestibular stimulation (rocking).
- Protective gloves may have unpleasant taste; wash and rinse first if inserting finger into infant's mouth.
- Oral medication—consider gavage, mixing with feeds.
- Protect infant from noxious smells (e.g., disinfectant).
- Placing a soft cloth infused with the parent's scent near the infant may be calming and facilitate feeding.

Auditory-Visual Sensory System Fetal Development (at Age of Viability) with NICU Implications

Auditory System

24 weeks: Ear (outer, middle, inner) and cortical auditory center essentially formed and functional.

26 weeks: Can elicit brainstem evoked potentials.

NOTE: Preterm infants have increased incidence of sensorineural hearing loss. Auditory processing problems also occur; some animal studies implicate sensory interference (inappropriate timing and intensity of exposure to sensory stimuli related to critical periods of development).

NICU Implications

Preterm infants are sensitive to NICU noise. Auditory overstimulation can cause physiologic stress.

"People" noise is the hardest to reduce and control.

Isolettes can be protective.

NOTE: Mechanical noises penetrate incubators better than speech sounds.

Efforts to reduce noise can occur at many levels:

- Environmental modifications (e.g., sound-absorbing ceiling tiles, carpet, padding bottoms and lids of trash cans, padded Isolette covers, no radios)
- Activity relocation (clerk, main phone, medical rounds all moved away from bedside areas)
- Caregiving practices (silence alarms quickly, speak softly, close Isolette doors quietly)
- Technology (visual alarms, vibrating beepers)
- Neonates demonstrate preference for mother's voice.
- Relaxing music may be effective with older infants.

BOX 21-4 Fetal Sensory System Development: Implications for Environmental and Caregiving Modifications—cont'd**Visual System**

Weeks	Development
22	All retinal layers present
25	Can distinguish rods and cones Light elicits blink reflex
25-26	All neurons of visual cortex present
26-28	Eyelids open (no longer fused)
27	May have brief spontaneous wakefulness Unable to visually focus
28-30	Eyes may remain open occasionally Eye movements typically rapid and jerky
30-32	Closes eyes to bright light Brief quiet alert state Visual attention still often stressful Monocular vision
32-35	Demonstrates visual preference Visually tracks horizontally past midline Efforts at visual attention may fatigue infant.
36-40	Retinal vascularization and optic nerve development complete Visually tracks in horizontal, vertical, and circular directions Head and eye movements not well coordinated Preference for curved lines and shapes (versus angular, straight) Can see colors

NICU Implications

The visual system is the least mature of all sensory systems at preterm birth; infant must consistently be protected while visual maturation continues.

- Eyelids are thin and do not block out all room light. Decrease NICU room light, cover bed space, and/or shield eyes of individual infants from direct or bright lighting (including during procedures).
- Avoid abrupt increases in lighting levels.
- Lower light helps reduce staff noise, activity, and stress.
- Studies suggest benefits in altering NICU light levels to provide day-night cycles.
- Supplemental visual stimulation does not seem to accelerate visual system maturation, can fatigue young premies, and can create significant neurobehavioral stress, including apnea and bradycardia.
- Allow infant to indicate readiness for visual stimulation (in quiet alert state, already attending to environment).
- Lower light levels facilitate eye opening for attention.
- Black and white designs are overstimulating for immature infants; the human face is the best model for visual stimulation when the baby is mature and stable.
- Black and white may be therapeutic for infants with significant visual impairments.
- Brainstem visual evoked potentials in preterm infants are difficult to interpret because of visual system immaturity.

sleep in a protected environment; an NICU infant has frequent sleep disruptions in a stressful environment.^{23,53}

The primary activity in brain development during the last trimester is synaptogenesis (neurons connecting to others neurons at an amazing rate of 1 to 2 million connections/second), which forms the primitive neuronal pathways that are later refined by experience.^{48,50} Synaptogenesis at this stage is endogenous (occurs spontaneously within the brain in the absence of external stimulation) and forms the early brain architecture that is later refined by exogenous (external) stimuli. Endogenous synaptogenesis produces brain complexity and plasticity, only occurs during sleep, and occurs only during REM sleep after 28 weeks' gestation.^{48,50}

Prior to 28 weeks, the only sleep state seen on an electroencephalogram (EEG) is an immature sleep stage termed *indeterminate sleep*. Indeterminate state and arousals are associated with less stable oxygenation and hypoxemic episodes, conditions frequently observed in this very immature population. The indeterminate sleep state is gradually replaced by the EEG-identifiable sleep states of active sleep (REM sleep) and quiet sleep (non-REM [NREM] sleep). Normal sleep organization demonstrates maturation. REM sleep may initially comprise up to 75% of total sleep time in the 30- to 36-week infant; REM

and NREM sleep are almost equal as the infant approaches term, and by 8 months of age NREM sleep occupies almost 80% of total sleep time.^{48,50,88}

Sleep preservation and organization are important determinants of an infant's developmental outcome. REM and NREM sleep cycling are essential for early neurosensory development, learning and memory, and preservation of brain plasticity (neuronal adaptability to new situations and demands) for the life of the individual.⁸⁸ Premature infants during childhood are known to have smaller brains than their full-term counterparts, with increased risks for problems with sensory processing, learning disorders, abstract thinking, behavior, coping, adaptability, and attention; brain wiring can be disturbed, even in the absence of structural brain pathology.^{24,48} Undisturbed sleep is absolutely essential for normal development of the infant brain and sensory systems during the last trimester, so interventions to protect and prolong sleep should be a top caregiving priority (Figure 21-7).

Minimizing Pain

From the first moments after birth, the premature infant is subjected to noxious sounds, bright lights, and a multitude of

FIGURE 21-7 24-week GA infant on high-frequency oscillating ventilation (HFOV). Efforts to protect sleep include placement of the infant in an incubator to decrease random handling and stimuli, clustered care, covering the Isolette to block overhead light (cover folded back for this picture), and supportive positioning in an individually contoured fluidized positioner. (Courtesy Sundance Enterprises, White Plains, NY; <http://www.sundancesolutions.com>.)

painful procedures, along with repetitive, non-nurturing handling and separation from the mother. Seemingly benign handling and caregiving by the NICU staff, such as bathing, weighing, and diaper changes, are perceived as stress by the infant.^{37,77} This altered sensory experience is inherently stressful and has negative effects on the infant's brain development.

Consequences of neonatal stress include increased energy expenditure, decreased healing and growth, impaired physiologic stability, and altered brain development. NICU stressors and painful interventions may raise cortisol levels, limiting neuroplastic reorganization and therefore learning and memory of motor skills. Infants who are exposed to repeated painful experiences can have negative short- and long-term consequences for brain organization during sensitive periods of development.⁵⁴ Minimizing stress in preterm infants may have many neurologic benefits, such as reducing the likelihood of programming abnormal stress responsiveness, which may help preserve existing neuroplastic capacity.¹⁰⁷ Infants have demonstrated markedly improved outcomes when the stress of environmental overstimulation is reduced. Pharmacologic and nonpharmacologic management of pain is a top priority in NICU caregiving. Non-nutritive sucking is often successful for soothing and self-regulation; a pacifier dipped in a 24% sucrose solution can be used to help manage minor procedural pain.¹⁴²

Preterm infants are extremely vulnerable to pain. Decreased ability to attenuate pain may allow even relatively benign procedures to be perceived as painful, especially when occurring just after handling or another painful experience.⁶⁵ Immediate consequences of severe or repetitive painful experiences in the NICU may include physiologic instability, medical complications, sleep disturbances, feeding problems, and poor self-regulation. Painful procedures may result in heightened pain sensitivity to routine handling, as well as delayed recovery from noxious and routine caregiving procedures.¹⁴² Repetitive or prolonged pain has been implicated in enhanced neuronal cell death in the immature brain, with concerns for future

FIGURE 21-8 A nurse and respiratory therapist plan ahead to coordinate their care. The infant benefits from fewer sleep disruptions (vital to sensory system and brain development) and is continuously supported by one caregiver as the other completes necessary tasks. (Courtesy NICU, Memorial Hermann Hospital Southwest, Houston. Photograph by Beverly Edwards.)

neurodevelopmental outcome.⁷ Although pain scores have typically been used to evaluate the effects of pain relief interventions, sleep structure has been documented as a more objective measure for prolonged effects of pain and its management.¹⁷ Preserving infants' sleep and relieving their pain are both important for their health; however, clinicians tend to disregard preterm infants' sleep needs because they cannot verbalize their need for sleep. Clinicians should provide preterm infants with neuroprotective interventions, not to only relieve pain but also to preserve sleep organization.⁷⁸

NICU Caregiving Minimizing Stress

NICU caregiving patterns differ significantly from those in the fetal intrauterine environment and the normal home setting. The sense of touch is highly developed in utero, with gentle human touch normally providing consistent positive tactile input after term birth. Touch in the NICU, however, is usually related to medical care rather than social nurturing. NICU interventions are often intrusive or aversive and are typically constant throughout a 24-hour span.

Caregiving procedures may contribute to an infant's physiologic instability (e.g., increased heart rate, fluctuations in blood pressure, alterations in cerebral blood flow, hypoxemia), motor stress, energy depletion, and agitation. Caregiving based primarily on external criteria, such as fixed schedules for vital signs and feeding, often ignores or delays the caregiver's response to the infant's cues that indicate that he or she needs care.⁴⁵ Conversely, coordinating care among disciplines can reduce sleep disruptions and provide an extra set of hands and eyes to support the infant during caregiving (Figure 21-8).

Developmentally supportive caregiving in the NICU strives to minimize avoidable stressors, facilitate infant medical and neurobehavioral stability, provide therapeutic positioning, facilitate and protect sleep, promote self-regulation, foster normal

developmental sequences, and encourage family participation.^{76,81} The individual infant's cues, sleep state, and ongoing medical status should determine the timing and sequencing of caregiving. Procedures and interventions for each infant should be based on necessity rather than nursery routines (including therapy schedules), avoiding unnecessary or rough handling and movement.

Caregiving based on ongoing infant cues is an integral part of developmentally appropriate care.⁵¹ Although seemingly efficient, the idea of clustering care may need modification because infants do not always tolerate all the care that is being clustered into one caregiving period. Infant-driven cues, rather than routinely clustered care, should be used for optimal caregiving practices. These cues can communicate an infant's needs and status at any given time, potentially indicating timing for interventions or opportunities for sensory input and interaction, as well as infant tolerance to stimulation. Frequent handling and touching can disturb sleep, leading to decreased weight gain, decreased state regulation, and significantly detrimental effects on brain development.

Moving preterm infants suddenly and quickly can be a negative and stressful experience that often results in autonomic deterioration with apnea, bradycardia, and/or increased oxygen requirement. A general rule of thumb for caregiving in the NICU is to use a slow interactive approach, with a single sensory input at a time. Caregivers prepare the baby for touch or movement by speaking softly and containing extremities during movement and lifting (Figure 21-9). Table 21-4 summarizes considerations for caregiving related to the infant's state of arousal. Caregiving is frequently controlled by the nurse, but developmentally appropriate caregiving can be achieved by effective collaboration of all therapists to negotiate timing, intensity, and appropriateness of interventions, tests, and procedures. Continuous observation and response to infant

FIGURE 21-9 Lifting an infant in a prone or side-lying position allows gravity to help keep the infant's arms and legs in midline, making it easier for the caregiver to support a fetal tuck position fully. This infant remained calm and restful during lifting. In contrast, infants lifted in a supine position are more difficult to contain, frequently showing extension, with flailing and agitation. (Courtesy NICU, Memorial Hermann Hospital Southwest, Houston. Photograph by Beverly Edwards.)

cues require caregivers to alter routines according to developmentally supportive principles.¹²⁷ A paradigm shift from task-oriented and scheduled care to infant-responsive care must occur to carry out optimal caregiving practice. Every caregiver must stay in the present and be mindful when interacting with the infant.

Skin Protection

The IDC core measure of protecting skin is inherent in NICU caregiving; skin care practices defining bathing practices, emollient use, humidity practices, use of adhesives, and overall caregiving touch for babies in each stage of development should be incorporated into unit practices and policies. The skin of very preterm infants (<30 week' gestation) is fragile, with an increased risk of epidermal stripping and a predisposition to edema; handling and positioning that minimizes forces of pressure, friction, and shear can help protect skin integrity.⁶¹ With skin considered to be the sensory interface of the brain with the external environment,⁴¹ therapeutic positioning, interface surfaces, and comfort assume greater significance.

Bath time is frequently stressful and exhausting to NICU infants. If the infant's body is well supported, with extremities contained, bathing by immersion in warm water is usually more soothing than sponge bathing. Swaddled bathing has proved successful, even with irritable and disorganized infants. The swaddled infant is immersed to the shoulders in a tub of warm water, and the face is washed first with clean water. Next, one body section is unwrapped for bathing and rinsing and then rewrapped in the wet cloth before proceeding to washing another section of the body—right upper body, then left upper body, then legs and buttocks.¹⁰⁸ The warmth and proprioceptive weight of a wet blanket seem calming, and infants are usually quiet and alert throughout this bath, making swaddled bathing a successful and enjoyable caregiving experience for parents (Figure 21-10). Not only does swaddled tub bathing promote more organized infant behavior, infants also show overall higher and less variability in body temperature.⁸²

FIGURE 21-10 Swaddled bath. A swaddled preterm infant is immersed in a tub of warm water for a developmentally supportive bath. (Courtesy NICU, Medical Center of Plano, Plano, TX. Photograph by Dana Fern.)

TABLE 21-4 Newborn States and Considerations for Caregiving

Newborn State	Comments
Sleep States Deep Sleep (Non-Rapid Eye Movement [NREM] Sleep) Slow state changes Regular breathing Eyes closed; no eye movements No spontaneous activity except startles and jerky movements Startles with some delay and suppresses rapidly Lowest oxygen consumption Light Sleep (Rapid Eye Movement [REM] Sleep) Low activity level Random movements and startles Respirations irregular and abdominal Intermittent sucking movements Eyes closed; rapid eye movement Higher oxygen consumption	Infant is very difficult if not impossible to arouse. Infant will not breast-feed or bottle-feed in this state, even after vigorous stimulation. Infant is unable to respond to environment; frustrating for caregivers. Term infants may exhibit a slow heart rate (80-90 beats/min), which may trigger heart rate alarms and result in unnecessary stimulation by neonatal intensive care unit staff. At birth, preterm infants have altered states of consciousness: Early dominant states are light sleep, quiet, and active alert. "Protective apathy" enables the preterm infant to remain inactive, unresponsive, and in a sleep state to conserve energy, grow, and maintain physiologic homeostasis. Full-term infants begin and end sleep in active sleep; preterm infants are more responsive than term infants to stimuli in active sleep. Infants may cry or fuss briefly in this state and be awakened to feed before they are truly awake and ready to eat. Lower and more variable oxygenation states
Awake States Drowsy or Semidozing Eyelids fluttering Eyes open or closed (dazed) Mild startles (intermittent) Delayed response to sensory stimuli Smooth state change after stimulation Fussing may or may not be present Respirations—more rapid and shallow Quiet Alert, with Bright Look Focuses attention on source of stimulation Impinging stimuli may break through; may have some delay in response Minimal motor activity	Infant may awaken further or return to sleep if left alone. Quietly talking and looking at the infant, or offering a pacifier or an inanimate object to see and listen to, may arouse the infant to the quiet alert state. Less mature infants (30 wk) demonstrate a drowsier quiet alert state than older infants (36 wk). Immediately after birth, term newborns exhibit a period of quiet alertness, their first opportunity to take in their parents and the extrauterine environment. Dimmed lights, quiet talking, and stroking optimize this time for parents. Best state for learning to occur because infant focuses all attention on visual, auditory, tactile, and sucking stimuli; best state for interaction with parents—baby is maximally able to attend and respond reciprocally to parents.
Active Alert—Eyes Open Considerable motor activity—thrusting movements of extremities; spontaneous startles Reacts to external stimuli with increase in movements and startles (discrete reactions difficult to differentiate because of general higher activity level) Respirations irregular May or may not be fussy Crying—intense and difficult to disrupt with external stimuli Respirations rapid, shallow, and irregular	Infant has decreased threshold (increased sensitivity) to internal (hunger, fatigue) and external (wet, noise, handling) stimuli. Infant may quiet self, may escalate to crying, or, with consolation by caregiver, may become quiet, alert, or go to sleep. Infant is unable to attend to caregiver or environment maximally because of increased motor activity and increased sensitivity to stimuli. Crying is infant's response to unpleasant internal and/or external stimulation—infant's tolerance limits have been reached (and exceeded). Infant may be able to quiet self with hand to mouth behaviors; talking may quiet a crying infant; holding, rocking, or putting infant upright on caregiver's shoulder may quiet infant.

Infant Neurobehavioral and Neuromotor Development

Evaluation of the Infant

The golden rule for developmental evaluation and intervention with all NICU infants is "Above all, do no harm!" The following guidelines consider that goal.

1. Safety for the infant takes priority over convenience for the occupational therapist in all aspects of care. Review

applicable medical conditions and equipment, be very aware of stress cues, and never perform an evaluation item simply to fill in a blank space on a form if the information obtained will not benefit the care plan for the baby.

2. Learn an evaluation tool thoroughly before touching an infant and be constantly aware of changes in an infant's stress level. Many occupational therapists use a structured assessment supplemented with data gathering and clinical observations. Administration of some structured neonatal

assessments requires specialized training and/or certification of reliability (e.g., Neonatal Individualized Developmental Care and Assessment Program [NIDCAP]); others may be used after independent study of the manual and practice (e.g., Hammersmith Neonatal Neurological Examination).

3. Appreciate the nurse's role in protecting the infant and use astute clinical observations of the infant and surrounding environment before any touching. Very fragile infants can be assessed entirely by skilled observation, with no additional touching.
4. Weigh the value of any hands-on evaluation procedures against potential stressful effects on the infant. Co-assessments with other disciplines may reduce unnecessary duplication of items that require handling.
5. Avoid fitting a baby into a convenient opening in your schedule. Instead, make it your priority to observe and respect the infant's sleep cycle, feeding schedule, caregiving routine, and medical status. Respect the infant's signs of stress during handling; switch to an observational assessment if the infant does not readily return to a calm organized state, even with caregiver assistance.
6. Performing an evaluation is easier than accurately analyzing the results; overinterpretation and mistaking immaturity for pathology are frequent errors of inexperienced developmental specialists. Preterm infants, especially those born at an extremely young gestational age, often differ in neuromotor and neurobehavioral progression from infants born at term.

Routine ongoing reassessment in the NICU and in a follow-up clinic as infants mature and recover is essential for developing sound clinical judgment about the meaning of early clinical findings.

Infant Neurobehavioral Development

Neurobehavioral Organization of the Preterm Infant

In-Turning, Coming-Out, and Reciprocity

An early description of preterm infant behavioral organization by physicians in the 1970s helped provide rule-of-thumb guidelines for developmental specialists in their approach to infants and in their supporting successful parenting in the NICU.⁴⁷ Infants in the in-turning stage are generally immature or critically ill; they require minimal handling, with maximal environmental and caregiving protection. Infants in the coming-out stage remain fragile and vulnerable but have brief periods of availability to attend to their environment; graded unimodal stimulation may be appropriate for brief periods based on observed infant state and tolerance. The more mature and stable infant in the reciprocity stage attends and interacts when in an appropriate quiet alert state, but the caregiver must respect approach and avoidance signals. Advancing postconceptional age and medical status (acuity and chronicity) affect an individual infant's progression throughout these stages.

Synactive Theory of Development

The research of Dr. T. Berry Brazelton in the 1970s focused primarily on the reactions and interactions of healthy term infants to environmental and social stimuli.²⁸ Heidiliese Als built on Brazelton's earlier work and adapted the model specifically to preterm infants.

Because preterm infants are continually affected by and responsive to environmental influences, Als proposed a model

for understanding these emerging capabilities of preterm infants to organize and control their behavior.³ Als' synactive theory of development identified five separate but interdependent subsystems—autonomic, motor, state, attention-interaction, and self-regulation in the infant. These subsystems are in constant interaction with each other (the neonate's internal functioning), the environment, and caregivers. Through recognizable approach and avoidance behaviors occurring in these subsystems, infants continually communicate their level of stress and stability in relation to what is happening to and around them (Table 21-5). Maturation and improved (or declining) health are reflected in sequential observations of subsystem development, although very preterm infants often do not reflect the same performance capabilities as an infant born at the equivalent older age (Table 21-6).

Synactive theory forms the basis for individualized developmentally supportive and family-centered care. Caregivers are trained to be sensitive to each infant's fragility and stress behaviors versus robustness and stability behaviors (Figure 21-11). The caregiver then uses these observations to modify the environment and caregiving practices to facilitate the infant's organization and well-being. Each infant's attempts to maintain or return to a calm, organized state are also noted and encouraged. The infant and family are seen as an integral unit, with parents supported in assuming an active role with their infant in the NICU.

FIGURE 21-11 Reading an infant's neurobehavioral cues: This infant's gape face is indicative of low muscle tone, low arousal, and lack of readiness to interact or feed orally. It is important for caregivers and parents to learn to read and respect infant behaviors to avoid pushing (stressing) the infant and frustrating the adult. (Courtesy NICU, Memorial Hermann Hospital Southwest, Houston, TX. Photograph by Beverly Edwards.)

TABLE 21-5

Synactive Theory of Development: Neurobehavioral Subsystems, Signs of Stress, and Stability*

Subsystem	Signs of Stress	Signs of Stability
Autonomic	Physiologic instability	Physiologic stability
Respiratory	Pauses, tachypnea, gasping	Smooth, regular respiratory rate
Color	Changes to mottled, flushed, pale, dusky, cyanotic, gray, or ashen	Pink, stable color
Visceral	Hiccups, gagging, spitting up, grunting, straining (as if producing bowel movement)	Stable viscera with no hiccups, gags, emesis, or grunting
Motor	Tremors, startles, twitches, coughs, sneezes, yawns, sighs, seizures	No sign of tremors, startles, twitches, coughs, sneezes, yawns, sighs, or seizures
Motor	Fluctuating tone, uncontrolled activity	Consistent tone, controlled activity
Flaccidity	Gape face, low tone in trunk, limp lower extremities and upper extremities	Muscle tone consistent in trunk and extremities and appropriate for postconceptional age
Hypertonicity	Leg extensions and sitting on air; upper extremity salutes, finger splays, and fisting; trunk arching; tongue extensions	Smooth controlled posture; smooth movements of extremities and head
Hyperflexions	Trunk, lower and/or upper extremities Frantic, diffuse activity of extremities	Motor control can be used for self-regulation—hand and foot clasp, leg and foot bracing, hand to mouth, grasping, tucking, sucking
State	Diffused or disorganized quality of states, including range and transition between states	Clear states; good, calming, focused alertness
During sleep	Twitches, sounds, whimpers, jerky movements, irregular respiratory rate, fussy, grimaces	Clear, well-defined sleep states Smooth transition between states
When awake	Abrupt state changes Eye floating, glassy eyed, staring, gaze aversion, worried or dull look, hyperalert panicked expression, weak cry, irritability	Good self-quieting and consolability Focused, clear alertness with animated expressions (e.g., frowning, cheek softening, "ooh" face, cooing, smiling) Robust crying
Attention-Interaction	Effort to attend and interact to specific stimulus elicits stress signals of other subsystems	Responsive to auditory, visual, and social stimuli is clear and prolonged
Autonomic	Irregular respiratory rate, color changes, visceral responses, coughs, yawns, sneezes, sighs, straining tremors, twitches	Actively seeks out auditory stimulus; able to shift attention smoothly from one stimulus to another
Motor state	Fluctuating tone, frantic diffuse activity Eye floating, glassy eyed, staring, worried or dull look, hyperalert panicked expression, gaze aversion, weak cry, irritability Becomes stressed if more than one type of stimulus given simultaneously Abrupt state changes	Face demonstrates bright-eyed purposeful interest varying between arousal and relaxation
Self-Regulation: Infant's efforts to achieve, maintain, or regain balance and self-organization in each subsystem as needed. Examples include motor strategies (e.g., foot clasp, leg and foot bracing, finger folding, hand clasping, hand to mouth, grasping, tucking, sucking, postural changes); state strategies (e.g., lowers state of arousal or releases energy with rhythmic, robust crying), and attention and orientation strategies, such as visual locking. The success of various strategies may vary among infants.		

*Modified from the works of Heidi Als on the synactive theory of development: Als, H. (1986). A synactive model of neonatal behavioral organization: Framework for the assessment and support of the neurobehavioral development of the premature infant and his parents in the environment of the neonatal intensive care unit. *Physical and Occupational Therapy in Pediatrics*. 6, 3–53.

TABLE 21-6

Neurobehavioral Development of Preterm Infants by Gestational Age

Neurobehavioral System	Developmental Behaviors
Infants at ≤30 Weeks' Gestation	
Autonomic	May exhibit periodic breathing, apnea, and bradycardia Color changes common with stimulation Eyelids are thin; infant has minimal ability to achieve or maintain protective tightening of eyelid against bright light. Eyes flutter open, often with rapid uncoordinated eye movements or with diffuse unfocused gaze.

TABLE 21-6 Neurobehavioral Development of Preterm Infants by Gestational Age—cont'd

Neurobehavioral System	Developmental Behaviors
Motor	Reflex smiling and startle response are present. Muscle tone is low; limp extension of extremities and flat resting postures are predominant. Uncontrolled spontaneous movements such as extremity twitches and tremors are common. Active movements of extremities are jerky.
State	Infant is unable to coordinate sucking, swallowing, and breathing. Light sleep states predominate, with rapid eye movement (REM) and frequent tonguing and mouthing apparent.
Attention-interaction	States are not yet well defined; drowsy or awake "alert" periods are brief. Visual acuity is poor, with little accommodation. Apnea may result when visual stimuli are intense. Hearing is well developed; preference for mother's voice is possible.
Self-regulation	Usually easily stressed by environmental and caregiving stimuli Self-regulation efforts are immature and ineffective.
Infants at 30-33 Weeks' Gestation	
Autonomic	May exhibit periodic breathing, apnea, and bradycardia Reflexive ability to constrict iris emerges Able to keep eyelids shut, but eyelids still thin
Motor	Muscle tone improving and more flexion apparent; motor tone better in lower extremities than in upper extremities Motor activity becoming smoother, but startles and tremors still common. Improved head control is evident.
State	Active sleep predominant, but quiet sleep increasing Increase in alert awake time States more distinct as sleep-wake organization emerges Arousal with feeding readiness cues may be observed.
Attention-interaction	Emerging coordination of sucking, swallowing, and breathing Brightens to sound; preference for human voice May be able to visually focus briefly (with much effort) on specific stimulus
Self-regulation	Limited capacity for social contact Still often stressed by environmental and caregiving stimuli Self-regulation efforts (e.g., grasping, foot bracing, hand to mouth) increasing with variable effectiveness
Infants at 34-36 Weeks' Gestation	
Autonomic	Generally more stable heart rate, respiratory rate, and oxygen saturation
Motor	Muscle tone, activity level, and motor control continue to improve Able to right head forward and backward Decreased tremors Usually able to breast- or bottle-feed
State	Increase in quiet sleep with more regular respiration and decreased random activity Smoother transition between sleep and awake states Infant usually awakens to stimulation, although duration and quality of alertness may be variable Arousal and crying more frequent in response to discomfort, pain, or hunger
Attention-interaction	More consistent behavioral responsiveness to auditory stimuli Visual orientation (focus, brief tracking) present, but infant may become overstimulated or fatigued with the effort Increased capacity for social attentiveness and responsiveness
Self-regulation	May tolerate just one type of sensory or social stimulation at a time Improving efforts and success at self-consoling and self-regulation
Infants at 37-40 Weeks' Gestation	
Motor	Extremity flexor tone present; movements increasingly smooth and controlled Wide variety of movements are observed Feeds by breast or bottle
State	Well-defined range of states, with smooth transitions Quiet sleep increases, with equal periods of active sleep Sleep-wake cycles shorter with less mature sleep-wake organization than infant born at term Crying more closely approximates that of term infant
Attention-interaction	Increasingly consistent behavioral responsiveness to auditory stimuli; prefers human voice Active "looking" behaviors increase during quiet alert periods. Infant displays preferences for visual stimuli (usually human face) and tracks objects; best visual focus is at 8-10 inches
Self-regulation	More reciprocal social interaction Self-regulation efforts more organized and successful

Data from Hadley, M. A, West, D., Turner, A., & Santangelo, S. (1999). *Developmental and behavioral characteristics of preterm infants*. Petaluma, CA: NICU; and Yecco, G. J. (1993). TABLE 21-7 Stages and Characteristics of Behavioral Organization in Preterm Infant

Als	Gorski, Davidson, & Brazelton
Physiologic homeostasis—stabilizing and integrating temperature control, cardiorespiratory function, digestion, and elimination. Characteristics—becomes pale, dusky, cyanotic; heart and respiratory rates change; all symptoms of disorganization of autonomic nervous system. Motor development may infringe on physiologic homeostasis, resulting in defensive strategies (vomiting, color change, apnea, and bradycardia). State development becomes less diffuse and encompasses full range: sleep, awake, crying. States and state changes may affect physiologic and motor stability. Alert state well differentiated from other states State changes may interfere with physiologic and motor stability.	In-turning—physiologic stage of mere survival <i>Characteristics</i>—autonomic nervous system responses to stimuli (rapid color changes caused by swings in heart and respiratory rates); no or limited direct response; inability to arouse self spontaneously; jerky movements; asleep (and protecting the central nervous system from sensory overload) 97% of the time. Preterm infants (<32 wk) are easily physiologically overwhelmed by stimuli. Coming out—first active response to environment may be seen as early as 34 to 35 wk (provided some physiologic stability has been achieved). <i>Characteristics</i>—remains pink with stimuli; has directed response for short periods; arouses spontaneously and maintains arousal after stimuli ceases; if interaction begins in alert state, maintains quiet alert for 5-10 min, tracks animate and inanimate stimuli; spends 10%-15% of time in alert state with predictable interaction patterns. Reciprocity—active interaction and reciprocity with environment from 36-40 wk <i>Characteristics</i>—directs response; arouses and consoles self; maintains alertness and interacts with both animate and inanimate objects; copes with external stress.

Adapted from Als, H. (1986). A synactive model of neonatal behavior organization: Framework for the assessment of neurobehavioral development in the premature infant and for support of infants and parents in the neonatal intensive care environment. *Physical and Occupational Therapy in Pediatrics*, 6, 3-55; and Gorski, P. A., Davidson, M. F., & Brazelton, T. B. (1979). Stages of behavioral organization in the high-risk neonate: Theoretical clinical considerations. *Seminars in Perinatology*, 3, 61-72.

When preterm infants were assessed and provided with developmentally supportive individualized care, Als⁴ saw significantly improved outcomes, including fewer days on the ventilator, earlier feeding success, shorter hospital stay, marked reduction in the number of complications, and improved neurodevelopmental outcomes during the first 18 months of life, findings that were sustained to 8 years of age.⁸⁹

Table 21-7 summarizes and compares the stages and characteristics of preterm behavioral organization of Gorski's in-turning, coming-out, and reciprocity model⁴⁷ with Als' synactive theory of development.

States of Arousal

State refers to the infant's degree of consciousness or arousal, with quality and consistency of state control in preterm infants generally improving as age and maturation increase. State significantly affects other areas, such as muscle tone, feeding performance, and reaction to stimuli. Caregivers need to be sensitive to an infant's state (see Table 21-4).

State is most frequently classified into six categories: state 1 (deep sleep); state 2 (light sleep); state 3 (transitional state of dozing or drowsiness); state 4 (quiet and alert); state 5 (active alert); and state 6 (crying). The smoothness or abrupt fluctuation as the infant transitions between states, both spontaneously and during handling, provides information on neural organization and control.¹⁰ The infant who cannot be aroused, is excessively irritable, or has wide swings between sleep and cry states, with no interim alert periods, may be demonstrating immaturity or pathology. A gradual awakening with smooth transition from sleep to alertness and eventually back to sleep is one sign of maturation and neurologic integrity.

A smooth transition between states requires appropriate regulation and response to a variety of sensory inputs. The

ability to modulate state is affected by intrinsic factors (e.g., pain, stress, immaturity, illness, intrauterine drug exposure) and extrinsic factors (e.g., light, noise, caregiving activities). Individual temperament may also be a variable in the infant's state of arousal; some infants are more active and demanding, whereas others are more relaxed. Sleep is essential for body and brain growth and development; supporting and protecting undisturbed sleep should be a caregiving priority.

Neuromotor Development and Interventions

Reflex Development

Neonatal reflex development has been well documented in medical and therapeutic literature. Although some occupational therapists include reflex testing in their standard NICU assessment, complete reflex testing is extremely stressful for young or acutely ill NICU infants and is unnecessary as an early routine evaluation. Self-regulatory reflexes such as suck and grasp can indicate primitive reflex integrity in young or ill infants. Selective reflex testing may be appropriate with older stable infants prior to discharge¹⁶ or if the infant has known or suspected neuropathology or neuromuscular pathology (e.g., spina bifida, periventricular leukomalacia, congenital neuropathy). Many reflexes (e.g., grasping, sucking, head righting) can be observed within the context of normal handling, which provides functional information with less stress than generalized formal reflex testing.

Muscle Tone

Hypotonia is normal for extremely preterm infants. Muscle tone gradually increases with age, and in caudocephalic (feet to head) and distal-proximal (extremities to trunk) directions. Active muscle tone, observed during spontaneous movement

or elicited by righting reactions when the infant is handled, develops before passive flexor tone is seen at rest.²⁶ An extremely preterm infant at term equivalency will typically demonstrate greater extension and less physiologic flexion than a newborn full-term infant. Twitches, tremors, and startles are common in preterm infants, but movements typically become smoother and tremors less prevalent as term equivalency nears.

In addition to PMA, state of arousal and medical status are significant variables when assessing muscle tone. A preterm infant may be active and feisty when awake, but hypotonic if assessed while drowsy or asleep. Muscle tone in an acutely ill infant cannot be accurately evaluated; the underlying muscle tone usually changes as the infant recovers. Many medications have neuromotor side effects. For example, phenobarbital for seizures may initially make the infant lethargic; caffeine for apnea may make the infant jittery; and midazolam for sedation may cause tremors.

The influence of evolving muscle tone on resting posture and quantity or quality of movement has implications for positioning and caregiving needs. Monitor atypical findings or asymmetric responses over time; unusual movement patterns that are not stereotypic and obligatory may resolve with maturation and physical recovery. If possible, distinguish a potential cause; for example, could an infant's asymmetry, tight retracted shoulders, or increased extensor tone be iatrogenic from poor positioning rather than neurologic in origin? Either cause will require intervention, but positional deformities have a better long-term prognosis, and positioning can be improved with future babies to avoid preventable problems.

Posture and Movement Patterns

A fetus has dynamic circumferential boundaries at all times. Flexion and symmetry are reinforced in developing neuronal pathways in utero; active fetal extension is always followed by a return to flexion because of flexible uterine constraints. An infant who has moved and developed within these constraints has a motor advantage at term birth from neuromuscular and neurologic predispositions to function in flexed postures with a midline orientation.^{60,64}

An infant born very early does not have this same advantage. Extremely preterm infants have incomplete development of muscle tone, joint structures, and bone density. Muscle tone is usually hypotonic, with active extension stronger than a corresponding return to flexion. Spontaneous resting posture is often flat, extended, and asymmetric, with the head to one side (usually the right); the extremities tend to be abducted and externally rotated, resting flat on the bed surface⁶⁴ (Figure 21-12). This “frogged” posture is reinforced by the effects of gravity, hypotonia, primitive reflexes, immature neuromotor control, illness, energy depletion, and weight or torque of medical equipment. Over time, neuronal connections are reinforced that favor this flattened, externally rotated, and asymmetric resting posture as the normal baseline for these infants; active extension and arching become unopposed dominant motor patterns (Figure 21-13).

Therapeutic Positioning in the NICU

It is well documented that lack of appropriate NICU positioning can create short-term and long-term positional deformities and functional problems for NICU infants, even in the absence of overt brain pathology (Figure 21-14). NICU positioning

FIGURE 21-12 Hypotonic posture of premature infant. Without therapeutic positioning, the W configuration of the arms, frogged posture of the legs, and asymmetric head position may lead to positional deformities.

FIGURE 21-13 Active extension and arching become unopposed dominant motor patterns when therapeutic positioning is not consistent during NICU hospitalization. (Courtesy Infant Special Care Unit, University of Texas Medical Branch, Galveston, TX. Photograph by Jan Hunter).

attempts to simulate the flexed, contained, and midline posture within flexible boundaries of the infant in utero; external supports provide a temporary substitute for an immature infant's diminished internal neuromotor control.

NICU positioning is an excellent example of how evolving knowledge and advances in technology have driven changes in developmental clinical practice. In the 1970s, few or no attempts were made to provide boundaries or positional support for infants in the NICU. In the 1980s, increased awareness of infant developmental vulnerability and environmental stressors resulted in the use of blanket rolls for boundaries, with variable effectiveness (Figure 21-15A). Commercially available positioning aids became available in the 1990s and increasingly replaced manually made nests of blanket rolls and sheepskin; commercial positioning aids provided greater ease and consistency of positioning among NICU staff, but still with variable

FIGURE 21-14 Illustrated are the developmental causes and consequences of lack of therapeutic positioning, with subsequent positional deformities in the NICU population. Hospital-acquired positional deformities are largely avoidable with good positioning. (Courtesy Sundance Enterprises, White Plains, NY; <http://www.sundancesolutions.com>.)

FIGURE 21-16 Postsurgical infant nested in a three-dimensional fluidized positioner that conforms to the infant, assumes the temperature of the incubator, and accommodates medical equipment. (Courtesy Sundance Enterprises, White Plains, NY; www.sundancesolutions.com.)

success in providing consistent boundaries without eliminating free movement (see [Figure 21-15B](#)).

NICU positioning has traditionally been a neuromotor developmental intervention to minimize positional deformities and improve muscle tone, postural alignment, movement patterns, and ultimately developmental milestones. The scope of NICU positioning focus expanded from developmental to therapeutic when fluidized positioners became available in 2007. These three-dimensional, whole-body positioners can infinitely and repeatedly conform to any body size, medical condition, and medical equipment ([Figure 21-16](#)). Empiric benefits reported by clinicians include the following: more consistent containment without limiting infant movement; increased comfort with decreased restlessness and agitation; energy conservation with frequently reduced energy requirement; more frequent and longer duration of sleep; reduced forces of friction, pressure, and shear on fragile skin because of fluidized properties; and reduced heat loss as the infant is immersed in a three-dimensional positioner that assumes the temperature of the incubator.⁶⁴

A recent randomized clinical trial in the NICU at a major children's hospital examined sleep in infants on fluidized positioners (termed *conformational positioners* in this RCT) compared with being swaddled on a standard mattress.¹³⁷ This study demonstrated improved sleep efficiency (percentage of time asleep) as measured by sleep EEG and improved self-regulation behaviors as measured by NIDCAP evaluation (Als' synactive theory). Because sleep is elusive in the NICU,⁷⁶ any intervention that improves sleep has major implications for increased brain synaptogenesis and plasticity^{50,81} ([Figure 21-17](#)).

FIGURE 21-17 Continuously restless 1000-g infant, unable to settle in cloth bunting. She relaxed and fell asleep quickly after being positioned on a fluidized, full-body positioner, with a smaller pad used as a prone roll. (Courtesy Sundance Enterprises, White Plains, NY; www.sundancesolutions.com.)

Range of Motion

Passive range of motion (PROM) may be appropriate for infants who demonstrate structural or neuromuscular limitation of movement and can tolerate a rehabilitation approach. PROM incorporated into therapeutic handling is preferable to conventional ranging techniques for most infants. Hypertonicity may relax more with sustained stretch and therapeutic positioning than with repetitive PROM. PROM occasionally may be appropriate for an infant who is sedated or chemically paralyzed (and thus nonmoving) for prolonged periods. However, experience suggests that prevention of positional deformities with therapeutic positioning may be sufficient intervention for infants whose movement is temporarily restricted. Therapists should never consider PROM to be a routine NICU intervention because it is unnecessary and often stressful to the general preterm population.

Splinting

With the exception of fractures, for which immobilization is desired for healing and comfort, splinting is rarely needed with

FIGURE 21-18 Newborn infant with congenital muscular dystrophy, right humeral fracture, and obvious hand deformities. Bilateral soft splints (fabricated from foam pencil grips, small Velfoam straps, and Velcro) had no pressure points. Movement was not restricted; corrected alignment actually increased the infant's active movements. (Courtesy Infant Special Care Unit, University of Texas Medical Branch, Galveston, TX. Photographs and slide by Jan Hunter.)

NICU infants. Although contractures may occur with specific diagnoses, rigid contractures are actually uncommon, and infants are notably pliable over time. Significant and rapid improvement is often seen with gentle stretch during therapeutic positioning, the effects of gravity, and spontaneous movement of the infant. Conversely, spontaneous movement is inhibited when the infant is wearing a rigid splint.

Protecting skin integrity and encouraging active movement are priorities when designing a neonatal splint. Thermoplastic material may create pressure points; adding sufficient padding may alter fit. It can also be difficult to maintain correct joint alignment on a rigid splint when extremity movement of $\frac{1}{4}$ inch can significantly change hand placement.

Less is better, and creative combinations of foams are often sufficient. **Figure 21-18** illustrates bilateral hand splints made from foam pencil grips, foam straps, and a little Velcro. Alignment is corrected by tension on either strap; spontaneous movement is facilitated rather than repressed; risk for pressure is minimal; and both splints fit either hand—eliminating the potential right hand–left hand misapplication. The serial photographs were posted at bedside and given to the Spanish-speaking parents for follow-up with the local early childhood intervention program. When appropriate, splints like these rarely cause problems, although monitoring, adaptation, and education are always required.

Feeding

A Word about Breastfeeding

Although this chapter focuses on bottle feeding, breast milk is the optimal nutrition for NICU infants; any breast milk that the infant receives is valuable.^{14,103} Term newborns are born

with the instinctive skill and motivation to breast-feed and are able to find the breast and self-attach without assistance when skin to skin.¹⁰⁴

Mothers of preterm or ill infants who are educated about the benefits of breast milk often choose to pump milk for their infants; many, however, are unable to maintain sufficient lactation for successful or exclusive breastfeeding at discharge. Early initiation and maintenance of frequent breast pumping with a hospital-grade double electric breast pump, skin-to-skin holding as soon and as often as possible, non-nutritive sucking at breast (breast pumped first, although the breast is never truly empty and some milk may be available), and establishing the basics of breastfeeding before offering a bottle are all useful for establishing and maintaining a milk supply.^{40,103} Late preterm infants (34–36 weeks gestation) are especially vulnerable to being discharged before breastfeeding is well established, with increased risk of significant medical complications. Breastfeeding educator (breastfeeding specialist) courses are often available through state health departments or Women, Infants, and Children (WIC) clinics; these courses are highly recommended to build knowledge, confidence, and competence. Websites such as those by the Academy of Breastfeeding (<http://www.bfmed.org>) can also provide useful information. Some neonatal developmental specialists may eventually choose to continue breastfeeding specialization by pursuing credentials to become an international board-certified lactation consultant (IBCLC; <http://www.ilca.org>).

Oral Feeding

Parents often ask when their baby can go home. For most NICU babies, the last obstacle to hospital discharge is accomplishing oral feeding. Historically, sufficient time was allowed for the preterm infant to gain endurance and for suck-swallow-breathe coordination to mature. Currently, however, oral feedings are often initiated at earlier ages or pushed more aggressively for earlier discharge.¹²⁶ Although early oral feeding may be successful for certain infants and families, others struggle when discharged and may be readmitted for dehydration or failure to gain weight.^{31,117} Because preterm infants do not orally feed like term infants, the following sections establish a foundation of infant feeding basics, terminology, and mechanics that are applied in subsequent sections to oral feeding practices in the NICU.

Non-Nutritive Sucking

Non-nutritive sucking (NNS), or dry sucking without fluid, such as on a fist or pacifier, is present but disorganized in infants younger than 30 weeks; sucking rhythm generally improves by 30 to 32 weeks' postconception. Because NNS sucking does not interrupt breathing, it is usually (but not always) established before an infant has the neurologic maturation to coordinate sucking with swallowing and breathing.

NNS has been described as a self-soothing activity. Benefits of NNS have been summarized as increased oxygenation, faster transition to nipple feeding, and better bottle-feeding performance. Infants who engage in NNS during tube feeding experience less time in fussy and awake states, quicker settling after feedings, fewer defensive behaviors during tube feeding, and a significantly decreased hospital stay. No short-term negative effects have been identified.¹⁰⁶ In addition, NNS on a pacifier

dipped in a 24% sucrose solution is advocated for the relief of procedural pain.⁹⁶

Nutritive Sucking Patterns

Nutritive sucking is stimulated by the presence of fluid that must be swallowed; suck and swallow must be coordinated with breathing. Infants with organized sucking patterns (mature or immature) who can coordinate sucks and swallows with breathing are generally safe feeders when behavioral cues are respected. Transitional or disorganized feeding patterns are common in preterm or ill NICU infants learning to feed orally; these infants have difficulty coordinating sucks and swallows with breathing and benefit from caregiver interventions, such as slow-flow nipples and pacing to force breaks for breathing. Dysfunctional feeders demonstrate abnormal movements of the jaw and tongue; oral feeding is often possible but with atypical oral mechanics.¹⁰¹ Identification of the infant's sucking pattern can guide the developmental specialist's expectations and interventions, prevent the inadvertent facilitation of increased disorganization, promote improved oral feeding mechanics, and hopefully minimize the risk of future oral aversion.

Mature sucking is an organized feeding pattern typical of healthy term infants. Sucking bursts are initially continuous for 10 to 30 sucks, with a smooth 1:1:1 or 2:1:1 suck-swallow-breathe rhythm in which respiration appears continuous and uninterrupted. Brief respiratory pauses between sucking bursts may be noted. Sucking bursts are usually longest at the beginning of a feeding (continuous sucking), followed by intermittent sucking, with more opportunities for breathing as the feeding continues. Aside from normal infant feeding techniques (e.g., adequate postural support, calm environment, burping), no therapeutic interventions are necessary. Some term newborns eat well from the start; others seem to need a few days to recover from birth, gain endurance, and develop hunger.

Instead of having the 1:1:1 or 2:1:1 suck-swallow-breathe coordination seen in term babies, infants with an immature sucking pattern often cluster three to five sucks together while holding their breath, swallow the accumulated bolus, and then cluster several rapid recovery breaths. Observed in healthy preterm infants as young as 32½ weeks, this pattern is slower and not as efficient as mature sucking, but may appear organized, because sucks and swallows alternate with breathing in a coordinated manner. Breath-holding during sucking is believed to be related to the infant's instinct to protect the airway from penetration by the liquid bolus. These infants should be allowed to set their own pace and avoid stimulating sucking when they are in the breathing pause of the cycle. If the rest pause becomes prolonged, a slight gentle outward tug on the nipple may encourage the infant to relatch and continue sucking; conversely, twirling the nipple in the infant's mouth can make the nipple difficult to grasp and can eject unwanted milk into the infants mouth, causing distress and/or aspiration. Forced oral feeding (caregiver working harder than the baby or passively milking formula into the mouth of a nonparticipatory infant) increases the risk of disorganization and aspiration. Endurance may be limited, with the remainder of a feed given by gavage tube if the infant becomes fatigued.

A transitional (disorganized) pattern, observed in some preterm infants and older medically fragile infants (up to 45 weeks' PMA), is characterized by difficulty coordinating suck

FIGURE 21-19 This infant has a transitional sucking pattern in which suck-swallow is not yet well coordinated with breathing. External pacing is provided when the caregiver tips the bottle (without removing nipple from mouth) to force a breathing break. (Courtesy Infant Special Care Unit, University of Texas Medical Branch, Galveston, TX. Photographs by Jan Hunter).

and swallow with breathing.¹⁰⁰ An infant tries to use the continuous sucking burst of a mature pattern, but does not yet have a smooth rhythm of suck-swallow with breathing. Sucking bursts are generally six to ten sucks, but frequent and significant variation in the length of sucking bursts may occur during the same feeding. Intermittent or increasing disorganization, air hunger with apnea after longer sucking bursts, and insufficient endurance to complete the feeding are common. Disorganized transitional sucking is a frequently observed feeding pattern in NICU infants. Suck-swallow-breathe coordination can be facilitated by providing secure postural support, reducing stimuli, and using a slow-flow nipple and pacing to allow breathing pauses (Figure 21-19). An infant with chronic lung disease may benefit from temporarily increased supplemental oxygen during feeding. A cue-based feeding approach (see later) allows an infant to drive the frequency and duration of oral feedings without being force-fed.

Oral motor interventions vary with each infant, but may include options such as prefeeding oral stimulation for a warm-up and use of different nipples, jaw support, inward and downward pressure on the tongue to inhibit excessive protrusion, and thickened formula for easier oral bolus control.

Liquid is removed (stripped) from the nipple by a combination of suction (negative pressure) and compression (positive pressure).⁶² Suction refers to negative intraoral pressure generated as the infant (1) enlarges the oral cavity by lowering the jaw and (2) prevents air entry by sealing the lips around the nipple and elevating the soft palate to close off the nasopharynx. Compression occurs when the nipple is squeezed against the premaxilla (gums) and palate by the tongue and lower jaw; compression is exerted by repetitive peristaltic motions of the tongue that strip fluid from the nipple. Compromise of either

FIGURE 21-20 This infant with Down syndrome has decreased feeding endurance, with an intact swallow but weak stripping of milk from the nipple. His mother is using a Haberman feeder for added nipple length and variable flow to help compensate and improve feeding function. (Courtesy NICU, Memorial Hermann Hospital Southwest, Houston, TX. Photograph by Beverly Edwards.)

of these sucking pressure components, as in a very hypotonic infant or one with a cleft lip and palate, reduces the efficiency of stripping. An infant with poor suction or stripping may demonstrate rhythmic sucking, with relatively little milk removed from the bottle. Special nipples and bottles may be useful (Figure 21-20). Note that nipple collapse and/or vacuum pressure in the bottle may also prevent milk removal.

Oral feeding compromises oxygenation and ventilation during nutritive sucking because the airway briefly closes during every reflexive swallow.⁷⁵ This compromise is more significant during continuous sucking than during intermittent sucking and worse with an indwelling nasogastric tube than without the tube.¹²⁵ Preterm and ill infants frequently demonstrate physiologic and neurologic immaturity, respiratory compromise, disorganized sucking, and inadequate endurance.¹¹ Disorganized sucking and breathing often persist in the infant with chronic lung disease because the need to breathe supersedes the infant's efforts to suck.

Improvement in feeding-induced apnea, often associated with multiple swallows without breathing, appears to correlate more with advancing age (maturation) than with practice.⁵⁸ Traditionally, this has been interpreted to mean that additional time to mature is more beneficial than more frequent opportunities to “practice” oral feeding for young preterm infants.

In addition to the suck-swallow reflex, a term neonate has anatomic and physiologic safety features that offer some natural protection against aspiration. These include proportionately

large soft tissue structures (tongue, epiglottis, and vocal folds), relatively small openings, shorter passageways of smaller diameter, and a higher resting position of the larynx under the base of the tongue, providing an umbrella or watershed protective effect. A preterm infant with less mature development and function of these structures may not have the same degree of protection from aspiration during feeding; trace aspiration may occur frequently, and frank aspiration often is silent—no clinical signs of choking, coughing, or color change.³⁸ Initiation of bottle feeding at 30 to 33 weeks' PMA has increased in some NICUs,^{63,74} but the possibility of silent aspiration during bottle feeding at 30 to 32 weeks' PMA has not been studied with definitive modified barium swallow studies, and therefore the ultimate safety of these early feedings is not known.

Developmentally Supportive Feeding Interventions

Developmentally supportive feeding focuses on the infant. Neurologic maturation, medical issues, ongoing physiologic status, current stage of feeding readiness and skills, and psychosocial and interactive skills have redefined feeding success in the NICU. Quantity becomes secondary to the safety and quality of the feed.^{118,123} The infant is supported during the feeding to avoid physiologic and neurobehavioral stress and instability, facilitate healthy adaptive feeding behaviors, and encourage nurturing interaction. The family develops confidence in their ability to read and respond to the infant's cues and nourish and nurture their baby as he or she learns to eat.

Because of an immature digestive system, preterm infants often struggle to achieve adequate nutrient absorption and gut tolerance of feedings.⁹ These medical issues, coupled with pressure to increase intake for adequate weight gain, often cause feedings (oral or tube) to be unpleasant and stressful for the infant. Significant feeding and nutritional problems may persist long after NICU discharge.^{59,117}

Late preterm infants (35–37 weeks' gestation) are expected to feed orally as competently as term infants, but they often struggle. The brain in late preterm infants remains underdeveloped. Physiologic and neuromotor immaturity, lack of endurance, poor state regulation, and medical complications can interfere with oral feeding.⁸⁶ Infants with anomalies or persistent illness who are unable to achieve oral feeding within a reasonable time may be sent home with feeding gastrostomy tubes (G-tubes). With an increased risk of disorganization and silent aspiration in the NICU population, each infant's feeding readiness and safety should guide caregiver efforts.

Oral feeding is complex, and an infant must develop many underlying skills to establish and maintain oral nutrition successfully.^{11,123} Ross and Browne have identified stage progression for an infant learning to feed orally¹¹⁶ (Box 21-5). These stages involve developing and maintaining stability in the physiologic, motor, and state subsystems during the work of feeding, and eventually interacting with the caregiver during feeding. (NOTE: Very early feedings should be nurturing, but not overtly and reciprocally social.)

The Supporting Oral Feeding in Fragile Infants (SOFFI) method is an evidence-based, clinical manual for providing quality bottle feedings for preterm, ill, and fragile infants.¹⁰² The SOFFI method provides evidence-based text, algorithms, and reference guides for the NICU developmental specialist and bedside nurse. It is not a tool to be used during feeding itself, but rather a learning and reference tool that provides

BOX 21-5 BROSS Feeding Stages**Stage I**

Stability while in bed during handling: The infant maintains stability in physiologic, motoric, and state systems while in the bed and interacting with a caregiver during routine caregiving.

1. Heart rate (HR) = 120-180 beats/min; respiratory rate (RR) = 40-60 beats/min; oxygen saturation (SaO₂) ≥ 90%
2. Able to maintain flexion of body and extremities and return to flexion after movement
3. Able to maintain body tone without flaccidity or limpness
4. Skin tone with underlying pink to slight redness overall, possible slight dusiness around eyes and mouth
5. Ability to come into an alert state emerging, with duration of <5 min
6. Mouthing on fingers and/or pacifier with support

Stage II

Stability of systems while being held; infant maintains stability in physiologic, motoric, and state systems while in the arms of a caregiver

1. Maintains stable HR, RR, and SaO₂ level
2. Able to maintain body tone without flaccidity or limpness
3. Able to remain softly rounded and maintain flexion of arms, legs, and back with support.
4. Maintains alert state for up to 10 min
5. More successful at bringing hands to face and mouth and sucking on fingers and pacifier

Stage III

Stability in arms while sucking on a pacifier—infant has a coordinated non-nutritive suck (NNS) pattern of two sucks/second

1. Maintains a stable HR, RR, and SaO₂ level
2. Maintains flexion and tone.
3. Beginning to have rhythmic sucking of pacifier or fingers, five to ten sucks/burst
4. Able to be alert and suck on fingers, pacifier for at least half of gavage feeding time

Stage IV

Obligatory—infant sucks on a nipple without stopping to breathe to the point of apnea and loss of subsystem stability unless caregiver intervenes

1. Vigorous sucking on the bottle nipple without apparent recognition of the need to integrate breathing
2. Often drops breathing rate and has a prolonged apnea spell
3. May result in a bradycardic event
4. Drop in oxygenation level if sucking and breathing are not paced by caregiver
5. Nipple expression is fairly strong, with large jaw excursions
6. Little modulation of suction and expression
7. 15-25 sucks/burst not uncommon
8. Sucking strength decreases as burst progresses
9. Will often lose motor tone if not paced by caregiver
10. Will often fall into light sleep quickly, before completing much volume

Stage V

Alternating—infant begins to alternate breathing periods with sucking bursts of 10-15 sucks/burst, followed by a breathing period

1. Alternation of sucking and breathing periods
2. Shortening of sucking bursts, down to five to ten sucks initially, then down to three to five sucks when more mature
3. May drop oxygen levels initially, until breathing every three to five sucks
4. Some variability in pattern of number of sucks per burst.
5. Appears to have less strength of suction and expression as infant tries to integrate sucking and breathing
6. Beginning to be alert prior to feeding and maintain alertness for most of the feeding
7. May use a drop in state to drowsy or light sleep as a self-regulatory compensatory skill

Stage VI

Intermittent—infant begins to integrate breathing with sucking burst, rather than alternating between breathing and sucking-swallowing; shows coordination of breathing during a sucking burst, initially has inconsistent pattern of one breath per two or three sucks, can maintain stability of subsystems

1. First coordination of sucking-swallowing-breathing
2. Brief catch breaths occur usually at least once every two or three sucks
3. Longer sucking bursts of 10-20 sucks beginning to appear
4. Oxygenation is (or oxygen levels are) stable during feeding
5. Suction becoming stronger, with collapse of nipple more common while the infant tries to integrate suction with expression
6. More efficient sucking, with greater volume
7. Length of each nutritive suck increases
8. Infant usually in alert state for entire feeding, but concentrates on feeding

Stage VII

Coordinated—infant can coordinate sucking, swallowing, and breathing, resulting in longer sucking bursts of 10-30 sucks.

1. Mature coordination of sucking-swallowing-breathing
2. Brief catch breaths occur usually at least once every one or two sucks
3. Longer sucking bursts beginning to appear, 10-30 sucks
4. Oxygenation stable during feeding
5. Suction integrated with expression, resulting in more efficient sucking
6. Greater volume consumed
7. Length of each nutritive suck burst increases
8. Infant usually maintains alert state for entire feeding, but concentrates on feeding

Stage VIII

Integrated—infant has a mature coordinated suck pattern while interacting with caregiver during the feeding.

1. Longer sucking bursts of 20-30 sucks/burst
2. Breathing occurs during sucking bursts, with 1:1:1 suck-swallow-breathe, very little variability
3. Catch breaths during sucking bursts
4. Rapid breathing between sucking bursts
5. Able to modulate suction and expression, which creates more efficient suck
6. Infant alert and demanding feedings
7. Able to integrate social interaction with caregiver during the feeding
8. Able to maintain alertness for the entire feeding; available for interaction after the feeding as well

clinicians and professional caregivers with guidance as they progress through assessment, decisions, and consequent actions. The goal of using such an all-encompassing method is to focus on the quality of the feeding rather than the volume, so that attainment of oral feeding success is done through nurturing experiences and at the infant's own pace. In turn, these methods increase the likelihood of building a foundation that will nurture continued success and reduce the risk for feeding problems in infancy and throughout early childhood.

Because premature infants rarely go home from the NICU with an integrated mastery of oral feeding (stage VIII), parents and caregivers need to be comfortable and confident in recognizing, interpreting, and responding to the infant's behaviors to support him or her appropriately through the final steps of feeding mastery at home.¹²⁴ The developmental specialist and bedside nurse educate the family to read subtle infant behaviors and teach them how to alter feeding to support the acquisition of healthy feeding behaviors.

Feeding Readiness and Cue-Based, Infant-Driven Feeding

A cue-based or infant-driven approach to oral feeding is the state-of-the-art approach. This individualized approach to feeding readiness considers factors such as the infant's medical status, neurobehavioral organization (vigor, sleep-wake cycle, ability to achieve some stable alert periods, autonomic, motor, and state stability), and feeding readiness cues (e.g., awakening or fussing prior to feedings, spontaneous rooting and sucking behaviors, gagging with gavage tube insertion).¹²³ Initiation of oral feeding, whether at breast or bottle, is based on when the infant shows readiness, and readiness is assessed at or surrounding each feeding time. If the infant awakens (either on his or her own or with caregiving) and shows readiness cues, he or she is given a chance to feed orally. Once the oral feeding begins, continual caregiver assessment of the infant's physiologic stability and participation in feeding determines how long the oral feeding lasts. Any volume that is not taken orally is simply given through the nasogastric tube.

For example, an infant who does not arouse with caregiving or initiate sucking on the nipple will receive a supplemental feeding by nasogastric tube; an infant who does well initially before becoming disorganized, tachypneic, or too drowsy may feed orally for a few minutes, with the remaining volume given by nasogastric tube.¹⁰² Staff members can offer oral feedings more often but avoid prolonged sessions of trying to force-feed preset volumes. Ideally, cumulative exhaustion is avoided, with improved weight gain and smoother transition to oral feeds. Because infant-driven feedings depend on active infant participation rather than on caregiver manipulations, organization and safety are increased.

Because the infant participates during cue-based feedings, parents often experience greater success feeding their baby. Teaching parents how to reduce extraneous external stimuli, read and respect their infant's individual cues, provide secure postural support, and facilitate rest pauses or breathing breaks as needed (external pacing) boosts their confidence and increases the success of oral feeding after discharge.

Descriptive scales can be included on nursing flow sheets (now usually in the form of an electronic medical record) to document feeding readiness and performance at each feeding

more consistently and objectively.^{97,141} These scales allow NICU staff to document behaviors and interventions quickly so that all caregivers involved in supporting the infant's oral feeding development can have a full picture of what is occurring (Figure 21-21).

Partnering with Families in the NICU

The admission of an infant to the NICU frequently puts the infant's family in crisis, with an intense onslaught of confusing emotions. The delivery was often unexpected, and the family is now separated. The appearance of the infant can be frightening and the NICU environment overwhelming. Unknown staff and unfamiliar terminology can hinder effective communication. Some mothers have continued physical complications or illness from the pregnancy or delivery, but think that they must ignore their own healing to focus on their infants. Financial considerations, transportation or travel issues, and conflicting needs of siblings can be worrisome. Parental shock, denial, depression, and grief over loss of the ideal birth and perfect infant are compounded by concerns for the recovery of a critically ill infant.

State-of-the-art NICUs have now moved from family-centered care to family-driven care to partnering with families, in which mutual collaboration exists between caregivers and families.^{27,90} The NICU environment can become comforting and inviting when attentive and compassionate caregivers welcome parents to the infant's bedside. Compassionate caregivers teach parents to understand their baby's behavioral cues and provide developmentally appropriate positioning and handling. They actively listen as parents process their shock, anger, and grief over the loss of a normal pregnancy and/or normal healthy term infant and help them heal the wounds of interrupted bonding with their infants. The concept of partnering with families in the NICU acknowledges that over time, the family has the greatest influence over an infant's health and well-being.⁹ Creating an effective partnership between professionals and families has shown benefits such as decreased length of stay, increased satisfaction for staff and parents, and enhanced neurodevelopmental outcomes for infants.³⁶

Facilitating attachment is a priority for all health care providers in the NICU. Early life attachment keeps the baby in the proximity of the mother to ensure infant survival, guides brain development and overall mental health, promotes emotional availability, and contributes to positive infant developmental outcomes such as cognition.¹³¹

A nontraditional work schedule that includes some evenings, weekends, and holidays greatly increases the developmental specialist's availability and benefit to families. Some family-friendly NICU routines and practices automatically facilitate parenting. Placing twins in adjacent bed spaces rather than in separate areas of the nursery helps create a family space. Staff efforts to make the infant as comfortable and as normal-looking as possible (e.g., positional nesting, dressing in baby clothes, adding a hair bow, providing a cute name tag) help parents look beyond the diagnosis and technology. Diligence in using an infant's name and correct gender demonstrates to the family that staff members acknowledge their baby as a real person, not just a sick patient. Caregiving can often be more flexible to accommodate parents' schedules. The inclusion of

Nipple (circle breast or write nipple color)	Breast Nipple Color	Breast Nipple Color	Breast Nipple Color	Breast Nipple Color	Breast Nipple Color	Breast Nipple Color	Breast Nipple Color	Breast Nipple Color
Initial								

Readiness*:

Score	Description
1 Bottle	Drowsy, alert or fussy prior to care. Rooting and/or hands to mouth / takes pacifier. Good tone.
	Drowsy or alert once handled. Some rooting or takes pacifier. Adequate tone.
	Briefly alert with care. No hunger behaviors. No change in tone.
	Sleeping throughout care. No hunger cues. No change in tone.
5 Gavage Only	Needs increased O2 with care. A/B with care. Tachypnea over baseline with care.

Quality Bottle*:

Score	Description
1	Nipples with a strong coordinated suck throughout feed.
2	Nipples with a strong coordinated suck initially, but fatigues with progression.
3	Nipples with consistent suck, but difficulty coordinating swallow; some loss of liquid or difficulty pacing. Benefits from external pacing.
4	Nipples with a weak/inconsistent suck. Little to no rhythm. May require some rest breaks.
5	Disorganized. Unable to coordinate suck / swallow / breathe pattern despite pacing. May result in frequent or significant A/B's or large amounts of liquid loss and/or tachypnea significantly above baseline with feeding.
6	Dysfunctional: Abnormal or deviant oral motor patterns evidenced by inability to extract fluid from nipple.

Caregiver Techniques*:

Score	Description
A	Side-lying Position
B	External Pacing
C	Adding or increasing O2 during feed
D	Imposed Breaks
E	Stimulation for / Recovery from A's / B's
F	Frequent Burping
G	Nipple Change
H	Other (Specify)

Quality Breastfeeding:

Score	Description
1	Latched well with a strong coordinated suck for >15 min.
2	Latched well with a strong coordinated suck initially, but fatigues with progression. Active suck for 8 - 15 min.
3	Difficulty maintaining a strong, consistent latch. May be able to intermittently nurse but only active for <15 min.
4	Latch is weak / inconsistent with a frequent need to "re-latch". Limited effort that is inconsistent in pattern. May be considered NNB.
5	Unable to latch to breast and achieve suck / swallow / breathe pattern. May have difficulty arousing to state conducive to breastfeeding. Could result in frequent or significant A/B's and/or tachypnea significantly above baseline with feeding.

CUE BASED FEEDING SCALES
 AND DOCUMENTATION TIPS

FIGURE 21-21 Cue-based infant feeding scales and documentation tips on nursing flow sheet, Baylor University Medical Center. (From Newland, L., L'Huillier, M., & Petrey, B. (2013). Implementation of cue-based feeding in a level III NICU. *Neonatal Network*, 32, 132–137.)

FIGURE 21-22 Family-centered care encourages and supports siblings to be an active part of their premature sibling's NICU stay. This can help relieve parental and sibling stress, as well as facilitate early attachment within the NICU setting. (Courtesy of the NICU, Memorial Hermann Hospital Southwest, Houston, TX. Photograph by Beverly Edwards.)

siblings, extended family members, and other support persons should be encouraged (Figure 21-22).

Parents are encouraged to ask questions about what they understand and want to know; staff responses need to be honest, consistent, and understandable. Parents become frustrated when information appears contradictory, but anxiety from incomplete information or a perceived lack of truth is often alleviated with a sincere collaborative partnership. The former approach of “therapist as expert, child as client, parents as students” has been replaced by reciprocal dialogue; the developmental specialist talks with rather than to parents, and facilitates the family’s active role with their infant and on the NICU team. Recognizing parental skills, celebrating successes, and facilitating parent’s expertise are invaluable.

Awareness that gentle nurturing touch from mothers to their infants can influence pain sensitivity, affect, and growth in neonates has prompted encouragement of kangaroo care, skin-to-skin contact, and infant massage. This reciprocal tactile stimulation between mother and infant may contribute to increased maternal responsiveness and infant attachment.³² When the quality and/or quantity of parental care toward infants is limited, such as with preterm infants in the NICU setting, these adverse experiences can lead to changes in brain architecture and function.⁵⁵

Skin-to-Skin Care: Kangaroo Mother Care

Because the optimal caregiving environment for the infant is the mother’s body, it is thought that separation from the mother plus noxious environmental and tactile stimuli in the NICU overwhelm the developing preterm infant’s self-regulatory abilities.⁹⁹ Kangaroo care (KC), also called skin-to-skin care (SSC), refers to the practice of parents holding their diaper-clad premature infant on a parent’s bare chest in an upright prone position; it is a fundamental component of neuroprotective and patient-family oriented care for hospitalized

FIGURE 21-23 Infant having a head ultrasound to rule out intraventricular hemorrhage while resting comfortably on his father’s chest during skin-to-skin holding. Infants tolerate many procedures better during kangaroo care. (Courtesy of the Infant Special Care Unit, University of Texas Medical Branch, Galveston, TX. Photographs by Jan Hunter).

preterm infants^{84,85} (Figure 21-23). Kangaroo care originated in Bogota, Colombia, in response to overcrowded nurseries and insufficient medical equipment but is now a global initiative.

Kangaroo care practices vary among individual NICUs according to age, weight, and acuity of the infant; skin-to-skin holding has historically been more widely accepted for stable infants not on ventilators. A Cochrane review of 16 RCTs, including 2518 infants, demonstrated a reduction in the risk of mortality, nosocomial infection and sepsis, hypothermia, and length of hospital stay. KC was also found to increase some measures of infant growth, breastfeeding, and mother-infant attachment.³⁹ A recent study has confirmed that SSC seems safe and effective for vulnerable preterm infants in the NICU, and SSC can be beneficial for ventilated, VLBW preterm infants.³³ These findings demonstrate a paradigm shift. Believing that “this infant is too unstable for SSC care” can be replaced by “this baby is too unstable not to implement SSC.” Earlier initiation, frequency, and duration of SSC may help contribute to improved neurodevelopment of these infants.⁸⁴

Both infant and parents benefit from skin-to-skin holding.^{39,84} Physiologic benefits to the infant from skin-to-skin holding include more stable heart and breathing rates, reduced apnea, stable body temperature, improved weight gain and growth, decreased or less severe infections, and improved tolerance of procedures during skin-to-skin holding (see Figure 21-23). Infant behavioral benefits include decreased agitation, less random motor activity, reduction in stress from environmental disturbances and medical interventions, improved state control, with less crying and better self-regulation, and more mature sleep organization. An easier transition to breastfeeding, earlier hospital discharge, and a positive effect on neurodevelopmental outcomes have also been reported.

Skin-to-skin holding facilitates maternal milk production and longer duration of breastfeeding. Parents develop an increased awareness of their infant's cues of well-being or distress and increased attachment and feelings of closeness to their infant. They demonstrate more positive touch of their infant, less focus on technical care, more confidence in their own caregiving ability, and decreased maternal stress.

Establishing Your Niche in the NICU Team

A neonatal developmental specialist must master specialized knowledge and skills to work effectively and competently as part of the high-tech, neonatal care team. In addition, a few distinctions may be helpful in understanding and directing this journey.

Although developmental specialists in the NICU are currently much more common than in years past, the uniqueness of this role is neither universally understood nor applied. Staff and leadership in some NICUs may continue with a traditional therapy rehabilitation role of a consult to treat pathology but not yet appreciate the neuroprotective role of developmental support beginning at birth or the value of total team inclusion in decisions affecting infant and family support and system changes. Effort invested in educating and eliciting NICU management support for your neuroprotective developmental role will be time well spent.

Therapy supervisors may not realize that not just any therapist can rotate through the NICU according to staffing and census patterns. NICU training is extensive and productivity can be affected by indirect but very important aspects of interventions, such as collaboration or advocating for NICU developmental care. Leadership roles in developmental care include helping develop or refine policies and procedures, orienting NICU staff and physicians, developing comprehensive programs to ensure inclusion of developmentally appropriate practices and equipment, enabling consistent staff support and encouragement, and keeping current with the evidence base for neuroprotective developmentally supportive care.

Aspiring developmental specialists with previous clinical experience who are new to the NICU often have difficulty with the concept of beginning over until they realize that the NICU culture is truly unique, with its own hierarchy, set of rules, timetable, and rhythm. Furthermore, NICU infants are different from all other patient populations; direct application of interventions common for the pediatric population and adults are often not appropriate in the NICU.

For novice developmental specialists, who tend to be concrete and want a formula for success, the task of discernment can be daunting. It is advisable to evaluate the credentials of presenters and writers thoughtfully and use caution before implementation; don't be the first to jump on the bandwagon or the last to jump off. It is also necessary to learn to read neonatal literature, remaining aware that information needs to be critically analyzed rather than blindly accepted.¹⁰⁹

Many new developmental specialists are tempted to rush into the many specialized training and certification courses now readily available. However, time spent in the NICU, with a focus on basics (e.g., respiratory management, nutrition and nonoral feeding, equipment, developmental care,

family-centered care) before pursuit of specialty certifications, especially if there is also inexperience with critically judging literature or presentations, will greatly increase the benefits of advanced training. Time in the NICU gives the new NICU developmental specialist a chance to observe the progression of multiple infants over time, learning the wide range of normal and what is truly atypical.

Building a Successful NICU Practice

Progressing from a perceived guest to an integrated and valued team member in the NICU will take time and may not always be smooth. Staff members who do not understand the NICU developmental specialist's role or are threatened by encroachment on their turf may initially exhibit opposition and competitiveness. This is especially true with someone new and inexperienced in the NICU; for example, a new developmental specialist's academic education on infant feeding is often not convincing to the seasoned nurse who "has fed a thousand babies."

Every new person in the NICU must individually earn staff's respect, acceptance and trust, all necessary components of any successful relationship. This does not come inherent with a degree or title, but instead comes from proving to be a skilled, knowledgeable, and compassionate colleague over time, willingly learning from staff and respecting their expertise. NICU staff instinctively and vigorously try to protect their vulnerable patients; even those whose caregiving or approach to parents could be considered nondevelopmental are probably convinced that they are doing what is best for their babies. See Box 21-6 on the Evolve website.

Connection with staff on a social level is a positive start; next comes engagement of staff on a professional and educational level. Unit culture, unit leadership expectations and support, and individual mind sets of staff all affect whether education and new learning and changes in practice are desired or dreaded. Either way, education and change are mandatory for providing ongoing optimal care. The successful developmental specialist learns staff's needs, quirks, and preferences and adapts necessary education approaches over time in ways that are accepted and inspiring.

NICU staff work in a high-pressure environment in which room for error is small or nonexistent. They are (rightfully) protective of their babies and may likely rebuff or ignore a motivated energetic newcomer who jumps right in with unsolicited bedside teaching or organized in-services before making connections or earning staff trust and respect. When a new developmental specialist is proactive by being patient and skilled before pushing for changes, he or she is more likely to earn acceptance and respect. When staff attend interdisciplinary trainings together, they bond and learn to appreciate each discipline's skill set. Professional practice acts set boundaries on performing some specific tasks, but knowing why something is important and how it is done fosters mutual understanding and appreciation. It prevents the perception that you think you already know it all and offers opportunities for positive reinforcement to staff when standards or expectations are exceeded.

The outline in Box 21-7 on the Evolve website provides some practical suggestions and words of wisdom for success in facilitating professional and educational engagement with NICU staff (Figure 21-24).

FIGURE 21-24 A and B, Using a poster and group e-mail to foster a climate of learning.

Reflective Practice

Finally, a staff culture of reflective practice can drive competency, motivation, and engagement in continuous learning. With reflective practice, occupational therapists consistently step back after doing something or observing an outcome, and ask what could be changed the next time for better results. Perhaps more open communication, more timely respect for the infant, or family cues could have changed the outcome. The process of reflection may allow illumination of ungrounded habits (“We’ve always done it this way”), bring unconscious knowledge to the forefront (“Oh! That’s why this technique works”), and open dialogue that leads to change. For example, after a procedure or feeding, the developmental specialist can ask staff questions such as “How do you think that went for the baby?” or “What do you think he or she had trouble handling?” The hope is that reflection will open communication

and awareness of how staff can collectively better support the infants. The term *reflective practice* was coined by Schon,¹²² demonstrating the significance of the role of practice for the development of professional knowledge. Two types of reflection were identified, reflection in action and reflection on action. Reflection in action occurs while the developmental specialist is practicing, and influences the decisions made and the care given. Experienced developmental specialists are able to reflect in action by showing their ability to explore and examine responses to a situation while actually being involved in it and can adapt their actions accordingly. Reflection on action is a retrospective contemplation of practice taken to uncover the knowledge used during a particular event by becoming self-aware.³⁴ The key to reflection is understanding that it is not complete without action, and the goal of reflection is to challenge and ultimately change practice.⁸

Summary

Developmentally supportive care has sometimes been perceived as consisting of optional practices in a primarily technologically driven environment. However, ignorance or dismissal of the evidence that supports neuroprotective care for a preterm infant is no longer acceptable. Consistent acceptance, practice, and accountability must be established to provide the high-quality care that every infant and family deserves. Use of established guidelines, policies, and procedures to guide neonatal practice is essential. Health care professionals must be cognizant of the growing body of research regarding the impact of the NICU environment on neurodevelopmental outcomes. Recognition of neurobehavioral stability and the links to developmental care and long-term outcomes are increasing. Follow-up studies of formerly sick and premature infants are important because they are used to examine developmental outcomes, the need for developmental care from birth, and the potential costs associated with physiologic complications and sequelae that might be reduced or avoided with proper developmental care.⁶⁹

The NICU is a complex hospital unit in which specialized care is provided to infants who are born prematurely or with significant medical problems. Neonatal developmental specialists who work in the NICU must be armed with specialized knowledge about neonatal medical conditions, intensive care equipment, necessary precautions related to handling the neonates, preterm infant development, and interventions that are neuroprotective and promote behavioral organization and interaction. This chapter described the NICU environment and emphasized how preterm neonatal neurobehavioral systems are affected by their sensory systems, especially in regard to sound and lighting conditions. The following points summarize this chapter:

- Historically, the focus of occupational therapists in the NICU was rehabilitation and developmental stimulation for older chronic infants with specific pathology or functional deficits. Currently, developmental specialists have a neuroprotective focus, beginning at birth, with any infant requiring neonatal intensive care. Examples include specialized knowledge of medical issues (e.g., conditions, procedures, equipment), neurodevelopmental organization, and the abilities and vulnerabilities of a range of infants who require the NICU.

- Developmental specialists in the NICU have advanced and specialized skills in working with families, navigating the NICU ecology, and selectively implementing hands-off (e.g., environmental modifications, change agents) and hands-on interventions (e.g., therapeutic positioning, feeding).
- Sleep protection is a top priority in the NICU. The primary activity in brain development during the last trimester is synaptogenesis, neurons connecting with other neurons at a massive rate of 1 to 2 billion connections/second. Early synaptogenesis forms the primitive neural pathways essential for developing complex brain activity and lifelong brain plasticity; during the last trimester, synaptogenesis only occurs during sleep.
- All evaluations or interventions should benefit the NICU infant. Trying an unproven technique for the practice, scheduling a baby when it is convenient for you instead of when the infant shows readiness, or seeing infants to meet productivity requirements are never acceptable practices—especially if sleep is disturbed.
- NICU positioning traditionally focused on neuromotor development of posture, muscle tone, movement patterns, positional deformities, and subsequent developmental sequelae. With recent advancements in technology, therapeutic positioning in the NICU supports and enhances the infant's energy conservation, thermoregulation, skin protection, sleep, and brain development.
- Cue-based infant-driven feeding focuses on infant readiness, participation, and physiologic and behavioral stability; the infant “drives” the volume, duration, and success of each and every feed. Cue-based, infant-driven feeding is considered the state-of-the-art approach to feeding.
- See Box 21-2 for a list of common abbreviations used in the NICU.

KEY TERMS

Coaching models	Natural environments
Consultative models	Part C of the Individuals with Disabilities Education Act (IDEA)
Early intervention	Primary service provider
Family-centered intervention	Service coordinator
Individualized Family Service Plan (IFSP)	Telehealth

GUIDING QUESTIONS

1. What is early intervention?
2. How do federal legislation and regulations provide the framework for occupational therapy services in early intervention?
3. What is best practice in early intervention?
4. How do occupational therapists partner with families and other professionals to provide developmentally appropriate and family-centered services?
5. Which occupational therapy practices and service delivery models support early intervention in the natural environment?
6. Which strategies do occupational therapists use to promote children's performance and participation?

Definition of Early Intervention Programs

The term *early intervention* connotes different meanings to different professionals. In this chapter, *early* refers to the critical period of a child's development between birth and 3 years of age. *Intervention* refers to programs and services designed to enhance the child's development as a member of a family and support families in caring for their child. Early intervention describes services for children ages birth through 2 years who have an established risk, have a developmental delay, or are considered to be environmentally or biologically at risk. Early intervention programs serve several purposes, including enhancing the development of infants and toddlers with disabilities, minimizing their potential for developmental delay, and recognizing the significant brain development that occurs during a child's first 3 years of life.⁵⁰ Another goal of early intervention as defined in Part C of the Individuals with Disabilities Education Act (IDEA) is to enhance the capacity of families to meet the special needs of their infants and toddlers.

Legislation Related to Early Intervention

The 1980s brought widespread acceptance and support for family-centered care for children with special needs.⁹⁷ Family-centered care is based on the principle that an infant is dependent on his or her parents and other family members for daily care and meeting his or her physical and emotional needs. At the same time, the birth of an infant with special health care needs affects the entire family emotionally, socially, and economically. In 1986, amendments to the Education of the Handicapped Act (EHA) established incentives for states to develop systems of coordinated family-centered care for infants with disabilities. These incentives were strengthened in 1990, when the EHA was further amended and retitled the Individuals with Disabilities Education Act.⁴⁹ Through Part C of IDEA, states must develop and make available comprehensive services for all infants and toddlers who have developmental delays. Revisions to IDEA were made again in 1997 and 2004; the newest version is P.L. 108-446, the Individuals with Disabilities Education Improvement Act of 2004.

States that participate in Part C of IDEA are required to maintain and implement comprehensive, coordinated, multidisciplinary, interagency systems of early intervention services for infants and toddlers with disabilities and their families. Part C defines the policies and regulations that participating states must follow in establishing early intervention services and systems. The most recent regulations for Part C were released in 2011.⁸² Table 22-1 summarizes the differences between Part C, which defines early intervention services for children from birth through 2 years of age, and Part B, which defines school programs for eligible students between 3 and 21 years of age (see Chapter 23). Part C is an entitlement program (acknowledges one's rights to services), and Part B defines mandated services and programs that are obligatory by law.

Importance and Outcomes of Early Intervention

The importance of early intervention is widely recognized. In particular, research on the developing brain suggests that influencing early development can significantly change a child's learning potential.^{15,95,96} Neural plasticity is at its greatest in the first 3 years of life, and, although not absent in later years, neural plasticity diminishes over time. Positive early experiences shape and strengthen the brain, and social-emotional and physical health influence cognitive and communication development. Early intervention not only has the potential to affect a child's development and health, but these services may also

TABLE 22-1 Comparison of Educational Programs by Age Group

	0-2	3-5	6-21
Legislation	IDEA, Part C	IDEA, Part B	IDEA, Part B
Program	Early intervention	Special education	Special education
Type	Entitlement	Mandate	Mandate
Eligibility	Noncategorical	Categorical	Categorical
Services provided	16 primary services, including occupational therapy, physical therapy, speech-language pathology, and special instruction	Related services only as support to special education	Related services only as support to special education
	Interdisciplinary and transdisciplinary assessment	Interdisciplinary and discipline-specific assessment	Discipline-specific assessment as related to education
	Individualized Family Service Plan (IFSP)	Individualized education program	Individualized education program
	Family-centered	Family-focused in theory, child-focused in practice	Child-focused, with emphasis on curricular standards
	Service coordination	Service coordination recommended but not mandated	Service coordination recommended but not mandated
	Natural settings	Home-, center-, or school-based	School-based

IDEA, Individuals with Disabilities Education Act.

reduce caregiver stress, thus increasing the capability of families to care for their child and support their child's needs.^{3,43} Early intervention services also reduce the need for special education when children transition to school.³

In 2010, more than 340,000 children received Part C services.¹⁹ To ensure that quality early intervention services are being provided to families and children, the Office of Special Education Programs began collecting states' early intervention data on child and family outcomes.^{27,28,28a} States must report on the percentage of infants and toddlers with Individualized Family Service Plans (IFSPs) who demonstrate improvement in the following:

1. Positive social-emotional skills (including social relationships)
2. Acquisition and use of knowledge and skills (including early language and communication [and early literacy])
3. Use of appropriate behaviors to meet their needs

States must also document the percentage of families participating in Part C who report that early intervention services made improvements in the following:

1. Family's knowledge of their rights
2. Family's ability to communicate their child's needs effectively
3. Family's ability to help their child develop and learn

Nationwide data from 2011 indicated that between 71% and 76% of children from birth through 2 years showed greater than expected growth in the three child outcomes, and between 85% and 90% of families reported that early intervention services had helped them meet the family indicators above as they exited early intervention.^{27,28} This chapter provides an overview of early intervention services and describes how occupational therapy services support and promote early intervention outcomes for children and families.

Occupational Therapy Services in Early Intervention Systems

Part C of IDEA considers occupational therapy to be a "primary service" for eligible infants and toddlers who qualify for early intervention services. As a primary service, occupational therapy can be provided as the only service that a child receives or in addition to other early intervention services. By its legal definition, occupational therapy includes services to address the functional needs of the child related to adaptive development (self-care); adaptive behavior and play, including social interaction; and sensory, motor, and postural development. Services include adapting the environment and selecting, designing, and fabricating assistive and orthotic devices to facilitate development and promote the acquisition of functional skills. Occupational therapy outcomes for children and families participating in IDEA Part C services include improved developmental performance, increased participation, and enhanced quality of life.¹⁰ Activities of daily living (ADLs), rest and sleep, play, and social participation are the primary areas of occupation addressed in IDEA Part C services.

Traditionally, occupational therapists provided early intervention services with a medical orientation. That is, occupational therapy was provided in a clinic or center, and sessions usually were conducted one on one with the occupational therapist and child or in a small group with peers who were also receiving early intervention services. With the changes to IDEA 1997 requiring services to be provided in the natural environment, approximately 94% of early intervention services occur in the home or other community-based settings.¹⁰⁴ As a result, occupational therapists have developed models and strategies appropriate for services in homes and other community environments. Therapeutic interventions are embedded

into family routines (i.e., performance patterns). Occupational therapists provide early intervention services in natural environments as part of a team, coach and consult with team members to support occupational therapy interventions, and use a family-centered approach that respects cultural differences. The following sections define the concepts that guide early intervention services and exemplify how occupational therapists apply early intervention practices.

Best Practices in Early Intervention

Partnering with Families

The early intervention system recognizes that families can be and often are knowledgeable consumers and effective change agents for their children. It also acknowledges that families need resources to support and raise a child with disabilities.^{70,103} The early intervention team helps each family identify its unique resources, priorities, and concerns and identifies goals that enable them to support the child as a member of the family unit.⁵⁶

The term *family-centeredness* encompasses several meanings—families are treated with respect; importance is placed on family strengths, not deficits; families have control and make choices regarding the care that their child receives; and families and providers work together to ensure provision of optimal early intervention services.^{4,24} Within a family-centered model, occupational therapists develop goals collaboratively with the child's primary caregivers. Using a family systems perspective, the occupational therapist recognizes the influence and inter-relationships of the family within various systems, such as the extended family, neighborhood, and early intervention programs. By thinking broadly about families and their subsystems, the occupational therapist can help parents communicate their concerns and identify their priorities for the child.

Families are participants in and consumers of early intervention services.¹⁰² The nature and extent of family involvement may vary according to family needs, values, lifestyles, and variables within the structure of the early intervention program itself. The degree of family involvement may fluctuate and change in response to external or internal factors that affect family functioning and coping. Some examples are degree of acceptance of the child's disability, job status of one or both parents, a new infant in the family, and changes in the family's support networks, such as grandparents, friends, and church groups.

To provide appropriate intervention within the family-centered model, the occupational therapist must be aware of and respect differences in beliefs and values based on culture. Multiple factors can affect family involvement, and families of children with disabilities may be under considerable stress and may be doing their best at any particular time.⁴² For example, a parent who is homeless or jobless may not be concerned about occupational therapy for the child. Another parent may believe that certain skills or goals are more important than those identified by the occupational therapist. As explained in [Chapter 5](#), family priorities need to be honored and services must follow the family's expressed priorities.

The families receiving early intervention services are highly diverse ([Research Note 22-1](#)), and acceptance of the individual

RESEARCH NOTE 22-1

Hebbeler, K., Spiker D., Bailey, D., Scarborough, A., Mallik, S., Simeonsson, R., et al. (2007). Early intervention for infants and toddlers with disabilities and their families: Participants, services, and outcomes. Final Report of the National Early Intervention Longitudinal Study (NEILS). Menlo Park, CA: SRI International.

Abstract

Beginning in 1996, the Office of Special Education Programs of the U.S. Department of Education sponsored research regarding early intervention (Part C). This longitudinal descriptive study was based on an ecologic model in which young children receiving early intervention (EI) services are considered to be influenced by a variety of factors, such as environment, genetics, and cultural attitudes. In particular, the interactions between child and family highly influence child outcomes. The study's purpose was to determine the characteristics of children and families who received services, types of services received, costs of services, outcomes experienced by children and families, and relationship among outcomes, services, and child-family characteristics. A nationally representative sample of 3338 children was included in the study, which drew data from a variety of sources over time—family interviews (telephone and mail), service records (i.e., IFSPs), service provider surveys, and kindergarten teacher surveys.

Implications for Practice

- The types of children and families that received EI services are highly diverse, and more than half of families are coping with multiple risk factors beyond disability or developmental delay in their children, including poverty, low level of maternal education, single-parent household, and having another child with special needs. The authors of NEILS pointed out that this diversity supports the requirement for individualized services in EI, which take into account how best to support families and are flexible regarding the needs of families and children at different points in time.
- Many of the children who receive EI services do not receive special education services in preschool or kindergarten, suggesting that for some children, disability and delay identified before 36 months may be transitory in nature. Occupational therapists need to be aware that many young children with mild impairments may need services for only a short time. In this case, EI can be considered a prevention program addressing specific developmental challenges in infancy and toddlerhood and preventing or reducing the need for additional services in the future.
- Areas of concern identified by parents and kindergarten teachers of children who received EI services included communication problems and social-emotional problems. Occupational therapists may benefit from training to address simple communication and behavioral issues within the context of different service delivery models and an understanding of when these issues need to be addressed by a professional with specialized knowledge.

- At the time of data collection (late 1990s), families were receiving typically two to four different services, with a median of 1.5 hours of scheduled service time per week. This limited amount of service time spread among several professionals supports the need for occupational therapists to incorporate families into intervention by addressing how intervention strategies will fit into family routines and daily activities in the natural environment.
- Most of the families who participate in EI identify positive outcomes associated with the program, such as knowing how to care for their child, helping their child learn and develop, learning how to work well with professionals, and feeling comfortable in asking for help and support from relatives and friends. However, ratings from low-income and minority families were lower in these areas, suggesting that EI providers, including occupational therapists, should be thoughtful of the specific needs of diverse families.

differences among families is a high priority. The occupational therapist who provides intervention in the home has an intimate view of such things as customs, eating habits, and child-rearing practices that may vary among cultures. The family's beliefs and views of disability and its cause, their view of the health care system, and their sources of medical information affect their attitude toward early intervention.¹¹⁰ Based on individual cultural backgrounds, the family may view the occupational therapist as a helper or someone who interferes, and occupational therapists should reflect on how a family's cultural values and beliefs influence their participation in early intervention programs (Box 22-1). Although providers acknowledge the value of considering one's culture, research suggests that early intervention providers do not consistently develop IFSP goals that consider cultural diversity (e.g., family income, location of residence).⁸⁹ Given the importance of the IFSP in directing program implementation, this finding indicates that early intervention service providers need to make certain that they include all family-identified priorities in addition to those that relate to the child's development.

Many of the areas in which occupational therapists provide interventions and suggestions involve caregiving and are closely tied to values and beliefs about parenting and cultural views of children. Practices regarding feeding, toileting, and bathing may vary among cultures. The occupational therapist considers the family's values and cultural beliefs about these practices before making recommendations for change.³⁹ As part of cultural values, occupational therapists consider family rituals and meaningful aspects of family life, such as celebrations, and family traditions that support the building of family relationships and occupations (e.g., saying goodnight, buying new school shoes).²³

Essential to family-centeredness is building ongoing relationships with families.²⁴ Relationships are fostered when practitioners exhibit effective listening, compassion, and empathy. Occupational therapists communicate with sensitivity their own concerns about the child's occupations and are open to the family's perceptions. Families who have children with special needs highly value services in which professionals provide clear, understandable, complete information; demonstrate respect for

BOX 22-1 Questions to Foster Cultural Competence

1. What do I know about the family's culture and beliefs about health?

This represents the basic knowledge of cultural health practices and beliefs. Conclusions or judgments should not be formed about why these practices are present.

2. Does the family agree with these beliefs?

Although a client may affiliate with a specific cultural group, the occupational therapist must investigate whether the cultural beliefs of health and the client's beliefs of health are similar.

3. How will these beliefs influence the intervention and outcomes of services provided?

The occupational therapist must acknowledge and respond to the influences of cultural beliefs and practices in the intervention plan. To design a plan that conflicts with cultural beliefs would not only be counterproductive to client-centered services, but would be disrespectful of the family's belief system. If a family, in deference to the authority of the occupational therapist, follows an intervention that conflicts with cultural practices, the family may risk not receiving support and affiliation with their cultural group.

4. How can the intervention plan support culturally endorsed occupations, roles, and responsibilities to promote the family's engagement in occupation?

The occupational therapist must consider the important occupations from a cultural perspective. Evening meals may include specific behaviors that possess strong cultural symbols for one family, but another family may view an evening meal as merely eating, with no prescribed rituals.

the child and family; provide emotional support; and provide expert, skillful intervention.⁹⁰

Partnering with Professionals

The success of an early intervention program depends largely on how a cooperative team of professionals develops and implements coordinated and integrated intervention plans. Teamwork is critical because the inter-related needs of a developing child and caregiving family are complex and call for the skills and resources of a team of professionals. Occupational therapists working with infants and toddlers have specialized knowledge of childhood occupations and generalized knowledge regarding young children with special needs. The emphasis of intervention is the child within the family unit, rather than the child alone, and intervention is carried out through collaboration among all professionals involved.

Although an occupational therapist may participate in various service delivery models, a transdisciplinary model in which one service provider is primary and other team members serve as consultants is considered optimal in early intervention.^{59,75} In transdisciplinary early intervention, one professional, sometimes called the primary interventionist, supports and provides the functions that traditionally were performed

by another professional.⁵⁹ Occupational therapists become teachers of their peers and benefit from learning about strategies and approaches used in other professions.⁷⁸ Through frequent collaboration (i.e., in-person meetings, co-treatment, and informal communication), team members build relationships characterized by mutual trust and respect, thus decreasing potential feelings of ownership over particular therapeutic approaches. Limited contact among team members may result in difficulties in supporting the roles of other team members. Coaching, described later in the chapter, is a form of early intervention consultation that allows team member to reinforce intervention strategies designed by other team members.

Coaching may be supported using telehealth, an emerging service delivery model in occupational therapy, which has become increasingly used in early intervention services.^{1,11-13,44,57} Telehealth is the use of telecommunication and information technology to provide increased access to services in which provider shortages exist and facilitates consultation, collaboration, and coaching among early intervention providers and families¹² (Figure 22-1).

Opportunities for participating in collaborative activities and teaming may be challenging when providing intervention individually in homes and other community settings. Importantly, team members need to schedule meeting times to plan and communicate and develop systems for communication using e-mail, an electronic file-sharing service (e.g., Dropbox or cloud computing technology), and regularly scheduled meetings.⁷

Evaluation and Intervention Planning

Early intervention evaluation consists of a series of steps and is an ongoing, collaborative process of collecting, analyzing, and gathering information about the infant and family to identify specific needs and develop IFSP goals. The evaluation, combined with a treatment program and ongoing reassessment, is a problem-solving process that continues throughout the period during which the infant or toddler is eligible for Part C services.⁷³

Two major goals in the evaluation of infants and toddlers are (1) determination of eligibility for early intervention programs and (2) development of goals and potential outcomes to guide the early intervention services.

Eligibility Determination

Certain infants and toddlers are diagnosed at birth or shortly after birth, such as children with cerebral palsy, Down syndrome, or spina bifida, and become automatically eligible for early intervention services. Infants and toddlers without a specific diagnosis who are suspected of having developmental delay are entitled to an evaluation that must be timely (completed within 45 days) and comprehensive and must include input by a multidisciplinary team. The occupational therapist is often a member of the evaluation team. Family-centered practices during the evaluation process include the following: (1) the family is treated with respect; (2) the evaluation should be individualized, flexible, and responsive to the family's culture and preferences; (3) the child and family's strengths should be emphasized rather than focusing on deficit areas; and (4) the family's expertise should be valued, and they should be included as a partner in all decision making.³¹ As much as possible, the team is responsive to the family's needs and desires when determining the time and location of the evaluation and who should be present. The family's involvement is central to the evaluation process, and the family's strengths and concerns are documented.

At the time of the initial evaluation, the team introduces families to the early intervention system and to concepts such as family-centeredness and natural environments.¹⁰⁶ Semi-structured interviews such as the routines-based interview (RBI)^{75,76} can be used to gather information about the natural environment and family priorities for intervention (see the Evolve website for an example of the RBI). The RBI includes six steps: (1) beginning statements (introduces the interview process and asks about the family's main concerns), (2) discussion about the daily routine of the child and family, (3) information about the daily routines and child's participation in these routines, (4) family's satisfaction with daily routines, (5) family's concerns and priorities, and (6) outcome writing (see later, "Writing Goals and Objectives"). The team can ask parents about their community activities, family supports, and perceived barriers to community participation.¹⁰⁶

With an understanding of family priorities and context, the team administers a standardized assessment of infant cognitive, communication, motor, social-emotional, and adaptive (self-care) development. Play is often the context for or a

FIGURE 22-1 An occupational therapist uses telehealth technologies to coach a parent on therapeutic techniques to implement in the child's natural environment.

component of the assessment, allowing team members to determine how well the child integrates related skill areas and how he or she playfully interacts with social and physical environments. Therapists may use informal assessment through observing the child playing with caregivers, siblings, or peers.⁶³ The Transdisciplinary Play-Based Assessment, second edition (TPBA-2), is an example of a commonly used play-based assessment in which the child's play is facilitated and observed by the team and family.⁶⁵

Administered frequently by early intervention teams, criterion-referenced assessments, including curriculum-based assessments, provide information about a child's ability to perform a certain set of skills that represent a developmental age range. Criterion-referenced tests can be favored over norm-referenced tests that compare a child's abilities with those of their same-age peers because children receiving early intervention services may not follow the typical ("normal") developmental sequence and may not respond to a standardized protocol. The Hawaii Early Learning Profile (HELP)⁸⁴ and the Assessment, Evaluation, and Programming System for Infants and Children, second edition (AEPS),⁵ are well-used, developmental, curriculum-based assessments. The assessments chosen by teams may vary from state to state and may be specified by policies of the state agency responsible for the implementation of IDEA Part C services. Because a standardized test provides a sampling of a child's abilities and behaviors observed at a particular time and situation, from a particular perspective and with a particular instrument, Part C regulations include the term *informed clinical opinion* as an essential aspect of the evaluation process.⁸² Practitioners' informed clinical opinions make use of qualitative and quantitative information to assist in forming determinations regarding difficult-to-measure aspects of current developmental status and the potential need for early intervention.⁶⁷ For example, an occupational therapist makes judgments about muscle tone abnormality or determines that a premature infant has oral sensitivity when fed.

Informed clinical opinion is the final opinion of the multidisciplinary team in establishing eligibility for early intervention. The team becomes informed through multiple sources, such as a review of medical records and developmental history, family interviews, child and family observations, and information from other professionals (e.g., social workers, medical providers), in addition to the findings from standardized assessments.⁶⁷ The following recommendations demonstrate the importance of integrating family-centered practices, standardized assessment, and other information sources during the evaluation of infants and young children⁷⁷:

- The occupational therapist should base the assessment on an integrated developmental model. Parents and professionals must observe the child's range of functions in different contexts to identify how the child can best be helped, rather than simply reporting a test score.
- Assessment involves multiple sources and multiple components of information. Parents and professionals contribute to forming the total picture of the child.
- An understanding of typical child development is essential to the interpretation of developmental differences among infants and young children.
- The assessment should emphasize the child's functional capacities, such as attending, engaging, reciprocating,

interacting intentionally, organizing patterns of behavior, understanding his or her environment symbolically, and having problem-solving abilities.

- The assessment process should identify the child's current abilities, strengths, and areas of need to attain desired developmental outcomes.
- The occupational therapist should not challenge young children during the assessment by separating them from their parents or caregivers. The parents' presence supports the child and begins the parent-professional collaborative process.
- An examiner who is unfamiliar to the child should not make an assessment. The occupational therapist should give the child a warm-up period. Assessment by a stranger when the parent is restricted to the role of a passive observer represents an additional challenge.
- Assessments that are limited to easily measurable areas, such as certain motor or cognitive skills, should not be considered complete.
- The occupational therapist should not consider formal or standardized tests as the determining factor in the assessment of the infant or young child. Most formal tests were developed and standardized on typically developing children and not on those with special needs.

Furthermore, many young children have difficulty attending to or complying with the basic expectations of formal tests. Formal test procedures are not the best context in which to observe functional capacities of young children. Assessments that are intended for intervention planning should use structured tests only as part of an integrated approach (Figures 22-2 and 22-3).

Once the team has defined a child's eligibility for early intervention services, further assessment is important for the occupational therapist and family to determine which intervention strategies and services are of greatest value to the child and family. At this point, evaluation becomes a comprehensive decision-making process to identify social-emotional, cognitive, adaptive, motor, and communication problems; develop goals; and define an early intervention program plan.

FIGURE 22-2 The occupational therapist can assess perceptual motor and motor planning skills through observation of puzzle completion.

FIGURE 22-3 Important assessment data are gathered through structured observations of the child's play in his or her daily environment.

Development of the Individualized Family Service Plan

The IFSP is a map of the family's services and informs everyone who will be working with the child and family about which services will be provided, where they will be provided, and who will provide them. IDEA Part C specifies that services must be provided in the infant's or toddler's natural environments—that is, those that are natural or typical for a same-aged infant or toddler without a disability and that may include the home or community settings (34 CFR §303.26). Development of the IFSP follows completion of the initial evaluation and assessment. The IFSP defines the environments in which the child is to receive services and provides a statement of justification if services are not provided in natural environments (34 CFR §303.126). The IFSP also specifies who the provider will be; the frequency, intensity, and duration of services; and the funding sources. In some states, telehealth is used to enable service providers to participate virtually in the IFSP development process, thus supporting collaboration that may not otherwise be feasible because of travel distance or provider shortages.¹³

Occupational therapy intervention, as with other early intervention services, is based on identified concerns and expected outcomes in the IFSP. **Box 22-2** lists the required components as stated in IDEA. The development of the IFSP occurs during a meeting facilitated by the service coordinator and attended by the family and at least one member of the evaluation team. It is a process in which professionals and families share information to assist the family in making decisions about the types of services that they believe will benefit them and the child. The service coordinator's role is to assist the family in accessing information and resources and coordinate implementation of the IFSP. Other service providers or anyone else the family would like to invite may also be in attendance.

BOX 22-2 Required Components of the Individualized Family Service Plan

The IFSP shall be in writing and shall contain the following (IDEA § 636):

1. A statement of the infant's or child's present level of motor, cognitive, communication, social-emotional, and adaptive development, based on objective criteria
2. A statement of the family's resources, priorities, and concerns related to enhancing the development of the infant or child
3. A statement of the major outcomes expected to be achieved for the infant or child and family and the criteria, procedures, and timelines used to determine the degree to which progress toward achieving the outcomes is being made and whether modifications or revisions of the outcomes or service are necessary
4. A statement of specific early intervention services necessary to meet the unique needs of the infant or child and family, including the frequency, intensity, and method of delivering services
5. A statement of the natural environments in which early intervention services shall appropriately be provided, including a justification of the extent, if any, to which the services will not be provided in a natural environment
6. The projected dates for initiation of service and anticipated duration of the services
7. The identification of the service coordinator from the profession most immediately relevant to the infant's or family's needs who will be responsible for implementation of the plan and coordination with other agencies and persons
8. The steps to be taken to support the transition of the child with a disability to preschool or other appropriate services

IFSP forms vary from state to state and among early intervention programs. Despite the differences in forms, each must include specific information, as specified by the IDEA regulations. The IFSP is a dynamic plan. To ensure that it meets the changing needs of the child and family, it is reviewed every 6 months or more often, if deemed necessary. During this meeting, outcomes are examined and families may opt to make changes, including the types of services the child receives.

Writing Goals and Objectives

The occupational therapist on the early intervention team focuses on outcomes from a family-centered perspective and identifies the child's occupational performance as it relates to daily family routines. **Box 22-3** identifies questions to discuss with families. An outcome is a statement of changes desired by the family that can focus on any area of the child's development or family life as it relates to the child.⁶⁰ It reflects family priorities, hopes, and concerns in a broad statement that the whole team addresses. Before an outcome is developed, the early intervention team collects information about the natural environments in which families and children spend their time (e.g., using the RBI), at the home or in the community (e.g., child-care center, playground, library). The team should also assist the family in identifying the activities that they typically do or

BOX 22-3 Discussing Routines and Activities with Families When Providing Intervention in the Natural Environment

- Ask open-ended questions such as “What activities do you and your child do throughout the day or a typical week?” and “Describe how your child participates in those activities.”
- Ask strengths- and interest-based questions such as “What activities go very well?” “What do you like to do together?” and “What do you wish you could do together?”
- Ask questions about activities the family might find challenging such as “What’s a tough time of the day or activity for you?” and “How does your child behave and interact with others in these challenging activities?”
- Use prompts and observations to encourage the family to describe their child’s engagement and participation, independence, and social interaction in various routines and activities.

Workgroup on Principles and Practices in Natural Environments, OSEP TA Community of Practice: Part C Settings. (2008, February). *Agreed upon practices for providing early intervention services in natural environments*. Retrieved from http://www.ectacenter.org/~pdfs/topics/families/AgreedUponPractices_FinalDraft2_01_08.pdf.

would like to do in those environments, such as a family who eats breakfast at the kitchen table and would like the child to participate in eating as a morning routine.^{76,91} Once routines, activities, and suggested strategies have been identified, outcome statements may be written. Criteria for high-quality IFSP outcomes include the following⁶⁸:

- The outcome statement is necessary and functional for the child’s and family’s life.
- The statement reflects real-life contextualized settings (e.g., not test items).
- The wording of the statement is jargon-free, clear, and simple.
- The outcome is discipline-free (e.g., not specific to occupational therapy, physical therapy, speech-language pathology, or other discipline).
- The statement avoids the use of passive words (e.g., tolerate, receive, improve, maintain).
- The wording emphasizes the positive.

“Lily will go fishing with her family and hold her own fishing pole” and “Marcus will play in the backyard getting around on his own using his walker” are examples of outcome statements that meet these criteria.⁶⁸ Other outcome statements are parent-focused and may include learning strategies to support the child or facilitate the role of a parent of a child with special needs. For example, a family-focused outcome may be a measurable outcome that relates to finding childcare for a child with special needs or understanding community resources to access appropriate services prior to exiting the early intervention program. See **Box 22-3** for examples of outcome statements.

After an outcome is developed, the next step is to describe what is happening now and what will happen when the outcome is achieved. Strategies are listed to address the outcome with individuals and resources that are needed. All relevant team

members should be included. For example, if the outcome is “to feed himself finger food at a family meal,” the current problems might be “unable to hold food in hand and bring to mouth, cannot sit at a table, cries during meals unless parent is feeding him.” The team will recognize progress when the child can sit at the table independently and pick up and eat small pieces of food. To achieve this outcome, a number of strategies are proposed. The strategies usually link to the practice areas of specific disciplines. For example, the physical therapist takes primary responsibility for developing strategies that increase the infant’s stability for sitting, the speech-language pathologist for communication, and the occupational therapist for the child to increase holding the food and bringing it to his or her mouth.

Outcomes focused on participation in community activities may be particularly meaningful for families and young children.⁸ Involvement in activities that occur in a setting outside the home, such as a local restaurant, place of worship, or library, may be a caregiver’s main concern. Strategies could include assistive technology or equipment that helps the family manage transport (e.g., an adapted stroller), comfort (e.g., a carrying device), or behavior (e.g., recommended busy box or computer tablet activities). A worksheet that may be used to help families and other team members determine how to incorporate ideas and strategies into routines in community settings is shown in **Table 22-2**.

Transition Planning

As a child turns 2 years old, the early intervention team begins to develop a plan for the child’s transition from the early intervention program to preschool (Part C to Part B services). The transition process for young children with disabilities and their families is often characterized by stress because of the many factors involved, such as a change of environment (e.g., receiving early intervention services at home and then moving to a preschool classroom), a change of providers (e.g., the child and family may have a close relationship with early intervention providers but will receive services from school personnel after the transition), and a difference in philosophy between early intervention programs and schools (i.e., family-centered in early intervention versus child-centered in schools).^{86,92} Parents’ stress may be decreased when transitions are well planned and support to families and children is provided throughout the process.⁴⁰

Occupational therapists have an important role in transition planning because their background in understanding how different contexts may influence participation is a distinctive part of occupational therapy intervention.^{79,80,85} Outcomes and strategies written on the IFSP may be used to guide the family during the transition process. For example, the family can place their child in a small play group (**Case Study 22-1**) to help him or her adjust to the social expectations of preschool. Potential activities in which occupational therapists may support families and children during transition include preparing caregivers for changes in roles and routines that will occur after the move to preschool, teaching caregivers how to work with their children to develop specific skills needed in preschool, and visiting the preschool classroom before the transition to assess needs for environmental modifications.⁷⁹ The occupational therapist can also support a smooth transition by making sure that the child’s

TABLE 22-2 Worksheet: Plan of Strategies to Promote Tunisha's Participation in Library Story Hour

Ways to Position Tunisha	
When the Other Children ...	Tunisha Can ...
Sit on the floor	Sit in her floor sitter chair. Sit with you, between your legs. Be propped up in a beanbag chair. Lie on her stomach.
Sit at a table	Sit in a chair pushed up to the table and with a strap at her hips. Sit in her stroller pushed up to the table.
Stand	Sit in her stroller. Stand in front of you, with you holding her at her hips (takes two hands). Stand in front of a table with you behind her so that your leg is between her legs (to keep them apart).
Helping Tunisha Manipulate Objects or Materials	
When the Activity Requires Objects ...	Tunisha Can ...
Storybook stick props, rhythm band instruments, other objects	Hold objects that are large when placed in her hand (e.g., instead of using a stick on the storybook props, staple Tunisha's prop to a paper towel cardboard tube). Hold objects that can be placed on her hand or arm so that she doesn't have to grasp (e.g., bells fastened to her wrist, puppets). Hold objects using her Velcro glove.
Markers, crayons, paint brushes	Hold the object with her Velcro glove. Use fat crayons (with knobs at the top). Finger paint instead. Draw with an adult or another child helping her hold the object and move her arms.

adaptive equipment is sent to the new setting and providing team members in the new setting with a video recording of the child and caregivers doing self-care routines.¹⁰⁸

Payment for Occupational Therapy Services

In general, states determine how occupational therapists are paid for their services. In some states, occupational therapists are employed by the state agency that oversees the early intervention program; in others, the occupational therapist is self-employed or employed through a private agency. In a typical scenario, the occupational therapist bills for the time spent in direct, face-to-face contact with the child, family, or other caregiver. It is important to note that "face-to-face" may be interpreted as in-person or as real-time interactions occurring through videoconferencing technology (e.g., telehealth). Billing for time spent in team meetings, on the phone with team members or family, and other indirect activities may or may not be reimbursed.

Because state funding for early intervention programs is the payment of last resort (IDEA § 635 [a][10][A]), occupational therapists are typically reimbursed through other federal programs (e.g., Medicaid) or private insurance, with families paying part of the cost of early intervention services.³⁴ Often the payment amount of the family share portion is determined on a sliding scale based on a family's income. Although occupational therapists working in early intervention must travel

throughout the community to provide services in natural environments, travel is rarely reimbursed.³⁷ Early intervention services provided by telehealth technologies may be reimbursed by Medicaid, private insurance, or IDEA Part C funds.¹³ Medicaid and private insurance reimbursement for services provided by telehealth vary by state. When billing for services provided by telehealth, providers may be required to use a distinct billing code that identifies the type of technology used (e.g., synchronous technology).^{1,14} Occupational therapists work with administrators and service coordinators to make these issues transparent, problem-solve barriers, and optimize resources in systems that are inevitably constrained by funding.

Working in Natural Environments

To enable the child to remain an integral part of the family, and for the family to be integral parts of the neighborhood and community, services should be community-based and in locations convenient to the family.^{50,103} The family should choose the natural environments that best fit their priorities and lifestyle and include typically developing children of the same age.⁸¹ Some examples are a play group, mother's morning-out program, childcare center, playground, or park (Figure 22-4). In addition, the outcomes on the IFSP should support the provision of services in the natural environment, with outcomes linked directly to family routines and contexts.^{54,55}

CASE STUDY 22-1 Jeremy

Background

Jeremy's pediatric neurologist referred him for a transdisciplinary assessment at 18 months of age because of motor delays caused by his mitochondrial encephalopathy. An early intervention team, which consisted of an occupational therapist, physical therapist, speech-language pathologist, and early childhood intervention specialist, assessed him in an arena assessment. Both parents participated in the assessment. Although Jeremy had received occupational therapy and physical therapy since he was 6 months old, his parents stated their desire for his inclusion with children who were typically developing and asked that therapies be integrated into his early childhood classroom.

Assessment

The team chose to administer the Battelle Developmental Inventory, second edition (BDI-2),* and the Hawaii Early Learning Profile (HELP).⁸⁴ The latter was administered through observation, direct administration of test items, and interview with the parents. The team modified portions to accommodate for Jeremy's physical limitations. Most important, the occupational therapists engaged him in play activities and used their interpretation of his interactions and movements to estimate his functional abilities.

Overall, Jeremy had very low muscle tone and poor physical endurance. He needed support for sitting and could bear only some of his weight when supported in standing. He was unable to roll or crawl. Head control was poor, with head stacking in a supported sitting position and lack of head righting in the prone position. He used his left hand very well to play with toys when he was positioned appropriately but did not use his right hand and protested when the occupational therapist attempted to evaluate his passive range of motion. Jeremy was alert and interested but was reluctant to leave his mother's lap. He said five words—mom, dad, baba for bottle, do for dog, and mo for more.

Intervention

Jeremy started in an inclusive playgroup two mornings a week. He received occupational therapy, physical therapy, and speech-language pathology on a consultative basis, with direct special instruction while in the play group. The team members agreed that Jeremy's goals included improved social interaction with peers, self-help skills, manipulation, and mobility. The team obtained adapted seating and eating utensils for him and modified group activities to enable him to participate actively and as independently as possible.

Individual Family Service Plan Review

After 6 months, the service coordinator, intervention team, and family members met to review the goals on Jeremy's IFSP and to update and modify it as needed. The family and team were pleased with Jeremy's progress and thought that he was benefiting from his intervention program. Jeremy was gaining confidence in a small group, developing good social and communication skills, and no longer tiring as easily. Jeremy's service coordinator arranged for him to participate

in a special grant program at a local childcare center. He was enrolled in a class for 2-year-old children that met a few hours a week and had the support of an assistant who had been trained to facilitate the inclusion of children with special needs in the typical childcare setting. Although this facilitator had several other children to work with and was not in Jeremy's class all the time, she was available whenever he needed help or when the teacher had a question or concern. After a few months, Jeremy started attending this program twice a week; meanwhile, he continued to receive therapy services on a consultative basis at home and at the center.

Annual Reassessment

One year after entrance into the early intervention program, the intervention team reassessed Jeremy in preparation for the development of a new IFSP. They did not perform this assessment in a formal testing session but over a period of weeks as Jeremy participated in various activities with the group. In addition to the BDI-2, Jeremy's team also updated the HELP.

Results of the reassessment indicated a happy, verbal, 2-year-old child. Although he had gained in physical abilities, Jeremy needed a stroller-type wheelchair with special inserts for appropriate seating. The removable seat also acted as a floor sitter so that Jeremy could be close to the same level as his peers when they played on the floor. He demonstrated improvement in his play skills and increased spontaneous interactions with his peers—for example, he took turns and shared toys with little prompting.

Jeremy continued to participate in the class at the childcare center and no longer needed the facilitator's support. The occupational therapist and physical therapist continued to provide on-site consultation. Through a problem-solving approach, with close cooperation among the family, childcare personnel, and therapists, Jeremy thrived in the class. Strategies that supported his participation included providing wheelchair access to the playground (they had been carrying him), teaching principles of lifting and carrying, and making the stroller available to transport him from room to room so that the teacher had her hands free to keep up with other active 2-year-old children.

Summary

Jeremy is an example of a child who was able to benefit from a combination of programming that included an inclusive playgroup and typical childcare setting. His program required close cooperation among the family, early intervention personnel, and community resources. His parents look forward to his graduation to the class for 3-year-old children and increasing his typical class time to 3 days a week. They have visited the neighborhood school and plan for him to attend a regular kindergarten class when he is 5 years of age, where he will be supported by therapies. Jeremy has age-appropriate cognitive skills, and with the right kind of support and technology, he can fully participate in school and in the community.

FIGURE 22-4 The occupational therapist encourages a child to participate in sensorimotor activities on the playground.

Intervention in natural environments includes using toys and materials that can be found in the home and will remain available to the family or other caregivers on a consistent basis. Occupational therapists who rely on clinical equipment, whether they bring it to home visits or use it in their centers, may be selecting equipment and toys most comfortable to them but not friendly or helpful to the family.^{38,78} Specialized equipment, such as suspended swings, therapy balls, or a child-sized table and chair, may be optimal for a clinic-based program to remediate sensory or motor deficits, but may not be available to families at home, caregivers at a childcare facility, or another environment in the absence of the occupational therapist. If early intervention is provided in a clinical setting, it is equally important for the occupational therapist to offer opportunities for the family and other caregivers to learn and practice therapeutic strategies and interventions to promote generalization in the natural environment.

The philosophy of inclusion extends beyond physical inclusion to mean social and emotional inclusion of the child and family.^{16,103} The Division of Early Childhood of the Council for Exceptional Children (DEC) and the National Association for the Education of Young Children (NAEYC) support the philosophy of inclusion in natural environments with the following statement: “Early childhood inclusion embodies the values, policies, and practices that support the right of every infant and young child and his or her family, regardless of ability, to participate in a broad range of activities and contexts as full members of families, communities, and society. The desired results of inclusive experiences for children with and without

FIGURE 22-5 Family involvement supports the child in the natural environment.

disabilities and their families include a sense of belonging and membership, positive social relationships and friendships, and development and learning to reach their full potential”²² (Figure 22-5).

Occupational Therapy Early Intervention Practices

Occupational therapists promote a child’s development, independence, and mastery in physical, cognitive, and psychosocial functions. They guide and support families and caregivers, implement intervention strategies, and recommend technology to enhance the child’s functional abilities and developmental performance. Occupational therapists also provide opportunities for children with disabilities to participate in natural learning environments with typically developing peers.

Occupational Therapy in Natural Environments

Occupational therapists provide services in a broad range of natural environments, including the homes of grandparents or relatives and other community settings when desired by families and of potential benefit to children. By providing early intervention services in natural environments, they take advantage of the actual contexts in which the occupations and co-occupations of children and families occur.¹⁰⁹ Examples include participation in a mothers’ morning out, mother-infant play groups, petting a puppy in the park, and playing on a gym set. Occupational therapists provide services at neighborhood pools, consulting with swimming instructors, and collaborate with librarians to create storytime sessions for young children with autism. Practitioners often make recommendations for increasing the child’s participation in dressing and bathing. Opportunities for learning in natural environments appear to be most effective for addressing the developmental needs of young children when the opportunities are interesting and

FIGURE 22-6 The occupational therapist uses materials in the childcare center to achieve the child's fine motor goals.

engaging and provide children with contexts for exploring, practicing, and mastering competence.²⁶

Natural intervention strategies use incidental learning opportunities during the child's typical activities and interactions with peers and adults (Figure 22-6), follow the child's lead, and use natural consequences. Intervention strategies that occur in real-life settings promote the child's acquisition of functional motor, social, and communication skills (Figure 22-7).^{25,74} When skills are learned in the natural setting, it is more likely that they will generalize to other activities and environments (Figures 22-8 and 22-9).⁴⁸ Two key advantages of providing occupational therapy in natural environments are that children tend to be more comfortable in familiar settings such as their homes and that teaching caregivers to implement natural learning opportunities within the daily routines of the child and family is feasible and practical¹⁰⁷ (Figure 22-10). Interventions in natural environments require the occupational therapist's ingenuity to develop strategies that are acceptable and supported by the caregiver(s).^{8,38}

Observation of the family and child at home allows the occupational therapist to be realistic in suggesting goals that are based on the resources available, problem-solve issues unique to the home environment, and individualize the program to meet the family's interests and needs. Intervention sessions can include not only the parents but also grandparents,

FIGURE 22-7 Inclusive settings support peer interactions and learning.

FIGURE 22-10 Play with peers in natural environments helps the child generalize newly learned skills.

childcare providers, and siblings, each of whom can promote the infant's development and participation.

Providing therapy in natural environments presents several challenges from the perspective of therapy providers, families, and governing bodies (particularly state and local agencies),⁷⁸ and research findings suggest that occupational therapists do not always consistently implement family-centered practices in the natural environment.^{18,32} To provide services effectively in natural environments, occupational therapists must be creative and flexible, taking advantage of teachable moments in children's play activities. For example, the occupational therapist may have plans to use the childcare center's playground for sensory motor activities and use the activity table inside to practice fine motor skills, only to find that it is a rainy day and the children cannot go outdoors. When arriving at the classroom, she or he sees that the children are engaged in a rainy day activity of playing dress-up and immediately uses the dress-up activity as the context for the intervention, developing a play scenario that includes donning the costume selected by the targeted child.

Family-Centered Intervention

In family-centered intervention, the occupational therapist is guided by family priorities and respects the level of involvement in intervention that various family members choose to have. One important way for occupational therapists to increase the effect of services is to make the program relevant to the family's lifestyle and time commitments.¹⁰¹ Therefore, occupational therapists select and recommend activities to improve behaviors and skills that the children can generalize to their daily routines at home, school, and community. Family demands and supports are always considerations when discussing home programs with parents. One mother stated the following: "There are times when even an acceptable amount of therapy becomes too much—when your child needs time just to be a child, or when you need time to be with the rest of the family. It is okay to say 'no' at those times, for a while. Your instinct will tell you when."⁹⁷ Occupational therapists support families by listening to them and giving positive feedback regarding parenting skills.²⁹ Because daily routines in a family with a child who

has a disability can take an excessive amount of time and energy, suggestions that make routines easier or that can easily be incorporated into the daily routine are the most successful. For example, occupational therapists make suggestions for positioning and handling to enhance the efficiency of feeding and for adapting a bath seat to make bathing less taxing. The parent can incorporate therapy strategies to encourage bilateral coordination or range of motion at bath time, or an older sibling can encourage the infant to reach for toys while the mother cooks dinner. Coaching parents is one method that combines listening with teaching and encourages parents' active participation.

Coaching Families

Coaching is a family-centered approach that takes advantage of adult learning styles. Natural environments offer opportunities for occupational therapists to coach caregivers to gain self-confidence and assume responsibility in their child's daily care. Occupational therapists also coach other professionals to implement intervention strategies that they have developed. Coaching is characterized by the coach (the early interventionist), who "has specialized knowledge and skills to share about growth and development, specific intervention strategies, and enhancing the performance of young children with disabilities," and the learner (the caregiver), who "has intimate knowledge of a child's abilities, challenges, and typical performance in a given situation, ... daily routines and settings, lifestyle, family culture, desirable goals for [the learner] and the child" (p. 38).⁹³ The coach supports the learner and the child to achieve outcomes through a process described by Rush and colleagues⁹³:

- **Initiation:** The coach or learner identifies a need, and a joint plan is developed that includes the purpose of the coaching and specific learner outcomes.
- **Observation:** The coach may use four possible types of observation: (1) the learner demonstrates an existing challenge or practices a new skill while the coach observes; (2) the coach models a technique, strategy, or skill while the learner observes; (3) the learner consciously thinks about how to support the child's learning while performing the activity; and (4) the coach and learner observe aspects of the environment to determine how they may influence the situation.
- **Action:** This includes activities that take place at times other than when the coach and learner are in contact, such as the learner's practicing the new skill or strategy or engaging in a situation that may be discussed with the coach.
- **Reflection:** The coach uses questioning and reflective listening and provides reflective feedback and joint problem solving to help the learner understand how to analyze practices and behaviors. The coach then reviews the discussion or observes the learner to assess the learner's understanding. The learner's strengths, competence, and mastery are acknowledged.
- **Evaluation:** The coach evaluates the effectiveness of the coaching process with the learner and with himself or herself. Evaluation with the learner may not take place every time the coach and learner have discussions; however, the coach should self-evaluate to determine if changes need to be made, if the coach is assisting the learner to achieve identified outcomes, or if the coaching needs to continue.

FIGURE 22-11 The coaching process. (Adapted from Rush, D. D., Shelden, M. L., & Hanft, B. E. [2003]. Coaching families and colleagues: A process for collaboration in natural settings. *Infants and Young Children*, 16(1), 33–47.)

- Continuation: The results of the coaching session are summarized and a plan is developed for what should occur before and during the following session.
- Resolution: Both the coach and learner agree that identified outcomes have been achieved. The learner has increased competence and confidence to support the child's learning opportunities in the natural environment (Figure 22-11).

Coaching may be especially helpful in a service delivery model in which one early intervention team member is the primary provider for the child and family (Case Study 22-2). In this model, the other team members provide coaching on a consultative basis for the family and also provide coaching to the primary service provider. As in any team process, coaching requires that team members use good communication skills and trust and respect one another. Opportunities for communication and collaboration are crucial to the success of coaching, thus necessitating support from early intervention programs and agencies for additional meeting times and co-visits. It is important for team members to understand that coaching is not a linear process, but rather a process in which feedback is used to refine solutions, as needed.

The occupational therapist may work with caregivers to plan and carry out therapeutic interventions for the child by integrating developmentally appropriate activities that are challenging for the child into daily routines and family-identified activity settings. For example, the occupational therapist coaches parents in methods for developing the infant's grasping competence as it relates to play with a favorite toy or finger

feeding. After identifying an area of delayed performance, such as eating and participating in mealtime, the occupational therapist collaborates with caregivers to identify natural learning opportunities in which the child participates in mealtime. To promote generalization of the self-feeding performance, the occupational therapist and caregivers can use snack time activities in an environment that enables the child to focus, allows sufficient time, and uses appropriate (easy to eat) foods. The selected eating activity involves the "just-right" challenge to the child across domains (including sensory, motor, cognitive and social domains).

Most developmental skills and play occupations are learned in the context of social interaction, including give and take with another child or adult, eye contact, praise, and delight at successful attempts. Integrating therapeutic strategies into the daily routine (Figure 22-12) requires a behavior change on behalf of the caregiver. Caregivers will benefit from continued coaching with modeling and reinforcement of behaviors in addition to practicing the therapeutic strategy with the occupational therapist and receiving feedback.⁶⁶

Use of Telehealth to Facilitate the Coaching Model

A telehealth service delivery model allows occupational therapists to use coaching within a family-centered framework. For example, an occupational therapist may use telehealth to coach a caregiver on strategies to assist a child in gaining independence in self-feeding using a spoon. Using an electronic tablet with videoconferencing software, the occupational

CASE STUDY 22-2 Alana

Background

Alana is a 2-year, 3-month-old child who was diagnosed with developmental delay. She receives early intervention services because of delays in motor, self-care and adaptive, and social-emotional domains. Findings from her initial assessment suggest that Alana's delays may be related to problems with sensory processing and appears to seek excessive amounts of sensory stimulation. Karen, the occupational therapist, is Alana's primary service provider. Alana's mother, Carmen, has requested that services be provided in the family's home at this time, so Karen has been making home visits once weekly. During the IFSP, the family identified that Alana has difficulty falling asleep. They would like the early intervention team to address this issue.

Intervention

At the first home visit, Carmen mentioned that Alana had been difficult to get to bed at night. Karen hypothesized that Alana's struggle to calm down in the evening and fall asleep may relate to her sensory processing difficulties. Karen initiated a coaching relationship with Carmen by asking her if she would like to work together to explore ways to help Alana sleep better. Carmen enthusiastically agreed.

Karen asked Carmen to explain what she and her husband, Ramon, had already tried with Alana during bedtime. Carmen explained that they typically gave Alana a bath, let her watch a video, and then moved into her room for some quiet time before going to bed. However, Alana, who recently switched from a crib to a toddler bed, refused to stay in bed. Instead she would pull her toys out, jump on her mattress, and run around her room, becoming increasingly active as the night wore on. Eventually, several hours later, Alana would crash on her bed and fall asleep. Carmen thought that the sleep problems were causing tension between her and Ramon because they were getting less sleep and becoming easily frustrated with each other.

Karen told Carmen that she suspected that there was a relationship between Alana's sensory processing and her difficulty falling asleep. She provided Carmen with two suggestions of strategies to incorporate increased sensory input to put into action before the next visit: (1) give Alana more opportunities for play that incorporated movement, such as climbing and crawling, before initiating the bedtime routine; and (2) use a textured bath mitt during the bath. Karen decided that it would be beneficial to observe Alana's bedtime routine, so she scheduled her next visit in the evening. When she arrived, she asked Carmen what happened when the sensory-based suggestions were implemented. Carmen reflected on the last several days and replied that it was difficult to give Alana more play time because of the late hour that the family arrived home after picking her up from day care. Carmen did think that the textured bath mitt helped calm Alana during her bath, but Alana continued to take a long time to fall asleep.

During her observation of the bedtime routine, Karen noted aspects of the routine that could be strengthened to support Alana's sensory needs and behaviors that were not necessarily sensory-based, but more likely a result of typical development in the toddler stage, such as Alana's refusal to go to bed. On arrival, Karen followed Carmen and Alana into the bedroom and Carmen turned on the video. Alana was running around the room in circles while the video, a cartoon with very little action, played. Karen asked Carmen if she had a video with characters that danced and sang. Carmen changed the video and soon Alana was dancing along with the characters. Karen explained that the dancing provided both movement and muscle work and helped meet Alana's sensory needs. After the video, she observed that Alana enjoyed her bath and sought out sensory experiences like splashing and rubbing soap on her arms and legs. Karen modeled to Carmen how to use the loofah sponge to provide deep pressure to Alana's arms, legs, and back while in the tub and how to use the towel to do the same while drying her off.

After the bath they went to Alana's room. Carmen shut the blinds and pulled the dark shades so that the room was dimly lit. Although Alana was calm when entering her room, she became increasingly active as the room got darker and the house grew quieter. Karen asked Carmen if she had an extra nightlight and Carmen placed one in the corner of Alana's room. Karen turned on Alana's small radio to the classical station at a soft volume. Karen explained that Alana might need extra visual and auditory input to help stay calm. After looking at books in bed, Carmen told Alana it was time to go to sleep. Alana began to protest, but Karen quickly suggested that they play the "Cloud Game" before going to sleep. She took Alana's pillow and placed it on Alana's back with Alana lying on her stomach. Karen pressed the pillow down firmly and told Alana "the clouds are carrying you off to sleep." Karen traded places with Carmen and encouraged Carmen to continue providing the deep pressure to Alana until Alana indicated she was ready to go to sleep.

After they left the room, Carmen called Ramon into the kitchen so that they could speak with Karen. They were both excited that Alana was asleep and how much easier it had been when using the strategies Karen suggested. Carmen and Ramon planned to implement the techniques and evaluate their effectiveness at the next visit.

Follow-Up

Karen arrived at Alana's home the next week and was greeted by Ramon. He told Karen that Alana continued to show improvement in going to sleep and was even asking to go into her bed so she could play the "Cloud Game." Karen, Carmen, and Ramon decided that further intervention regarding Alana's sleep was not needed and ended the coaching relationship for that particular need.

therapist can observe the caregiver positioning the child at mealtime and assisting the child in using a spoon, provide instruction to the caregiver on therapeutic techniques (e.g., active assistance, backward chaining, or postural supports), and observe the caregiver implementing the therapeutic techniques. The occupational therapist can provide feedback, discuss the caregiver's concerns, and problem-solve strategies for skill progression (Figure 22-13). Research suggests that the use of telehealth within early intervention services promotes family participation, supports child and family outcomes, and results in high levels of family satisfaction.^{11,44,57} See Table 22-1e on the Evolve website for relevant research on telehealth and young children.

FIGURE 22-12 The occupational therapist adapts communication to promote the child's independence in using the toilet.

Telehealth also supports collaboration among specialists, remote providers, and families for the purpose of interdisciplinary evaluation, care coordination, and team-to-team consultation.⁴¹ Evaluations by an interdisciplinary team of specialists (e.g., physicians and rehabilitation professionals) administered through telehealth technologies in collaboration with families and local providers have been perceived as effective as in-person evaluations, and a high level of satisfaction among participants (families and providers) was reported. Additionally, significant cost savings because of the decreased need for travel to specialty clinics, enhanced care coordination, family empowerment through participation in the evaluation and discussion of recommendations with providers, and mutual enhancement of professionals' skills occurred as a result of a telehealth service delivery model. Factors to consider when deciding who would benefit from telehealth services include the complexity of the child's condition; child's context and natural environments; family's preferences and access to technology (Box 22-4); nature and complexity of the interventions to be provided; requirements of the practice setting (i.e., early intervention program); and knowledge, skill, and competence of the occupational therapist¹ (see Figure 22-14).

Occupational Therapy Interventions

Primary outcomes of occupational therapy intervention for infants and toddlers are play, including object and social play; social participation, including parent-child, peer-to-peer, and group interactions; and self-care, for example, eating and sleeping. Intervention principles and strategies for each area are described in this section. See Table 22-3 for examples of evidence-based interventions for infants and toddlers.

Play is an essential element of occupational therapy with a young child and has been defined as both an intervention means (strategy to promote developmental progress) and goal (occupational outcome).⁸³ Therefore, occupational therapy interventions improve play outcomes and use play as a therapeutic context to promote developmental skills.

Play as an Intervention Outcome

Play is a most important child occupation. It is open-ended, self-initiated, self-directed, and unlimited in its variety. Play can

FIGURE 22-13 An occupational therapist uses telehealth technologies to coach a child's caregivers' on a backward-chaining technique to promote the child's independence with self-feeding.

BOX 22-4 Telehealth Models in Early Intervention

The remote therapist collaborates with the following:

- The child and family in the child's natural environment
- The child and family and another provider on the child's IFSP team in the child's natural environment
- The child and family (and perhaps other providers on the child's IFSP team) at a telehealth conferencing site in the child's local community
- An interpreter who is in the home with the family or who is also remote and connected with the family via videoconferencing technology
- The IFSP team to participate in an IFSP team meeting remotely

Technology Options

- Use existing technology in the natural environment (e.g., computer, electronic tablet, smartphone).
- Loan equipment to the family to support a telehealth service delivery model.
- Technology is brought into the child's natural environment by the provider to support consultation and collaboration with a remote provider.
- Leverage existing technology infrastructure available within the child's community (e.g., state telehealth network site, public health department facility, community-based site with videoconferencing equipment).
 - A telehealth network site in the community is not considered a natural environment; however, recommendations

provided through telehealth by specialists and discipline-specific providers not available within the local community can be implemented by families and providers in a child's natural environment.

- When a non-natural environment provides access to a discipline-specific provider not available in the child's local community, and all other early intervention services are provided in the child's natural environment, services will meet OSEP requirements that the *majority* of services occur in the child's natural environments.

Benefits

- Improves access to services otherwise unavailable because of provider shortages
- Facilitates family-centered service provision with the child's family and other IFSP team members receiving consultation, coaching, and support from the remote provider via telehealth technologies in the child's natural environment
- Enhances knowledge and skills of local providers through consulting and collaborating with a remote provider with discipline-specific knowledge and expertise
- If session is recorded and archived via secure platform, recording may be used as a resource for families and IFSP team members to view and practice intervention strategies and promote integration of strategies into daily routines
- Supports more efficient use of interpreters with potential cost savings because of decreased travel

be exploratory, symbolic, creative, or competitive in nature (see Chapter 17). Table 22-4 presents the developmental progression of pretend play skills as these emerge in young children.^{64,83,99}

Learning how to play can be a goal of intervention, particularly for children with significant disabilities that affect multiple performance areas. Children with medically related disabilities may not develop play skills because of limited opportunity due to long hospitalizations, being connected to medical technology, or having impaired physical function. Toddlers at risk for autism may demonstrate rigid or stereotypic play that is missing important social and pretend elements. Children with motor disorders may have limited object manipulation or mobility to engage fully in sensorimotor play. Other children may experience deficits in play because of cognitive limitations or difficulties in social interactions. To increase a child's initiation and participation in play, the occupational therapist models playfulness in interactions with the child. Whether it is a game of hide and seek, knocking down a pretend wall, or digging for a treasure in sand, the activity should elicit a sense of enjoyment and fun. Chapter 17 describes interventions that promote play occupations.

Play as a Means to Learning Specific Skills

The child's participation in play activities allows him or her to practice mastered developmental skills and learn new skills. Skills that are the foundation for engagement in other occupations, such as the ability to manipulate objects, problem-solve, and attend to tasks, can be developed and practiced

FIGURE 22-14 Using the toddler's own toys, the occupational therapist creates a social opportunity to promote joint attention while practicing perceptual motor skills.

during play. Occupational therapists and caregivers create play scenarios that encourage specific skills development. Intervention activities use objects and materials typically found in the natural environment (Figure 22-14), rather than items brought into the home by the occupational therapist (e.g., therapy balls).⁷⁸ Occupational therapists can show caregivers how to

TABLE 22-3 Examples of Evidence-Based Occupational Therapy Interventions for Infants and Toddlers

Goal Area	Developmental Problem	Evidence-Based Interventions	Occupational Therapist Coaching and Family Participation
Social play	2-year-old with Down syndrome	Supported play with children with higher level development skills can increase performance. ^{99a} Computer or tablet activities encourage social interaction with peers. ⁶	Occupational therapist helps parents create a play group for their daughter that includes other neighborhood children. Occupational therapist helps parents select computer play activities that encourage turn-taking and social interaction.
Sensorimotor play	6-month-old with cerebral palsy	Switch-operated toys increase the infant's engagement in a play activity. ^{6,62}	Families can obtain switch-operated toys from local adapted toy libraries. Occupational therapy clinics may lend switch-operated toys to families.
Caregiver-infant interaction	12-month-old with sensory processing problems, at risk for autism spectrum disorder	Sensitive responding to infant's cue increases the infant's responsiveness. Imitating the infant's actions can increase the infant's initiation of social gestures and responsiveness. ⁶¹	The occupational therapist coaches parents in how to read the infant's nonverbal cues, imitate the infant's actions, and respond positively to the infant's communication attempts.
Peer interaction	28-month-old with cerebral palsy	Social toys, such as puppets and dress-up clothes, can promote social interactions among young children. Child-directed play promotes more positive social interaction than adult-directed play. ⁵⁸	Families can encourage the child's social interaction with peers using socially oriented toys such as dolls, puppets, dress-up, and toys that require sharing.
Eating	8-month-old infant born preterm with low oral muscle tone and jaw instability	Feed in an infant seat at 85 degrees upright, with small blanket rolls on the sides to support the head in midline. Using a flat latex-covered spoon with hand supporting the lower jaw can improve the infant's tongue, lip, and jaw movements for efficient suck-swallow of pureed foods. ^{30,33}	Mother feeds the child using the adapted infant seat. The occupational therapist coaches the mother in jaw support techniques. The occupational therapist provides the family with small flat spoons for improved suck-swallow.
Sleeping	2-year-old with self-regulatory difficulty	Limit nighttime sounds and lights; establish a nighttime routine that reinforces quiet behavior and does not reinforce active behavior. Weighted blankets may be helpful when use is carefully monitored. ^{53,88}	Families can establish a nighttime routine that helps the child quiet, establishes an environment that allows low arousal, and provides the child with a preferred sensory environment associated with low arousal (e.g., deep pressure, white noise, very dark).

create games and toys out of everyday objects such as plastic containers and wooden spoons, develop specific arm movements, facilitate sequential pretend play cooking or make music, and/or enhance joint attention. For example, a toddler with hemiplegic cerebral palsy plays with stuffed animals and uses his or her affected arm to stabilize the trunk when reaching into a bin to remove the toys. This activity supports a motor-based occupational therapy goal for the child to incorporate the affected arm in play and may be repeated for practice with gradual adaptation (e.g., the toddler gives the animals a hug before putting them back in the bin); it is a learning opportunity that uses play as initiated by the child with his or her own toys.

When a child has motor delays, the occupational therapist works with caregivers to determine how various age-appropriate toys, games, sensorimotor experiences, and other strategies may be incorporated into the child's daily routine to remediate

motor skill deficits. For example, a family who enjoys hiking may encourage their toddler to pick up fallen leaves on the trail and put them into a small bag, an activity that encourages refined grasp and release skills. A caregiver in an infant's child-care center can play peek-a-boo with the infant to encourage reaching and grasp.

Engaging the Child in Play

To engage the infant or toddler fully in play as an outcome or intervention context for skill development, the therapists provides activities that do the following: (1) arouse and engage the child, (2) encourage and prompt practice of emerging developmental skills, (3) reinforce learning of higher level skills, and (4) promote transfer of play skills to multiple activities.

Arousal and Engagement

Occupational therapists use a variety of methods to stimulate the child's interest and motivation to engage in a play activity.

TABLE 22-4 Developmental Levels of Play Skills (0-2 years)

Play Category	Approximate Age (months)	Definition	Examples
Sensorimotor	2-4	Child explores objects, practices motor skills, enjoys sensory motor exploration	Child bounces when held, bangs rattles, mouths toys
Relational	6-10	Child relates one object to another	Child holds two objects, stacks blocks, places one object in or on another
Functional-conventional—discriminative; realistic object play	10-12	Child relates object in a social, conventional manner; uses objects for functional (real) purposes	Child places toy phone on ear, stirs with spoon in cup
Symbolic			
Pretend self; single play actions	12-18	Child relates objects to self in pretend; one-step play actions	Child pretends to drink from a cup, brush own hair
Child as agent—passive; substitute object play; multiple play actions	18-24	Child extends familiar actions to dolls, figures; can use an object as a substitute for the actual object; carries out a sequence of two or more play actions	Child feeds doll, pretends to brush teddy bear's hair, puts doll in cart to ride; pretends that a block is an airplane or a car
Child as agent—active; imaginary objects	24-30	Child includes dolls or figure action in short scenario; pretends an action without the actual object.	Child pretends that teddy bear holds a cup, doll talks on the phone; drinks from an imaginary cup
Child uses imaginary objects in complex play actions	30-36	Play is complex, with multiple steps in planned story	Child plans and carries out snack time with dolls; plays house in role as mother

Adapted from Lifter, K. (2000). Linking assessment to intervention for children with developmental disabilities or at-risk for developmental delay: The developmental play assessment (DPA) instrument. In K. Gitlin-Weiner, A. Sandgrund, & C. E. Schaefer (Eds.), *Play diagnosis and assessment* (2nd ed., pp. 228–251). New York: Wiley; Takata, N. (1974). Play as a prescription. In M. Reilly (Ed.), *Play as exploratory learning* (pp. 209–246). Beverly Hills, CA: Sage.

The key to optimal arousal is a comfortable environment, with sensory elements that promote the child's self-regulation. For certain infants, self-regulation may require modifications to the environment to lower arousal, such as lowering the lighting, turning off the television,² or using other preferred sources of sensory input, such as rocking rhythmically to music.⁷² Providing the infant's preferred types and levels of sensory input supports self-regulation and optimal arousal. An infant who has optimal arousal is alert and attentive and can engage in an activity.

Another method for engaging the child and sustaining interest is to use the child's preferred objects or activities. The caregiver can help identify toys, materials, and objects of high interest. The play activity also needs to be developmentally appropriate—that is, at the child's developmental play level. Features of a play activity that can motivate or interest a child include toys that have interactive components.⁵¹ Toys that are known to be preferred (e.g., trains are often preferred by children with autism) and activities that are known to be personally meaningful and intrinsically motivating to that child should be included.^{9,98} The meaningfulness of the play activities can be confirmed by the parents and observed in the child's level of engagement. Preferred play contexts can create and facilitate meaningful social interactions between the child with a disability and the occupational therapist or caregiver. When the child is engaged in a meaningful play activity, the occupational therapist can introduce variations to play or developmentally

higher level play activities that elicit and challenge the child's emerging skills.⁷¹

Allow Practice of Emerging Developmental Skills

Because they are fun, play activities are easily repeated and easily varied. Engaged children may stay focused on play for long periods, allowing the type of practice that can result in skill mastery. Occupational therapists design activities to target, practice, and extend specific skills, such as building a train track on the carpet, filling a sand bucket, or making dozens of snakes out of Play-Doh. Unstructured play activities can easily be adapted or graded to promote a child's higher level response (e.g., the child can line up or stack blocks but also can create designs and build houses and bridges). A play activity that fits well into the caregiver's routine is more likely to be repeated; in this way, play skills become incorporated into the daily life of the child and family.

Reinforce Higher Level Skills

As the child plays, the occupational therapist provides appropriate (and almost universally positive) reinforcement. Because play is often internally reinforcing, the need for praise and verbal encouragement (external reinforcement) can be minimal. Often the occupational therapist's interest in and observation of the child's play are reinforcing; positive affect and enjoyment also reinforce the child's actions. Peer interaction during play can provide modeling and naturally reinforce the child's effort.⁵⁸ The occupational therapist carefully plans activities that are intrinsically reinforcing, such as climbing up and jumping into

FIGURE 22-15 Play in the sandbox offers an opportunity for children to practice sensorimotor function and social play skills.

FIGURE 22-16 Adapted seating promotes good postural alignment for fine motor play at a table.

pillows, walking on a curb or the edge of a sandbox, or sharing a game with friends (Figure 22-15). In addition, the occupational therapist clinically reasons the timing of reinforcement (sometimes delayed feedback results in the sustained child performance), whether to use specific or general feedback (usually the child benefits from more specific feedback), and when to fade feedback (as the child becomes more independent, the occupational therapist or caregiver gives less feedback). Often play activities, particularly social play with peers, are intrinsically rewarding and can reinforce new skill development simply because play is fun.

Facilitate Generalization of Play Skills

The occupational therapist's goal when encouraging new skill development is that the child can generalize performance to a range of play activities and environments. Because play is usually embedded in the daily routines of young children, occupational therapists coach caregivers on how to use a variety of toys or play activities to support the child in generalizing newly learned skills. The occupational therapist works with families to determine the natural environments in which play takes place or environments in which caregivers and children spend time, such as in the backyard, the child's bedroom, or a community playground. Childcare providers may also receive support to learn strategies and approaches that will enhance the child's play and support generalization of emerging skills.

Adapting Play: Role of Assistive Technology

When a child has significant disabilities or developmental delay, the occupational therapist and family may provide adapted seating or adapted stander, adapted toys, or modify the

environment to enable the child's play.⁶² For children with low postural stability and limited extremity movement (e.g., a child with spinal muscular atrophy), a supportive seating device is needed to promote the child's use of the eyes and hands together in play activities. Adapted chairs (e.g., Rifton toddler chairs [Rifton Equipment, Rifton, NY]) can include head, trunk, arm, and foot supports so that the child has a stable trunk, head positioned at midline, and increased control of extremity movements (Figure 22-16). Prone standers also promote the child's alignment and postural stability to use hands and eyes for play activities. Standing with support may be the child's preferred position for interaction in play activities with peers. For toddlers with minimal arm and hand movement, the occupational therapist may suggest use of battery-operated toys with adapted switches or games on electronic tablets that use simple touch. A wide range of games that require simple motions to operate are available for tablets or computers. Tablets and battery-operated toys can be accessed with the child in a supported sitting or side-lying position. Computer play can promote social interaction between children with disabilities and their peers.⁴⁶

Toys and materials can be adapted so that they are more accessible and easier for the child to handle. Occupational therapists or caregivers may place hook and loop fasteners on doll clothes to replace small buttons, use enlarged handles or special grips so that the child can hold a toy, or recommend use of a tray as a stabilizer for toys. Switch-activated toys can be operated by a button or squeeze switches that require a simple hand motion.²¹ Families and occupational therapists collaborate when selecting assistive technology for the child

because devices can be expensive and need to be appropriate for the home environment, and technology requires training for optimal use.

Social Interaction and Participation

Positive social interactions are foundational to learning and developing relationships, suggesting the importance of nourishing social emotional growth in the first years of life.^{35,96} Children may have delays in social-emotional competence when they spend their first weeks of life in a neonatal intensive care unit or have significant medical and developmental problems that affect cognition, communication, and/or self-regulation. Infants and toddlers with sensory processing difficulties can be challenging for caregivers, particularly infants and toddlers who appear to have hypersensitivity to touch or sound—primary sensations of human interaction. Toddlers with autism spectrum disorder by definition have delays in social interaction skills, which include communication delays, rigid or repetitive behaviors, and difficulty understanding and responding to nonverbal communication. Social competence can also be delayed when a child has cognitive delays. The environment can also constrain social-emotional development; for example, caregivers with mental health disorders, limited social supports, and limited parenting skills can negatively affect a young child's social-emotional growth, particularly in the case of child neglect or abuse. Occupational therapists provide interventions that support the child's social-emotional development in the context of the family.

Parent-Child Interaction

Social skills are among the first skills that an infant develops; the infant demonstrates eye gaze and cuddling with caregivers in the first weeks of life and, by 6 to 8 weeks, social imitation of smiling. The purposes of infants' first social interactions are to communicate discomfort and hunger as well as pleasure. An infant who has sensory processing disorder or is at risk for autism spectrum disorder may show delays in these first social skills. For example, he or she may cry when picked up or cuddled, sleep only for short periods, feed poorly, and smile infrequently. These behaviors are difficult for caregivers to manage, can be stressful, and may have a negative effect on caregiver-child interactions.¹⁰⁵

Occupational therapists facilitate caregiver-infant interaction by observing the interaction, listening to caregiver concerns, and coaching caregivers on reading cues, responding with sensitivity, and supporting the infant's communication efforts. For an infant with cerebral palsy and low muscle tone, the occupational therapist may model handling and holding that increase the infant's comfort and ability to interact (e.g., holding the infant more upright during a feeding interaction). Occupational therapists can teach caregivers massage or touch-based interventions that can calm the infant and reduce tactile hypersensitivities to promote optimal arousal.⁹ Touch-based interventions with neonates are effective in promoting bonding and social-emotional development.¹⁰⁰

Caregivers may desire interventions that promote their interactional skills and enhance their relationship with their child, particularly when children have delayed communication skills or demonstrate behaviors consistent with autism. Often occupational therapists coach parents using relationship-based interventions.^{20,36,69} In these interventions, occupational

therapists teach and encourage caregivers to become more sensitive to the child's cues and more responsive to the child's communication efforts. Nonverbal interaction and imitation of the child's actions are emphasized. Modeling and coaching are key strategies that can promote increased caregiver sensitivity and responsiveness to the infant. Relationship-based interventions have shown promising positive effects on mother's responsiveness and child's self-regulation, social competence, and adaptive behavior.^{9,61,69}

As infants become toddlers, most parent-child interactions occur in joint activities, requiring the young child to attend to the activity and caregiver. The caregiver reciprocally interacts with the toddler in the context of purposeful play.⁶¹ Joint attention and sustained interaction can be limited or missing in young children with developmental delays or disabilities. Occupational therapists promote joint attention by designing a context that supports joint engagement, selecting an activity of high interest, modeling for the caregiver and child, and supporting the child's engagement with positive affect and reinforcement. For children who are hypersensitive to sound or touch, a quiet environment and less stimulating activity are carefully selected. The occupational therapist selects specific cues, prompts, and reinforcement to encourage but not overwhelm the child in the social interaction.

Peer Interaction Interventions

When toddlers approach 3 years of age, they become more interested in their peers. Occupational therapists promote peer-to-peer social interactions and social play opportunities in childcare centers, preschools, and other natural environments. These interventions use specific strategies to promote social competence in the context of naturalistic play.⁹ For example, the occupational therapist selects engaging and preferred activities in natural social elements (e.g., a turn-taking game or art activity with shared materials) and with peer models who have higher level social skills. Computer and tablet activities have been shown to increase the engagement of young children and have been used with dyads or small groups of children.^{6,45} Interactive or social toys, such as puppets, dress-up, dolls, trucks, and housekeeping toys, can promote social interaction in children with cognitive delays, particularly when they are paired with children who have higher level cognitive skills.⁵⁸ In these play groups, the occupational therapist models and reinforces social interaction skills and promotes interactions by designing activities that require sharing, imitation, or social interaction. Often young children need supports, such as prompting or cueing, to enter a social activity, stay in or sustain attention to the activity, or leave the activity using socially appropriate behaviors. The occupational therapist is fully engaged in the child's social interactions to provide timely cueing and reinforcement. The occupational therapist coaches caregivers in the strategies that most effectively support the child's social participation.

Adaptive Behaviors: Eating and Sleeping

Feeding and sleeping are essential daily activities that are often the focus of occupational therapy intervention. These adaptive behaviors are primary occupations of infants and toddlers and are strongly linked to health, development, and growth. Feeding and sleeping are also primary concerns of the caregivers, and infants who struggle in these areas can create high stress and great concern for caregivers. When infants struggle

to eat or sleep, occupational therapists and families often prioritize interventions to improve these functional areas.

Feeding and Eating Problems

Feeding problems are common in infants with developmental disabilities and may be linked to oral sensorimotor problems, oral structural abnormalities, aspiration, self-feeding delays, failure to thrive, and selective eating.^{17,47} For example, children with cerebral palsy may have difficulty with sucking, jaw stability, or coordination of swallow and breathing. Infants born prematurely may have oral sensitivity or low muscle tone, with related problems in suck-swallow-breathe coordination. Other infants may have dysregulation or irritability that affects eating and caregiver-infant interaction during feeding. Children who have multiple medical problems or cerebral palsy can have significant feeding problems in the first years of life. Infants with medical problems may not have sufficient oral motor skills for feeding by mouth, and receive nutrition first through a nasal-gastric tube and then through a gastrostomy tube. These infants miss the oral motor and oral sensory experiences needed to develop feeding competence.

Interventions to Improve Feeding Mechanics

To improve the mechanics of eating, occupational therapists develop and recommend strategies to improve the oral motor skills of sucking, chewing, and swallowing, the components of feeding competence. Infants with cerebral palsy can exhibit oral motor weakness and, as a result, struggle to eat. They benefit from additional trunk and head support during eating to optimize a coordinated suck-swallow-breathe pattern. Firm support to the head and trunk through adapted seating or therapeutic positioning can promote optimal jaw and tongue movements during eating. Infant seating that includes firm and complete trunk and head support also positions the infant for safe swallowing and facilitates higher level feeding skills. Occupational therapists may recommend adapted equipment for positioning during eating or may teach caregivers holding techniques to provide additional support of the infant's posture. Selecting specific nipples can promote improved sucking coordination, and flat spoons can enable the infant to take in food with minimal tongue and lip movement. When a child has difficulty with jaw or lip closure, or when tongue movement is insufficient for safe swallowing, occupational therapists also teach caregivers oral handling techniques that support the jaw. Chapter 14 describes occupational therapy feeding interventions in depth. In their systematic review of occupational therapy interventions for eating, Howe and Wang⁴⁷ reported that positioning,³³ oral support,³⁰ and pacing⁵² have positive effects on infants' feeding performance.

Infants with delayed feeding skills who exhibit immature oral motor patterns or oral sensitivity may benefit from sensory strategies. Sensory strategies include full body containment (swaddling to calm the infant), gentle and firm touch pressure to the mouth or inside the mouth, and non-nutritive sucking. For infants with oral sensitivities to textures and tastes, the occupational therapist systematically introduces different textures and tastes, from most to least preferred. These sensory experiences can be paired with positive reinforcement when the child actively participates or attempts to eat. Non-nutritive oral strategies can help the toddler develop the oral motor strength needed to transition to oral eating.

When toddlers begin to eat solid foods, they may continue to need external trunk and head support in addition to leg and

foot support. The occupational therapist may recommend adapting a child's highchair to provide additional trunk support or may recommend purchasing adapted equipment. When recommending an adapted feeding chair, the occupational therapist considers the family's resources and priorities; he or she also identifies seating equipment that can grow with the child or be used for multiple purposes. As the child develops self-feeding skills, the occupational therapist may recommend adaptive equipment or supports to increase the child's success and can be easily implemented at home. The occupational therapist works with the family to determine which strategies are most acceptable and successful in promoting the child's self-feeding competence.

Caregiver-Infant Interaction During Feeding

Given the importance of caregiver-infant interaction during eating, occupational therapists also coach parents in methods and strategies to improve communication and interaction during feeding. Feeding a child who struggles to eat can be challenging and stressful for the caregiver.^{17,94} Caregivers are anxious about the child's health and growth in addition to their own ability to feed their child. By observing a caregiver-infant interaction during feeding, the occupational therapist can make recommendations on how to hold the infant, pace the feeding, read the infant's cues, respond to nonverbal cues, and maintain the infant's engagement. Using coaching techniques, the occupational therapist observes the feeding interaction and, with the caregiver, reflects on the feeding interaction to identify goals and strategies that might improve the infant's eating success. The occupational therapist also provides emotional support to caregivers when infants need high levels of support during eating, given the frequency of feeding interactions and the consequences of poor eating on growth and health. Studies on interventions to enhance mother-infant feeding interaction have shown that the infant's feeding competency and mother-infant interaction improve.^{48,87}

Sleeping and Rest

Many infants and toddlers with sensory processing problems, self-regulation difficulty, or autism spectrum disorders have sleep problems. Infants with sensory processing disorders or who are at risk for autism spectrum disorders often have disrupted sleeping patterns characterized by difficulty falling asleep or waking during the night. Between 40% and 80% of children with autism spectrum disorder have sleep problems⁵³ that can affect the entire family's sleep. When caregivers and children suffer chronic fatigue, family functioning and quality of life are negatively affected. Occupational therapists problem solve with families to identify how changes in routines or the sleeping environment can help children regulate their sleeping patterns.

Interventions to promote sleep generally include behavioral and sensory strategies. The occupational therapist and family develop strategies to improve sleeping patterns by discussing the nighttime routine and problem-solving antecedents and consequences of the child's behavior at bedtime and during the night. They develop a plan to reinforce the child's independence in falling asleep and to reward quiet nighttime behaviors that prevent disruption of the entire family's sleep.

Hypersensitivity and sensory modulation disorders appear to be contributing factors to sleep problems.⁸⁸ Children with autism spectrum disorder who demonstrate sensory modulation disorder appear to be more prone to sleep difficulties than

those who do not have sensory modulation disorder.⁸⁸ In particular, children with high arousal who have difficulty filtering sensory stimuli appear to have difficulty lowering arousal to fall asleep. When infants or toddlers exhibit sensory modulation problems and sleeping difficulty, the occupational therapist and caregiver can identify sensory strategies to calm the child or to limit sensory stimulation at bedtime. A number of sensory strategies (e.g., rocking, music, total darkness, fan, white noise) can be tried to identify a good fit to the family's routine and

nighttime patterns ([Case Study 22-3](#)). Generally, a combination of sensory and behavioral strategies is needed, as well as consistency in applying the strategies. Occupational therapists encourage good sleeping habits and help the family identify and sustain routines and patterns that allow healthy rest and sleep. Because good sleeping patterns affect not only the child's development and growth, but also the family's mental health and quality of life, sleeping routines should remain a priority for the occupational therapist and family.

CASE STUDY 22-3 Amelia

Background

Amelia is a 24-month-old child referred to an early intervention program by her pediatrician because of concerns with gross and fine motor development, feeding, and suspected sensory processing problems. Amelia cries often in a distressful manner. Problem areas for Amelia, as reported by her mother, include uncooperative behaviors, "extreme meltdowns," whining and fussing, feeding problems associated with aversion to food textures, fearfulness, and poor balance. Although she sat independently at 6 months of age, she did not reach for and grasp an object until 8 months of age. She rolled from back to stomach at 9 months of age and began crawling at 11 months.

Assessment

An arena assessment model, with the child and primary caregiver interacting with one professional throughout the evaluation session and the other professionals observing and occasionally directly testing the child on specific skills and interviewing the caregiver, was used to determine Amelia's eligibility for services, and present levels of development and to facilitate intervention planning. The evaluation team consisted of a physical therapist and developmental interventionist. Participation by an occupational therapist was indicated; however, Amelia lives in a rural community with no access to an early intervention occupational therapist. The nearest hospital or outpatient rehabilitation clinic with an occupational therapist onsite was a 50-minute drive from the family's home.

Telehealth

The early intervention program in Amelia's area recently began using telehealth as a service delivery model to improve access to services for children living in rural and underserved areas. Amelia's mother gave consent for the use of videoconferencing to augment Amelia's early intervention services delivered in person. The physical therapist brought an electronic tablet with secure videoconferencing software to the family's home to enable the occupational therapist to participate virtually in the arena assessment.

During the assessment, Amelia was pleasant. She preferred not to be touched or held. The physical therapist took the lead in the arena assessment with the educational specialist (sometimes referred to as a developmental interventionist) assuming an observatory role. Amelia interacted with the examiner with caution after a brief period of ignoring her.

Her mother remained in the room and participated in the assessment. The occupational therapist interviewed Amelia's mother via videoconferencing to obtain a sensorimotor history. Her mother reported that Amelia had difficulty with being touched and pulled away when touched. Sometimes she stiffened and arched her back when held. Amelia's mother reported that she was irritable when held and resisted having her hair or face washed. Amelia was bothered by noises, such as those from the vacuum cleaner and hair dryer. Although her aversion to sound had improved, she remained apprehensive of toys with noises. Amelia became anxious in situations with auditory and visual stimulation, such as a shopping mall. Amelia enjoyed swinging and other activities with movement.

During the arena assessment, which consisted of a criterion-referenced, five-area assessment by the early intervention team, the occupational therapist observed Amelia via videoconferencing technology. The occupational therapist noted that when handled, Amelia exhibited a mildly defensive reaction to touch. The occupational therapist asked the lead examiner (the physical therapist) to place a mitt on Amelia's foot and a piece of tape on Amelia's hand. Amelia became upset when removing the mitt from her foot and cried when a piece of tape was placed on the back of her hand. She seemed unable to plan the movements needed to remove the mitt or tape. Although she seemed to be visually oriented, visual tracking was delayed and inconsistent. Amelia enjoyed vestibular input as she was held and moved up and down or in circular motions by her mother under the direction of the lead examiner. She also enjoyed upside-down positions. Through videoconferencing, her mother completed the Infant/Toddler Sensory Profile with the occupational therapist, and Amelia's sensory responses placed her in the sensory sensitivity category.

Summary and Interpretation

The arena assessment confirmed the pediatrician's concerns associated with Amelia's gross and fine motor development, feeding, and sensory processing and established eligibility for early intervention services. Based on the occupational therapist's observations and Amelia's scores on the Infant/Toddler Sensory Profile and the motor and adaptive subtests of the criterion-referenced assessment, the occupational therapist concluded that Amelia experienced significant difficulties in receiving and modulating sensory information. This was evident particularly in her irritability and intolerance to touch and auditory stimulation. Inadequate adaptive motor

CASE STUDY 22-3 Amelia—cont'd

function and feeding difficulties stemming from aversion to textures seemed to be related to her hypersensitivity. Amelia's tactile sensitivity probably contributed to her fine motor delays. Amelia's short-term goals were: Using sensory strategies to help her prepare for activities, Amelia would demonstrate the following: (1) consuming an increased number of foods and variety of textures; (2) improved tolerance of touch, as demonstrated by improved affect when she is held or touched; and (3) improved play skills so that she could stay in a social play interaction for 10 minutes.

Intervention

The team recommended weekly occupational therapy for Amelia, which became part of her IFSP. A modified computer capable of videoconferencing and an Internet access card not accessible for other uses was loaned to the family to facilitate remote occupational therapy services, which would otherwise be unavailable to Amelia and her family because of provider shortages in her area. The occupational therapist provided sensory-based strategies and recommendations to be implemented by Amelia's parents during daily routines. Co-visits through technology occurred with the physical therapist or educational specialist who was with the family in the home. The occupational therapist, within a transdisciplinary practice model, collaborated with Amelia's parents and providers to support implementation of strategies and recommendations in Amelia's natural environments.

The occupational therapist recommended play-based activities that incorporated vestibular, proprioceptive, and tactile input (as tolerated). Intervention included coaching

Amelia's parents and other providers to incorporate sensory strategies, such as crawling activities and sand and water play, and activities that encouraged the use of both hands at the midline to facilitate cooperative, bilateral hand use. The occupational therapist provided Amelia's mother with reading material and a video to help her understand how sensory processing affects behavior.

Amelia responded well to the intervention approach and began to show indications of more efficient sensory processing and the ability to modulate sensory input. Within a few weeks, Amelia began to mold to her mother when she held her and was less irritable and more relaxed in situations with auditory stimulation. After 3 months of therapy, Amelia's mother reported increased cuddling and noticeable improvement in eating. She attempted a greater variety of foods and displayed fewer aversions; feeding time was shorter; and it was no longer necessary to use the television as a diversion to get her to eat. Amelia began to interact more with her older sister and began to explore her environment. Play skills and hand use also appeared to increase.

Implications

The use of a telehealth service delivery model allowed Amelia's family to access occupational therapy services otherwise not available because of provider shortages in her area. Videoconferencing facilitated consultation, collaboration, and coaching among Amelia's early intervention providers and family and promoted improved outcomes by ensuring that the unique perspective and contributions of occupational therapy were available to Amelia's IFSP team.

Summary

- Early intervention programs serve children from birth through 2 years who have an established risk, have a developmental delay, or are at risk for developmental delay.
- A primary goal of early intervention programs is to enhance the capability of families to help their infants and toddlers develop and learn.
- Under Part C of IDEA, occupational therapy is a primary service to meet the functional needs of the child related to adaptive development; adaptive behavior and play, including social interaction; and sensory, motor, and postural development.
- Occupational therapists provide early intervention services in natural environments, are members of interprofessional teams, coach and consult with team members, and use family-centered approaches that respect cultural differences.
- Family-centered intervention means that family strengths are emphasized; families have control and make choices regarding interventions; and families and providers work together to ensure provision of optimal early intervention services.
- In early intervention, occupational therapy services are guided by the Individualized Family Service Plan, which defines the child's present level of performance; the family's resources, priorities, and concerns; a statement of major outcomes expected; the services necessary; and the natural environment in which services will be provided.
- The child's transition from early intervention to early childhood programs is carefully planned by the team; child and family supports are needed to facilitate a smooth transition.
- Natural intervention strategies use incidental learning opportunities, follow the child's lead, and use natural consequences to promote the child's acquisition of functional motor, social, and communication skills.
- Coaching, including occupational therapists coaching caregivers through telehealth, is a family-centered method of teaching that includes the occupational therapist's observation of the caregiver and the caregiver's observation of the coach, practice, reflection, and evaluation.
- Play, including adapted play, is a primary context and outcome for occupational therapy intervention.
- Occupational therapists promote social participation of young children by fostering positive parent-child interactions, using relationship-based interventions, and facilitating peer interactions in the context of social play.
- Occupational therapists provide interventions to enhance self-care and adaptive behaviors, including specific interventions to improve feeding, eating, and sleeping.

CHAPTER

23

School-Based Occupational Therapy

Susan Bazyk • Susan Cahill

KEY TERMS

Individuals with Disabilities Education Act	Individualized Education Program
Section 504 of the Rehabilitation Act	Health-related quality of life
Elementary and Secondary Education Act	School transitions
No Child Left Behind	Multitiered services
Least restrictive environment	Early intervening services
Integrated service delivery	Co-teaching
Related services	Coaching
	Response to intervention
	School mental health

GUIDING QUESTIONS

1. What major legislation guides and regulates education for students with and without disabilities?
2. How do the Individuals with Disabilities Education Act (IDEA), Section 504 of the Rehabilitation Act, and Elementary and Secondary Education Act (ESEA) affect the role of occupational therapists in schools?
3. What major amendments to IDEA have been implemented over the past 3 decades?
4. What are the major provisions of Part B of IDEA—free appropriate public education (FAPE) in the least restrictive environment?
5. How do occupational therapists provide services under Part B of IDEA, including referral, evaluation, individual education program (IEP), and interventions?
6. How are occupational therapy services that support students with and without disabilities integrated into the classroom and across school environments?
7. What are examples of indirect and direct occupational therapy services?
8. How do occupational therapists under the IDEA 2004, ESEA, and No Child Left Behind Act (NCLB) provide early intervention services (EIS) and response to intervention (RtI)?
9. How do occupational therapists promote school mental health within a multitiered, public health model?

The task of a sound education, Plato argued twenty-five centuries ago, is to teach young people to find pleasure in the right things. If children enjoyed math, they would learn math. If they enjoyed helping friends, they would grow into helpful adults. If they enjoyed Shakespeare, they would not be content watching television programs. If they enjoyed life, they would take greater pains to protect it (p. 39).³⁶

Education systems worldwide have the responsibility of preparing children for adulthood, and, therefore, most professionals agree that schools must provide the intellectual and practical tools needed for successful participation in classrooms, families, future workplaces, and communities.³⁸ Occupational therapists help people of all ages engage in and enjoy meaningful and purposeful life activities; in schools, this means helping children participate in the academic, social, extracurricular, independent living, and vocational activities needed for student success and transition.^{2,107} Given occupational therapy's focus on a broad range of occupational performance areas (e.g., education, social participation, play, leisure, work, activities of daily living [ADLs]), it is not surprising that occupational therapists enjoy a long tradition of providing services in schools and early intervention settings, making these the primary work environments for occupational therapists.⁵⁷

Practice in schools is influenced by an educational versus medical model requiring a set of knowledge and skills unique to occupational therapy and school settings. School-based occupational therapists must combine a sound understanding of occupational therapy's domain of practice with a current understanding of the school context, which is guided by federal laws and regulations. In a U.S. survey, school-based occupational therapists identified the greatest need for knowledge and skills in the areas of federal and state regulations, role of occupational therapy, evaluation and intervention approaches, writing IEP goals, collaboration, and evaluation for assistive technology.²¹ This chapter provides information to prepare occupational therapists for school-based practice.

Federal Legislation and State-Led Initiatives Influencing School-Based Practice

Federal policy, which is shaped by trends in health and education practice, directly influences services for children. In the 1930s, federal legislation establishing the rights of children

FIGURE 23-1 Timeline of important legislation and developments influencing occupational therapy's role in schools.

related to education and general well-being were established. However, it was not until 1975, with the introduction of the Education for All Handicapped Children Act (EHA; P.L. 94-142), that policy specifically addressed the needs of children with disabilities. This legislation was championed by parent advocacy groups who were seeking normalization, or opportunities for their children to participate fully in everyday routine activities.¹⁰⁴ The introduction of this legislation occurred at a time when it was estimated that more than 1 million children with disabilities were excluded from school, and many were institutionalized. Although occupational therapists' early work with children occurred primarily in medical rather than educational settings, a rapid shift to practicing in schools took place with the EHA legislation. Figure 23-1 depicts a timeline of important legislation, policy changes, and practice developments influencing school-based practice. The following section provides a more detailed discussion of contemporary legislation, such as IDEA, ESEA, and Section 504 of the Americans with Disabilities Act (ADA), as well as the major shifts in occupational therapy practice that have been influenced by this legislation.

Individuals with Disabilities Education Act

The EHA has been reauthorized several times, with the current iteration of the legislation known as the Individuals with Disabilities Education Act (2004; P.L. 108-446). In keeping with the intent of the original legislation, IDEA requires that states and public educational agencies provide a free appropriate public education (FAPE) to children with disabilities in the least restrictive environment (LRE). This legislation also guarantees parents and children with special needs certain rights

based on a set of procedural safeguards that dictate the policies and procedures that educational teams need to follow to be in compliance with the law. Part B of IDEA specifies that an individualized education program (IEP) must be designed to include special education and related services to all students from 3 to 21 years of age if it is determined by the educational team that the student requires such services to benefit from his or her public education (§ 300.17).

According to Part B of IDEA, occupational therapy is considered a related service. Related services are described as "such developmental, corrective, and other supportive services as are required to assist a child with a disability to benefit from special education..." (IDEA 2004, Final Regulations, § 300.34, 2006). School districts are legally mandated to provide the services that a child requires to benefit from their IEP, and, therefore, occupational therapists are critical members of the educational team.

IDEA is scheduled for reauthorization every 5 to 7 years. Once it is reauthorized, the U.S. Department of Education develops rules and regulations to guide implementation. Then, state departments of education and local educational agencies (school districts, special education cooperatives) further refine the rules and regulations to establish a process of implementation. It is critical for school-based occupational therapists to be familiar with special education legislation and policy to provide educationally and functionally relevant services.^{57,84} Furthermore, understanding national, state, and local policies ensures that occupational therapy practitioners can expand school-based practice to meet the needs of children with and at risk for physical, cognitive, and social-emotional problems. Most children receiving occupational therapy in schools have disabilities and receive services under IDEA. IDEA maintains that

BOX 23-1 Principles of the Individuals with Disabilities Education Act*

1. *Free appropriate public education (FAPE).* Every eligible child is entitled to an appropriate education that is free to families (supported by public funds).
2. *Least restrictive environment (LRE).* Children with disabilities are most appropriately educated with their nondisabled peers. Special classes, separate schooling, or other removal of children with disabilities from the regular educational environment is to occur only when the nature or severity of the disability of a child is such that education in regular classes with the use of supplementary aids and services cannot be achieved satisfactorily [§ 612 (a)(5)(A)].
3. *Appropriate evaluation.* All children with disabilities must be appropriately assessed for purposes of eligibility determination, educational programming, and individual performance monitoring.
4. *Individualized education program.* A document that includes an annual plan is developed, written, and (as appropriate) revised for each child with disabilities.
5. *Parent and student participation in decision making.* Parents and families must have meaningful opportunities to participate in the education of their children at school and at home.
6. *Procedural safeguards.* Safeguards are in place to ensure that the rights of children with disabilities and their parents are protected, and that students with disabilities and their parents are provided with the information they need to make decisions. In addition, procedures and mechanisms must be in place to resolve disagreements between parents and school officials.

*Formerly EHA (P.L. 94-142).

children with special needs are ensured both FAPE and LRE.⁸⁶ Four additional assurances directing the education of children with disabilities were adopted with the original law in 1975; these have remained constant, with the exception of a few subsequent amendments (Box 23-1).

Free and Appropriate Public Education

A free and appropriate public education means that special education and related services must do the following: (1) meet the standards of the state education agency (SEA), (2) be provided at public expense, (3) be under public supervision and direction, (4) include an appropriate education at all levels (preschool, elementary, and secondary levels), and (5) be provided in accordance with the child's individualized education program (IEP). *Free* means that parents will not incur any costs associated with these services, beyond typical incidental fees that are charged to all students. *Appropriate*, a term that is less objectively defined, means that children must receive the educational supports and services that adequately meet their unique needs. It does not, however, guarantee that children will receive the most advanced or innovative educational methods or have access to state-of-the-art technology and materials to meet their needs. The IEP, which legally documents the child's educational needs, also documents the individualized set of supports and services determined to be appropriate by the special education team to allow the student to benefit from his or her

education and participate at school. The IEP is developed based on the contributions of the special education team, including the occupational therapist, informed by a comprehensive, multidisciplinary assessment.

Least Restrictive Environment

The LRE mandate requires that students with disabilities receive their educational program, including all their academic and related services, with children who are not disabled to the maximum extent appropriate (§ 300.114). LRE does not guarantee that all students will receive services within general education for the duration of the school day. Rather, it means that the IEP team must first consider general education as potentially meeting the student's needs, before moving on to a more restrictive setting.⁵¹ LRE should be applied to all students with special needs, regardless of their disabilities. Removing a child from general education should only take place after it is determined that the nature of the child's disability inhibits him or her from making progress, with the addition of supports and services. IDEA states that the "removal of children with disabilities occurs only when the nature or severity of the disability of a child is such that education in regular classes with the use of supplementary aids and services cannot be achieved satisfactorily" (32 C.F.R., § 612[5][A]). All decisions regarding placement must be made on an individual basis, based on the child's unique educational needs, and reviewed annually. Placement decisions should not be based on the availability of space or resources.

Depending on the child's individual educational needs, students may receive supports and services in a variety of settings. An example of LRE is a student receiving consultative services and accommodations and modification within a general education classroom at the child's school of residency—that is, his or her home school. If the child is not able to benefit from his or her IEP at this level of LRE, he or she may receive services in a special designated classroom or a designated school building. If LRE services in these settings are not adequate, the child may receive services in a therapeutic day school, at home, in a hospital, or at a residential facility. Most children with disabilities spend at least a portion of their day with peers from general education. However, some children with very significant disabilities may not be included with peers from general education. When this is the case, it is up to the child's IEP team to document the severity of the child's educational needs and to articulate clearly why other, more inclusive settings are not adequate to meet them. Removing a child entirely from general education without the option for inclusion in at least some special classes (e.g., music class, physical education, art) or nonacademic activities (e.g., lunch, recess) should be considered by the team as the last option.

Evolution of IDEA

Although the original goal of FAPE in the LRE for children with disabilities has not changed, each reauthorization of IDEA has prompted reflection and a re-evaluation of educational services, which, in turn, has brought about important shifts in the delivery of special education and related services.

In 1986, amendments allowed states to provide preschool and early intervention services for children with disabilities from birth to age 5 years. To reflect current language, the law's name was changed to the Individuals with Disabilities

Education Act in 1990. This amendment authorized additional services (assistive technology services and devices and transition planning). The reauthorization in 1997 was significant in placing greater emphasis on delivering related services to children with disabilities within the context of the student's general education curriculum.^{83,89} As a result, there has been a gradual shift in service delivery from traditional pull-out approaches to the integration of occupational therapy services into the student's classroom and other relevant school environments (e.g., lunchroom, playground, restroom).¹¹⁰ This shift has required occupational therapists to become knowledgeable about the curriculum adopted in specific classrooms and within the school district so that they can better specify how a student's disability affects functioning within the educational environment and develop relevant intervention strategies. The IDEA Amendments of 1997 also focused on student outcomes by requiring students with disabilities to be included in state- and district-wide assessments.

IDEA was most recently reauthorized in 2004 as the Individuals with Disabilities Education Improvement Act. The primary goals of IDEA 2004 are to increase the focus of education on results, prevent problems through early intervention, and improve students' academic achievement, functional outcomes, and postsecondary success.⁵⁷ By focusing on accountability and improving educational outcomes, Congress intentionally aligned IDEA 2004 with NCLB (formerly ESEA) of 2002. The long-term goal of special education and related services according to IDEA is to prepare students with disabilities for further education, employment, and independent living. New provisions related to early intervention services were also emphasized in IDEA's most recent authorization. IDEA was scheduled to be reauthorized again in 2013 or 2014.

Section 504 of the Rehabilitation Act and Americans with Disabilities Act

Section 504 of the Rehabilitation Act of 1973 and Title II of the ADA 1990 complement IDEA to ensure nondiscrimination against children with disabilities in public schools.¹²² Section 504 requires schools receiving federal funds to provide access to public education to qualified students with disabilities. The ADA ensures that the educational program is accessible to individuals with disabilities and may include providing specific accommodations. The definition of "disability" under Section 504 and ADA includes any student with "a physical or mental impairment that substantially limits one or more major life activities, who has record of such an impairment, or is regarded as having such an impairment" (34 C.F.R. 104.3(j)(2)(i)). Some examples of impairments that may substantially limit major life activities are mental illness, specific learning disabilities, arthritis, cancer, diabetes, and hearing impairment. Major life activities include caring for oneself, education and learning, performing manual tasks, seeing, hearing, speaking, working, walking, and breathing. Because this definition is broader than IDEA's definition of disability, students who are not IDEA-eligible may be 504-eligible for accommodations to access to the learning environment. "Under Section 504, occupational therapy can be provided alone or in combination with other education services and may be provided directly to students or as program supports to teachers working with the student"

(p. 1).³ Student eligibility for Section 504 services are documented in guidelines developed by each state and local school agency.

Sometimes students with diagnoses such as attention-deficit/hyperactivity disorder (ADHD) are not eligible for special education programs. However, these students may struggle to participate fully in classroom activities and often benefit from occupational therapy services. Occupational therapy in the schools can be provided to these students under Section 504. Because the definition of disability is broader in this civil rights act, a child may be eligible for occupational therapy even when he or she is not eligible for special education services. Although school personnel are not required to develop IEPs for students served under the Rehabilitation Act, a team should develop a written plan that states goals, services, and accommodations needed to meet those goals.⁵⁷

Although additional federal and state funds are not provided for these laws, school districts that do not provide accommodations to students who are eligible through Section 504 and ADA can lose federal funding. Occupational therapists may assist the school team in determining the most effective and efficient solutions for meeting students' needs under Section 504 and the ADA.

Elementary and Secondary Education Act and No Child Left Behind

The ESEA of 1965 as a part of the "War on Poverty" was designed to ensure that all children have an equal opportunity to participate in and receive a good education in school.⁹² This law, which is considered a key component in the education reform movement, covers all public schools in all states. In 2002, Congress amended ESEA, making major changes, and reauthorized it as NCLB (P.L. 107-110).

NCLB was mainly understood to be a general education law that emphasized increased accountability for educational outcomes on the part of school districts. Under this law, states worked to close the achievement gap by establishing high achievement standards for all students, especially those who were disadvantaged because of poverty or disability.¹¹³ A major component of NCLB was adequate yearly progress (AYP). AYP required that school districts demonstrate that their students were meeting rigorous standards based on yearly testing and annual state and district report cards. Another major component of NCLB was the waiver system. This system allowed parents whose children were attending Title I (low-income) schools that did not make AYP for several years the option to transfer their child to a better-performing school or obtain free tutoring.¹¹⁴ The final component introduced by NCLB was the requirement that public school teachers in all states meet the standards of "highly qualified." Highly qualified was defined as holding at least a bachelor's degree and having passed a state test of subject knowledge.

Since 2007, Congress has been working on the reauthorization of ESEA-NCLB.⁷⁰ However, because of political debate, the legislative process has been delayed. In order for a new bill to be passed, each branch of the legislature proposes a draft. Specific members of the House of Representatives and Senate then convene to negotiate with a combined bill. Both branches are required to vote on the proposed bill before a final bill is sent to the president for his approval.

Common Core Standards: A State-Led Initiative

NCLB caused a shift in practice by emphasizing educational accountability for all students. As a result, 45 states have voluntarily adopted the Common Core Standards (CCS) to guide the educational outcomes of all students, including those with disabilities. The development of the CCS was guided by state governors and state education commissioners. The process of developing the CCS was led by two professional organizations, the National Governors Association (NGA) and Council of Chief State School Officers (CCSSO). The CCS were drafted after a review of current state standards and research regarding what students need to know to prepare for postsecondary opportunities. In addition, the academic standards used in other high-performing countries were also influential in the development of the CCS. Input regarding the content and structure of the CCS was solicited from teachers, parents, and school administrators in the United States. As such, the CCS represent a set of clearly defined goals and expectations for children K-12 in math and English.⁸⁷ The focus of these standards is to promote college and career readiness through the development of higher order thinking skills. The CCS are to be used by teachers as a content guide and do not prescribe a specific method or form of instruction. These standards are also used to guide the education of students with disabilities and are integrated into the IEP. Students with disabilities may need support to access the rigorous content aligned with the CCS. This can be achieved through using evidence-based and individualized instructional methods, applying Universal Design for Learning (UDL) principles, supporting the use of assistive technology, and offering general accommodations.⁸⁷ In many districts, occupational therapists are encouraged to use these and other state standards as a guide for developing measurable IEP goals and educationally relevant intervention plans.

This synthesis of federal legislation and state-led initiatives provides the foundation for understanding the evolving role of occupational therapists working in schools. Changes brought about by the reauthorization of IDEA and the enactment of ESEA have been instrumental in providing opportunities for expanding occupational therapy's role in serving all children attending school.⁵⁷ In the following sections, occupational therapy's role in serving children with and without disabilities is presented, followed by a discussion of emerging roles in school mental health.

Occupational Therapy Services for Children and Youth in Schools

Occupational Therapy Domain in School-Based Practice

Education has been identified by the American Occupational Therapy Association as one of the key performance areas; it refers to the "activities needed for being a student and participating in the learning environment" (p. 620).¹ The occupation of education includes academic (e.g., math, reading, writing), nonacademic (e.g., recess, lunch, self-help skills), extracurricular (e.g., sports, band, cheerleading, clubs), and prevocational and vocational activities.⁶³ Consequently, in addressing a student's education, attention to a broad range of occupational

performance areas, including play, leisure, social participation, ADLs, and work, is often required to help children succeed in their student role.

Occupational therapists working in schools must skillfully align their professional knowledge and skills with the definition of occupational therapy in federal and state education legislation. School districts are mandated to provide related services, including occupational therapy, when a student who receives special education requires such services to benefit from special education. "Related services" means "transportation, and such developmental, corrective, and other supportive services (including speech-language pathology and audiology services, interpreting services, psychological services, physical and occupational therapy, recreation, including therapeutic recreation, social work services, school nurse services[,] ... counseling services, including rehabilitation counseling, orientation and mobility services, and medical services, except that such medical services shall be for diagnostic and evaluation purposes only as may be required to assist a child with a disability to benefit from special education, and includes the early identification and assessment of disabling conditions in children" (§ 300.320(a)(4)). Special education and related services may be provided in a number of settings, including schools, homes, hospitals, juvenile justice centers, and alternative education settings.²

Occupational therapy services must be educationally, developmentally, or functionally relevant by contributing to the development or improvement of the child's academic and functional school performance. The regulations of IDEA define occupational therapy broadly as "(A) improving, developing or restoring functions impaired or lost through illness, injury or deprivation, (B) improving ability to perform tasks for independent functioning when functions are impaired or lost, and (C) preventing, through early intervention, initial or further impairment or loss of function" (§ 300.34(c)(6)). Occupational therapy services can promote self-help skills (e.g., eating, dressing), positioning (e.g., sitting appropriately in class), sensorimotor processing, fine motor performance, psychosocial function, and life skills training.⁸⁸ Services must be provided by a qualified occupational therapist or service provider under the direction or supervision of a qualified occupational therapist. Although regulations focus on what constitutes "highly qualified" teachers, requirements beyond adhering to state licensure laws have not been created for occupational therapy.⁵⁵ However, some school districts are beginning to apply teacher evaluation models,⁷⁷ such as the Danielson model, to related service providers. For example, the Danielson model provides for the examination of 22 different components of teaching. The components of teaching are broken down into four main categories: planning and preparation, classroom environment, instruction, and professional responsibilities. In practice, some of the components of the model may need to be adjusted slightly so that they are representative of therapy services. However, such models would provide a way to assess, plan for, and capture professional development.

Shifts in Occupational Therapy Service Provision

The reauthorization of IDEA in 1997 ended a long period during which special education and general education were viewed as separate programs serving separate populations.¹⁰⁶

FIGURE 23-2 Tiered model of education.

IDEA 1997 placed greater emphasis on the inclusion of students with disabilities in general education by embedding special education and related services in the classroom and extracurricular activities when possible. General and special education practices have been further aligned as a result of IDEA 2004 and NCLB, providing school personnel, including occupational therapists, with increasing opportunities to expand their role in schools, particularly in the area of health promotion and prevention.²³ In addition, as a result of IDEA reauthorizations, school-based practice has advanced to include two new groups of students more fully: (1) those in general education without disabilities and (2) those with disabilities who are older than 18 years and receiving transition services.

The shift in occupational therapy services can be visualized as a movement from a two-tiered to a multitiered model of service delivery (Figure 23-2). The traditional two-tiered system represents students falling into one of two categories: children with disabilities who meet eligibility criteria as outlined in IDEA or Section 504 and receive services or students in general education who do not receive services. A concern with this system is that some children in general education with learning, behavioral, or functional difficulties do not qualify for services under IDEA. In such cases, children may experience frustration and failure before becoming eligible for special education and related services.²⁴ In contrast, a multitiered model of supports and services commits to the success of all students by providing early identification and intervening services.

Current practice supports occupational therapy services geared toward the development and achievement of students in general and special education by collaborating with other members of the educational team. Such practice requires that occupational therapists be knowledgeable about federal legislation and local policies, learning standards, the curricula used by their school district to achieve the standards, and the frameworks and processes used by their district to provide services to students. The following sections describe the roles and functions of occupational therapists in general and special education.

Occupational Therapy Process in General Education

To address increasing concerns among parents, teachers, and policymakers that some students have not received needed help

in a timely manner, two provisions in IDEA 2004 enabled schools to provide services to students struggling with learning or behavior before being referred to special education.⁸⁶ These are early intervention services (EIS) and response to intervention (RtI).

IDEA legislation permits school districts to allocate up to 15% of their federal dollars to provide EIS to students who are in danger of school failure because of learning or behavioral concerns.²⁴ Comprehensive EIS are designed to help students in general education who are not eligible for special education but who need additional academic and behavioral support to succeed in school (34 CFR § 300.226). Schools are allowed to spend up to 15% of special education funds for EIS, including professional development for teachers and other staff, and to fund direct services, such as small group instruction, behavioral evaluations and supports, and information on the use of adaptive and instructional software. In cases in which the school district has a disproportionate number of minority students in special education, the school district is required to spend 15% of their funds on EIS (IDEA 2004).⁵⁶ Early intervening services include “scientifically based academic instruction and behavioral interventions, including scientifically based literacy instruction, and, where appropriate, instruction on the use of adaptive and instructional software; and providing educational and behavioral evaluations, services, and supports” (34 CFR § 300.224). Related services are specifically included in IDEA 2004 (§ 300.208) as possible EIS. In addition, under NCLB, occupational therapists may function as pupil services personnel (professionals who provide services to students) in providing EIS.

The second provision in IDEA 2004 developed to prevent school failure is the RtI process. Federal regulations (34 C.F.R. §§300.307–309) require that states adopt criteria for determining whether a child has a specific learning disability.¹¹⁶ RtI is a research-based model of school-wide support services that focuses on providing high-quality instruction and intervention matched to student needs, followed by systematically evaluating their response to education and intervention.^{85,100} Although originally explored as an approach assisting students with specific learning disabilities, evidence has supported its effectiveness for any student with academic or behavioral problems.^{6,66}

The overall purpose of RtI is one of prevention and early intervention—to identify and address student problems early to reduce the need for more intensive services later. Typical

BOX 23-2 Response to Intervention Process

1. Identify and define problem (i.e., the discrepancy between the target student and his or her peers).
2. Analyze the problem to hypothesize causes that are related to the discrepancy.
3. Establish a student-centered performance goal.
4. Establish an intervention plan and system for monitoring progress.
5. Implement plan and monitor progress.
6. Evaluate progress using performance data.

From Illinois State Board of Education. (2008). The Illinois State Response to Intervention (RtI) Plan, January 1, 2008. Retrieved from http://www.isbe.state.il.us/pdf/rti_state_plan.pdf.

practices underpinning an RtI model include the following: (1) high-quality general education instruction based on scientific evidence, (2) continuous progress monitoring of student performance, (3) universal screening of academics and behavior, and (4) the use of multiple tiers of instruction that are progressively more intense, based on the student's response to intervention.¹¹⁶ Many states and local districts that use RtI frameworks have adopted problem-solving teams to analyze and interpret progress-monitoring data and make decisions about when specific students would benefit from more intensive instruction.²⁴ Problem-solving teams typically attempt to identify the reason for the student's difficulty, develop an intervention, and plan for systematically monitoring the student's progress. This team also determines when a student changes tiers to receive more intensive services. **Box 23-2** depicts a common RtI process that is used by many school-based, problem-solving teams. Most multitiered models of interventions and supports are made up of three levels: tier 1 (universal or core instruction), tier 2 (targeted intervention), and tier 3 (intensive intervention). In a three-tiered model, the first tier provides school- or classroom-wide interventions made up of high-quality instructional, behavioral, and social supports for all students.¹⁰⁰ Whole-class screening is used to assess whether academic and behavioral performance is appropriate for the student's age and grade. For the group of struggling students, tier 2–targeted interventions may be developed by the problem-solving team, sometimes referred to as the student support team (SST), to address specific needs. Interventions and supports at this level may include small group interventions or more intensive instruction such as tutoring. At this level, interventions reflect more intensive 1:1 services and supports provided within general education or special education.

Many school districts are opting to use a multitiered problem-solving framework, such as RtI, to provide EIS. RtI is designed to encourage the use of responsive instructional methods and supports to remediate a student's learning or behavioral difficulties in general education.^{1,85} Many RtI frameworks consist of three instructional tiers. Tier 1 is designed to meet the needs of most students in the school or classroom, tier 2 is designed to meet the needs of small groups of students, and tier 3 is designed to meet the needs of individual students.¹¹⁷

RtI frameworks have several common characteristics.^{19,24} For example, all RtI frameworks have universal screening measures embedded in the curricula to identify students who are at risk of failing. In addition, they use evidence-based

BOX 23-3 Examples of Occupational Therapy Tier 1 Supports

Recommend an evidence-based handwriting curriculum to be adopted by the school district.
Identify universal screening methods for handwriting and social-emotional skills.
Recommend changes to the physical environment to promote the access and success of all students.
Provide professional development training to teachers on how to address the sensory needs of their students in order to optimize learning and participation.

Goal attainment scaling as a measure of meaningful outcomes for children with sensory integration disorders. *American Journal of Occupational Therapy*, 61, 254-259; and McLaren, C., & Rodger, S. (2003). Goal attainment scaling: Clinical implications for paediatric occupational therapy practice. *Australian Occupational Therapy Journal*, 50, 216-224.

interventions at all tiers of instruction and engage in continuous progress-monitoring activities to inform service delivery decisions.

Educational teams may approach special education referral differently in light of RtI.²⁴ Many students who are identified as being at risk for learning or behavioral needs may move through the different RtI tiers before being referred for a special education screening or evaluation. In other cases, a child might be referred to the special education team before receiving tier 2 or 3 RtI services.

RtI provides occupational therapists in school-based practice a unique opportunity to expand their role and provide services to students who are at risk and may not traditionally be part of their caseloads.²⁴ Depending on the state's licensure law, occupational therapists can participate at every level of RtI. Tier 2 and tier 3 services parallel the types of services that occupational therapists have traditionally provided in the schools because the focus is often on providing direct intervention or consultation to meet the needs of individual students or small groups. Tier 1 services, however, provide an opportunity for occupational therapists to effect change at the systemic level (**Box 23-3**).

Occupational Therapy Process in Special Education

Despite recent trends in education and federal policy, occupational therapists in school-based practice continue to spend most of their time providing services to students with special needs. In collaboration with other members of the education team, occupational therapists contribute to the referral, evaluation, intervention, and outcome processes. With these important outcomes in mind, a key question guiding the special education process should be the following: "What does the child need or want to do to be successful as a student now and to prepare for future roles?"⁷² The special education process is depicted in **Figure 23-3**. This section describes the occupational therapy processes of referral, evaluation, and intervention.

Referral

Each school district or local education agency (LEA) has a Child Find system that locates, identifies, and evaluates all children who have disabilities and need special education.⁶¹

FIGURE 23-3 Special education process. (Adapted from Office of Special Education and Rehabilitative Services, U.S. Department of Education. [2000]. A guide to the individualized education program, pp. 5-7. Retrieved from <http://www2.ed.gov/parents/needs/speced/iepguide/iepguide.pdf>.)

A referral of a child suspected as having a disability may be made by any source, including parents, teachers, or other individuals. An occupational therapist evaluation may be requested at the time of initial referral if the team perceives that information provided by an occupational therapist will contribute to the evaluation process. This suggests how critical it is for school administrators and other team members to have an accurate understanding of the domain and scope of occupational therapy

practice—that occupational therapists address the education, ADLs, play, leisure, work, and social participation areas of function related to the student's academic and nonacademic expectations. If team members have a narrow understanding of the scope of occupational therapy practice (e.g., occupational therapists address handwriting issues), then it is likely that the role of occupational therapy in that setting will also be narrow.⁴² Efforts spent in informing principals, teachers, school

FIGURE 23-4 Top-down versus bottom-up approaches to evaluation and intervention. (Adapted from American Occupational Therapy Association. [2004]. Occupational therapy services in early intervention and school-based programs. *American Journal of Occupational Therapy*, 59, 681-685; and Coster, W. J. [1998]. Occupation-centered assessment of children. *American Journal of Occupational Therapy*, 52, 337-344.)

psychologists, and other personnel about the role of occupational therapy in special and general education ensure that students who may benefit from occupational therapy services are identified.

Evaluation

“Evaluation means procedures used in accordance with §§ 300.304-300.311 to determine whether a child has a disability and the nature and extent of the special education and related services that the child needs” (§ 300.15). After obtaining parental consent, a full and individual evaluation is completed by a multidisciplinary team to determine whether the child is eligible for special education, and, if so, it identifies educational and related service needs (§ 300.301). This multidisciplinary evaluation is needed even when the child has an obvious disability (e.g., cerebral palsy, Down syndrome) and has received therapeutic services in the past (e.g., in an early intervention program). In addition, this team determines the nature and scope of the full and individual evaluations for each child and decides whether related services evaluations, including occupational therapy, are needed.

IDEA and the Occupational Therapy Practice Framework (OTPF) define evaluation and assessment consistently.¹ Evaluation refers to the process of gathering and interpreting information about the student’s strengths and educational needs. Assessment refers to the tests or measures used to obtain data about specific areas of function. IDEA specifies that school personnel evaluate referred or eligible students in all areas of suspected disability. Furthermore, a variety of assessment tools or evaluation strategies must be used to obtain relevant academic, functional, and developmental information about the student (§ 300.304(b)(1)). The evaluation must be completed within 60 days of initial parent consent, unless the state specifies otherwise.

Top-Down or Occupation-Based Approach

Although one of the main purposes of evaluation according to IDEA is to determine eligibility, which is based on qualifying as a child with a disability, the law has placed greater emphasis on assessing the child’s participation needs in relevant school contexts. This thinking is in agreement with current social views regarding the evaluation of children and those adopted within the profession of occupational therapy. A top-down

approach to evaluation is believed to reflect more accurately the true nature of occupational therapy and has been referred to as occupation-based evaluation.⁹⁵ A top-down approach to evaluation begins with gathering information about what the person needs and wants to do across a variety of occupational performance areas and settings (Figure 23-4).^{33,39} The School Function Assessment,³⁴ representing a top-down strategy, is used to initiate the evaluation process. Performance skills are assessed to the extent that they are thought to limit participation in occupation. An occupational therapist’s ability to implement this approach is dependent on using appropriate evaluation strategies and assessment tools, developing the knowledge and skills needed to implement these strategies, and then actually using them in practice. Refer to Box 23-1 on the Evolve website for a summary of evaluation of performance skills as related to participation in school.

Evaluation Strategies

“Occupation-based evaluation approaches help the IEP team make decisions about the student’s ability to participate and perform in the school setting and identify the ways that the disability affects the student’s participation in school activities and routines” (p. 35).⁹⁵ The occupational therapy evaluation focuses on strengths and weaknesses in educationally relevant occupational performance areas (e.g., education, social participation, ADLs, play, leisure, work) related to the student’s suspected disability (Table 23-1). Obtaining an occupational profile initiates the evaluation process by exploring the student’s educational history, interests, values, and needs. The student may be interviewed using questions such as the following:

- What do you like about school?
- What kinds of things are going well for you?
- What are some of your challenges?
- What would you like to see changed?

The occupational therapist can also observe the student during typical classroom instruction, as well as during nonacademic time (e.g., during lunchtime and recess). Such observations will assist the occupational therapist in understanding the child’s interests and preferences. Observations might also help the occupational therapist gain important information about the child’s social participation, as well as his or her habits and routines. The occupational therapist might also interview the teacher about classroom expectations for the student. The

TABLE 23-1 School-Related Occupational Performance Addressed During Evaluation and Intervention

Occupational Area	Examples of Participation in School-Related Occupational Performance	Examples of Occupational Therapy Intervention	School-Related Outcomes
Education	Access to and participation in classroom curriculum Organizational skills Attending to instruction Fine motor skills and hand function Written communication and handwriting	Assist with adapting assignments with high or low technology; adapt child's positioning so child can perform handwriting as effectively as possible Help manage books and notebooks, desk, homework assignments, and backpack Enable child to use self-regulatory activities to foster attending; provide strategies to enhance work completion Provide classroom materials and activities to promote fine motor skills development and in-hand manipulation skills Consult with curriculum committee in selection of a handwriting curriculum; direct services in groups or individually to assist students in letter formation; provide modifications to complete written communication including use of technology	Achieves in the learning environment, including academic (e.g., reading, math), nonacademic (e.g., recess, lunch, relationships with peers), prevocational, and vocational activities (e.g., professional and technical education)
Social participation	Successful interaction with teachers, other school personnel, and peers Ability to adapt to environmental demands	Foster appropriate interaction with peers during group interventions; attend to social interaction during lunch and recess; foster development of friends Provide strategies for coping with test anxiety; adapt procedures to reduce stressful school expectations	Develops appropriate social relationships at school with peers, teachers, and other school personnel in classroom, extracurricular activities, and preparation for work
Play and leisure	Plays with peers during recess Participates successfully in class games Develops structured extracurricular interests (e.g., sports, art, dance)	Assist in making play environments (e.g., playground) accessible; consult with school administration to ensure recess is play-based; assist students in exploring leisure interests; consult with parents to promote structured leisure participation during after-school time	Identifies and engages in age-appropriate toys, games, and play activities; participates in meaningful selection of art, music, sports, and after-school activities
Work	Prevocational	Advocate for embedding productive occupations into the school day (e.g., putting supplies away, cleaning work spaces); involve students with disabilities in work activities within the school environment (e.g., wiping down lunch tables); develop group programs to foster work skills Provide direct intervention using a chaining approach to teach dressing or self-feeding Teach appropriate transferring strategies for wheelchair to toilet Provide group activities to promote participation in independent living skills, such as shopping, cooking, and clean up	Develops interests, habits, and work skills needed to work or volunteer in the community after graduation from school Attends to basic self-care needs in school (e.g., eating, toileting, managing shoes and coats); uses public transportation to travel in community; develops health management routines; develops home management routines to the maximum extent possible (e.g., cleaning, shopping, meal preparation, safety and emergency responses, budgeting)
Activities of daily living (basic and instrumental)	Dressing (putting on and taking off coat, dressing for gym) Eating lunch and/or snack Toileting (bowel and bladder management) Basic hygiene and grooming Using communication devices Meal preparation in class Using computers Shopping Doing laundry

(2003). *Personnel issues in school-based occupational therapy: Supply and demand, preparation, certification and licensure (COPSE document no. IB-1)*. Gainesville, FL: University of Florida, Center on Personnel Studies in Special Education; and Kentucky Department of Education. (2006). *Resource manual for educationally related occupational therapy and physical therapy in Kentucky public schools*. Frankfort, KY: Kentucky Department of Education.

parents are also asked to identify their priorities for the child. Information obtained from the occupational profile assists the occupational therapist in developing initial impressions about the student's difficulties, which may be useful in directing the rest of the evaluation process.

In addition to observations and interviews, other useful evaluation strategies include document or chart review to obtain background information and construct an educational history. The evaluation process involves an examination of the dynamic relationship among the student's participation and performance skills, educational context, and specific educational and activity demands that may be contributing to the problems.¹¹¹ For example, to understand fully a student's difficulty with written communication during test taking, the occupational therapist may observe the student while taking a test, compare work with that of peers in the same environment, and explore curricular demands with the teacher.

Evaluation of the school environment includes the classrooms, cafeteria, playgrounds, restrooms, gymnasium, and other spaces. For children using wheelchairs or walkers, the focus of this part of the assessment may be accessibility. For children with sensory processing problems, the focus may be the degree and types of sensory stimulation in the environment. Classrooms tend to be highly visually stimulating environments, and they can be disorganizing and overwhelming to students with sensory processing problems. For children with social and emotional needs, the focus may be on aspects of the social environment and classroom routines.

To analyze educational and/or activity demands, the expected performance (as defined by the teacher and curriculum) must be understood fully. When a teacher expects neat, precisely aligned, and well-formed handwriting, a student with poor handwriting will have a significant problem in meeting that teacher's standard. As another example, some teachers show high tolerance for disruptive behavior and allow students to move freely about the room. A student with a high activity level and sensory-seeking behaviors would have greater success in a classroom in which movement was allowed, rather than one in which students were expected to remain in their seats. Often a student's goals and services are based more on the discrepancy between the student's performance and classroom teacher's expectations than on performance delays as determined by norms that reference the student's age. In addition, occupational therapists need to consider the CCS and their state's specific learning and achievement standards, which are accessible from the state's department of education website.

Assessment Measures

The occupational therapist may also decide to administer informal or formal assessment measures to obtain a full evaluation of the child's occupational performance related to curricular and extracurricular needs. However, according to IDEA, the use of assessment tools is not required if observations and interviews have provided the needed information for decision making. Because the number of standardized pediatric assessments available today has grown significantly over the past 2 decades, it is important for occupational therapists practicing in schools to make informed decisions when selecting assessments.

Pediatric assessments can be categorized as developmental, functional, and health-related quality of life (HRQL; [Table 23-2](#)).⁴⁸ Although developmental assessments may be particularly helpful when working with infants and preschoolers to

identify developmental delays, they are less useful with the school-age population, for whom the emphasis shifts to functional performance and participation in context. Developmental assessments measure a child's behavior and skills rather than the ability to function as a student.¹¹² With a developmental approach, intervention emphasizes normalizing the underlying processes to achieve greater function.³² Current intervention approaches, however, suggest that in addition to assessing characteristics of the individual, physical and social aspects of the environment and features of the activity also need to be considered.³³

In contrast to developmental assessments, functional assessments measure abilities and limitations in performance of necessary daily activities.³⁷ Functional assessments are most aligned with an occupation-based, top-down approach. For example, the School Function Assessment (SFA)³⁴ and a growing number of functional, top-down assessments are now available. Although a number of occupation-based assessments have been published in the past decade, one survey found that school-based occupational therapists primarily used developmental assessments of gross and fine motor skills (e.g., Bruininks-Oseretsky Test of Motor Proficiency, Peabody Developmental Motor Scales, Beery Test of Visual Motor Integration).²³ When the findings of this survey were compared with previous research, similar trends in the use of motor and visual perception tests were found.

One of the major obstacles to using functional assessments is the dominance of the developmental model.³³ Functional assessments have only been available during the past 10 years, and time is needed for occupational therapists to become educated and skilled in using them. Most functional assessments (e.g., the SFA) are often designed so that multiple team members (parents, teachers, and therapists) knowledgeable about the student's performance can contribute to the data-gathering process, yielding a comprehensive understanding of the child. In a study of the validity and reliability of the SFA, findings have suggested that occupational therapists and teachers view students' functioning similarly.³⁷

Studies have indicated that in addition to using adult informants, children can also participate actively in the evaluation process and goal setting if the procedures used are developmentally appropriate.⁸¹ The Perceived Efficacy and Goal Setting System (PEGS)⁸² is one example of such a measure. The PEGS was designed to help children with disabilities reflect on their ability to perform everyday activities and identify goals for occupational therapy intervention. Other assessment tools developed to gather information directly from the child are the School Setting Interview (SSI)⁵⁴ and the Child Occupational Self-Assessment (COSA). The information gathered from these measures on children's thoughts and feelings about their ability to fulfill childhood roles can complement results obtained from functional assessments and provide a more complete picture.⁹⁹ In addition, occupational therapists may consider using HRQL measures to obtain a clear sense of the child's life satisfaction.

Documentation of Evaluation Findings

The final step in the evaluation process involves effectively communicating the findings and recommendations in a written report. In general, an occupational therapist's evaluation report includes an overview of the student's occupational profile, assessment measures that were used, child's performance on such measures, and occupational therapist's recommendations.

TABLE 23-2 Types of Assessment Tools

Type	Description of Purpose and Implications	Assessment
Developmental	- Assess underlying performance areas to determine the following: - Presence of a developmental delay - Presumed cause of the functional limitations - Areas assessed—gross motor, fine motor, sensory, self-care, social, visual perceptual, communication, adaptive-cognitive - Setting—secluded testing room - Problem perceived to be within the child - Assessments tend to be norm-referenced, comparing child's performance with that of a normative sample - Intervention—focuses on development of isolated skills	- Peabody Developmental Motor Scales, Second Edition (PDMS-2) - Bruininks-Oseretsky Test of Motor Proficiency (BOT-2) - Beery-Buktenica Developmental Test of Visual-Motor Integration (VMI)
Functional	- Assess function in context; focus is on personal capacities, not failure of organ function - Areas assessed—hygiene, handwriting, play, social participation, material management - Setting—natural environment; parent or teacher may provide the data - Assessments tend to be criterion-referenced, determining how a child performs in relation to a set of standards - Intervention focuses on successful participation in all school activities and settings	- WeeFIM System (Functional Independence Measure for Children) - School Function Assessment (SFA) - Children's Assessment of Participation and Enjoyment (CAPE) and Preferences for Activities of Children (PAC)—CAPE/PAC - Miller FUNction and Participation Scales (FUN Scale) - Social Skills Rating System (SSRS) - Evaluation Tool of Children's Handwriting (ETCH) - Short Child Occupational Profile (SCOPE) - Canadian Occupational Performance Measure - Evaluation of Social Interaction (ESI) - Minnesota Handwriting Assessment - The Print Tool - School Version of the Assessment of Motor and Process Skills (School AMPS) - Sensory Processing Measure (SPM)
Child-reported health-related quality of life (HRQL)	- Assess how child feels about his or her life, abilities, and overall sense of well-being - Aim is to complement functional assessments by providing more complete picture of the person - Areas assessed—person's feelings about participating in childhood roles and over-all sense of well-being	- Perceived Efficacy and Goal-Setting System (PEGS) - School Setting Interview (SSI) - Child Health Questionnaire (CHQ) - Child Occupational Self-Assessment (COSA) - Youth Quality of Life Instrument (YQOL)

Adapted from references 5, 15, 18, 22, 33, 34, 37, 40, 41, 48, 54, 60, 69, 91, and 97; and Schneider, J. W., Gurucharri, L. M., Gutierrez, A. L., & Gaebler-Spira, D. J. (2000). Health-related quality of life and functional outcome measures for children with cerebral palsy. *Developmental Medicine and Child Neurology*, 43, 601-608.

Occupational therapy documentation should reflect a top-down presentation of the student's strengths and limitations regarding participation in academic and nonacademic activities across all student environments. Performance component impairments (e.g., body structure and function) that affect participation should be reported using language understandable to all team members, including parents.

Eligibility

After the evaluation process, the team reviews all the data to determine eligibility for special education and related services. A student is eligible for special education under IDEA if he or she meets two criteria, that this is a child with a disability under one of the disability categories or is under the developmental delay category and needs special education services. The disability categories include intellectual disability, hearing impairment (including deafness), speech or language impairment,

visual impairment (including blindness), serious emotional disturbance, orthopedic impairment, autism, traumatic brain injury, another health impairment, specific learning disability, deaf-blindness, or multiple disabilities (34 C.F.R. § 300.8). The term *child with a disability* for children aged 3 through 9 years may, at the discretion of the SEA and LEA and in accordance with § 300.111(b), include a child who demonstrates developmental delays as defined by the state and as measured by appropriate diagnostic instruments and procedures in one or more of the following areas—physical development, cognitive development, communication development, social or emotional development, or adaptive development—and who, by reason thereof, needs special education and related services.

If the team determines that a child is eligible for special education, the IEP process begins; the IEP team meets to develop a special education plan and determine if related services are necessary. Occupational therapy evaluation data

provides the IEP team with “information related to enabling the child to be involved in and progress in the general education curriculum, or for preschool children, to participate in appropriate activities” (§ 614(b)(2)(A)(ii)). The determination of need for occupational therapy services should not be based on evaluation alone but should be driven by the student’s educational program and annual goals.

A child with a disability who is not eligible for special education under IDEA may be eligible for services under Section 504 of the Rehabilitation Act of 1973. Using information from multiple sources, a multidisciplinary team determines if the child has a disability (as defined in Section 504) that substantially limits a major life activity.

Individualized Education Program

The IEP represents the formal planning process and resulting legal document that establish the services and programs that will enable the student to participate in school activities and receive an “appropriate education.” Refer to Table 23-3 for a review of the IEP process. According to IDEA (34 C.F.R. §§ 300.320-300.324), the IEP is a written statement for each child with a disability that outlines the student’s educational

and functional needs and the supports and services required to meet those needs. It is developed, reviewed, and revised in a meeting in accordance with the guidelines of the IDEA.

The IEP team comprises at minimum the child’s parents; one regular education teacher of the child; one special education teacher of the child; one special education provider, when appropriate; a representative of the public agency who has knowledge and qualifications; an individual who can interpret the instructional implications of the evaluation results (perhaps one of the other members); other individuals who have knowledge or special expertise regarding the child (e.g., related services personnel), as appropriate; and the child with a disability, when appropriate (34 C.F.R. § 300.321(a) and (b)(1)). Although related services personnel are generally considered “discretionary” team members (§ 300.321(a)(6)), if an occupational therapist is formally identified as a member of a particular IEP team or if occupational therapy is being discussed at the meeting, it is fitting and desirable that the occupational therapist attend the meeting.⁵⁷

Collaborative Planning

The collaborative planning procedure that guides the process of developing an IEP involves many components. The

TABLE 23-3 Process Depicting the Development of the Individualized Education Program

Step	Description
Vision of Child’s Needs 1. Determine present levels of academic achievement and functional performance. 2. Describe how the student’s disability affects participation in general education.	Interpretation of the full and individual evaluation (FIE) Consideration of how disability influences access to and participation in academic and functional activities Identification of the student’s strengths and needs Discussion of parent, student, and team member priorities for the child
Measurable Goals Develop measurable and attainable annual goals (academic and functional)	One-year goals All team members contribute to goal development Goals may be linked to state curriculum content standards Plan for measuring progress toward annual goals Related services goals must be “educationally relevant” For children with disabilities who take alternate assessments aligned to alternate achievement standards, a description of benchmarks or short-term objectives is given
Special Education and Related Services Determine the special education, related services, supplemental aids and services, modifications, and supports	Represents services student needs to accomplish IEP goals Team determines all needed services Services meet academic, functional, and extracurricular needs Services based on peer-reviewed research to as much as practicable Projected dates for initiating services; anticipated frequency, location, and duration of services
Statement of Accommodations Needed to measure academic achievement and functional performance on state and districtwide assessments	Statement of why child cannot participate in the regular assessment and why the particular alternate assessment selected is appropriate for the child
Placement in Least Restrictive Environment	Educate students with disabilities with their nondisabled peers to the maximum extent appropriate. Consider general education environment first Placement determined annually Must offer a range of service delivery options
Transition Plan Beginning at 16 years of age	Based on age-appropriate transition assessments related to training, education, employment, and independent living skills Identifies transition services needed to assist the child in reaching goals that may include vocational training, supported employment, independent living, work experience, community participation, or planning appropriate high school classes in preparation for college

school-based occupational therapist contributes to many of those components when participating as a member of a student's IEP team. Although the exact components may vary from state to state, depending on the special education policies and procedures adopted by the state, the following items are mandated as general requirements by IDEA (34 C.F.R. § 300.320(a))(see Table 23-3).

The first steps involve interpretation of the most recent evaluation of the child, consideration of the child's performance on any general state or districtwide assessment programs, and identification of the student's strengths and needs. These also involve discussion with the parents, educational team, and sometimes the student regarding priorities and goals. During this initial phase, it is important to "create a team 'vision' about who the student is and what a student needs to succeed in school" (p. 1).⁶³ This information is documented on the IEP as the present levels of academic achievement and functional performance and description of how the student's disability affects participation in general education. For a preschool student, consideration is given to whether the disability affects participation in any activity appropriate for a preschooler. Typically, all team members participate in developing this statement, which includes a summary of all evaluation results, thus giving a total picture of the student's academic and functional performance. Occupational therapists should be ready to share evaluation results, which are included in the student's present levels of performance. They should specify how the student's performance influences participation in the general education curriculum, including classroom routines and functional activities—for example, sharing the student's time delay before initiating work, percentage of time engaged in off-task behavior, or how writing speed relates to educationally relevant performance in written expression. In the case of a preschool student, the occupational therapist should document whether the performance results suggest problems that will affect the student's access to typical preschool activities. Table 23-4 provides examples of educationally relevant present levels of performance and statements of need.

The next step involves the development of measurable annual goals (academic and functional) designed to enable the student to have access to and make progress in the general

education curriculum and meet the child's other educational needs that result from the child's disability (34 C.F.R. § 300.320(a)(2)(i)(B)). The goals are statements of measurable and attainable behaviors that a student is expected to demonstrate within 1 year. Many states are linking goals to the CCS or their state curriculum content standards.⁵⁵ This ensures that the goals are related directly to the learning objectives mandated by the SEA for all students. IDEA 2004 eliminated the requirement of writing short-term objectives (benchmarks) in the IEP, except for children with disabilities who take alternate assessments aligned to alternate achievement standards (§ 300.320(a)(2)(ii)). Congress opted to eliminate short-term objectives as a way to reduce paperwork and because parents are informed of short-term progress through the use of quarterly and other periodic reports. Although short-term objectives are not required for all students receiving special education, some school districts require them. At a minimum, a plan for measuring progress must be documented, specifying how the child is meeting IEP goals and when periodic progress reports will be provided (e.g., through the use of quarterly reports concurrent with the issuance of report cards; 34 C.F.R. § 300.320(a)(2)). It should be noted that the frequency of reporting progress must be at least as often as the progress reports received by the parents of nondisabled students, often on a quarterly basis. The actual progress attained toward the goals must be included. Occupational therapists are responsible for measuring progress toward annual goals and objectives when they are one of the services listed to support that student's goal. Often, several members of the IEP team share data keeping for a student's progress toward general education goals.

Goal Writing

This is a collaborative process and is completed at the IEP meeting with the input of all team members, including the parents and, in some cases, the student. Goal writing in most districts is facilitated by an online process that enables the IEP to be developed on a shared website. Student needs are prioritized and academic and functional goals are selected based on identifying skills needed to progress in the general educational environment. Team members, including occupational therapists, must relate their activities and recommendations to the

TABLE 23-4 Educationally Relevant Levels of Performance and Educational Need

Present Performance Level	Educational Need
Forms all letters correctly in isolation	Increasing speed and spacing so written words and sentences are legible
Highly sensitive to unexpected touch; will push other children when in line or moving through the hallways	Strategies and supports to tolerate being close to peers;
Eyes remain fixed when reading	accommodations to leave class early to avoid crowded hallways
Desk and workspace cluttered; unable to locate assignments and homework	Accommodations and instruction to read text without skipping or rereading words
Enjoys recess but tires after 5 minutes on the playground	Learning to use an organizational system
Has adequate skills for hands-on prevocational work experiences; personal hygiene not sufficient for work settings	Frequent rest breaks and strategies to understand and communicate fatigue to teaching staff
	Awareness and training for increased independence and carry-over in self-care areas

Adapted from Knippenberg, C., & Hanft, B. (2004). The key to educational relevance: Occupation throughout the school day. *School System Special Interest Section Quarterly*, 11(4), 1-4.

general education curriculum and extracurricular activities. Therefore, all team members must be knowledgeable about the classroom curriculum, behavioral expectations, and state educational standards. Target behaviors are actions and skills that students typically do or need to develop, such as participating in physical education, writing an essay, eating lunch independently, playing with friends during recess, and participating in after-school clubs.⁶³ Although occupational therapists may identify limitations in discrete performance skills that negatively affect school participation, such separate clinical goals should not be suggested to the IEP team. Goals need to address academic achievement and functional performance. Furthermore, the occupational therapist may think that a particular skill is a priority for a child. However, when viewing the whole child, the team may not agree. If this is the case, some negotiation among IEP team members may be needed to select priorities for the child so that appropriate goals and objectives can be developed for the student. A description of how to develop goals is provided in [Box 23-4](#).

Once the IEP goals have been developed, the team determines the special education, related services, supplemental aids and services, modifications, and supports to be provided by the school. These pertain to the student's advancement toward the annual goals, access to the general education curriculum, and participation in nonacademic and extracurricular activities. The IEP team determines if related services are "required to assist a child with a disability to benefit from special education" (34 C.F.R. § 300.34(a)). "One of the most important clarifications that teams should understand is that students with disabilities do not attend school to receive related services; they receive services so they can attend and participate in school" (p. 6).⁴⁵ Therefore, the role of the school-based occupational therapist is not to provide a full rehabilitation program but to support the child's efforts within the academic environment and only if necessary.⁴³ In general, occupational therapy services under IDEA are not provided when a student has a temporary impairment (e.g., a fractured bone) or when an impairment does not interfere with the student's performance in school. For example, a bright first grader had mild left hemiparesis cerebral palsy. This student participated in all aspects of the educational program, including physical education, with few adaptations. The disability did not interfere with the student's educational program. Therefore, she was not eligible for occupational therapy in school, despite the fact that she did not have the full use of her left hand.

It is important, however, for the occupational therapist to communicate the domain and scope of occupational therapy services effectively to the entire IEP team so that an informed decision will be made regarding service provision. On the basis of evaluation findings, the occupational therapist articulates recommendations to the IEP team regarding the need for occupational therapy services to enable the child to benefit from his or her education. Therefore, it is critical that the occupational therapist understand the full scope of his or her practice and how practice is shaped within the educational context. The IEP team makes the decision about whether or not occupational therapy services are warranted based on the student's educational program and unique needs. "Occupational therapy services are appropriate when the unique skills and expertise of the occupational therapist are needed to support the priorities identified by the team" (p. 78).⁴⁹

BOX 23-4 Steps to Developing Goals: Questions Asked by the Occupational Therapist

Collaborate with the team to identify the student's educational needs.

- What is the biggest priority?

Align educational need with Common Core Standards or other state learning standards.

- Is this priority educationally, developmentally, or functionally relevant?
- Is it an appropriate focus for occupational therapy services in the school context?

Identify the observable target behavior.

- Which behaviors need to change?
- How should the behavior be described in terms that are universally understood?

Establish a baseline for the target behaviors.

- How is the student performing right now?

Establish an outcome for the target behavior.

- Given the student's past learning trajectory, what target behavior can be accomplished in 1 year?
- Which conditions or criteria need to be in place for the student to be successful?

Determine how progress-monitoring data could be collected on target behaviors.

- How can the occupational therapist document that the student has made progress?
- What will the data collection form look like?
- How often should progress be monitored?
- Would another provider be able to collect data on this behavior?

Write the objective.

- Has the objective been written in parent-friendly language?
- Is the student the focus of the objective?
- Does the objective include one specific and observable target behavior?
- Does the objective clearly indicate positive change in the target behavior and include relevant conditions and criteria?

If the occupational therapist is to provide services to the student, it must be noted specifically in this section of the IEP along with the projected date for initiating services and anticipated frequency, location, and duration of these services. Documentation of the type of occupational therapy service delivery should ensure that a range of service approaches be available to the student—direct (to the child) and indirect (on behalf of the child) services. Based on the individualized needs of the student, direct intervention may be necessary during 1 week, whereas indirect consultation provided to the teacher on the student's behalf may be useful during the next week. In addition, flexibility in documenting time and frequency is also recommended (e.g., 2 hours/month or 1 hour/grading period), rather than specifying set weekly visits. "For example, a high school student may need 3 hours the first month to set up a prevocational program and to train the instructional team. Much smaller periods of time, such as 1 hour per month, may be needed when the OT returns in subsequent weeks to evaluate the effectiveness of the program and revise as needed" (p. 3).⁹⁴ Recommendations for duration of services, generally written as beginning and ending dates, and location of services

(e.g., cafeteria, classroom, playground, hallway) must also be specified.

The occupational therapist may also participate in suggesting appropriate modifications and support based on the assessment results. As an example, the occupational therapist may suggest limiting the amount of information on the student's worksheets because of a student's poor visual figure-ground processing. If the team were to agree to the recommendation, it would be documented on the IEP. Similarly, a statement of any individual appropriate accommodations necessary to measure the academic achievement and functional performance of the child on state and districtwide assessments consistent with § 612(a)(16) of the IDEA must also be determined by the IEP team.⁸⁶ In addition, if the IEP team determines that the child must take an alternate assessment instead of the regular state or districtwide assessment of student achievement, a statement of why the child cannot participate in the regular assessment and why the alternate assessment is appropriate for the child must be documented. The occupational therapist may contribute to the team discussion about appropriate testing modification. For example, the occupational therapist may suggest testing a student with sensory sensitivities in a separate room. For a student with motor limitations and difficulty with handwriting, the occupational therapist may suggest using an electronic text format of the test that would allow the student to use a keyboard. Other typical accommodations include allowing extra time for the student to take the test and reading portions of the test to the student. Each state determines the allowable modifications.

Once the IEP team has determined what the child needs in terms of special education services, the team can determine where the services should be provided. Placement decisions are made annually based on where the IEP team has determined that the student's IEP goals can be met.¹²³ In accordance with LRE as defined in the IDEA, children with disabilities are required to be educated with their nondisabled peers to the maximum extent appropriate (34 C.F.R. § 300.114(A)(2)(i)). This means instruction must be available in a continuum of placement options, ranging from regular education classrooms to specialized classrooms, residential facilities, and home-based programs. Removal to separate classes is permissible only "if the nature or severity of the disability is such that education in regular classes with the use of supplementary aids and services cannot be achieved satisfactorily" (34 C.F.R. § 300.114(A)(2)(ii)). On the basis of student's IEP goals, the team should consider whether supplementary aids and services provided within a general education classroom would allow the student to receive an appropriate education or whether such a placement would impede her or his learning and/or the learning of other students. If a child will not be participating fully with children without disabilities in a regular classroom in nonacademic and extracurricular activities, the team must write an explanation on the IEP as to why the child will not participate in these activities.

Full inclusion refers to a child's access to and participation in all activities of the school setting. Supports and adaptations are provided as needed to enable the child with disabilities to participate in activities with his or her peers. These services are typically provided in the child's neighborhood school. For example, Josh, a child with spina bifida and mild learning disabilities, attends his local home elementary school in a rural

community. Josh is in the regular classroom for the entire day, with a classroom aide assisting him with self-care tasks, as needed. The school's special education teacher helps the classroom teacher in adapting Josh's assignments when needed.

Inclusion can consist of a variety of learning options. A student may spend a portion of the day in a resource room and a portion in regular education classes. For example, Brian, who is in the sixth grade, participates in the regular education classroom for all his classes except math and reading. For these subjects, he receives instruction from the resource room teacher because his performance in these classes is significantly lower than that of his peers, and he requires a special curriculum to progress in these areas.

Modifications and accommodations are made to support Brian's learning needs so that he can participate in learning activities. Often the regular classroom teacher groups students for science and social studies projects so that each student is given a task that he or she can manage. Because Brian has difficulty with manipulation, the teacher gives manipulation tasks to the other students in the group and often selects Brian to search the Internet or oversee final project assembly. Tests are read to Brian, and he is allowed to dictate his answers.

Finally, once the child turns 16 years old, or before that if determined appropriate by the IEP team, the IEP must include a written transition plan. It is recommended that students as young as age 14 participate in transition activities, even if they do not yet have a formal transition plan.⁵⁹ Transition is the process of beginning to plan for the student's completion of education and postgraduation life. This plan is based on age-appropriate transition assessments related to training, education, employment, and, when appropriate, independent living skills. The transition plan should include a statement of the services needed and should clearly connect the student's goals for after-school life and a planned course of studies in high school. The transition services (including courses of study) needed to assist the child in reaching those goals may include vocational training, supported employment, independent living, work experience, community participation, and planning appropriate high school classes in preparation for college. When the student reaches age 16, a statement of interagency responsibility to support his or her transition is also included in the IEP.

The literature suggests that occupational therapists are not fully participating in the development of transition plans, despite their capability to do so.⁷⁵ One reason for this may be because the beliefs of the educational staff regarding the scope of occupational therapists and their potential contributions to transition planning.⁷⁴ Although educators may be knowledgeable regarding the scope of occupational therapy,⁷⁵ occupational therapists would benefit from educating administrators and members of their local school board about the potential contributions that they could make in this regard. Occupational therapists may be involved in transition planning by completing assessments to target the student's motor and process difficulties⁵⁹ and by providing input on the student's functional capabilities related to postsecondary education, vocational planning, and community living.⁶ Occupational therapists may be involved in this process by providing input on the student's functional capabilities related to vocational planning and community living.

The development of IEPs can be a daunting task because of the changing legal requirements with each reauthorization

of IDEA and the changing face of each IEP team. Occupational therapists need to develop the skills to work effectively with a multitude of parents and professionals. Although IEP teams have characteristics that make them similar to other types of working teams, there are also characteristics unique to IEP teams that need to be considered by the various members. It has been suggested that IEP teams differ from other teams in the following ways³⁵:

1. There is a legal framework of required relationships among partners. Federal, state, and local laws and policies spell out in some detail who must participate and what they must do. This is especially true for the school district, which has many legal responsibilities regarding the education of students with disabilities.
2. The team members share responsibility and accountability for the success of the student in meeting his or her goals.
3. The process is “results-oriented,” meaning that what matters is not how happy everyone is with the process, but the success of the student’s educational program.

As a result of these differences, development of the IEP involves high levels of collaboration and, at times, negotiation among and consensus building by all team members. The written IEP document is developed in a formal meeting so the contents reflect the consensus of the team. Parents and other team members, including occupational therapists, contribute equally to the process. Team members discuss the student’s strengths and needs and then develop goals, outcome statements, and plans through a collaborative process. By developing the student’s IEP using a team process that includes the family, the team assures the family that the IEP belongs to the student and is unique to that student’s educational needs.

In addition to the required documentation for the IEP and follow-up progress reports, routine documentation of service provision is not mandated by IDEA. The occupational therapist should develop a method of documentation of services to record the student’s progress toward goals, response to interventions, other changes in performance, and strategies that were promising or ineffective.²⁶

Annual Review and Re-evaluation

The student’s IEP must be reviewed by the IEP team at least once a year or more often if the parents or school personnel request a review. Outcomes are measured by student achievement of the IEP goals, including participation in state and districtwide assessments.² At the time of review, it is important to keep in mind one of the primary goals of IDEA 2004—to improve student academic achievement and functional outcomes in addition to postsecondary success. The long-term goal is for students with disabilities to leave high school prepared to work, attend higher education, and live independently.

Termination of related services may be decided at an annual review if the team determines that the related service is not necessary for the student to benefit from his or her IEP. The occupational therapist may recommend termination when the student has acquired the needed skills and uses them during school, when needed adaptations and supports are in place, or when services have failed to produce the targeted IEP outcomes despite numerous approaches and lengthy attempts.⁹⁴ When making a recommendation to terminate services, occupational therapists should be prepared to bring data to support their recommendations. The child must be re-evaluated at least

every 3 years to determine if he or she continues to be a “child with a disability,” as defined by IDEA, and to redefine the child’s educational needs.

Data-Based Decision Making and Special Education

Data-based decision making is becoming increasingly important in school-based practice because of recent trends in education and federal policy. Occupational therapists providing services in special and general education need to be familiar with how to monitor a student’s progress and objectively determine whether or not their intervention is effective in supporting a student’s achievement of established outcomes. In general education, progress monitoring is used to assist problem-solving teams in determining when a student needs additional support to meet the objectives of the curriculum. Data collected through progress monitoring may be used to justify a change in the intensity, frequency, or type of service provided (e.g., moving from tier 1 services to tier 2 or 3 services).¹⁰⁸ In special education, progress monitoring can be used to determine whether a specific intervention strategy or accommodation is effective in supporting the student to meet his or her IEP goals. It can also be used as evidence to support the recommendation to discharge a student from occupational therapy services. This section provides an overview of progress monitoring and goal attainment scaling.

Progress Monitoring

Goal writing and progress monitoring are inextricably linked. An occupational therapist should not recommend an IEP goal or target a student behavior in RtI without having a plan to monitor the student’s progress. Designing a strategy to collect data at the time of goal writing helps ensure that the target behavior is objectively defined, observable, and measurable.

The first step in monitoring progress is determining the target behavior. The target behavior should be described in specific and observable terms. The target behavior should also be sensitive to small increments of change and growth over time. Baseline data should be collected on the target behavior three to five times and during typical conditions to ensure that it is representative of the student’s performance.⁴²

Once baseline data are collected, a goal is established. The goal represents the desired level of change that will be achieved related to the target behavior and as a result of the intervention. For the purposes of progress monitoring, goals can be written in terms of reducing target behaviors (e.g., a reduction of talking out in class) or increasing target behaviors (e.g., an increase in time spent working on an assignment). As with other types of goals, conditions and criteria associated with performance and a time line are established.

After the goal is established, a strategy is designed to capture and document the student’s response to intervention. Data are collected at regularly scheduled intervals, ranging from once a week to once a month, depending on the setting in which data are being collected, as well as the nature of the target behavior.¹⁰⁸ Occupational therapists may choose to use available data collection tools or develop and customize their own. [Figures 23-5 and 23-6](#) provide examples of data collection tools. More data collection tools are available at the National Center for Response to Intervention’s website (www.rti4success.org).

FIGURE 23-6 Data collection tool, example 2.

Progress monitoring data are analyzed after three to five measures have been collected. Progress monitoring data are typically graphed, visually analyzed, and/or compared against predefined criteria. For example, a student's goal might be to write all the uppercase letters of the alphabet independently from memory. For this student, the occupational therapist collects progress monitoring data on this goal every other week using the data collection tool in Figure 23-6. Once these data are collected, the occupational therapist charts the number of possible letters written in uppercase on the y axis and the number of weeks during the intervention period on the x axis. The occupational therapist then graphs the student's progress by plotting the number of uppercase letters that the student wrote from memory each time data were collected. If the occupational therapist is monitoring this student's progress in RtI, then he or she also plots the performance of two or three of the student's peers on the same target behavior. This comparison demonstrates whether the student's performance differs from that of other students on the same outcome (Figure 23-7). If a discrepancy is noted, and the student is not performing at the same level as his or her peers, more intensive intervention may need to be provided. On the other hand, if visual analysis of the graph and comparison to peers' performance suggests that the student has made substantial progress, the student may no longer need services. As students continue to develop and progress throughout the school year, this process of data collection may need to be repeated continually and

FIGURE 23-7 Progress monitoring graph used for RtI.

shared with the student's educational team to ensure that he or she is responding to the instruction being provided.

Goal Attainment Scaling

Goal attainment scaling (GAS) is another way to monitor progress in school-based practice. GAS is an individualized, criterion-referenced approach used to measure progress and document incremental changes on specific functional outcomes.^{76,78} GAS

classroom co-teaching models, for example, offer opportunities to serve integrated groups of students with services that blend promotion, prevention, and restorative intervention strategies.

Target of Services: Who Occupational Therapists Serve

General Education

Within general education, occupational therapists have opportunities to provide services to children and youth without disabilities and those at risk for developing academic and/or functional delays. With the growing movement to a three-tiered system of service provision, it is important for occupational therapists to envision, articulate, and advocate for their role in each tier. For example, occupational therapists should educate student support teams on how their services can meet the academic, health, developmental, functional, and behavioral needs of students in general education.⁵⁷ Refer to [Box 23-7](#) for an example of how occupational therapists can promote a healthy lifestyle and prevent obesity in schools.

At tier 1 (schoolwide services), occupational therapists can assist the general education team in helping students access and participate in the curriculum by paying careful attention to areas of function within their scope of practice—education, social participation, play and leisure, ADLs, and work. For example, the occupational therapist may participate in universal screening of handwriting to identify students who are struggling, depending on whether the state allows screening.³ This might be followed by providing a teacher in-service training presentation on multisensory strategies for teaching handwriting and joining a curriculum committee to assist in identifying an appropriate handwriting curriculum. To help foster student attendance and positive behavior, the occupational therapist might assist educators in implementing programs designed to help students regulate arousal for attending (e.g., the Alert program) in their classrooms.¹²¹ In addition, the occupational therapist might join a school team working on a student conduct and behavior management program to become aware of issues in this area and offer strategies from an occupational therapy perspective.

BOX 23-7 Occupational Therapy Services Focusing on Health Promotion and Obesity Prevention: A School-Based, Healthy Lifestyle Initiative

Program Development

The school-based healthy lifestyle initiative consists of a multi-tiered program designed to do the following: (1) promote participation in healthy occupations, (2) support the development of volition, and (3) establish healthy performance patterns in children with and at risk for obesity. The need for the program was identified by related service providers and the school's principal after they noticed an increasing number of referrals to occupational therapy and physical therapy because of concerns related to children's overweight status. Some examples of the concerns noted by the school personnel included fatigue and inattention in class, as well as not being able to perform in physical education. They were increasingly concerned about these issues because they knew them to be symptoms of significant medical problems that children with obesity often encounter. Medical problems that are common in this population include diabetes, sleep apnea, high cholesterol levels, and high blood pressure; in addition, many children with obesity face social isolation and stigma.¹⁰³

Prior to the introduction of the healthy lifestyle initiative, the school's principal had removed the vending machines from the school and required that parents only send healthy snacks for birthday treats. In addition, a physical therapist started a weekly open gym to allow students to participate in physical activity before the school day. Finally, local businesses were made aware of the initiative, and the school accepted donations of pedometers, other equipment, and incentives for children who participated in the program.

1. The activities included in the first tier of the program included the weekly open gym, a whole-school fitness walk, and a cook off—style competition among the different classrooms. In addition, a bulletin board space was dedicated to the initiative, and its content was changed on a weekly or biweekly basis.
2. The activities included in the second tier included training on how to develop new health-promoting habits. For

example, students at this tier learned how to use and record steps with a pedometer, how to measure and record personal body mass indexes (BMIs), and how to keep food and activity logs.

3. The activities included in the third tier were designed by occupational therapy students and guided by the Model of Human Occupation. The activities at this tier centered around a collection of classroom-based groups focused on building capacity and increasing students' self-efficacy for participating in physical activities.

Program Evaluation

Although the entire school participated in this initiative, one classroom was selected to provide qualitative information for the program evaluation. Seventeen fifth-grade students participated in a picture-taking assignment that was integrated into their science class. This assignment was developed based on the Photovoice methodology.¹¹⁹ Students were given disposable cameras and prompted to take pictures of things that helped them or did not help them maintain a healthy lifestyle. After the photographs were developed, students sorted their pictures and participated in two discussions that followed the typical Photovoice prompts. Students were asked to reflect on their photographs and answer the following questions:

- What do you see here?
- What is really happening?
- How does it relate to our lives?
- Why does the situation exist?
- What can we do about it?

The students who participated in this assignment were able to identify activities that promoted a healthy lifestyle and those that did not. In addition, they set goals about what they wanted to do to change specific unhealthy situations.

This program illustrates one way that occupational therapists can be involved in promoting healthy lifestyle development in children in the school context.

This program is discussed in further detail in Cahill, S., & Suarez-Balcazar, Y. (2009). Promoting children's nutrition and fitness in the urban context. *American Journal of Occupational Therapy*, 63, 113-116, and Cahill, S., & Suarez-Balcazar, Y. (2012). Using Photovoice to identify factors that influence children's health. *Internet Journal of Applied Health Sciences and Practice*, 10, 1-6.

FIGURE 23-8 Range of occupational therapy service delivery.

At tier 2 (targeted interventions for those at risk), the occupational therapist might develop a social skills group for students struggling with behavior management and social interaction with peers. Tier 3 interventions call for more individualized interventions for those not responding to tier 2 interventions. At this level, students may receive such services as a part of RtI or may be referred for special education.

With opportunities to expand occupational therapy's role in general education, occupational therapists might be questioning how they can create time to provide prevention and early intervention services. Traditionally, an occupational therapist's job expectations have been based on a caseload model of counting the number of children receiving direct intervention as part of their IEP.⁴ This model often neglects to account for essential indirect services, including collaborative consultation, team meetings, and in-service trainings.¹⁰⁷ In contrast, the concept of workload encompasses all the direct and indirect services performed to benefit students, making a workload approach helpful for conceptualizing work patterns that optimize effectiveness and impact.⁴ Occupational therapists must have the flexibility of organizing their work patterns to serve students in their LRE, collaborate with teachers and other school personnel, attend meetings, supervise and train occupational therapy assistants, plan interventions, and collect data. Careful documentation of workload using a time study may help state regulatory boards become knowledgeable about the range of occupational therapy services and encourage them to adopt a workload versus caseload system of documenting service provision. Kentucky, for example, has adopted a workload model, defining workload as "the amount of minutes per day, week, or month a therapist needs to work to adequately perform his/her duties" (p. 43).¹⁰⁶

Special Education

In special education, occupational therapists provide services to children and youth with disabilities who are eligible for special education. Once the IEP team agrees that occupational therapy services are necessary to support the student's goal achievement, the occupational therapist can propose how to provide services. IDEA 2004 recognizes that services and supports need to be delivered in different ways for children with disabilities to benefit from education. Although the primary client is the child, intervention may also target general and special education teachers, other related service providers (e.g., music therapists), administrators (e.g., principals), and paraprofessionals involved in supporting the child's IEP.^{26,50}

Range of Service Delivery Options: What Occupational Therapists Provide

Intervention with a variety of clients occurs as a direct result of using a range of service delivery options. Traditionally, services

in schools were provided directly to the child in an isolated therapy setting, similar to clinical practice. This type of service delivery involves primarily one client, the child. However, IDEA does not mandate any one service model and allows for a range of services, including those provided directly to the child (direct), on behalf of the child (indirect), and as program supports or modifications for teachers and other staff working with the child (indirect; § 614(d)(IV)). Refer to [Figure 23-8](#). Decisions about how occupational therapy services are provided are based on the child's needs, the educational program, and expected outcomes.^{26,93} Examples of the range of services provided by an occupational therapist include working individually with children, consulting with the teacher about a student, co-leading a small group in the classroom, providing an in-service education for school personnel, and working on a curriculum or other school-level committee.¹⁰⁹

Direct Services

Direct services may be provided in a variety of ways, including one to one (occupational therapist works individually with the student), small groups (lunch bunch), or large groups (in the classroom, during recess), and can take place in a variety of settings within the school (e.g., separate therapy room, special education resource room, general education classroom, cafeteria, playground). Individualized direct services in isolated settings may be useful during initial evaluation of levels of performance or during the initial stages of learning a skill. The benefit of providing services in small groups is that interaction within a group provides students with opportunities to develop and practice social skills. In addition, in an effort to meet LRE, the occupational therapist can blend students with and without disabilities in a small group intervention, targeting those at risk of delays but who are not eligible for special education. For example, an occupational therapist might co-lead groups with a special education teacher, as discussed in [Box 23-8](#) ([Figure 23-9](#)).

Indirect Services Provided on Behalf of the Child or to Provide Program Supports

These require the therapist to work directly with a range of other clients, including regular and special educators, parents, and paraprofessionals. For example, an occupational therapist might consult with the classroom teacher to help modify instructional materials and methods for a student with physical or organizational needs requiring close interaction with the teacher. Documentation of evaluation, intervention, and outcomes is an important service and should be included in an occupational therapist's weekly schedule. Educational in-service sessions to groups of school staff (e.g., teachers, administrators, paraeducators) or parents are beneficial for providing information on discipline-specific areas of performance, such as fine motor development and handwriting, sensory

BOX 23-8 “Brownie Busters”: An Occupation-Based Work Group for Children with Multiple Disabilities**Program Development**

The Brownie Busters program aims to do the following: (1) provide a community-based functional curriculum for students with multiple disabilities attending elementary school; (2) provide tasks that are meaningful to elementary school students while teaching them skills needed for future employment and independence in their homes and neighborhood community; and (3) encourage collaboration among school team members, including the teacher, teacher’s assistant, occupational therapist, and parents.

The foundation for the development of the 6-week Brownie Busters work group was based on literature regarding the development of work skills in children with multiple disabilities, which indicated the following: (1) preparation for employment needs to begin at an early age,⁵⁸ (2) participation in meaningful activities within an educational or work context reinforces interest,^{10,67} and (3) programs for students with moderate intellectual disabilities should emphasize skills that are functional and longitudinally relevant.⁸¹ An occupational therapist working in a large Midwestern municipal school district developed and facilitated the 1½-hour weekly groups over a period of 6 weeks. The classroom teacher, teacher’s assistant, and a parent volunteer served as helpers for the groups.

The overall purpose of the Brownie Busters work group was to have the students make and sell brownie-making kits to teachers, students, and staff at their school. The groups were designed to promote the development of several independent living and work skills, including the following: planning a work task, functional reading (reading labels and recipes), safety issues related to walking in the community, grocery shopping, simple cooking (learning about ingredients and measuring, pouring, and mixing ingredients), using an oven, sanitary food handling, and selling a product.

Participants

The work group consisted of eight elementary students ages 9 to 12 years with multiple disabilities, including mild to

moderate intellectual impairment and language delays. The diagnoses of the students included cerebral palsy, Down syndrome, and autism.

Group Sessions

The group sessions involved weekly discussions of basic work skills, a trip to the grocery store, making the brownie mixes, putting them in jars, decorating the jars, and selling them. Each session also involved clean up.

Qualitative Research Findings

Qualitative research methods were used to explore the meaning of group participation from the children’s perspective. Each of the eight group members were interviewed during weeks 2 and 6 of the program by the occupational therapist to explore the personal meaning ascribed to the group experience. Participant observations served as the second form of data and consisted of weekly observations of the group. Based on a qualitative analysis of the interviews and participant observations, three essential themes unfolded: shopping, special ingredients, and doing everything. When asked what comes to mind or what they liked the most when they think of the occupational therapy groups, all the participants talked about walking to and shopping at the neighborhood grocery store, ingredients needed for the project, and doing the tasks necessary for making the brownie jars. By being actively involved in the shopping process, students learned first-hand about how to locate the baking ingredients needed for the brownies. The students began to take on the role of shoppers by looking for items needed for baking and using a shopping list. Students also learned about each special ingredient’s unique properties by handling, measuring, and tasting it. Finally, students expressed joy in doing everything and began to function like workers—doing the task, sharing, demonstrating care with the ingredients, using sanitary strategies for handling of food, and preparing the jars to sell. Findings support the importance of occupation-based practice in fostering the link between doing and becoming.

Contributors: Eileen Dixon, MS, OTR/L, and Susan Bazyk, PhD, OTR/L, FAOTA.

processing, positioning for function, and mental health and well-being. Time spent serving on school-wide committees (e.g., positive behavioral interventions and supports [PBIS], bully prevention) is also an important indirect service, allowing occupational therapists opportunities to share expertise and become contributing members of the school community. Planning time for embedding intervention is an important indirect service and one that is not always acknowledged as an essential part of an occupational therapist’s workload. However, in an outcome study of one occupational therapist’s full integration of services in a kindergarten curriculum, it was found that 50% of indirect services were spent in planning integrated services.¹⁴

In addition to determining the most effective range of services for a child, occupational therapists are also encouraged to provide services in a flexible manner, depending on the student’s stage in the therapy process and particular needs. For example, the occupational therapist may choose to work directly with a student for several weeks to teach the student how to implement the Alert Program for Self-Regulation,¹²¹ followed by consultation with the teacher or paraprofessional to ensure generalization of the strategies in the classroom.

Integrated Service Delivery: Where Services Should be Provided

Integrated services delivery involves the provision of occupational therapy in the child’s natural environment (e.g., in the classroom, on the playground, in the cafeteria, on and off the school bus), emphasizing nonintrusive methods and common goals.¹⁴ Although sometimes viewed simply as “treatment that takes place in the classroom,” integrated therapy is actually complex, requiring team collaboration and a combination of teacher education, consultation with various team members, and direct service that is skillfully embedded in the natural context.⁸⁹ IDEA does not specify the type of service delivery provided, but it does indicate that all related services be provided in the LRE to foster participation in the general education curriculum. Simply stated, integrating occupational therapy services in general education settings to the maximum extent possible is the law. Also, it is important to keep in mind that “students with disabilities do not attend school to receive related services; they receive services so they can attend and participate in school.”⁴⁵ Related services must be educationally relevant, which differs from therapy that occurs in an outpatient

FIGURE 23-9 A-D, Brownie Buster group pictures.

clinic or hospital setting. It is critical for occupational therapists to articulate these differences to school staff and parents.¹¹⁸ Because occupational therapy services support academic goals (e.g., handwriting, literacy) and nonacademic functional goals (e.g., organizing learning materials, using the restroom, playing during recess), the service context can include a wide range of natural settings, including classroom, playground, cafeteria, restroom, and hallways.

Another reason for providing services in an integrated setting is that theories of and research on motor control have indicated that the practice of a meaningful occupation in a natural context is most effective for achieving new skills or modifying movements.^{16,73,90} Performing meaningful activities in natural settings requires children and youth to problem-solve and adapt to inherent variability, which helps reinforce

learning.⁹⁰ In addition, interventions provided in natural settings during daily routines are more likely to be applied consistently, leading to functional changes.² Therefore, pull-out services in isolated therapy rooms filled with contrived activities and equipment are no longer considered best practice in schools. Such services may only be appropriate during initial stages of learning a task, when the student's skill level is far below the tasks presented to other students in the classroom or when the intervention activities cannot appropriately occur in a typical classroom (e.g., therapeutic use of equipment such as a swing). "Although therapists may pull students out of the classroom for brief periods to explore strategies or to introduce a new skill, time away from instruction is minimized" (p. 3).⁹⁴ McWilliam has cautioned that pull-out therapy is less effective than integrated services.⁷⁹

Benefits

All parties benefit from integrated services. By working in natural settings, the occupational therapist learns about the curriculum, academic and behavioral expectations, teacher preferences, and unique culture of each classroom. Observing and interacting with students in the classroom and other school settings (e.g., physical education area, music, cafeteria) enables occupational therapists to analyze the relationships among the child's abilities, activity expectations, and physical and social environment fully. When the task-environment demands are greater than the student's abilities, the therapist and teacher must adapt the environment or task to foster successful participation. Integrated therapy ensures that the therapist's focus has high relevance to the performance expected in the student's classroom and other school contexts.

The therapist's presence in the classroom also benefits the instructional staff, who observe the occupational therapy model interventions that are practical and realistic.²⁷ With integrated services, teachers, paraeducators, administrators, and other related service providers have opportunities to learn about occupational therapists' scope of practice and skill sets. The blending of teacher education, collaborative planning, and embedded direct intervention provides a natural way for occupational therapists to contribute discipline-specific information and the strategies needed to enhance particular areas of function that are typically not within a teacher's expertise.

Students with disabilities benefit from the teacher's increased ability to implement therapy strategies when the occupational therapist is not present.¹⁰⁵ In a study of fine motor and emergent literacy outcomes following fully integrated occupational therapy in a kindergarten curriculum, it was found that children with and without disabilities made significant gains in fine motor and emergent literacy skills.¹⁴ In this particular school, the principal expressed pleasure in these results, exclaiming that she was "getting the biggest bang out of her therapy buck." When providing integrated services, occupational therapists need to measure outcomes in students with and without disabilities and share these data to communicate the benefits of therapy to administrator, parents, and teachers. **Figure 23-10** illustrates an occupational therapist embedding a sensorimotor activity into the classroom to foster self-regulation of attention for learning.

Challenges

Despite the well-documented benefits of integrated services, successful implementation requires time and effort. Findings from several survey and qualitative studies have indicated that the greatest challenge associated with providing integrated services is time for occupational therapists, teachers, and other relevant school personnel to meet and plan embedded services.^{8,20,53} Although informal collaboration with teachers in the hallways or during lunch is useful, time for regular formal meetings is essential.

Suggested Strategies for Moving Toward an Integrated Service Model

Strategies that can be used to foster the provision of integrated occupational therapy services include the following:

1. Obtain school administrative support to free teachers and OTs from their teaching and therapy schedules.

FIGURE 23-10 The occupational therapist may embed movement and/or sensory strategies to help students regulate alertness for attending.

Bazyk and colleagues¹⁴ found that when providing integrated services, time spent collaborating with the teacher and other personnel outweighed time spent in direct intervention by a 2:1 ratio. As the face of occupational therapy shifts from pull-out to embedded services, occupational therapists need to make a case for time spent in planning as a legitimate part of service because of the complexity of integrated therapy.

2. Allocate time for collaborative planning with relevant school personnel based on the specific service and setting.

When integrating sensorimotor strategies into a pre-school classroom, for example, it is important to collaborate with the teacher and paraeducator. Embedding services in the cafeteria will involve collaboration with the lunch supervisors. The need for regularly scheduled meeting times is consistently reported by therapists and teachers.^{8,20,53}

3. Commit to collaboration. Develop positive relationships with teachers, paraeducators, and other relevant stakeholders (e.g., parent, mentor, physical therapist, school psychologist, speech-language pathologist, principal, cafeteria supervisor, bus driver).

Because integration of occupational therapy services requires working closely with teachers, administrators, families, related service providers, and support staff, effective collaboration is essential. Commit to a collaborative style of interaction built on mutual trust and respect and effective communication surrounding common goals, characterized by the equal status of all parties involved in working toward a shared goal.²⁰ Consider developing a community of practice (CoP) to enhance collective work and impact.¹²⁰ A CoP is a group of people who are committed to a common cause, interact regularly, and share leadership and work for collective competence and impact.¹²⁰

4. Learn about the unique classroom culture or school setting, the curriculum, and performance expectations.

Occupational therapists need to understand school board policies, curriculum, and classroom practices of teachers to develop educationally relevant approaches to providing

service. Informally observe physical and social aspects of the environment (e.g., classroom layout, teacher-student interactions). Talk with the teacher about challenges and needs specific to occupational therapy's scope of practice (e.g., issues related to social participation, attention, handwriting). When working with students in a classroom, the occupational therapist needs to have a clear understanding of classroom expectations. This includes knowledge of classroom rules, routines, and dynamics and of the general education curriculum and special education adaptations. Each classroom teacher has unique teaching and classroom management styles. Intervention techniques conducted in the classroom that may be acceptable to one teacher may not be acceptable to another teacher; they may even be considered intrusive.

5. Griswold has recommended that occupational therapists offer interventions that fit the existing classroom structure and culture.⁴⁷

For example, a teacher who values child-directed learning and hands-on learning centers may respond well to an occupational therapist's suggestions for activities to be included in the learning centers. Another teacher who uses a strong teacher-directed classroom may prefer to engage in team-teaching activities with the occupational therapist.

6. Provide information about occupational therapy's role and full scope of practice using informal opportunities to share information (e.g., conversations in the hallway, one-page information briefs) and formal in-service education.⁵³

Make a point to describe how occupational therapy can contribute to areas of student function beyond handwriting and sensorimotor processing, such as social participation, play, leisure, and work. Explain occupational therapists' expertise in a wide range of performance areas, including physical and motor, mental health and well-being, sensory processing, cognitive, and behavioral functioning.

7. Explore teacher preferences for integrated services.

Be sensitive to the regular education schedule and do not disrupt the child's and the classroom schedule, if possible. Teachers may prefer to have the occupational therapist in the classroom at certain times or on certain days. These preferences should be negotiated with the teacher before intervention, and attempts should be made to schedule times for providing services to the child that coincide with targeted goal areas. For example, handwriting interventions can be integrated into the student's language arts time, and keyboarding skills can be integrated into the student's computer or language arts class. (Refer to [Box 23-2](#) on the Evolve website, From pull-out to integrated service provision: How one school district made the transition)

Informal Strategies for Integrating Direct Services

Direct services can be embedded throughout the school day to enhance participation in a number of ways, including the following: (1) modify the physical or social environment, (2) modify the activity or task, and (3) modify the instruction.

Modifying the school environment aligns with the educational initiative called Universal Design for Learning (UDL), which focuses on fostering performance in the classroom via environmental modifications. To modify the physical environment, the occupational therapist may give the teacher materials helpful for implementing the intervention (e.g., pencil grips, slant boards, games that foster fine motor skills) or help adapt the environment so that the child can participate (e.g., establish a sensory corner, obtain supportive seating, set up a prone stander). To enable the person who is chosen to implement the strategy, the occupational therapist uses modeling and coaching as the child attempts the activities in his or her natural routine. Regular contact is necessary to update programs and supervise the manner in which the activities are implemented. Refer to [Table 23-5](#) for examples of integrated services

TABLE 23-5 Examples of Indirect Intervention Strategies When Integrating Services

Intervention Strategies	Examples
Reframe the teacher's perspective.	Explain the functional consequences of the perceptual problems observed in children with spina bifida. Identify that a child with autism is hypersensitive to tactile and auditory stimuli. Suggest that a child's difficulty in sitting quietly is related to his or her low arousal level and need for sensory input.
Improve the student's skills.	Recommend that a student use carbon paper to monitor the amount of force applied with the pencil. Recommend that a student practice letter formation using wide-lined paper and beginning at the top of the letter. Recommend that a teacher provide standby assistance when the child practices carrying a lunch tray in the cafeteria.
Adapt the task.	Recommend that a student begin to use a computer keyboard. Introduce compensatory methods for putting on a jacket. Teach one-handed techniques during toilet training. Recommend that a student use earphones with music during written tests.
Adapt the environment.	Establish a quiet area with a tent in which students can hide and remove themselves from the stimulating environment.
Adapt the routine.	Suggest that excess visual stimulation be removed from the wall in front of a student. Recommend that a student have opportunities for exercise three times each day. Recommend that a student be given extra time to complete certain written assignments. Suggest that the student receive speech therapy after occupational therapy so that he or she can be focused and attentive during the session.

involving a combination of indirect (consultation) and direct interventions.

Formal Strategies for Integrating Direct Services

School-based occupational therapists apply a wide array of intervention methodologies based on a variety of theoretical frames of reference (e.g., sensory integration, motor learning, behavioral, biomechanical). According to IDEA 2004, and consistent with NCLB, schools are required to “ensure that such personnel have the skills and knowledge necessary to improve the academic achievement and functional performance of children with disabilities, including the use of scientifically based instructional practices, to the maximum extent possible” (§ 601(c)(5)(E)). Formal strategies for integrating occupational therapy services with emerging research evidence include co-teaching models, occupational performance coaching, and provision of specially designed programs.

Co-Teaching

Although co-teaching originally was designed as an instructional strategy for general and special educators to share teaching responsibility within an integrated classroom,²⁹ it has also been used by occupational therapists as a formal way to integrate services.^{27,28,105} Cook and Friend have defined co-teaching as “two or more professionals delivering substantive instruction to a diverse, or blended, group of students in a single physical space” (p. 1).²⁹ In general, co-teaching involves collaboration to design, plan, implement, and evaluate the learning experience. In addition to working with teachers, occupational therapists may also choose to co-teach with other relevant school staff, such as the guidance counselor, health educator, or speech-language pathologist, depending on curricular need. The occupational therapist’s time is scheduled for the co-teaching activities, rather than for individual sessions.

Cook and Friend have defined five variations of co-teaching: (1) one teaching and one assisting (occupational therapist takes the lead and teacher assists, or vice versa), (2) station teaching (teachers divide instructional content into two segments, teach half the content to half the class at a time, and then trade student groups and repeat the same instruction), (3) parallel teaching (teachers plan a unit of instruction and present it simultaneously to half the class, resulting in a lower student-to-teacher ratio), (4) alternative teaching (one person teaches a small group of students who need specific accommodations while the other teaches the remaining larger group), and (5) team teaching (both teachers teach at the same time, sharing the lead in the discussion).²⁹

Although co-teaching may appear to require more time and effort, the benefits can outweigh the cost. The benefits of co-teaching include the following: expanded instructional options because of the combined expertise of the two teachers, improved program intensity because of a higher teacher-to-student ratio, and enhanced educational continuity for students with special needs who are not pulled out of the classroom for services.²⁹ Not only do the targeted students with disabilities benefit from the interventions, but students without disabilities in the class also benefit from the multidisciplinary input. For example, the classroom teacher and occupational therapist might co-plan a handwriting session. Another example might involve an occupational therapist and guidance counselor co-teaching a unit on the Zones of Regulation, a cognitive behavioral approach developed by an occupational therapist to

teach children how to regulate their emotions to improve social interaction with others at school.⁶⁸

Case-Smith and associates have examined the feasibility and effects of a 12-week, co-taught handwriting and writing program, Write Start, using a one-group, pretest–post-test design with 36 first graders.²⁸ The program, using a combination of station teaching and team teaching, was found to benefit students with diverse learning needs by increasing handwriting legibility and speed and writing fluency. During final interviews, the teachers and occupational therapist reported that the students received more individualized instruction and that they gained skills from working together. Specifically, the occupational therapist learned about the curriculum and behavior management approaches and the teachers learned handwriting strategies.²⁸

Occupational Performance Coaching

Occupational Performance Coaching (OPC) was initially developed by Fiona Graham to provide a process for helping parents promote their child’s occupational performance.⁴⁶ OPC involves three major components: emotional support, information exchange, and a structured process. Although originally developed to be applied with parents of children with disabilities, the basic elements may be used as a guide when working with teachers and other school-based personnel.

Emotional support, for example, may be provided in a way that acknowledges the interpersonal challenges associated with serving children in their specific context (e.g., classroom, cafeteria). When working with cafeteria supervisors while implementing the Creating a Comfortable Cafeteria program, it was important for the occupational therapist to acknowledge their challenges and needs. One of the biggest challenges expressed by the supervisors was dealing with the noise levels that occur when large groups of children eat together in a large room. The occupational therapist can help process reactions to and feelings about noise levels and problem-solve positive strategies for dealing with the noise levels without enforcing rules about eating in silence.

Information exchange is important to understand individual perceptions of the problem and/or occupational performance expectations. In the same cafeteria program, a discussion about noise levels resulted in supervisors talking about their personal sensory preferences for and tolerance of noise. Some cafeteria supervisors did not mind loud cafeteria environments and were happy to see children talking with each other and having fun. Others struggled with being in a loud environment.

The final component of OPC involves a clear sequence of steps including setting goals, exploring options, planning action, carrying out the plan, checking performance, and generalizing abilities. The occupational therapist’s ultimate goal is guided by the dual intention to improve children’s occupational performance in school contexts and assist school personnel in promoting successful participation and enjoyment. For the cafeteria program, an initial orientation session, embedded activities, and follow-up coaching were used to create a comfortable cafeteria for children with and without disabilities.

Formal Occupational Therapy–Embedded Programs

With integrated services becoming more accepted and pursued as the most preferred form of related service delivery, a growing number of occupational therapists have recently developed creative programs designed to be embedded in a variety of school contexts (e.g., classroom, cafeteria, recess) with the purpose of

helping children participate in, succeed at, and enjoy learning, socializing with peers, eating a meal, and playing during recess. Table 23-6 provides a summary of some of these programs. It will be critical for occupational therapists to conduct studies that examine the feasibility and effects of embedded programs.

School Mental Health: Emerging Roles for Occupational Therapy

School Mental Health Movement

Although mental health services for children have historically been provided in hospitals and community mental health centers, the EHA of 1975 was the first federal initiative that required schools to meet the mental health needs of students with emotional disturbances, playing a key role in blurring the lines of responsibility for where such services should be provided.^{11,67} Because IDEA focuses solely on students with identifiable disabilities that interfere with educational achievement, only a small percentage of children needing mental health services actually receive such care in school. Nonetheless, most

children receiving mental health services obtain care in schools, making schools the “de facto mental health system for children in this country” (p. 62).⁶⁷

“Education and mental health integration will be advanced when the goal of mental health includes effective schooling and the goal of effective schooling includes the healthy functioning of students” (p. 40).⁷ Over the past 2 decades, there has been a national movement to develop and expand school mental health (SMH) services because of the high prevalence of mental health conditions among youth and an awareness that more youth can be reached in schools. This movement is also attributed to prominent federal initiatives, including the NCLB and the President’s New Freedom Commission on Mental Health.⁶⁷ Schools must be active partners in the mental health of children because it is currently accepted that a major barrier to learning is the absence of essential social-emotional skills and not necessarily a lack of sufficient cognitive skills.⁶⁴ Approximately one in every five children and adolescents has a diagnosable emotional or behavioral disorder, with the most common being anxiety, depression, conduct disorders, learning disorders, and ADHD.⁶⁵ Emotional and behavioral disorders can adversely affect a child’s successful participation in a range of school activities, including

TABLE 23-6 Examples of Occupational Therapy Programs Developed for Integration into Classrooms and Other School Contexts

Program	Description	Additional Information and Resources
Write Start	This is a classroom-embedded, comprehensive activity-based program for first-grade students co-taught by a trained occupational therapist and teachers focusing on handwriting and written expression. The goal is to help first-grade students become legible and fluent writers. Type of collaboration—co-teaching Length of time—12 wk, two 45-min sessions/wk Sessions include modeling of letter formation and opportunities to practice; small group activities focusing on foundation skills (visual motor integration, fine motor skills, and cognitive skills); adult modeling, monitoring, and feedback; and provision of peer supports and evaluation.	Website: http://www.write-start-handwriting.org
Zones of Regulation	This curriculum provides a systematic, cognitive behavioral approach to teach children about their emotional and sensory needs to self-regulate and control emotions and impulses, manage sensory needs, and improve the ability to problem solve conflicts. The Zones of Regulation program combines social thinking concepts and visual supports to help students identify feelings, understand how behaviors affect others, and learn tools that can be used to move to a more acceptable state. The four zones are the following: • Red zone—heightened state of alertness and intense emotions resulting in being out of control • Yellow zone—less heightened state of alertness and elevated emotions allowing for some control but that result in stress, anxiety, silliness, or nervousness • Green zone—calm state of alertness associated with being happy, content, focused, and ready to learn • Blue zone—low state of alertness that may occur when one feels sad, sick, bored, or tired Students learn strategies for regulating their emotional and sensory needs to meet the demands of the context and succeed academically and socially.	Website: http://www.zonesofregulation.com

TABLE 23-6 Examples of Occupational Therapy Programs Developed for Integration into Classrooms and Other School Contexts—cont'd

Program	Description	Additional Information and Resources
Drive-Thru Menus—relaxation and stress busters, attention, and strength	Similar to how drive thru restaurants can provide food without taking a lot of time, these drive thru menus were developed to help students engage in meaningful activities that take only a short amount of class time. Type of collaboration—consultation to educate the teacher about the program and how and when to embed it into the classroom Length of time—each activity takes about 3-5 min of class time to help students manage stress and relax or engage in active movement to attend. Program contents—each program consists of a large, laminated colorful poster with 10 activities, a DVD of the author's overview of the program, and a leader's manual that explains the purpose, how to prepare for the activity, how to do the activity, and suggested adaptations. • Relaxation menu activities use visualization and meditation to bring about a sense of peacefulness and tranquility. • Stress-buster menu activities involve active movements to relieve stress. • Strength menu activities help students who have difficulty completing fine motor tasks because of muscle weakness. • Attention menu activities help students who struggle with attention and keeping their bodies quiet enough to learn.	Websites: http://www.therapro.com/Drive-Thru-Menus-Attention-and-Strength-C307797.aspx http://www.therapro.com/Drive-Thru-Menus-Relaxation-and-Stress-Busters-C307798.aspx
Alert Program for Self-Regulation of Arousal	The Alert Program was initially developed for children with attention and learning difficulties, ages 8-12 years, but has been adapted for preschool through adult-age individuals with and without a variety of disabilities. The purpose of the program is to teach individuals (children and youth, school personnel, and parents) how to understand their unique sensory processing to help them use sensory strategies to maintain optimal states of alertness for successful functioning throughout the day. An engine analogy is used to teach children and adults how to self-regulate levels of alertness throughout the day to participate in activities they need or want to do. Three car engine levels are taught: • High—feeling hyper • Low—feeling lethargic • Just right—able to attend and focus on task at hand Five strategies for changing “engine speeds” and alertness include putting something in the mouth, move, touch, look, and listen. Children analyze how their engine speeds vary throughout the day and learn how to use sensory strategies to regulate their alertness to feel good and function well for the task at hand.	Website: http://www.alertprogram.com Products include Leaders' Guide, introductory booklet, games (Alert Bingo), and songs (Alert Program CD).

classroom work and social participation during lunch and recess. Children with disabilities are at increased risk for developing mental and/or behavioral challenges. Almost one in three children with developmental disabilities is diagnosed with a co-occurring mental health problem.¹⁰²

School Mental Health

SMH refers to a framework of approaches that have expanded on traditional methods addressing mental health by emphasizing

promotion, prevention, positive youth development, and school-wide approaches (<http://www.schoolmentalhealth.org/Resources/ESMH/DefESMH.html>). This SMH framework promotes interdisciplinary collaboration among mental health providers, related service providers, teachers, and school administrators to meet the mental health needs of all students. As a result of federal support, two national technical assistance centers were developed in 1995 to promote mental health in schools—the Center for Mental Health in Schools at the

University of California at Los Angeles (UCLA) and the Center for School Mental Health Analysis and Action (CSMA) at the University of Maryland.

Mental Health Continuum

All too often, the term *mental health* is interpreted to mean services focusing on mental illness because of a long-standing emphasis on healing pathology. Evidence indicates, however, that the “absence of mental illness does not imply the presence of mental health, and the absence of [or limitations in] mental health does not imply the presence of mental illness.”⁶² Keyes⁶² has advocated for the adoption of a two-continuum model, with mental health belonging to a continuum separate from mental illness. It is important for occupational therapists to be aware of this distinction and help school personnel, students, and families understand the emotional and behavioral indicators of mental health, as well as the symptoms associated with mental illness.¹²

Mental health is defined as a “state of successful performance of mental function, resulting in productive activities, fulfilling relationships with people, and the ability to adapt to change and cope with adversity.”¹¹⁵ Mental health encompasses more than demonstrating the presence of good behavior. It involves feeling good emotionally and doing well in everyday functioning.⁸⁰ The terms *mental illness* and *mental disorders* are commonly used to refer to diagnosable psychiatric conditions that significantly interfere with a person’s functioning, such as bipolar disorder, schizophrenia, and dementia. The term *mental health problems* often refers to more common issues, such as anxiety and depression, which may be less severe and of shorter duration but, if left unattended, may develop into more serious conditions.⁹

Why Care About Mental Health and Happiness?

Individuals who are mentally healthy and feel happy demonstrate greater degrees of everyday functioning,⁶² healthy behaviors,⁹⁶ and perceived good health.¹⁰¹ Children and youth who experience positive mental health and well-being function better during academic and nonacademic times of the school day.

Use of Naturalistic Resources

Integrating mental health initiatives involves using the naturalistic resources in schools to implement and sustain effective supports for promoting positive mental health in students with and without disabilities. Although the mental health field has traditionally been viewed as the domain of mental health specialists, who provide services to individuals when mental health problems interfere with everyday functioning, it is now recognized that addressing mental health issues is far too complex to relegate to a small number of professionals and is more effectively addressed in promotional and preventive ways. Leaders in the field of SMH have been calling for a paradigm shift to better prepare all school personnel (e.g., teachers, administrators, psychologists, social workers, related service providers) to address the mental health needs of all students proactively.⁶⁴ Teachers and other front-line personnel, including occupational therapists, play a critical role in the development of children from academic and personal, social, and emotional perspectives. “An important component of integrating mental health efforts into the ongoing routines of schools

is the identification and support of indigenous persons and resources within schools as agents of change” (p. 42).⁷ Occupational therapists can be important change agents in integrating mental health efforts into everyday practice in schools.

Multitiered Public Health Model of School Mental Health

The failure to provide mental health services adequately for children has been viewed as a major public health concern, causing leaders in the field to propose a public health model of service delivery to address the needs of all children.^{22,44} A public health model supports a system-wide shift from an individual, deficit-driven model of intervention to a school-wide, strength-based model focusing on promotion, prevention, early intervention, and integration of services for all children. Similar to RtI, addressing the mental health needs of students can be envisioned within a three-tiered framework of mental health promotion, prevention, and intensive individualized interventions^{64,104} (Figure 23-11).

At the school-wide level (tier 1), services are geared toward the entire student body, including most students who do not demonstrate behavioral or mental health challenges. At this level, the emphasis is on promoting positive mental health and preventing behavioral problems. Strategies for promoting positive mental health include the following: (1) creating physical and social environments and activities that are enjoyable for all students (e.g., sensory-friendly contexts, caring adults, just right activities) and (2) embedding strategies and activities that help children and youth cope with challenges (e.g., yoga, deep breathing). Targeted intervention (tier 2) is geared toward students at risk of mental health or behavior problems (e.g., students with disabilities, those who are obese or overweight, students living in poverty). Students at this level are generally not identified as needing special education and/or mental health services and may include children with mild mental disorders, ADHD, and those living in stressful home environments. General education students demonstrating behavioral or learning difficulties because of such mental health conditions may be provided coordinated early intervention services, even if special education is not needed, according to the 2004 amendments to IDEA. For some students with mild mental health disorders, accommodations provided under Section 504 are sufficient for enhancing school functioning. When targeted interventions do not meet the needs of students, intensive interventions (tier 3) are developed to address behaviors or mental health challenges that are highly disruptive or prevent learning. All school personnel, under the leadership of professionals with a background in mental health intervention (e.g., occupational therapists, school psychologists, school nurses, guidance counselors), can embed tier 3 interventions into everyday school experiences.¹²

Role of Occupational Therapy

With occupational therapy’s rich history of addressing mental health in all areas of practice, along with the call for all school personnel to address children’s mental health proactively, the role of occupational therapy in SMH seems clear.⁷ Occupational therapists have specialized knowledge and skills in addressing psychosocial and mental health needs of individuals

FIGURE 23-11 Public health approach to school mental health in occupational therapy.

and thus are well positioned to contribute to all three levels of promotion, prevention, and intervention. A continuum of occupational therapy's EIS, aimed at social, emotional, and mental health promotion, prevention of problem behaviors, and early detection through screening is recommended.¹²

Occupation-Based Services

Although many approaches specific to mental health promotion are important to know about and apply, all occupational therapy services share a common emphasis on the use of meaningful occupation to promote occupational performance (e.g., education, play, leisure, work, social participation, ADLs, instrumental activities of daily living, sleep, and rest) within a variety of contexts.¹ Figure 23-13 shows students engaged in an educational activity at school. The findings of a recent evidence-based literature review, for example, indicate that activity-based interventions help improve children's peer interactions, task-focused behaviors, and conformity to social norms.¹³ In schools, occupation-based services can be embedded in a number of natural contexts, including the cafeteria (e.g., lunch groups), recess (e.g., game clubs), art, and physical education. Increased emphasis is placed on participation in

extracurricular activities, opening the doors wider for occupational therapists to help children and youth develop and participate in structured leisure interests during after-school hours.^{52,71}

What Do Lunch, Recess, and Extracurricular After-School Participation Have to Do with Mental Health Promotion?

Nonacademic aspects of the school day (lunch, recess, extracurricular after-school activities) are significant contributors to students' and schools' success. Studies have shown that increased student connection to school enhances classroom engagement, academic performance, school attendance, and completion rates and decreases dropout and problem behaviors.¹⁷ Numerous factors are associated with students' positive attachment to school, including having good friends at school, participating in extracurricular activities, and perceiving school personnel as supportive and caring. Boxes 23-9 and 23-10 summarize major elements of occupational therapy-embedded cafeteria and recess programs aimed at helping all children and youth enjoy participation in these settings. Figure 23-12 shows students engaged in and enjoying a craft activity during recess.

BOX 23-9 Integrating Occupational Therapy into the Cafeteria: Creating a Comfortable Cafeteria Program

This 6-week program involves occupational therapy services embedded in the cafeteria 1 day/week. The purpose of the program is to create a cafeteria environment that helps all students enjoy a meal and social time with peers and adults.

Role of the Occupational Therapist

- Orient the principal, cafeteria staff, and students about the Comfortable Cafeteria Program.
- Develop and embed activities that promote mealtime enjoyment.
- Provide 6 weeks of coaching to staff to problem solve challenges and offer supports.

Vision Statement

Our school will provide pleasant and positive mealtimes so that students will enjoy eating their meal and socializing with peers and adults.

Program Principles

Based on current literature, a commitment to providing a positive mealtime experience is based on the following four principles:

1. Creating a positive environment (adequate time to eat; comfortable, clean, and safe environment)
2. Providing recess before lunch (students are more relaxed, better behaved, and eat more of their lunch when recess occurs prior to eating)
3. Respecting the importance of the social climate, which includes the integration of students of varying abilities (value the importance of the lunch period as an important time for students to relax and socialize with friends; commit to respecting and including students with varying abilities)
4. Promoting a nutritional philosophy that encourages healthy eating habits

Program Components

1. Orientation for principal and all cafeteria staff about the Comfortable Cafeteria program. This involves in-service

education, needs assessment, and problem solving (1-2 hours). Orient students to the Comfortable Cafeteria program, review code of conduct, and hand out a Comfortable Cafeteria bookmark that summarizes content.

2. Six weeks of embedded occupational therapy services involving weekly themed activities, problem solving with staff, and follow-up coaching. Themes include being a good friend, positive mealtime conversations, including others and accepting differences, and trying new and nutritious foods.
3. Supplemental materials to provide social marketing for the program and reinforce weekly themes. Examples include Colorful Cafeteria posters and bookmarks and weekly newsletters for teachers and parents.

Pilot Data and Findings

This program was piloted at two elementary schools with 168 first- to third-grade students and 20 cafeteria supervisors. The program was well received by the principals, cafeteria supervisors, and students. Pre- and postsurveys of the students using visual analogue scales indicated statistically significant changes ($P \leq 0.01$) changes in perceived enjoyment and friendliness of peers and supervisors in students initially rating questions at 75 mm or lower on a 100-mm scale. These findings suggest that students with mid to lower levels of enjoyment of lunch, perceptions of supervisor or peer friendliness, and enjoyment of mealtime conversations prior to the program documented statistically significant improvements of enjoyment and friendliness at the end of the program. Survey outcomes of the cafeteria supervisors indicated positive changes in the following areas: feeling adequately trained to supervise lunch, knowing how to find resources to encourage healthy eating, having the necessary supports to be an effective cafeteria supervisor, knowing how to promote positive behavior and interact socially with children, and knowing how to resolve conflict successfully. The principal reported a decrease in the number of office referrals during lunchtime.

Contributing authors: Frances Horvath, OTR/L; Louise Demirjian, MA, OTR/L; and Susan Bazyk, PhD, OTR/L, FAOTA.

BOX 23-10 Integrating Occupational Therapy into Recess: Refreshing Recess Program

This 6-week program involves occupational therapy services embedded during recess 1 or 2 days/week. The purpose of the program is to create a recess environment that helps all students enjoy play and social time with peers and adults. Recess is important for promoting physical and mental health and academic performance. To create a positive recess environment, recess supervisors will gain the necessary knowledge and skills needed for implementation, including the following: the importance of establishing positive relationships with all students, strategies for promoting positive behavior, ideas for indoor and outdoor games, safe and enjoyable playground equipment, and supporting documents (e.g., handouts, newsletter) to reinforce best practices during recess.

Role of the Occupational Therapist

- Orient the principal, recess staff, and students about the Refreshing Recess Program.
- Develop and embed activities that promote enjoyment.

- Provide 6 weeks of coaching to staff to problem solve challenges and offer supports.

Vision Statement

Our school will provide positive play and social activities during indoor and outdoor recess so that all students have fun doing meaningful activities and enjoy time with their peers.

Program Principles

Based on current literature, a commitment to providing a positive recess experience is based on the following four principles:

1. Promote positive social interaction and friendships (encourage positive, caring relationships with children, promote the integration of students with varying abilities).
2. Promote positive behavior and the prevention of bullying (clarify expectations, model appropriate interaction and strategies for conflict management).

BOX 23-10 Integrating Occupational Therapy into Recess: Refreshing Recess Program—cont'd

3. Provide unstructured and adult-guided play opportunities (provide a balance between adult-led and child-initiated activities; children who struggle socially do better with structured group play).
4. Provide attractive and safe play materials and games.

Program Components

1. Orientation for principal and all recess staff about the Refreshing Recess program. This involves in-service education, needs assessment, and problem solving (1-2 hours). Orient students to the Refreshing Recess program, review code of conduct, and hand out a Refreshing Recess bookmark that summarizes content.
2. Six weeks of embedded OT services involving weekly themed activities, problem solving with staff and follow coaching. Weekly themes include orientation and needs assessment, fostering friendships, positive behavior supports and conflict

resolution, including others and accepting differences, and bullying prevention.

3. Supplemental materials to provide social marketing for the program and reinforce weekly themes. Examples include bookmarks and weekly newsletters for teachers and parents.

Pilot Data and Findings

The program was piloted on 162 students in the third and fourth grade at one elementary school. Pre- and postsurveys of student participation demonstrated an increase in students who rated recess to be fun, who looked forward to recess, and who reported more adult-initiated games. Recess supervisor pre- and postsurvey outcomes revealed positive changes in the following areas: feeling adequately trained to supervise recess, having the necessary supports, knowing how to interact socially with children, and knowing how to resolve conflict successfully.

FIGURE 23-12 The occupational therapist may work with recess supervisors to help students participate in enjoyable activities.

In addition to traditional occupational therapy intervention approaches, other approaches developed in the fields of public health, psychology, and education can be applied by occupational therapists, such as mental health literacy, positive youth development, social-emotional learning (SEL), and positive behavior supports (PBSs). Refer to [Table 23-7](#) for a description of each, with supporting literature.

FIGURE 23-13 The occupational therapist may work with students to enhance their participation in a variety of different educational activities.

Within a three-tiered public health model, occupational therapists can provide a continuum of services geared toward mental health promotion, prevention, early identification, and intervention. Intervention strategies should be integrated into the student's classroom schedule, school routine, and curriculum. Sample occupational therapy activities for each tier of the public health model of SMH are depicted in [Table 23-8](#).^{24,25} These activities should be designed in accordance with research evidence as much as possible.

TABLE 23-7 Approaches Applied in School Mental Health

Approach	Description	Supporting Evidence	Implications for Occupational Therapy
Mental health literacy	<i>Mental health literacy</i>, a fairly new area of study, refers to providing all children and youth with a working knowledge of mental health as an essential part of overall health (Barry & Jenkins, 2007). It includes many components, such as learning about mental health and strategies for becoming and maintaining mental health, recognizing when a disorder is developing and where to seek help, effective self-help strategies for mild problems, and how to support others facing a mental health crisis (Jorm, 2012). Mental health first aid training courses for youth educate adults on how to provide support for adolescents showing symptoms of a mental health disorder until professional help is obtained (Kelly et al., 2011). Randomized control trials comparing mental health first aid course attendees with wait-list controls found improvements in knowledge, helping behaviors, and stigmatizing attitudes (Jorm, 2012).	Jorm, A. (2012). Mental health literacy: Empowering the community to take action for better mental health. <i>American Psychologist</i>, 67, 231-243. Kelly, C. M., Mithen, J. M., Fischer, J., A., Kitchener, B. A., Jorm, A. J., Lowe, A., & Scanlan, C. (2011). Youth mental health first aid: A description of the program and an initial evaluation. <i>International Journal of Mental Health Systems</i>, 5(4), 1-9. Pinto-Foltz, M., Logsdon, C., & Myers, J. A. (2011). Feasibility, acceptability, and initial efficacy of a knowledge-contact program to reduce mental illness stigma and improve mental health literacy in adolescents. <i>Social Science & Medicine</i>, 72, 2011-2019.	Look for opportunities to raise awareness of mental health and educate students and staff about mental health and well-being as well as mental health disorders Reinforce the attitudes and actions associated with mental health such as participating in enjoyable occupations, exercising, thinking positively, and keeping stress in check. Host Children's Mental Health Awareness Day events every May (http://www.samhsa.gov/children/) Collaborate with health educators, teachers, and school nurses to embed educational activities related to mental health literacy into the school ecology.
Positive youth development and structured leisure participation	<i>Positive youth development</i> emphasizes building and improving assets that enable youth to grow and flourish throughout life (Park, 2004). Larson (2000) emphasizes the development of initiative as a core quality of positive youth development and makes a case for participation in <i>structured leisure activities</i> (e.g., sports, arts, organized clubs) as an important context for such development. An important aspect of occupation-based practice when promoting mental health in children is attention to the development of structured leisure participation during out-of-school time. Extracurricular participation may be included as a standard item on individualized education plans. Highly structured leisure activities are associated with regular participation schedules, rule-guided interaction, direction by one or more adult leaders, an emphasis on skill development that increases in complexity and challenge, and performance that requires sustained active attention and the provision of feedback (Mahoney et al., 2005). Correlational research has demonstrated a positive relationship between participation in structured leisure and positive outcomes such as diminished delinquency, greater achievement, and increased self-efficacy and self-control (Larson, 2000).	Larson, R. W. (2000). Toward a psychology of positive youth development. <i>American Psychologist</i>, 55, 170-183. Daykin, N., Orme, J., Evans, D., Salmon, D., McEachran, M., & Brain, S. (2008). The impact of participation in performing arts on adolescent health and behavior: A systematic review of the literature. <i>Journal of Health Psychology</i>, 13, 251-264. McNeil, D. A., Wilson, B. N., Siever, J. E., Ronca, M., & Mah, J. K. (2009). Connecting children to recreational activities: Results of a cluster randomized trial. <i>American Journal of Health Promotion</i>, 23, 376-387.	Encourage students to explore and participate in out-of-school interests (arts, music, sports, clubs, etc.). Commit to helping all students engage in at least one meaningful hobby and interest. Conduct environmental scans to identify a range of extracurricular participation options for students—both school- and community-sponsored options. Provide coaching to help students with disabilities and mental health challenges successfully participate in structured leisure interests. Coaching may involve adapting entry into the activity and educating the coach or adult leader about strategies for promoting successful participation based on the individual needs of the child/youth.

Social and emotional learning (SEL) Website: www.casel.org	In 1994, <i>social and emotional learning</i> was developed as a conceptual framework to focus on the emotional needs of children and address the fragmented programs meant to address those needs.³⁴ SEL is defined as “the process of acquiring the skills to recognize and manage emotions, develop caring and concern for others, make responsible decisions, establish positive relationships, and handle challenging situations effectively.”¹⁵ Programs developed to enhance SEL help children recognize their emotions, think about their feelings and how one should act, and regulate their behavior based on thoughtful decision making.²⁶ As a national leader in the field, the Collaborative for Academic, Social, and Emotional Learning (CASEL) focuses on the development of high-quality, evidence-based SEL programs, promoting these as a necessary part of preschool through high school education. Under the leadership of CASEL, the state of Illinois, by developing social and emotional learning standards for schools, has become an example for the nation.	Carter, E. W., & Hughes, C. (2005). Increasing social interaction among adolescents with intellectual disabilities and their general education peers: Effective Interventions. <i>Research and Practice for Persons with Severe Disabilities</i>, 30, 179-193. Durlak, J. A., Weissberg, R. P., Dymnicki, A. B., Taylor, R. D., & Schellinger, K. B. (2011). The impact of enhancing students' social and emotional learning: A meta-analysis of school-based universal interventions. <i>Child Development</i>, 82, 405-432. Payton, J., Weissberg, R. P., Durlak, J. A., Dymnicki, A. B., Taylor, R. D., Schellinger, K. B., & Pachan, M. (2008). <i>The positive impact of social and emotional learning for kindergarten to eighth-grade students: Findings from three scientific reviews</i>. Chicago, IL: Collaborative for Academic, Social, and Emotional Learning.	Investigate whether the school has adopted an SEL curriculum. If so, become involved in school-wide implementation. Tune into student's feelings on a daily basis. Simply asking “How is your day going?” or “How are you feeling?” can communicate an interest in the child's emotional life. Help students develop a feeling vocabulary and use words to express feelings. Foster the ability to recognize and respond to other's emotions. Refer to Illinois' SEL academic standards in order to determine age-appropriate SEL expectations and intervention supports. Embed SEL goals and activities into all interventions.
Positive behavioral interventions and supports (PBIS) Website: www.pbis.org	Positive behavior supports (PBS) interventions and supports are designed to prevent problem behaviors by proactively altering a situation before problems escalate and by concurrently teaching appropriate alternatives. PBIS is an implementation framework designed to enhance academic and social behavior outcomes for all students by: (1) using data to inform decisions about the selection, implementation, and progress monitoring of evidence-based behavioral practices and (2) organizing resources and systems to ensure implementation fidelity. This approach recognizes that a number of relevant factors can influence a student's behavior, including those existing within the child and those reflected in the interaction between the child and the environment.⁶⁷ Schoolwide PBS systems support all students along a continuum of need based on the three-tiered prevention model. For students receiving services under IDEA, PBS is mandated for those whose behavior impedes the child's learning or that of others (§614(d)(3)(B)(i)).	Bradshaw, C. P., Koth, C. W., Thornton, L. A., & Leaf, P. J. (2009). Altering school climate through school-wide positive behavioral interventions and supports: Findings from a group-randomized effectiveness trial. <i>Prevention Science</i>, 10(2), 100-115. Bradshaw, C. P., Mitchell, M. M., & Leaf, P. J. (2010). Examining the effects of schoolwide positive behavioral interventions and supports on student outcomes: Results from a randomized controlled effectiveness trial in elementary schools. <i>Journal of Positive Behavioral Interventions</i>, 161-179.	Determine whether your school has adopted PBIS as the behavioral framework. If so, explore opportunities to participate in and contribute to school-wide PBIS committees. Help create environments that focus on proactively promoting positive behavior. Collaborate with all school personnel to foster consistency in communicating behavioral expectations and reinforcing positive behaviors in classroom and nonclassroom settings.

TABLE 23-8 Some Activities Provided by Occupational Therapy Under a Public Health Model of School Mental Health

Tier	Student Populations	Suggested Intervention Strategies
Tier 3—intensive interventions for students with identified mental health challenges	Mental health challenges and disorders: • Anxiety disorders • Depression • Bipolar disorder • Schizophrenia and other thought disorders • Autism spectrum disorder • Obsessive compulsive disorder • Post-traumatic stress disorder • Severe emotional disturbance	Analyze the student's unique sensory needs and develop intervention strategies to promote sensory processing and successful function in multiple school contexts (e.g., classroom, cafeteria). Identify ways to modify or enhance school routines to reduce stress and the likelihood of behavioral outbursts. Provide individual or group intervention to students with serious emotional disturbance (SED) through special education or Section 504 to enhance participation in education, social participation, play and leisure, and ADLs. Assist teachers in modifying classroom expectations based on the student's specific behavioral or mental health needs. Collaborate with the school-based mental health providers to ensure a coordinated system of care for students needing intensive interventions. Assist in the implementation of the Functional Behavior Assessment (FBA) and development and implementation of the Behavioral Intervention Plan (BIP).
Tier 2—selective or targeted intervention for students at risk of mental health challenges	Situational stressors causing children to be at risk of mental health challenges: • Disabilities (e.g., ADHD, autism spectrum, physical disabilities) • Overweight, obesity • Poverty • Bullying	Assist in early identification of mental health problems by providing formal and/or informal screenings of psychosocial function to at-risk students (e.g., Social Skills Rating Scale). Recognize symptoms of illness at their onset and create intervention and or modifications to prevent acute illness from occurring. Evaluate social participation with peers during all school activities, including recess and lunch. Analyze the sensory, social, and cognitive demands of school tasks and recommend adaptations to support a student's participation Provide early intervening services or Section 504 accommodations for students demonstrating behavioral or learning difficulties because of mild mental health disorders or psychosocial issues. Consult with teachers to modify learning demands and academic routines to support a student's development of specific social-emotional skills. Provide parent education on how to adapt family routines or activities to support children's mental health, especially with high-risk children. Develop and run group programs to foster social participation for students struggling with peer interaction Provide psychoeducation in-services to educate teachers about the early signs of mental illness and appropriate accommodations. Provide an in-service to school personnel, including the mental health providers, about occupational therapy's unique role in the promotion of mental health and interventions for mental health dysfunction.

TABLE 23-8 Some Activities Provided by Occupational Therapy Under a Public Health Model of School Mental Health—cont'd

Tier	Student Populations	Suggested Intervention Strategies
Tier 1—school-wide, universal	All students with and without disabilities and mental health challenges	• Mental health promotion: • Look for opportunities to teach students about mental health, what it is, and how to develop it (Jorm, 2012). • Adapt activities and/or the environment to promote enjoyable participation throughout the day (e.g., lunch, recess, classroom). Experiencing positive emotions is thought to contribute to mental health (Fredrickson, 2004). • Mental health prevention: Informally observe all children for behaviors that might suggest mental health concerns or limitations in social-emotional development. Bring concerns to the educational team. • Positive behavioral interventions and supports (PBIS): Assist teachers and other school personnel in developing and implementing school-wide PBIS for various contexts—classroom, hallways, lunchroom, playground, and restrooms (e.g., establish clear rules, foster a positive classroom environment) • Provide in-service training to teachers and staff on the following topics: • Sensory processing—how to adapt classroom practices based on students' varying sensory needs to enhance attending and behavior regulation (e.g., Alert Program, Zones of Regulation) • Social-emotional learning (SEL)—how to embed SEL activities into classroom routines and activities (e.g., identifying feelings, thinking about how feelings influence behavior, perspective taking) • Psychoeducation—educate teachers about the early signs of mental illness and proactive, strength-based prevention strategies. • Provide tips for promoting successful functioning throughout the school day, including transitioning to classes, organizing work spaces such as desk and locker, handling stress, and developing strategies for time management. • Consult with teachers to help them recognize the student's most effective learning styles. Ensure that students are able to meet classroom demands and create modifications, if needed. • Clearly articulate the scope of occupational therapy practice as including social participation, social-emotional function, and mental health (all tiers).

Summary

Occupational therapists must skillfully combine a sound understanding of occupational therapy's role with children with a current understanding of the evolving school context. Over the past 10 years, special and general education services have gradually aligned as a result of IDEA 2004 and ESEA, providing occupational therapists with opportunities to expand their role,

particularly in the direction of promotion, prevention, and early intervention. Providing integrated services in natural contexts, collaborating effectively with school personnel and parents, shifting from caseload to workload models, developing promotional and prevention strategies, and advocating for a role in general education are among the important roles of occupational therapists. By embracing these changes and developing the knowledge and skills to work in new ways, occupational

therapists can help all children participate successfully in and enjoy school.

The following summarizes the main points in this chapter:

- Legislative changes (IDEA, ESEA) and a growing emphasis on LRE have resulted in a gradual alignment of general and special education and inclusion of students with disabilities into general education settings.
- Best practice in occupational therapy involves service provision in natural school contexts including classroom, recess, cafeteria, and after-school settings.
- Integrated occupational therapy services provide opportunities to work within a multitiered model involving promotional and prevention efforts in addition to intervention for students with identified disabilities.

CHAPTER

24

Hospital and Pediatric Rehabilitation Services

Brian J. Dudgeon • Laura Crooks • Elizabeth Chappelle

KEY TERMS

Hospital-based services	Acute care
Children's hospitals	Intensive care
Evidence-based practice	Specialty units
Prioritization of care	Oncology
Documentation	Rehabilitation services
Medical teams	Outpatient services

GUIDING QUESTIONS

1. What are characteristics of children's hospitals and the functions of occupational therapists in these settings?
2. Which types of children are commonly treated in hospital-based rehabilitation units, other specialized inpatient units, and outpatient therapy services?
3. What are occupational therapy interventions in children's hospitals, and what evidence exists to support interventions for children with common diagnoses?
4. Which intervention approaches and teaching strategies are commonly used in pediatric rehabilitation?
5. How do occupational therapists establish collaborative relationships with other providers in interdisciplinary and transdisciplinary teams?
6. How do occupational therapists promote family participation in rehabilitation and address transition home as part of discharge planning?

Children receive care at a hospital for a wide variety of diagnostic and intervention reasons. Although respiratory and gastrointestinal problems are the most common reasons for hospital care,^{24,27} rehabilitation services, including occupational therapy, are usually provided to children with neurologic and musculoskeletal disorders. See [Box 24-1](#). For children who need hospitalization, issues of safety for the child and concerns about the influence of hospitalization on the child's life experiences often arise.¹³ Historically, physicians and families were

reluctant to hospitalize children, given the potential for psychological reactions accompanying separation from home and family. However, the need for careful, ongoing medical monitoring, specialized equipment and areas for diagnosis and treatments led to the inevitability of hospitalization for many types of conditions that can affect children. In addition to acute onset problems, chronic disease and disorders appear to be on the rise among children in the United States and other developed countries.⁷⁴ These problems may relate to children's challenges with weight management, greater inactivity, and other lifestyles that do not promote fitness.

With the unique specialized care needs of children, beginning in the late 1800s, hospitals developed to care exclusively for and manage children's health challenges. The first children's hospitals in America began in the 1850s in Philadelphia, and others soon followed. Today there are more than 150 such institutions. These community and regional efforts often led to programs that addressed not only health, but also special education needs of children. Although modern hospitals serve medical concerns almost exclusively, educational needs are still paramount in children's lives, and, not surprisingly, school-based services are often a part of children's experience with hospitalization. In addition to addressing needs for education, children's hospitals also strive to create special environments that cater to children and families.⁵⁹ Environmental features such as art, colors, and areas that are friendly, warm, and inviting allow space for play and enable families to gather and communicate. Volunteers assist with child and family services and fundraising to support costs and offset expenses for children's care. Also unique to these settings are child life specialists who attend to children's emotional and developmental needs. They may help reduce the stresses of a hospital stay by assisting families in coping with the hospital experience by providing information about play, child development, and adjustment to illness.

The demands of an evolving health care system, varied medical conditions of the children, family dynamics, and hospital's milieu all influence occupational therapy practices. This chapter describes occupational therapy services to pediatric patients in the children's hospital setting. It illustrates varied models of service delivery and explains the roles and function of hospital-based occupational therapists.

In the past, children who required hospitalization frequently had long-term stays, which included programs addressing socialization, education, and vocation.^{9,21} Currently, hospital-based programs focus on acute-onset problems and provision

I wish to thank the children and families involved with Seattle Children's Hospital, Seattle, Washington, for their willingness to share their experiences. I also want to acknowledge the advice and help of colleagues from Children's Hospital of Alabama in Birmingham for the preparation of this chapter.

BOX 24-1 Habilitation Versus Rehabilitation

A primary concept in the practice of pediatric rehabilitation is the differentiation of habilitation and rehabilitation. For children, the term *habilitation* is generally used to denote attention to the child's acquisition of expected age-level skill and function. The term *rehabilitation* is used to reflect the process of an individual working to regain skills and functions that had been established but subsequently lost. For most practitioners in pediatrics, the term *rehabilitation* is used to encompass both concepts. This is true because disability, whether new or chronic, creates ongoing challenges to current function and future demands that evolve as part of growth and development. In this chapter, the term *rehabilitation* is used to express both concepts.

of specialized services for children and adolescents with disabilities that may occur infrequently but are highly complex. Hospital-based programs continue to evolve, in part because of newly identified health threats. Hospital programs now extend into the community, offering increased resources to the community and emphasizing the partnership with families in caring for a child with medical needs.

Characteristics of Children's Hospitals

Hospital-based services may include inpatient and/or outpatient care for the ill and injured, as well as prevention or wellness programs designed to reduce the need for future care needs. Hospitals in which pediatric patients are served generally fall into three categories: general hospitals, trauma centers, and children's hospitals. General hospitals strive to serve the needs of the community in which they are located. Given specific local populations, a wide variety of patients can be served in this type of hospital, which often includes those of all ages, from an infant to a geriatric population. The occupational therapist working in the general hospital setting may serve pediatric and adult patients. Hospitals that offer labor and delivery services often have neonatal intensive care services that include occupational therapy services. Some general hospitals may also have special units dedicated to serving the needs of pediatric populations; however, children with more involved or complex needs are often referred to a children's hospital.

Trauma centers are hospitals organized and certified to treat patients with more acute life-threatening injuries. Usually situated in large metropolitan areas, patients taken to trauma centers may have extensive musculoskeletal, neurologic, skin, and internal organ injuries requiring multiple specialists. As in the general hospital setting, the occupational therapist working in the trauma center may serve patients who have a variety of injuries or illnesses. Such centers often have burn units and other special trauma units or programs organized to handle the evaluations and treatments that initially focus on lifesaving and sustaining procedures and to prevent unnecessary complications (e.g., splinting, positioning, evaluating oral motor skills for feeding). As a child in such a setting becomes more stable, additional types of interventions, such as training in activities of daily living (ADLs) and age-appropriate play,

can be implemented. Stress on family members from having their child in the trauma center may be compounded by having other family members also receiving care, or the hospital may be some distance from their home. Occupational therapists need to be sensitive to the stress that families experience when their children are in these centers. Once patients are stabilized, and treatment has been established, they may receive ongoing care in that particular hospital or they may be transferred to a children's hospital or general hospital closer to their own community.

Children's hospitals are specialty hospitals that offer a full range of inpatient and outpatient services for infants, children, and adolescents. The occupational therapist working with children in such a hospital may be involved with children who have a wide range of diagnoses and sometimes rarely seen conditions, and thus may have limited information available on treatment protocols or expected outcomes.

Region (Location) Served

Children's hospitals, as specialized health care institutions, tend to serve a broader geographic region than general hospitals. This may result in a child being hospitalized a significant distance from home, increasing the sense of separation from family, peers, and familiar environments. The distance between the home and hospital may affect the family's ability to visit the child and remain in contact with the those caring for the child. Frequently only one family member may be able to remain with the child. This can pose additional challenges for the family, creating not only a financial burden and psychological strains of having a child in the hospital, but the distances between family members may produce additional pressures. The size of the service area and population of the region may also mean greater cultural diversity and socioeconomic variation among those served by the hospital. Diversity in clientele requires the medical team to be sensitive to the cultural beliefs and practices of the patient and family.⁷² The broader geographic region served by most children's hospitals usually requires hospital personnel to interact with a great number of practitioners and service programs across the region. This distance can pose challenges for the hospital-based occupational therapist to communicate with community-based occupational therapists regarding the child's intervention programs. Regardless of distance, hospital- and community-based occupational therapists coordinate the child's transition to home by accessing community resources and outpatient or school-based programs.

Missions of Children's Hospitals

Goals of children's hospitals often include effective advocacy for child health, conducting leading-edge pediatric research to improve on clinical outcomes, and creating and implementing a model for family-centered and community-based care. These and other program-specific missions influence the daily operations of these institutions and provide guidance about how clinical care is approached and conducted. Promotion of child health may be seen in local outreach programs in which children's hospital staff educate others in public schools and community programs regarding a wide range of children's health and safety issues. At the national level, advocacy for policies and programs to promote public health, as well as health care

reforms that would enable pediatric health care coverage and the conducting of research to prevent and address pediatric health conditions, are often cited (see information provided by the National Association for Children's Hospitals and Related Institutions [NACHRI]⁵²).

Research on Systems and Care Outcomes

Research missions of children's hospitals and research conducted as part of clinical care can be broad or specific. They are generally motivated by particular interests and needs identified by practitioners or other advocates. Research specializations may be stand-alone efforts of the hospital faculty and staff; affiliated with local research universities; or part of regional, national, or international research programs.

Two prominent types of research conducted at children's hospitals include assessing and reducing risks of care to reduce iatrogenic causes of ill-health and developing best practices and evidence for effective outcomes with specific clinical services. NACHRI recognizes safety as a major concern and that hospitals pose risks for infection and other medical and behavioral consequences of care. For example, children's hospitals' staff recognizes that infections are sometimes transmitted by hand contact. Transmission of germs is thus carried from one patient to another, sometimes by practitioners. Effective hand washing habits have been difficult to implement, with most hospitals striving to enable and monitor such habits by reminders, providing multiple cleaning opportunities, and enforcing routines by monitoring and creating a culture of peer-to-peer feedback. Other safety measures relate to body substance isolation through conditional uses of gloves, masks, and gowns, with proper disposal of at-risk materials. Departments of risk management and infectious diseases work to identify potential risks and institute measures that prevent new and ongoing hazards, usually through repeated trainings.

Occupational therapists participate in evaluation of clinical services and client outcomes. For example, the status of ADLs and instrumental activities of daily living (IADLs), discharge placement, health-related quality of life, and well-being are some of the typical measures used to document rehabilitation outcomes.²⁹ Occupational therapists use research to describe medical and functional effects, validity of assessment tools related to clinical decision making, and effectiveness of specific treatment approaches or techniques. Over the past few decades, increasing emphasis has been placed on outcomes and ways to use research outcomes in evidence-based decision making.⁴³

In pediatric rehabilitation, most outcomes research relates to common diagnostic groups seen in such settings. For example, Dumas and associates²⁰ reported functional gains demonstrated by children with a traumatic brain injury (TBI) undergoing inpatient pediatric rehabilitation. The greatest gains were made in mobility, but also in social function and self-care for all ages of children. Bedell⁴ reported similar findings from a series of children treated for TBI and other acquired brain injuries, and also found that social functioning continued to be greatly impaired. Among school-age children at the time of injury, many with moderate and most with severe injury show persisting and widespread cognitive, language, academic, behavioral, and functional deficits. Although many children with such injuries are identified, referrals to therapy service may be limited⁶ and recommended interventions

may not be followed,⁵⁶ making associated outcomes difficult to predict.

Evidence regarding the efficacy of specific intervention strategies is lacking because it is difficult and costly to conduct research that analyzes the application of particular techniques or rehabilitation strategies. Experimental research on rehabilitation effectiveness is particularly difficult to conduct because of the heterogeneity of the participants and ethical conflicts encountered by suspending or withholding services to specific children. Randomized clinical trials can be problematic,⁵³ and alternate research strategies have been proposed, such as those with an emphasis on humanistic elements as part of therapeutic practice³⁴ and client's views about process and outcomes.² In a review of services and outcomes in 12 hospital-based pediatric rehabilitation programs, reporting on 814 admissions, the intensity of specific service delivery was associated with client outcomes.¹¹ Those receiving more occupational therapy services made the most gains in ADLs; those receiving more physical therapy services made greater mobility gains; and those receiving more speech-language services made greater communication and cognitive gains.

Family and Child-Centered Care

Family-centered care of hospitalized children is a hallmark of most children's hospitals and has led to new insights and directions for care.²² To implement family-centered care, families are designated as a member of the health care team and encouraged to take an active part in decision making about treatments. The occupational therapist working in a hospital setting in which family-centered care has been adopted uses clear descriptions to communicate evaluation results to the family, seeks input from the family on which intervention outcomes for the child have priority, and comes to a mutually agreed-on intervention plan. As evaluations are completed and team meetings established, the family has an integral part in decision making about care.

The occupational therapist's knowledge of age-appropriate developmental tasks and understanding of the importance of purposeful activity can help the child achieve a sense of control in the foreign environment of the hospital. Occupational therapists can also help other members of the medical team understand developmental issues of concern and suggest strategies to caregivers, family members, and others to support typical development that may help the child better manage the hospitalization experience.

Accrediting and Regulatory Agencies

Pediatric rehabilitation advocates and service providers have influenced and been shaped by accreditation processes. For example, the Centers for Medicare and Medicaid Services (CMS) designate requirements for services that are organized and paid to provide "medical rehabilitation." To meet CMS guidelines for rehabilitation, rules are placed on such systems that mandate specific program emphasis, dedicated space and personnel, admission and discharge procedures, service intensity, goal setting, and monitoring of progress toward goals. Most rehabilitation programs also pursue voluntary accreditation by groups such as The Joint Commission (TJC)³⁹ and the Commission on Accreditation of Rehabilitation Facilities

(CARF),¹² as well as government agencies, such as the Occupational Safety and Health Administration (OSHA), that set standards regarding hospital operations. These organizations assign additional mandates that also shape program characteristics. Such guidelines may include integrated planning with community-based services and continuous quality improvement procedures. Every few years, accreditation standards and procedures based on TJC and CARF shift their emphasis and specification of essential requirements. Generally, after initial accreditation, reaccreditation reports or visits are scheduled every 3 years, and programs may be subject to periodic interim reviews and reporting about their overall performance.

Employee education regarding safety practices (e.g., risk of exposure to patient blood or other body fluids or to hazardous materials) and attention to suspected abuse are also mandated. Importantly, occupational therapists are required to report any suspicion of abuse to designated personnel within the hospital setting who, when appropriate, contact community support services, such as law enforcement personnel or Child Protective Services (CPS). Specific training in each institution regarding reporting protocols must be established and provided to the occupational therapists.

Children's hospitals are often affiliated with similar institutions, offering opportunities for consolidation of information and equipment, achievement of common goals, and program development.⁷⁰ Hospitals may be part of a medical system directed by a single administration and linking facilities that share certain resources and specialized personnel. A spectrum of care options, from acute and subacute rehabilitation, satellite outpatient clinics and programs, and home health care may be provided.

Reimbursement for Services

Inpatient services are typically funded by a combination of private insurance carriers, Medicaid or special programs within a state, and under some circumstances by Medicare. Occupational therapy has typically been recognized as a service that is reimbursed in hospitals and medical rehabilitation units, home health care, and, to a lesser extent, outpatient services. Medicare guidelines are generally universal across different states. However, each state's Medicaid rules and regulations and local insurance companies have differing provisions related to the funding of occupational therapy services and supplies or assistive devices that may be required. Local regulations must be reviewed to ensure that appropriate levels of reimbursement are available and that families are informed about service options and expected costs.

The length of stay in children's hospitals varies, from as short as a few days to weeks or perhaps months. As in other hospitals, third-party payers and other regulators strive to control costs by seeking shortened lengths of stay and transferring patients more quickly to less costly skilled nursing facilities or home care, outpatient, or school-based services. Changes within and across treatment settings can be problematic, often creating confusion in families about entitlements and expectations for services. Clearly stated goals and time frames for outcomes in each care setting are desirable.⁷⁰ Case managers who are familiar with funding rules and regulations work with families and service teams to coordinate care and prepare the family for transitions among care settings.

An issue of concern facing hospitals that provide services to children is the cost of health care. In recent years, health maintenance organizations (HMOs) and preferred provider organizations (PPOs) have proliferated, and many families are now insured in these and other managed care plans. Prospective payment systems, created within Medicare to estimate and contain costs better, can have strong impacts on reimbursement for services. This system uses preestablished rates of reimbursement for diagnostic groups using the Healthcare Common Procedure Coding System (HCPCS) for billing, which is based on the American Medical Association's Current Procedural Terminology (CPT) codes. Payers take these guidelines into consideration when authorizing care for inpatient stays. The occupational therapist should be aware of payment limitations when providing care and clearly communicate with families when establishing treatment plans and explaining the scope of services being offered.

Occupational Therapy Services in a Children's Hospital

Organization of occupational therapy and other rehabilitation services in a hospital can vary. Programs in this chapter focus on three broad types of services: acute care, rehabilitation, and outpatient clinics. Each of these services is described in more detail with case studies later in the chapter. In brief, acute care services are those wherein therapy services are ordered directly from a medical service or unit (e.g., intensive care neurology and neurosurgery, oncology or cancer care, general surgery, orthopedics, heart and pulmonary services, and, in many children's hospitals, transplantation services). Children are generally referred to acute care services for an occupational therapist's appraisal, interventions for immediate needs, and assistance in planning transition to other service settings or discharge to home. Pediatric rehabilitation services are often located in a specific location of the hospital, which may include special facilities with bedrooms and bathrooms to enable effective independence training with lifts, mobility devices, and other durable medical equipment. Spaces for individual and group intervention, socialization, and group engagements are often available as well. Outpatient services include regularly scheduled specialty clinics that address children's and family's ongoing needs and individual children's services in community-based satellite clinics.

This chapter applies a systematic approach to hospital service areas, including prioritization of care, evaluation strategies used, goal-setting guidelines, and selection of interventions. For each service area, the breadth of diagnoses and clinical approaches is described.

Functions of Occupational Therapists

A primary focus of the occupational therapist in a children's hospital is on ADLs and other instrumental tasks associated with independent living, education, and community participation. Occupational therapists use many frames of reference to develop insights about the child's function; establish intervention priorities; and guide development of goals with the child, family, and local care providers. In most forms of hospital care, the occupational therapist follows a prioritization system that

focuses first on prevention of problems associated with illness, trauma or disability; then resumption of the able self; and finally restoration of lost skills and functions. Occupational therapists use learning principles^{23,64,67} and clinical reasoning strategies.⁵⁰ They often use behavioral and cognitive learning principles and therapeutic use of self, blending technical competency with personal caring.

Evaluation

In almost all cases, occupational therapy services in hospital-based care are initiated through physician's orders. Often required by law or regulatory guidelines, occupational therapists respond to an initial referral or orders and then negotiate as necessary with the physician to add specific elements to assessment and intervention activities.

A review of medical records and discussions with other providers may form the initial basis for evaluation. Usually the occupational therapist uses a clinical interview and observation to initiate the assessment process, followed by physical examination and direct observation with the use of standardized tests. Once the occupational therapist formulates hypotheses about the impairment(s) and initiates intervention plans, the repeated use of clinical examination and standardized tests serves as objective measures of skill improvement. For diagnostic purposes, the occupational therapist judges a child's performance against normed scores, but for evaluative purposes, the occupational therapist usually judges a child's scores on reassessment against his or her previous performance. Selection of a specific measure should be based on its reliability, sensitivity, and appropriateness, given the child's age and diagnosis.

The therapist may organize assessment of ADLs and IADLs around checklists or other reporting tools that specify activities and methods of rating the individual's level of skill. The Functional Independence Measure (FIM; UDS-PRO) and a pediatric version, called the Wee-FIM II, were developed for children of developmental age 6 months to 7 years.^{51,69} Eighteen specific ADL tasks, including communication and social cognition, are rated for dependence, based on the individual's need for adaptation and assistance from a helper. The Pediatric Evaluation of Disability Inventory—Computer Adapted Test (PEDI-CAT)³³ can be selected as a tool to report on ADLs, mobility, social function, and responsibility shift for children 7 months to 21 years of age. A wide number of tools may be used to appraise performance skills.

Determining Intervention Goals

A critical component of all intervention planning is the occupational therapist's attention to goal development and setting of outcome expectations. A collaborative process with families is essential in specifying goals, although the goals must also relate to the particular therapeutic techniques being used.^{8,49}

Goals describe specific tasks that the child will perform, conditions of performance, and type and frequency of assistance needed. The occupational therapist may specify short-term goals as interim steps toward reaching long-term goals. He or she may define specific performance component targets that link to meaningful functional outcomes (e.g., achieve eye-hand coordination and manipulation skills sufficient for desktop activities and writing at school).

Functional goals include specification of skills and the expected level of independence. Levels of independence

describe varying degrees of dependence on personal assistance, adaptive environments, and the use of assistive technology (AT) devices. In the case of a child with greater and long-standing disability, ADL goals may describe how he or she will manage personal care assistance to achieve a self-managed dependence. On most ADL scales, the level of independence is rated as the amount of physical and cognitive assistance needed as a proportion of the amount of time required for a partial task, whole task, and task transition assistance by a care provider). However, when concerned with the integration of an individual back into his or her home, the concept of interdependence among family members may be an important consideration. Given the negative connotation associated with dependence in Western culture, a more positive term to express shared needs between family members may be termed *interreliance*. Such language is suggested to focus on the shared duties within households.

Interventions

For most children referred to occupational therapy, services are provided in a relatively brief period, requiring the occupational therapist to be highly efficient. Relatively brief intervention periods necessitate that the occupational therapist establish realistic priorities appropriate for the child's projected length of stay in the hospital. To do this, the evaluation process is streamlined, goals prioritized, and discharge plans proposed at the start of the admission and initial evaluation.

Preventing Secondary Disability and Restoring Performance

Primary prevention is a term used to denote efforts that decrease the likelihood of accidents, violence, or disease for everyone. The terms *secondary* and *tertiary prevention* refer to specific interventions, arrangement of care systems, and environmental modifications to prevent the onset of problems in at-risk populations. Children admitted to the hospital are typically at risk for developing a number of secondary disabilities. Prevention measures may include safety in positioning and movement, prevention of aspiration in swallowing, provision of orientation, and appropriate measures to reduce stresses experienced in an unfamiliar environment and prevent self-injury. Occupational therapists must be aware of risks and avoid involving the child in activities that would be harmful or perpetuate behaviors that could hamper recovery. Complications from immobilization, abnormal muscle tone, and other neuromuscular abnormalities often necessitate careful attention to maintaining range of motion, strength, and general fitness (Figure 24-1).

The occupational therapist typically addresses neuromuscular and musculoskeletal complications by using programs designed to help the client maintain or regain normal range of motion. Through the use of special handling techniques, occupational and physical therapists carry out daily programs that can involve slow stretch and joint mobilization. Occupational therapists can correct existing limitations by using a combination of these techniques and specialized positioning and splinting. The occupational therapist may also apply splints for various purposes, including maintaining positions (e.g., resting hand splint), increasing range of motion (e.g., dropout splints, dynamic splints with spring tension forces, serial casting), or promoting function (e.g., wrist cockup or tenodesis splints). See Chapter 29.

FIGURE 24-1 Dynamic sitting balance is challenged with an air-filled tube to address core trunk responses, seat and foot pressure, with visual-head orientation practice that simulate typical task demands in home or school activities.

FIGURE 24-2 Visual motor skills are addressed with manipulative work using various materials and textures to promote sensory recognition, tolerances, and skilled performance.

The occupational therapist facilitates improved movement and strength by using activities and exercises that are usually incorporated into play routines. For children and adolescents with musculoskeletal and lower motor neuron or motor unit disorders, the use of progressive exercise and activity routines may be appropriate. For those with brain injury that causes upper motor neuron dysfunction, muscle tone and voluntary motor control are focused on using various sensorimotor techniques to promote postural stability, balance, visual motor skills, and fine motor performance (Figure 24-2; see Chapters 7 and 8).

Concern for wound healing and protection of insensate skin are also essential to early planning and ongoing interventions to achieve goals and education of the child and family. The entire medical team, including the occupational therapist, applies skin care, monitors the child's skin, and implements measures to prevention pressure ulcers. Pressure areas from bed positioning, static sitting, and the use of orthotics call for careful and routine skin monitoring. The child may require several days to develop a tolerance to new positioning strategies and orthotic applications. The child's skin tolerance affects decisions to change bed position, increase sitting time, and alter the wearing schedule for orthotic devices.

Individuals often experience perceptual, cognitive, and behavioral impairments after TBI, and similar concerns also arise with other diagnostic conditions. With a prevention emphasis, programs to ensure safety with physical activities and handling of objects are critical. Environmental modifications are often made to ensure the child's safety. The occupational therapist implements methods to help the child compensate for

disorientation and memory loss, although restricted environments and restraints may be necessary initially. Family pictures or other familiar items from home may be used to create a stimulating and more comforting environment. When the child is more alert and aware of his or her surroundings, the occupational therapist may use an educational approach coupled with behavioral interventions. The occupational therapist should inform the child of unit rules, post these rules, and emphasize strict adherence to them. Occupational therapists may use daily orientation programs and memory books to ease the burden of confusion. It is important to teach the family about the child's perceptual and cognitive impairments and create programs to help ensure the child's orientation, safety, and comfort.

Resuming and Restoring Occupational Performance

The second level of priority for occupational therapy is a focus on resuming the use of available skills and independence in easily accomplished tasks. The occupational therapist emphasizes the able self by recommending that the child resume doing tasks on his or her own and by suggesting how others can support the child's performance of ADLs. Enabling optimal independence may be important for preventing the child or adolescent from developing dependent behaviors or learned helplessness. Efficiency demands placed on nurses often result in the child becoming a passive recipient of care. The occupational therapist should strive to provide the child with sufficient time to perform activities on his or her own. Early emphasis on providing children with opportunities to make choices about

FIGURE 24-3 The occupational therapist provides the child with cues and performance feedback while he carries out an adapted IADL cooking task to address sequencing and functional bimanual performance.

the types of assistance they receive or activities they pursue may help them develop confidence in their skills and returning abilities.

Once the occupational therapist negotiates goals for ADL performance, he or she determines what the child needs to learn, how such learning will take place, and how training can best be organized within the clinical care setting. By embedding therapeutic strategies in the child or youth's natural routine, he or she may discover simple strategies to resume activity performance within a few sessions. Often the occupational therapist recommends structured routines and the use of assistive devices and other modifications to achieve performance and guide the child and other care providers in joint problem solving to determine the most effective methods of performance.

In guided learning of new performance methods, the occupational therapist uses instructional aids, such as visual supports, visual modeling, touch cues, or verbal instruction. For example, the occupational therapist may demonstrate the task to be learned and have the child imitate. The occupational therapist may also use verbal or manual guidance cues to assist learning (Figure 24-3). For some tasks, predetermined scripts or learning materials are available.^{54,55}

Occupational therapy services also promote restoration of lost skills and function using biomechanical, sensorimotor, perceptual-cognitive, and rehabilitative approaches in various combinations to restore function. The occupational therapist helps the child or youth practice activities that selectively challenge an individual's skills, with the expectation that these will then transfer or generalize to occupational performance areas. Biomechanical and sensorimotor approaches include the use of therapeutic activities and exercise, splinting and positioning, facilitation of movement, and use of biomedical devices such as functional electric stimulation (Figure 24-4). Other physical agent modalities such as superficial heat or cold may also be used, whereas deep-heating techniques such as ultrasound are often avoided because children's bone epiphyseal (growth plate) areas may be damaged.⁴⁸ See Chapter 29 for additional information on physical agent modalities.

FIGURE 24-4 The therapist provides guidance in strengthening both arms using an exercise device that monitors force and repetition in a progressive manner.

Adaptations for Activities of Daily Living Skills

Rehabilitative approaches contrast with biomechanical and sensorimotor techniques that are designed to address underlying performance skills and factors. In the rehabilitative approach, occupational therapists teach clients compensatory techniques that use existing skills to restore occupational performance. Occupational therapists teach clients to use adapted routines and AT devices and modify environments to promote optimal manipulation, mobility, cognition, and communication function. Basic principles apply to adapted performance of ADL skills, described in Table 24-1. Principles of joint protection and work simplification are commonly used; performance is geared toward functioning in a barrier-free environment with the use of familiar conveniences. Adaptations of a routine are aimed at reducing complexity, ensuring safety, and minimizing complications if errors occur.

Adaptive methods of ADL and IADL skills may include the use of different strategies and devices (see Table 24-1). A client's reliance on AT devices may be temporary or permanent. The early use of devices can increase safety or immediate function during recovery. The permanent use of devices is also common when the child exhibits residual difficulties that necessitate ongoing adaptations. When selecting devices, occupational therapists often choose to adapt existing equipment that is already familiar to them or direct the family toward the purchase of items with features that are more compatible with the child's special needs (e.g., enlarged handles on utensils, clothes with color contrast, toys with specific visual, sound, or tactile features).

Client outcomes may be optimized when occupational therapists use complementary strategies to improve the child's skills, adapt functional activities, and modify environmental contexts. For example, the occupational therapist may help the child memorize a routine so that the child can guide his or her own performance using verbal, visual, or tactile feedback. If the child cannot memorize a routine, the occupational therapist can prepare written instructions, pictorial step cues, and audiotapes with specific directions. Whole-task instruction and the use of forward- or reverse-step sequence training are commonly used methods. The occupational therapist can implement

TABLE 24-1 Rehabilitation Strategies*

Types of Limitation	Accommodations
Motor and Movement	
Limited Range of Motion	
Reach to all parts of the body and objects within the immediate environment	Extended and specially angled handles (e.g., long-handled spoon or fork, bath brush, dressing stick, or shoe horn) Use devices that extend contact and prehension, such as reachers Mount objects on the floor, wall, or table and bringing the body part to the device (e.g., boot tree for removing shoes, friction pad on floor for socks, hook on the wall to pull pants up or down, sponges mounted in the shower to wash) Replace reach requirement with use of a bidet for hygiene after toileting or manual or electric feeders operated by switches to bring food to the mouth
Limitations of hand motion reducing holding and handling of objects	Provide enlarged or differently styled handles that reduce the grasp requirement, such as a T-handled cup. Replace holding functions by the use of universal cuff or C-shaped handles. Friction surfaces may provide more secure grasp. When forearm rotation is limited, swivel spoons or angled utensils may assist bringing food to the mouth.
Gross motor movements, such as in bed mobility and elevation changes	Raise or lower surface levels to limit the extent of elevation change required. Lower the bed height to allow ease in wheelchair transfers or raise it to ease in coming up to standing from sitting. Raised chairs, toilet seats with toilet safety frames, and bath benches reduce extreme changes in elevation required in transfers.
Decreased Strength and Endurance	
Reduce the effects of gravity	Use lighter weight objects, movements in the horizontal plane, reduced friction, and, when possible, the use of body mechanics for leverage and gravity to assist movement
Efficiency of movement and reduced efforts are essential	Electrically powered devices may meet goals of work simplification. Extended handles may be necessary, but increased weight and forces required to handle and apply leverage might increase difficulty. Universal cuffs or C-cuffs limit needs for grasp and sustained holding. Use hooks and loops on clothing and adapt fasteners by using Velcro, zippers, enlarged buttons, or elastic or stretch shoelaces. Have lever handles on faucets, doors, and appliances. Use surfaces to support posture and proximal limb positions through bed positioning, seating adaptations, and the use of arm rests and table surfaces.
Limit the need to sustain static postures and prolonged holding.	Mount devices or stabilizing devices with friction from Dycem (nonslip material) or a spike board, using enlarged lightweight objects
Cardiac or pulmonary disorders limiting ADLs based on metabolic equivalents levels or by direct monitoring.	Change heights of surfaces and using devices such as sliding boards or hydraulic lifts to aid movement Schedule and pace tasks, simplifying work, using rest breaks during tasks in response to cardiopulmonary limitations
Incoordination	
Difficulty with manipulation skills	Consider range of movement required, weight and resistance of objects being handled, and positioning of the body in relation to objects used in tasks. Achieve proximal stability when executing limb movements. Stabilizing the trunk and head as one moves the arm and hand is thought to improve skilled movements. Stabilize proximal segments of the limb while manipulating the hand by resting the elbow and forearm on the table while using the wrist and fingers to manipulate objects. Friction surfaces and containers that hold objects being manipulated may also be suggested for stabilization with pads or a nonslip cup. Increased weight may dampen exaggerated movements and tremor. Select heavier objects or add weight to objects. Attach a weight to the arm or apply resistance to movement by placing devices across joints, such as using elastic sleeves or a friction feeder. Mount devices on stable surfaces and bring the body to these devices.
One-Handed Techniques	
Replacing the stabilization function of the other limb	Many tasks can easily be carried out with practice using one hand. If the hand being used was not previously the preferred or dominant hand, skilled movements may take a greater amount of time to develop. With perceptual and cognitive impairments, learning to use one hand may become particularly difficult. With hemiplegia, various dressing routines have been scripted that follow the rules of dressing the affected limb first and avoiding the use of abnormal postures.
Improving the skills of the hand being used	Assist or replace the stabilization function of the impaired or lost upper limb by mounting devices or by use of friction surfaces.
Adapting tasks that require alternating movements of two hands	Using specially designed devices or methods (e.g., a rocker knife or cutting-edged fork to help cut; buttonhook to aid in buttoning; special lacing technique to aid in shoe tying; a one-handed keyboard arrangement and training to aid in typing.

Continued

TABLE 24-1 Rehabilitation Strategies—cont'd

Types of Limitation	Accommodations
Perceptual and Cognitive Limitations (with or without movement disorders)	
Performance errors caused by faulty use of visual cues and spatial orientation	Substitute for impaired skills by using more intact sensory, perceptual, or cognitive skills (e.g., using a bell on the hemiplegic arm to draw attention if being neglected tactually or visually)
Sequencing errors because of memory or task attention difficulties	Design step-by-step routines with cueing systems; repeat them in training Use work simplification principles and modified equipment and adaptive devices as substitution strategies. Train children to rely on memorizing and reciting a verbal routine or follow audiotaped instruction, written instructions, or pictorial cues. With impaired visual perception, the child may need to learn reliance on tactile feedback cues. Use color-contrasted clothing, texture, or color-coding cues with objects. Appraise using a mirror to give the child feedback about his or her performance.
Visual Impairment	
Blindness or severe visual impairment requiring a substitute for vision by the use of other sensory skills and cognitive routines	Consistent organization of the environment and storage of items is necessary. Use tactile identifiers such as raised letters on objects and locations of more transient items described by a companion, or a standard technique, such as an analog clock location. Build sound feedback into some items to aid in orientation or search. Mobility specialists instruct use of techniques such as long canes or guide dogs for ambulation or wheelchair guidance and the use of a leader's arm for guidance in walking.

*Occupational therapists use several strategies for specific types of dysfunctions to adapt activities for children with functional limitations. In addition to these suggestions, ADL and IADL adaptations have been described (see [Chapter 16](#)) along with the uses of assistive technology (AT) (see [Chapter 19](#)).

training over several sessions that capitalize on the times when tasks are routinely performed (e.g., dressing in the morning and at night or before and after swimming). As training progresses, the occupational therapist gradually reduces the extent of external cueing from a person or instructional aids so that only a minimal amount of such support is required for safe and efficient performance. Often the team and family plan for the gradual withdrawal of aides and assistance after the child is discharged from the inpatient hospital setting. Occupational therapists teach family members or staff strategies that promote the child's participation in daily activities, including school.

To help the child generalize learning from clinic to home, he or she may visit the home. The home visits allow the child and family to survey and collaborate in planning for equipment needs, accommodations, and perhaps architectural modifications that would enable transition to home. Day or weekend home passes for the child are desirable, when possible. Feedback from the family about the time at home can be important to prioritizing goals, equipment, and family educational needs.

Documentation of Occupational Therapy Services

Documentation of patient care is an essential component of occupational therapy service provision in hospitals. Occupational therapy evaluation reports, intervention plans, patient progress notes, and discharge summaries are used to communicate occupational therapy intervention to the physician, other members of the medical team, patient and family, and reimbursement agencies. Format and frequency of documentation are determined by the policies and procedures of the hospital

and occupational therapy department. Accreditation guidelines regarding documentation are provided to institutions by agencies such as TJC and CARF. Agencies that reimburse services, such as Medicaid or private insurance, also have requirements for documentation with which occupational therapists must comply.

Occupational therapy evaluation reports, intervention plans, progress notes, and discharge summaries are readily available to other health professionals in a paper-based or online medical record. Documentation of occupational therapy intervention is also made available to referring physicians or other agencies in the community, and copies become part of a permanent medical record. Regardless of the format, documentation of services must meet the criteria established by accrediting and reimbursement agencies.⁴⁰

Scope of Occupational Therapy Services

Children are admitted to the hospital setting for many different reasons, and they can move through different care units as symptoms stabilize or effects become more apparent. Referrals to occupational therapy may be made at admission, during a stay, or near the end of a hospitalization. The occupational therapist responds to the physician's request and, when needed, may ask for greater involvement in a child's care or recommend that other services become involved as well.

Children may be admitted for acute care of their illness or injury. The occupational therapist performs an initial assessment and provides caregivers and the child with instructions, home programs, or follow-up outpatient services. The occupational therapist may also contribute to the diagnostic evaluation

of a child specifically admitted for a comprehensive evaluation who is then transitioned to outpatient services. When a child requires more extensive and comprehensive therapy interventions as part of rehabilitation services, the occupational therapist evaluates the level of functioning of the child, develops an intervention plan, and involves the family in implementation of the goals and objectives.

The patient with a single injury (e.g., a hand injury) or a single episode of illness tends to have a short hospital stay, with a predictable course of treatment. Some patients admitted for an acute illness or injury may require extended rehabilitation, depending on the severity of the injury and resulting complications (see [Chapter 30](#)). TBI and spinal cord injury are two examples of injuries that require initial acute treatment and long-term rehabilitation. The length of the hospital stay for this type of patient during the acute phase of illness or injury tends to vary because the potential for complications is greater, and these patients need to be relatively stable medically before being transferred to the rehabilitative service. See [Chapter 30](#).

Chronically ill children or adolescents may be hospitalized periodically for acute episodes of an illness or complications of an illness. Children with diabetes, cancer, or cardiac conditions are in this category. When children who are hospitalized for diagnostic testing or adjustment of medications experience a comparatively short hospital stay, the occupational therapist focuses on evaluation and intervention planning that is likely to transfer to community providers. An occupational therapy evaluation in acute care services focuses on the child's functional status within the context of the illness or injury that has resulted in hospitalization.

Organization of Hospital-Based Services

Most patient care activity in hospitals is acute care. Acute care refers to short-term medical care provided during the initial phase of an illness or injury, when the symptoms are generally the most severe. The degree of severity that categorizes an illness or injury is matched to levels of acute care designed to meet these needs. The occupational therapist providing services to children during this phase must consider the long-term implications of the illness or injury while addressing the acute needs of the patient. Families may experience increased stress during this phase and therefore may require that the information be repeated or may need more time to process the results from evaluations.

Critically ill patients who require continuous monitoring and frequent medical attention, and patients who often need special equipment to maintain or monitor vital functions, are admitted to intensive care units (ICUs) or critical care units (CCUs). Hospitals may have various levels of intensive care units, each of which is designated for a specific patient population or purpose. These can include neonatal intensive care units (NICUs), pediatric intensive care units (PICUs) for older children, and postsurgical intensive care units (SICUs). Personnel who provide care for patients in ICUs receive special training to enable them to respond quickly and effectively to meet the needs of medically unstable patients in this challenging environment (see examples in [Chapter 21](#)).

A child whose illness or injury results in hospitalization but who does not need the continuous attention, high technology,

and specialized care of an ICU may be admitted to a medical or surgical acute care unit. Medical and surgical units also tend to be designated for specific types of patients. For example, children requiring neurosurgical services may be cared for on one unit, whereas children requiring orthopedic-related treatment may be served on another. Children may also be grouped according to age within the designation of these units. Placing children of similar ages together can facilitate developmentally appropriate care and allow for environments that are well designed to match children's and youth's age-based interests.

Children with infectious conditions may have a variety of diagnoses that require isolation conditions. If this is the case, these patients are often placed in special care units. Three conditions that require a child to be treated in a special care unit are (1) acute burns, (2) infectious diseases, and (3) bone marrow transplantation.

Often chronically ill patients are admitted for an exacerbation of their illnesses, for special treatments, or for complications. Diabetes, asthma, cystic fibrosis, and cancer are examples of chronic illnesses occurring in children who may require periodic hospitalizations. Patients who have progressive illness may also be seen for acute issues relating to the next stage of the disease process. For example, a youth diagnosed with Duchenne muscular dystrophy may experience a decrease in oral motor skills and subsequently be admitted for aspiration pneumonia.

Hospital-Based Therapy Teams

In hospitals, the child and family benefit from a wide range of medical care specialists and services that they can access as needed. Hospital teams are usually led by physicians who are trained as pediatricians and in other areas of practice, such as neurology, orthopedics, or developmental medicine. An important characteristic of medical teams is their dynamic nature. Because the health care disciplines represented in a specific case depend on the patient's needs, the medical team is continually changing. For example, a child with a feeding disorder who is failing to grow and gain weight may have a physician, nurse, occupational therapist, dietitian, and social worker as members of the medical team. However, a child hospitalized with multiple injuries resulting from a motor vehicle accident may have several physicians, nurses, occupational therapist, physical therapist, speech pathologist, dietitian, respiratory therapist, and social worker as members of his or her medical team. In addition, the team during one child's hospitalization may change. For example, the child admitted to the hospital for pneumonia may initially be seen by the pulmonary physician and perhaps a social worker, along with nurse(s); later the occupational therapist and speech-language pathologist may be involved when aspiration is suspected, and a physician from gastroenterology may be involved later when it is discovered that reflux is the culprit.

As a potential member of multiple medical teams within one hospital, the occupational therapist communicates and collaborates with professionals from many different health-related fields. The occupational therapist may need to redefine or explain the role of the occupational therapist continually to other team members and develop an understanding of the ways in which different team members' roles complement each other

in the provision of services to children. Occupational therapists employed by hospitals face increasingly complex challenges in defining their roles in different care settings within one integrated system and participating in a variety of medical teams across the spectrum of care.

Team Interaction

Interdisciplinary care within a hospital or medical system is common and mandated by most regulatory mechanisms. The success of this collaboration often depends on a shared mission that focuses the team's energy and creativity. The team holds family conferences on admission, at key decision points during the hospitalization, and at discharge to ensure communication and clarification of care recommendations with the family and local care providers. In addition, the team conducts weekly rounds to review the progress of each child and discuss any changes in treatment plans designed for each problem.

The occupational therapist's holistic concerns related to health, function, and participation necessitate and are enriched by the collaborative relationships among team members of multiple disciplines. Partnerships between occupational therapists and occupational therapy assistants can broaden the scope and timeliness of services. The need for frequent re-evaluation and trials with new strategies necessitate dynamic and shared interventions. Team efforts are typical in medical systems. For example, occupational and physical therapists often take a joint interest in interventions to promote the child's gross and fine motor skills and make joint decisions about positioning, transfers, wheelchair seating, and functional mobility (Figure 24-5). Occupational therapists collaborate with speech-language pathologists to evaluate and plan interventions for feeding and swallowing and augmentative communication. Nurses and occupational therapists typically have collaborative roles dealing with skills such as grooming, dressing, bathing, and training in special care routines of toileting and skin care. Occupational therapists may work together with therapeutic recreation specialists and child life specialists to provide adaptive play and socialization through activity and community outings.

A primary goal with children is to improve their participation and performance in educational programs. Children's hospitals typically have teachers on staff, and, in conjunction with occupational therapists and other team members, these educators and developmental specialists address skills and special needs that the child will have on returning to school. Psychologists and those who specialize in neuropsychology also provide suggestions for school placement and may work with occupational therapists to adapt learning strategies for the child as he or she returns to the classroom. Social workers often address issues of adjustment and coping with the child and family. All team members strive to be sensitive and supportive when educating family members to assume their new duties as care providers. Recommendations should seek a realistic balance within the family culture, established roles, and new responsibilities for care.

Families

The occupational therapist must recognize that families are often coping with tragic events or at least unexpected complications that seriously affect their life processes. Children and adolescents are challenged to adapt to significant functional and

FIGURE 24-5 Functional mobility, often with walking aid devices, enables greater freedom in activity selection and accomplishment in a variety of settings.

physical changes with bereavement,^{42,46,63} and this process can be further complicated by their own cognitive or behavioral impairments.¹⁷ An educational model may provide a helpful perspective. Recognizing that family members have a short amount of time to learn how to care for their family member who is faced with new disabilities, rehabilitation team members devote their time and attention to understanding the family's priorities and learning preferences. In nearly all cases, the typical routines of the family are severely altered by hospitalization and residual disability, resulting in worry, grief, and financial hardships that necessitate a transformation of relationships.³² Families function in different ways, and variations in styles influence effective coping.⁵⁷ Healthy and resilient families show strong and exceptional caring, open communication, balancing of family needs, and positive problem-solving abilities.⁶² Families with limited coping skills may need increased support and help in identifying resources to meet immediate needs and in coping with problems that they will face in managing the child at home. In either case, the needs of families often change during the rehabilitation process, requiring ongoing attention to maintain a collaborative partnership that can achieve the best outcomes for the child.

Acute Care Units

Intensive Care Unit Services

In the ICU, the child is often evaluated and treated at bedside because of the critical nature of the illness or injury and the need for constant monitoring of the child's physiologic status. Occupational therapy intervention in intensive care units supports medical priorities and goals for the child. It is essential that the occupational therapist be knowledgeable about the child's diagnoses and potential precautions, implications of medical procedures, use of life support or monitoring equipment, and contraindications for certain activities or positions. The occupational therapist monitors and knows immediate responses to changes in the child's vital signs, respiratory function, appearance, and symptoms.

Prolonged bed rest and immobility often occur as a result of ICU stays, during which medical technology and equipment and/or the need for restraints for the child's safety and care are in use. The average length of stay for a child in the ICU may be just a few days; however, it may be extended if the illness or injury is severe. The potential impact of extended immobility includes contractures, generalized weakness with decreased endurance, and cardiopulmonary compromise. Occupational therapists provide services to prevent these secondary problems by using graded activities and soliciting the child's participation to maintain strength and enhance functional capacities. Although the occupational therapist may have goals of increasing participation, independence, and endurance for the child, the nurse or family may believe that rest is required. Discussing the basis for the occupational therapist's intentions includes consideration of medical precautions to facilitate the team's desired outcome. Establishment of a routine, including regular therapy times within the constraints of the ICU, can also help with orientation for the patient and facilitation of regular participation. Family members or other caregivers may also be involved in carrying out interventions, such as range of motion, throughout the day. This provides them with the opportunity to become more involved in the care of their child during this portion of their hospitalization.^{37,68}

Occupational therapy interventions often include positioning recommendations and use of orthotics to preserve range of motion and prevent deformity. A plan for wear or use should be established and communicated with the family and other care providers to ensure follow-through. Caregivers should also be instructed on any potential side effects, such as pressure areas with orthotics, so that interventions can be modified as needed.

Sensory deprivation and stress resulting from the ICU environment may also complicate a child's medical status and recovery. The lack of privacy, immobility, and continuous sounds and lights of the ICU provide the child with an atypical sensory experience. In addition, the ICU setting has few indicators of night and day cycles. Over a prolonged period, ICU psychoses have been reported, in which the child may have altered mental status.^{3,36} Occupational therapy intervention may help counteract the effects of disorientation and sensory deprivation by fostering the establishment of a routine for the child and providing purposeful activities to facilitate cognitive, psychosocial, and motor functions.¹ Positive social interaction and the use of entertainment and play activities may be especially helpful for reducing stress and promoting engagements

of young children in the ICU. [Case Study 24-1](#) describes intervention in the ICU.

General Acute Care Unit

General acute care units tend to be designated by medical specialty. Children of various ages, with different types of conditions and treatments, may be served in the same acute care unit. Similarly, children requiring different types of surgery may be admitted to the same general surgical unit for preoperative and postoperative care. Designating units in this manner generally enables physicians and other members of the medical team to use their patient care time and equipment more efficiently.

In acute care units, children tend to be more medically stable and less dependent on life-sustaining equipment as part of their care. A lesser need for medical monitoring may enable them to benefit from greater involvement by rehabilitation specialists, including the occupational therapist, who may provide services at bedside or in the hospital's therapy clinic. Occupational therapists may be responsible for children in a variety of acute care units, requiring them to be familiar with the procedures of each unit, types of children admitted to the different units, and nurses and other hospital personnel who provide services. [Case Study 24-2](#) describes interventions for failure to thrive.

Specialty Units

Children's hospital units are also often designated for specialty care that congregates medical and support services for diagnostic and treatment purposes. These may include a focus on orthopedics, cardiac and pulmonary services, oncology, or other hospital-specific organization of units, such as burns.

Oncology and Bone Marrow Transplantation Units

A highly specialized acute care service is the oncology unit, which may also include bone marrow transplantation services. Children served on these units may include those diagnosed with various types of cancer, immunodeficiency disorders, hemophilia, and aplastic anemia. These units and services may be housed close together and share some resources, including staff, or may be located in separate areas within the hospital setting.

The staff on the oncology unit provides care for children who are newly diagnosed with cancer and undergoing induction chemotherapy, are receiving chemotherapy courses that require close monitoring, may have complications from their treatment such as fever with neutropenia, or may have undergone high-dose radiation and surgical tumor resections. The occupational therapist working with these patients may encounter patients and families in different stages of the diagnostic and treatment continuum. Because of the chronic nature of illness for children and youth located on these units, the occupational therapist may have time to develop relationships with the child and family. Children may come in and out of the hospital throughout their treatment, and the occupational therapist may see the child for inpatient and outpatient therapy or coordinate care across services. Children may also vary greatly in their

CASE STUDY 24-1 Intervention for Child in the Intensive Care Unit

Presenting Information

Michael is a 6-year-old boy admitted to the ICU with a diagnosis of necrotizing fasciitis with sepsis. He was initially seen at the general hospital in his community, approximately 2 hours' distance from the children's hospital in the area. On initial examination, Michael was found to have decreased sensation, with decreased circulation to his fingers and toes. He had a high fever (104.7°F) and was lethargic. He was airlifted to the children's hospital, and en route he began experiencing organ failure, including a cardiac arrest. His mother was able to accompany him in the airlift, but his father had to drive because of space constraints.

Background Information

Prior to his hospitalization, Michael was a typically developing young boy. He resided on a reservation with both of his parents. He attended first grade at the local elementary school, achieving average grades for his age. He also took pride in participating in the Native American dance troupe associated with his tribe and had been participating in exhibits nationally with his troupe since age 3.

Michael was playing in the park near his home with friends when he fell out of a tree and was deeply scratched by a branch. Because there was a little bleeding, he did not return home right away, but once he did return, his mother noted that the area was red and slightly warm. She cleaned the area with soap and water and placed Band-Aids on the cut. The next day, Michael had a slight fever and was complaining of generalized discomfort. By the second day, he vocalized more physical complaints, would not let anyone touch his arm, and his fever increased, even with medication and home remedies. He was taken to his family physician. By this time Michael had increased lethargy, was in and out of consciousness, and had a high fever. He was subsequently airlifted to the local pediatric hospital because of his quickly advancing disorder.

Medical and Occupational Therapy Intervention

On arrival at the children's hospital, Michael required a respirator for ventilation support, and his medical status continued to deteriorate. Evaluation revealed staphylococcal sepsis with intravascular coagulopathy, and he was admitted to the

intensive care unit. During the first 48 hours, Michael continued to decline and showed evidence of organ failure. He required continuous medical interventions, including dialysis, ventilation support, and surgical intervention for increasingly necrotizing digits, including amputation of several toes and fingers.

With a focus on prevention, occupational therapy was consulted early in his care to provide positioning and maintain range of motion of affected and unaffected joints and soft tissues. The occupational therapist fabricated orthotics for both his hands and feet. He was required to wear them at all times, except during dressing changes. His parents were also instructed to carry out range of motion routines to maintain his range and participate in his care.

Although Michael's condition initially continued to deteriorate, necessitating amputation of one leg above the knee, the other at the ankle, and all but two fingers, his family held out hope that he would come through this devastating illness. The parents called in the assistance of their tribal leaders to provide guidance and use tribal medicine to enhance Western medicine techniques. Leaders were granted permission to visit Michael in the intensive care unit, with clear guidelines about acceptable procedures that could be used.

During this time, the occupational therapist continued to monitor positioning and range of motion. The occupational therapist collaborated with nursing personnel to help position Michael and his medical devices to enable his mother to rock him in a chair at bedside. As his medical condition stabilized, Michael was weaned from ventilator support and could engage in strengthening and endurance activities. Occupational therapists also began to help Michael resume personal ADLs by introducing adaptive devices to enable his independence. Michael was provided with an appropriately sized wheelchair, and gloves were adapted to ease the use of his upper limbs so that he could propel the chair around the hospital unit. As he continued to increase his strength and function, he was eventually discharged from the intensive care unit and transferred to pediatric rehabilitation services, where his functional performance challenges were further addressed by prosthetics fitting and learning adaptive methods and other compensatory strategies to restore capabilities in personal care as well as home and school functioning.

ability to participate in treatments throughout the day or during the week. Coordinating therapy with other medical interventions may enhance therapeutic benefits by providing interventions when the child's energy is highest.

A bone marrow transplantation unit has certain similarities to the oncology unit, with intensified therapies and additional toxic agents used as life-saving treatments. Bone marrow transplantations are used as part of a medical treatment protocol for a number of life-threatening childhood illnesses, including leukemia, aplastic anemia, immunodeficiency syndromes, and tumors.⁷³ Because of the complications of the treatment, the occupational therapist must be aware of the stages that the child is in during the transplantation process and must strictly adhere to any precautions required.^{16,58,65}

Oncology Treatment

During the initial phase of treatment for cancer, children undergo a series of evaluations to determine cancer type and staging, which includes determining whether the cancer has metastasized. Patients generally receive a permanent line placement through which they receive their chemotherapy. They are often hospitalized for their induction chemotherapy, which is the initial course and may be quite intense for some children. Hospitalization is required initially to assess the effects of chemotherapy and watch for any complications. Children frequently decrease their oral intake during treatment, so nutrition and hydration need to be carefully monitored.

As treatment progresses, children are often discharged from the inpatient setting and are monitored between chemotherapy

**CASE STUDY 24-2 Intervention for Child Who Fails to Thrive****Background Information**

Failure to thrive (FTT) is a diagnosis given to children, frequently infants and young children, who fail to grow or gain weight. FTT may be designated as organic, arising from a diagnosable physical cause, or nonorganic, which denotes impaired growth without an apparent physical cause.²⁸ Children with FTT often require hospitalization and receive acute care services that address complications, including immunodeficiencies, generalized weakness, and developmental delay because of their malnutrition and behavioral difficulties.

Although organic FTT can be attributed to a specific physical disorder, nonorganic FTT is primarily (but not exclusively) associated with psychosocial factors. Disturbances in parent-child interaction and development of attachment early in life, difficult infant temperament and behavior, maternal social isolation, and financial difficulties within the family are some of the variables associated with nonorganic FTT.^{51,59}

The complexity of factors implicated in FTT emphasizes the need for a coordinated team approach that offers medical, nutritional, developmental, and psychosocial intervention. As a member of the hospital-based team, the occupational therapist may contribute to the diagnosis and intervention for the child with FTT. A comprehensive occupational therapy assessment provides the medical team with information regarding the infant's developmental status, feeding behaviors, infant-caregiver interactions during play and feeding, and infant interactions with unfamiliar adults. Stewart and Meyer⁶⁶ also stressed that infant assessment emphasizes interactional issues with the caregivers, whereas the assessment of older children focuses more on behaviors in the feeding situation and attempts to differentiate between environmental factors and neuromotor difficulties that may be affecting feeding.

Occupational therapy intervention goals with a child who has FTT may include ensuring effective oral-motor and feeding skills and facilitating development. Promoting positive parent-child interaction may also be emphasized by using strategies that help the parent understand the infant or child's behavioral cues and engage them with positive and developmentally appropriate play experiences. This emphasis on positive parent-child interaction also encourages parents to develop behavioral expectations consistent with the child's level of functioning. Ongoing outpatient therapy is often necessary following discharge to support goals established on the inpatient stay and foster effective feeding behaviors.

Presenting Information

Kevin was a 3-month, 7-day-old boy brought to the emergency room by his parents because of his unresponsive behavior and concern regarding possible seizure activity. Initial diagnoses included the following: rule out abuse, severe nonorganic FTT, and other risks, including seizures. Kevin was noted to have bruising above both knees and over his right buttocks. He had diaper rash and muscular wasting around the left hip and extremities. He demonstrated poor oral feeding and was subsequently admitted to the hospital for observation and monitoring. An attending physician referred Kevin to occupational therapy on the third day of hospitalization to address oral feeding skills.

History

Kevin's parents brought him to the hospital's emergency room after a home visit by a Child Protective Services worker. On his hospital admission, his parents left and did not visit during his week-long stay at the children's hospital. His maternal great aunt visited occasionally, and she expressed interest in adopting him.

Kevin was born at term and weighed 5 pounds, 12 ounces. He went home after a 48-hour hospital stay. He was hospitalized at 2 months of age for FTT, upper respiratory tract infection, and otitis media. He was discharged to his parents with home health nursing, a Child Protective Services referral, and pediatrician follow-up. Kevin's parents had missed all follow-up appointments until they brought him to the emergency room.

Medical and Occupational Therapy Intervention

A pH probe showed severe gastroesophageal reflux. An upper gastrointestinal series was performed, which ruled out anatomic abnormality. Stool samples were analyzed and showed malabsorption, reducing substances, increased fatty acids, and *Giardia lamblia*, all of which combined to reduce his level of nutrient absorption and increase fluid loss. As a result, Kevin was severely underweight and lethargic. Treatment for the reflux included positioning on an elevated wedge and the use of thickened feeds.

Kevin was evaluated by occupational therapists using clinical observations of his oral-motor, feeding, and developmental skills. He demonstrated intact oral structures and sensation, with functional oral skills for safe oral feeding. He had small sucking pads with a weak suck and fair coordination of suck-swallow-breathe. His suck and coordination improved with support at his jaw and cheeks. Kevin's developmental skills were delayed, and he demonstrated poor state control, with high irritability.

It was the occupational therapist's impression that Kevin's weak suck, poor feeding, and irritability were from overall weakness, malnutrition, and recent intubation, rather than from a neurologic deficit. The occupational therapist developed a bedside plan of specific facilitation techniques to be used during feeding. These included jaw and cheek support, external tongue stimulation, flexion swaddling, decreasing external stimulation, upright and well-aligned feeding positioning, limiting oral feeding to 30 minutes, and turning off the continuous pump that fed Kevin through a nasal gastric tube.

After implementation of occupational therapy recommendations by nursing staff, Kevin's oral intake increased dramatically over the next 3 days, with the occupational therapist feeding him once daily to monitor progress. Once the acute feeding issues were resolved, the emphasis of occupational therapy focused on developmental activities to improve self-calming, visual tracking, and social interactions.

Kevin was referred for outpatient occupational therapy and early intervention services before discharge. Child Protective Services assumed custody of Kevin, and he was discharged to a foster home with a weight increase of 2.4 pounds (follow-up weekly weight checks were scheduled with his pediatrician). The occupational therapist provided the foster parents with a home program, including positioning, feeding, and activities to promote Kevin's play development.

sessions in outpatient visits. If the child does not have a negative reaction, or if the agents given do not have high levels of toxicity, the child may receive chemotherapy on an outpatient basis. Children receiving chemotherapy are often at high risk for infections and are susceptible to contagious diseases; therefore, they need to take precautions, particularly if they are neutropenic, which affects their ability to fight off disease. Being neutropenic is a frequent cause for admissions between chemotherapy sessions and can mean that children are readmitted multiple times throughout their treatment.

The occupational therapist working with these children should be aware of the cancer types and have general knowledge of chemotherapy drugs and their complications, radiation therapy effects, and surgical approaches that may be taken. All personnel must adhere to infection control procedures. Occupational therapists may focus on the prevention of secondary complications by implementing strengthening, range of motion, and endurance activities and resuming ADLs, feeding, or play activities with patients, depending on their needs. Children and families frequently develop a close relationship with care providers because of the physical aspects of treatment, along with the normalcy and expectation of survival that families can perceive with daily activities. Cancer survival can be a realistic outcome for many children, but residual difficulties, including post-traumatic stress disorders, may be encountered that necessitate attention years after medical treatment has been discontinued.⁴⁴

Occasionally cure is not an option for a child and family, and the focus of treatment may change to be palliative in nature. The occupational therapist working with the dying child and his or her family must respect the cultural beliefs of the family, along with the grief process. The occupational therapist can assist with suggesting energy conservation techniques to enable the child to continue to play and interact with family members. Positioning may become particularly important as the child develops increased weakness, difficulty with breath support, or pain, and the occupational therapist can help families problem solve alternative positioning to be close to their child when comfort is of the utmost importance.¹⁸ It is also important that the occupational therapist respect the family and child's wishes for withdrawal or discontinuation of services. Some may wish to discontinue therapy intervention, choosing to narrow the circle of support, whereas others develop a closeness with the occupational therapist throughout the treatment and want to continue contact. The occupational therapist needs to examine his or her own support systems, beliefs, and feelings around end-of-life issues to assist the child and family during this difficult time,⁷¹ during which communication with families is essential,³⁵ but receipt of palliative care approaches may be limited.⁴¹

Transplantation Procedures, Complications, and Interventions

The procedure for bone marrow transplantation involves chemotherapy, radiation, or both before transplantation. This is followed by the intravenous infusion of the bone marrow taken from a compatible donor or from the patient before the pretransplantation regimen of chemotherapy and radiation. Children who are undergoing treatment for disease processes that do not invade the bone marrow may be eligible to undergo stem cell transplantation.⁶⁰ This involves the harvesting of stem

cells throughout their initial chemotherapy treatment while in the remission stage. Although bone marrow and stem cell transplantations both involve intense chemotherapy and radiation, individuals who undergo stem cell transplantation experience lower rejection rates and fewer complications from graft-versus-host disease (GVHD). The intense chemotherapy or radiation before transplantation and underlying disease processes cause severe immunosuppression in patients, making them highly susceptible to life-threatening infections until the new bone marrow is established and the child's immunohematopoietic system is once again functioning effectively.^{45,75} Continued long-term effects are also a complication of transplantation. GVHD, abnormal neuroendocrine function, secondary malignancies, and avascular necrosis are some of the complications seen in pediatric patients.⁵⁹ Stretching, extremity weight bearing, and general endurance exercises improve function in children experiencing these GVHD complications.⁷

Because these children have significant compromise of their immune systems, the hospital environment is carefully designed to reduce the risk of infection significantly. Common strategies to protect bone marrow transplantation patients include room isolation, reverse isolation, and laminar airflow in a clean or sterile environment.⁷⁶ Additionally, those having access to the unit may be limited. Staff and visitors who have flu- or virus-related symptoms may not be allowed onto units serving these severely compromised patients.

Intervention by occupational therapists may include pretransplantation assessment of the child's development and functional abilities, as well as identification of limitations or problems caused by the underlying disease process. After the transplantation, the occupational therapist's goals may be as follows: (1) promote age-appropriate play, daily living, and social participation; (2) enhance coping and interaction skills; and (3) develop a plan for follow-up in the community. [Case Study 24-3](#) describes a child from initial diagnosis and chemotherapy through the transplantation process and posttransplantation intervention.

Rehabilitation Services

Levels of rehabilitation services can be subacute, acute, and outpatient or ongoing care. Subacute rehabilitation services are typically organized within skilled nursing facilities (SNFs) or other long-term care settings. Such programs are designed for children and adolescents who are too medically fragile or dependent to be cared for at home but who are not yet able to engage in or benefit from the intensive efforts of acute rehabilitation.³¹ Such settings can also address later stages of care, which may involve palliative care or extended stays. After initial hospitalization, children and adolescents with moderate to severe head injury, multitrauma, or other systemic illnesses may be admitted to an SNF with subacute rehabilitation services. In these settings, they may receive daily therapy to prevent secondary complications and work toward goals of greater independent function. This interdisciplinary care may culminate in admission to an acute rehabilitation program or planned discharge to an organized home- and community-based service system of care.

Acute rehabilitation is characterized by inpatient hospital units and services. The most common of these are dedicated

**CASE STUDY 24-3 Intervention for Child with Cancer****Presenting Information**

Danielle was a 21-month-old girl who was initially seen at a general hospital near her home when she experienced a decrease in standing and sitting balance. She was subsequently admitted to a pediatric tertiary care center approximately 400 miles from her rural community. Initial examination and imaging revealed a neuroblastoma in her spinal cord. Danielle was immediately placed on the pediatric oncology unit, a peripherally inserted central catheter (PICC) line was placed, and chemotherapy induction was initiated. At initial presentation, both parents flew in with Danielle, although they had separated just prior to diagnosis.

Background Information

Prior to diagnosis, Danielle was a typically developing 21-month-old girl, described by her parents as shy and reserved. She resided with her mother; her father had moved out 1 month prior to her diagnosis. Both parents were English-language learners, having immigrated from South America. They lived in a small town, with many community friends available for support. Her parents moved from a large city prior to conceiving Danielle to “obtain a simpler life-style.” On hearing the diagnosis, the mother revealed that her grandfather had died of a glioblastoma 1 year previously.

Medical and Occupational Therapy Intervention: Oncology Phase of Treatment

Danielle was initially referred to occupational therapy immediately after diagnosis. She had initial complications coping with the increased noise and number of caregivers, along with decreased performance. She was also seen by a child life specialist for developmentally appropriate coping strategies, such as creating a calming environment and playing to facilitate release of her emotions. Danielle did not sit independently, and her overall strength was diminished.

Danielle was given chemotherapy to reduce the size of the tumor and keep it from spreading. Because of its location, tumor resection was not possible. Stem cell transplantation was discussed at initiation of treatment as the best course of possible cure for her cancer. Thus the medical plan was to reduce her tumor size, obtain remission, harvest stem cells, and prepare Danielle for transplantation. She was placed on a chemotherapy protocol recommended for her tumor type, and the family was informed of all complications, side effects, and likely outcome possibilities.

In an initial assessment, the occupational therapist evaluated Danielle’s performance skills and strength. She completed family interviews to learn about the child’s previous skill levels, occupations, and particular interests. A plan was made in conjunction with the parents and nurse for a daily schedule, including times when Danielle could receive therapy. She was moved to a corner room to decrease noise, and times were posted when curtains were to be drawn to allow the family private time. Pictures of caregivers, including therapists, primary nurses, and physicians, were posted for reference for Danielle and her parents.

Ongoing communication was established among all team members through online documentation and team rounds, and a care book was placed at Danielle’s bedside where

information and questions could be posted to facilitate communication between parents and medical personnel further. In addition, care conferences were held weekly, during which all team members, including parents, discussed and planned ongoing interventions.

Occupational therapy intervention consisted of age-appropriate play activities to facilitate strengthening and continued motor skill development. Self-feeding was encouraged and supported. The occupational therapist instructed family members and the nurses on position strategies to increase Danielle’s function and enable participation. Danielle did not always participate in regular sessions because of medical treatments that resulted in nausea and neutropenic compromise, causing additional weakness and lethargy. During particularly difficult periods, intervention sessions were limited to gentle range of motion or were sometimes canceled for the day.

As medical intervention, including chemotherapy, progressed, Danielle experienced an increase in function. Her occupational therapy intervention plan was continually revised to reflect increased strength and independence. In response to chemotherapy, Danielle began to have reduced oral food intake. Strategies were implemented to help maintain oral-motor skills and optimize self-feeding.

Danielle eventually transitioned to outpatient care, where both her oncology treatment and occupational therapy continued. Because of behavior challenges, family requests, and training expertise, direct physical therapy was discontinued. Instead, a collaborative approach of consultation with the occupational therapist at regular intervals to facilitate ambulatory and lower extremity skills was established. Her parents divided care and alternated times when each parent would be present.

Once the transplantation regimen was initiated, Danielle was hospitalized for an extended stay. She underwent intensive chemotherapy and radiation to ablate her current marrow and subsequently received stem cell transplantation. During the initial stages, Danielle experienced a significant decrease in her strength and developmental skills. She had toxicity-related complications, including sloughing of her skin and mouth sores, which made participation in activities difficult. As an added complication, Danielle also experienced life-threatening pulmonary complications that required ventilation support and necessitated a 2-week stay in the intensive care unit.

Family stresses throughout this portion of her treatment were enormous, and Danielle’s mother asked Danielle’s maternal grandmother to come for support. Once there, interpreters were called in to translate necessary information, as the parents desired. Danielle eventually achieved slow engraftment, and transplantation-related complications diminished.

As engraftment progressed, Danielle regained her play and daily living skills, including ambulation. She was transferred to outpatient services and continued to receive occupational therapy intervention to address decreased strength and delayed motor skills. She was discharged to her community once she had completed her 90-day post-transplantation evaluation and engraftment was clear. She continued to receive ongoing occupational therapy in her community to help facilitate progress in her development.

rehabilitation units within a children's hospital. Another form of organization is the specification of beds and services for pediatric patients in a large rehabilitation hospital. Adolescents 15 years of age or older may be admitted to rehabilitation units that commonly serve adults. Children and adolescents are admitted to acute rehabilitation from other acute or transitional care medical services within the hospital, other local hospitals, or subacute rehabilitation settings. See [Chapter 30](#). Overall, admission to pediatric rehabilitation facilities and length of inpatient stay is largely based on the child's or youth's level of function and services needed.¹⁵

Essential to acute rehabilitation programs is the presence of a broad range of services, including occupational therapy. The mixture and intensity of services are planned to meet systematically developed goals. Such programs are characterized as meeting three types of needs:

1. Organize and implement a planned approach for the management of recovery and rehabilitation of children post-trauma or with rapid-onset disorders.
2. Redirect care after onset of complications in children with chronic disorders.
3. Provide an environment for specialized medical or surgical procedures that involves specific care regimens and protocols.

Children and adolescents who sustain a sudden illness or injury are the most common type of admission in acute rehabilitation. [Table 24-2](#) indicates the common problems that affect a typically developing child who experiences injury from accidents, violence, or rapid-onset disease. Acquired injuries or diseases represent a substantial health threat to children.⁷⁷ Injuries are the leading cause of death and disability among children older than 1 year of age.²⁵ TBIs, including closed head injury, skull fracture, and penetrating brain injuries, are an ongoing concern for children and adolescents caused by transportation-related crashes, falls, recreational injury, and violence.^{47,61} [Case Study 24-4](#) describes rehabilitation for a child with a TBI. Acute rehabilitation is also required for children who sustain spinal cord injury (SCI) and multitrauma. Environmental

hazards, accidents, and abuse are also implicated in children who experience burns, near-drowning, smoke inhalation, carbon monoxide poisoning, or drug overdose.

Aside from known hazards, children also develop infections that involve the central nervous system (CNS); they may sustain a cerebrovascular accident or develop other neurologic disorders, such as transverse myelitis or Guillain-Barré syndrome. Cancer and its treatment may cause children and adolescents to develop problems that necessitate acute rehabilitation. All these disorders are characterized by typical development until an acute health crisis causes a severe loss of function, a likelihood of prolonged recovery with residual disability, and potential chronic health complications associated with disability. For these children and their families, the purpose of rehabilitation is to optimize recovery, prevent complications, and organize and implement an approach to initial and long-term management that optimizes function in family and community life.

Children with congenital or chronic disorders may also require acute rehabilitation. Many with genetic disorders or other congenital abnormalities or who experience chronic disease often have delayed or atypical patterns of functional skill development. These children are also at risk for complications that can create a gradual or critical loss of function. Episodes of respiratory complications, bony fractures and dislocations, skin breakdown, or other systemic complications may be associated with functional deterioration. Children with cerebral palsy, spina bifida, or other types of congenital deficits are included in this at-risk group. Similarly, those with congenital limb deficiency or arthrogryposis multiplex congenital syndrome may have reconstructive surgery necessitating acute rehabilitation. Children with osteogenesis imperfecta can have episodes of curtailed functional gains after injury, and children with juvenile rheumatoid arthritis and systemic disorders can experience periods of rapid functional decline. For these children, the goals of rehabilitation are to prevent further losses and facilitate the reacquisition of skills consistent with the pattern of functional progression that was previously shown.

A third major group of children who receive acute rehabilitation services includes those who are hospitalized for treatment with special medical, surgical, or technologic procedures. For children with cerebral palsy, the use of medical interventions such as selective dorsal rhizotomy, continuous intrathecal baclofen, or other neurosurgical techniques to reduce spasticity may involve admission to acute rehabilitation.²⁶ Children with severe pulmonary complications or those who become ventilator-dependent may be admitted for acute rehabilitation; their families learn how to perform care procedures and use medical technology¹⁰; long-term outcomes can be positive.³⁰ More and more children are also receiving organ transplants, which may necessitate teaching special care procedures and redeveloping fitness following a prolonged disease process. These interventions often necessitate occupational therapists, following specific evaluation and treatment protocols designed to optimize functional outcomes.

TABLE 24-2 Rapid-Onset Conditions

Type of Onset	Examples
Accidental injury	Traumatic brain injury (e.g., closed head injury) Skull fracture or penetrating head injury Burns and smoke inhalation Multitrauma Near-drowning Spinal cord injury
Violence	Multitrauma Traumatic brain injury (e.g., gunshot wound) Burns, iron burns, cigarette burns, and scalding
Disease processes	Central nervous system infection (e.g., encephalitis and meningitis) Transverse myelitis Guillain-Barré syndrome Cancer Organ transplantation

Transition from Rehabilitation to the Community

To facilitate continuity of care when the child is discharged from a pediatric rehabilitation hospitalization, the team and family develop a comprehensive plan of transition.⁷⁴ For

**CASE STUDY 24-4 Intervention for Child with Traumatic Brain Injury****Presenting Information**

Devon was a 6-year-old boy with a severe traumatic brain injury caused by an accidental gunshot wound to the head. Immediately following this incident, he was evacuated to the level 1 regional trauma center, where he underwent a decompressive left craniectomy for evacuation of intraparenchymal and subdural hematomas. Once stabilized and able to tolerate multiple daily therapies, Devon was transferred 13 days later to the regional children's hospital for rehabilitative services. At that time, he was delayed in following simple verbal commands, not moving the right side of his body, unable to sit unsupported and walk, and he did not speak.

Background Information

Previously healthy, Devon lived with his parents and 8-year-old brother. His brother Daniel had just finished third grade and Devon was to enter first grade in the fall. Prior to the accident, both boys were at a friend's house, where apparently they found a gun. The gun was somehow fired, and Devon was shot in the head. No one except for the children witnessed the event. The family was understandably grieving and his mom or dad had been at his side at all times during his hospitalization. His mother described Devon as a warm, loving child who knew everyone's name in the neighborhood. He loves playing with cars, riding bikes, and competing on computer-based video games.

Medical and Occupational Therapy Intervention

In addition to being cared for by the medical team and rehabilitation nurses, Devon received services from occupational therapy, physical therapy, speech therapy, recreational therapy, hospital-based school and rehabilitation psychology. Devon's family was supported by a social worker and the rehabilitation unit care coordinator.

The occupational therapist completed an initial evaluation with Devon and discussed a plan of care with Devon's family. Because Devon was not showing any movement of his right arm, the occupational therapist started a daily range of motion program to maintain full range of motion and fabricated a wrist-hand orthotic to be worn when Devon was resting in bed and at night. Once Devon tolerated this program well, the occupational therapists trained his mother and father to complete the range of motion program. As Devon began vocalizing, however, he was difficult to understand; his parents were concerned that he was unable to communicate basic needs. The occupational therapist worked with the speech therapist so that Devon would be able to point to a picture symbol board with his left hand to communicate when he was afraid, felt pain, needed to use the bathroom, and was hungry.

It was also important to Devon's family that he remain safe when he was not in therapy. The occupational therapist

taught Devon how to complete his daily activities safely, with assistance and modifications as necessary, such as first dressing with sitting supports on his bed and then progressing to dressing while seated at the edge of his bed. Devon learned how to use his nonaffected left arm as his newly preferred hand to dress in loose-fitting, nonfastener clothing using one-handed techniques and with equipment to modify the task, such as elastic laces on his shoes and a ring on his zipper pull. Devon learned how to manage a spoon and a fork, eat with his left hand, and write his name. He practiced these new skills in therapy and with his family, as well as when attending the hospital schoolroom and with recreational therapy. The occupational therapist scheduled Devon for one-to-one therapy sessions twice each day and planned morning personal ADL training and afternoon therapeutic activities. In addition to structured ADL routines and orientation and memory programs, the occupational therapist also engaged him in selected activities to facilitate the use of his left arm and provide cognitive challenges in organizing steps, following sequences, and sustaining engagement in familiar and novel tasks. The occupational therapist taught Devon to carry out daily range of motion and whole-body stretches to maintain normal range and facilitate symmetric trunk and limb use.

Devon continued to have difficulty performing activities using his nondominant left hand, and left hand movements were awkward and unsuccessful. The occupational therapist cued and encouraged him to use both hands together, with the left hand assisting the right hand. This strategy improved his personal ADL performance so that the occupational therapist discontinued the use of adaptive devices, such as a button aid and rocker knife, after 2 weeks. Handwriting with the right or left hand was not satisfactory for schoolwork because of a language disorder, illegibility, and slow speed. The occupational therapist introduced a computer keyboard and initiated supplementary handwriting activities to facilitate movement and augment function.

On discharge, his parents expressed concern about him returning to school. They worried about how Devon would adjust to school. Specifically, they wanted him to perform in a regular classroom, eat lunch with his friends, and go to the bathroom by himself. The occupational therapist provided the school with results from standardized fine motor, visual perceptual, and visual motor assessments and made recommendations to the school so that they would understand what assistance Devon would need. The occupational therapist suggested accommodations for writing, cafeteria assistance, and bathroom facilities. Devon returned home with his family and continued his recovery, with outpatient therapies focusing on sensorimotor skills and school-based therapies focusing on enabling classroom participation and educational performance.

example, a child with a brain injury often requires special education services after discharge from the medical center, and readiness to return to school may be particularly problematic because of social-behavioral challenges.⁵ Team and family activities and communication focus on the transition from rehabilitation to school and community as soon as discharge is considered. Transition activities include interagency team meetings at which school and rehabilitation team members are represented. Ideally, at least one interagency meeting occurs in the rehabilitation unit and at least one in the school. By sharing where the meeting is hosted, team members get a realistic picture of the child's environments. When the meeting is at the team's home site, most, if not all, team members who worked with the child can be involved.

In a visit to the school, the occupational therapist from the hospital shares information with the school-based therapists related to concerns, priorities, and results of intervention approaches (i.e., what worked and what did not). The child's rehabilitation team helps problem solve issues regarding the school's accessibility and possible modifications to the classroom and curriculum. Visits to the child's classroom can help identify accommodations that need to be in place. During these visits, the rehabilitation team can present information to the other students in the class about the child's disability, his or her rehabilitation, and types of changes that they may expect in their peer. When a child returns to his or her preinjury classroom, the hospital therapist can provide an in-service presentation about the injury so that the student's peers have expectations about his or her behavior and personality or, in the case of severe burns, about the student's appearance. In addition, before discharge, the child should visit his or her school and other important environments to determine what accommodations will need to be made.

The rehabilitation team often monitors the child's progress during the first few months after discharge. The child may continue with outpatient services while initiating school-based services. Consistency during the transition is maintained by the family members, who ultimately support the child through the transition to the home. In support of this, the teams involved provide the parents with comprehensive information about the special education system in their community, their rights as parents of a child who newly qualifies for special education services, and other community programs, supports, and resources that they can access.

Outpatient Services

Another major component of pediatric rehabilitation exists in specialized outpatient services and clinics that provide ongoing care. Typically, as part of children's hospitals or rehabilitation hospitals, interdisciplinary outpatient clinics are organized to provide monitoring and interventions for children who experience particular types of chronic health risks and disabilities. Occupational therapists often provide follow-up and follow-along attention to children and families after hospitalization, but many of these children are never hospitalized. Occupational therapists who work at these clinics often focus on the child's or adolescent's health status and development, emphasizing functional progress and participation in home, school, and community activities.

TABLE 24-3 Outpatient Clinics and Programs Often Served by Occupational Therapists

Client Disorder	Clinic or Services
Congenital disorders	Spina bifida
Neuromuscular disorders	Cerebral palsy
Developmental disabilities	Down syndrome
	Fetal alcohol syndrome
Rheumatologic disorders	Juvenile rheumatoid arthritis
	Systemic lupus erythematosus
Adolescent medicine disorders	Reflex neurovascular dystrophy
Craniofacial abnormality	Cleft lip and palate
Orthopedic disorders	Traumatic hand injury
	Congenital limb deficiency
Rehabilitation	Traumatic brain injury
	Spinal cord injury
	Constraint-induced movement therapy program
Muscular dystrophy	Duchenne muscular dystrophy
	Spinal muscle atrophy
Limb deficiency disorders	Congenital amelia
	Traumatic amputation
Cystic fibrosis	Cystic fibrosis
Assistive technology	Seating and positioning
	Wheelchair control
	Augmentative communication
	Computers and information technology
	Environmental controls

Outpatient clinic programs that often include occupational therapy services are listed in Table 24-3. Such programs may be scheduled weekly, monthly, quarterly, or even annually, as needed. Sometimes these programs are conducted away from the hospital facility at community sites such as schools. Occupational therapists who work in specialized hospital programs are provided with unique exposure to otherwise uncommon diagnoses and clinical procedures and can pass this experience on to other families and therapists as a conduit of information and new ideas. For example, school personnel may have limited experience with children who have arthrogryposis, brachial plexus and limb deficiency, or various forms of muscular dystrophy, whereas the hospital clinic therapists would have regular experiences with these disabling conditions. Specific study and preparation for consultation are suggested for entry-level therapists to develop as part of pediatric rehabilitation,¹⁹ particularly in working with more local, community-based therapists who may have limited experience with some diagnostic conditions and related treatment approaches that are used.

Outpatient services are important components of the total spectrum of hospital care and may be provided at the hospital, at a hospital satellite center, or as part of an interdisciplinary hospital-based clinic (e.g., rheumatology clinic, neurodevelopmental palsy clinic, special feeding clinic). Outpatient occupational therapy is generally provided for one of three purposes: (1) as part of a diagnostic assessment, (2) to provide needed intervention and assistive technology after hospital discharge,

**CASE STUDY 24-5 Occupational Therapy in Spina Bifida Specialty Clinic**

Stacie is an 8-year-old girl with midlumbar myelodysplasia. She ambulates with ankle-foot orthotics (AFOs) and uses Lofstrand crutches for longer distances at this time. Although she is functional for mobility in her home and at school, her future mobility demands may necessitate use of a wheelchair. She exhibits delayed coordination skills and less than expected quality and speed in handwriting tasks. Stacie uses a computer to complete some school work in her third-grade integrated classroom.

Stacie is assisted at home in dressing (managing clothing fasteners) but is otherwise independent with her morning and evening ADLs. With a neurogenic bowel and bladder, she is on a clean intermittent catheterization (CIC) program and daily bowel program (BP). Her mother has traditionally done her catheterization and is trying to transition to have her perform more of it on her own. At school, a nurse assists with her catheter routine twice daily. She is somewhat successful with her bowel program, typically having bowel movements in the morning or during the evenings at home. Timed programs include the use of diet and suppositories. Occasional bowel accidents are acknowledged, and she uses pull-ups to manage.

Although many of the activity and participation concerns with Stacie are addressed as part of school therapy and reflected in her individualized education program (IEP), the role of the specialty clinic follow-up has two major purposes. One of these is to monitor her motor skill development and status carefully. Children with spina bifida often have neurosurgical shunt placement early in life to reduce hydrocephalus. These shunts can become obstructed, and families, as well as

service providers, are vigilant in attending to signs of shunt failure. Worsening of coordination and visual-perception skills can be one of these signs. The occupational therapist at the specialty clinic often performs normative hand function assessment to determine stability of performance over time. In this clinic, the occupational therapist measures grip and pinch strength and coordination testing using the Jebsen-Taylor Hand Function Test, which has norms for children, adolescents, and adults of both genders. Developmental visual-perceptual tests may also be used. In her most recent visit, Stacie's scores were similar to the prior year's findings, with her scoring about 1.5 SD below the mean on most tasks. Her grip and pinch strength were also around the 40th percentile for her age and gender.

Another role of the clinical specialist is to facilitate growth in children's ADL and IADL skill independence. Children with spina bifida have different timing and patterns of skill development that often need specific advice and the use of adaptive methods and devices.^{14,41} For example, the clinical specialist may provide advice on techniques to manage orthotic and other devices, methods to develop wheelchair skills, and strategies to promote independence in bladder and bowel care programs. Stacie managed most of her personal care and participated in a few chores at home. The occupational therapist suggested that she and her family select clothes to be worn to school the night before and recommended purchasing clothes without fasteners or with a zippers and snaps. Clinical follow-up emphasized health monitoring, health promotion, and increasing her independence and participation as she transitioned to middle school.

or (3) to provide occupational therapy intervention for individuals with disabilities or other medical conditions not requiring hospitalization.

Outpatient services provided as part of an interdisciplinary specialty medical clinic usually have a specific focus (e.g., feeding clinic, behavioral disorders clinic). See [Case Study 24-5](#). Occupational therapy services in specialty clinics are limited because children typically attend only once or twice a year. In some cases, the occupational therapist functions as a consultant, completing an assessment, and then making recommendations to the physician. In other cases, the occupational therapist is an integral part of the decision-making team and may be involved in child assessment, intervention or equipment recommendations, or the provision of orthotics and adaptive equipment.

In AT clinics, occupational therapists evaluate how the child could benefit from the use of aided and augmentative communication systems, computer access and use of information technologies, therapeutic seating, powered mobility, or other technologies that enable environmental access and control. These applications of special procedures and AT devices are characterized by preplanned and often short trials leading to the prescription of devices.³⁸ Efforts culminate in intensive family training and transitions to follow-up in the community, often as a partnership with local providers in the environments in which the devices are used.

Residential or intensive day treatment programs characterize another form of outpatient pediatric rehabilitation service. These extended care programs focus on direct assistance with community re-entry and participation. Simulated or actual environments become the training sites for skills that enable community participation and effective performance toward goals of independent living, education, and work activities.

Summary

The provision of occupational therapy services to children in hospitals is a specialized and challenging area of practice. Occupational therapists in hospitals must have a thorough understanding of the characteristics of health care systems, the factors and trends that affect hospitals, including legal and accreditation requirements, and the specialized needs of hospitalized children and their families. To achieve health and functional goals, the occupational therapist must also understand the roles of other professionals involved in the care of children. Occupational therapists who are employed in hospitals have the opportunity to gain expertise in assessment and intervention of children of various ages, with many different diagnoses, often within a dynamic, fast-paced environment. As hospitals broaden their range of services in response to a changing health care system, hospital-based occupational therapists

will have opportunities to broaden their areas of expertise, apply different models of service delivery, and develop new practitioner roles.

- Hospital-based pediatric therapy services play a unique role in the overall management of children and adolescents with a new or chronic disability.
- In addressing acute and chronic problems, the occupational therapist's emphasis is on function and participation in life's events at home, at school, and in the community.
- New and established impairments and disabilities pose risks for further complications, which necessitate a prevention prioritization through subacute, acute, and outpatient or ongoing rehabilitation interventions.
- Medical services follow policies and regulations imposed by accreditation and regulatory agencies and third-party payers. Collaboration with caregivers, school personnel, and community-based practitioners is critical to effective intervention and transition from hospital to home.

Americans with Disabilities	Assistive technology
Act	Collaborative
Cradle to College and	interdisciplinary and
Career	interagency teamwork
Common Core State	
Standards	

GUIDING QUESTIONS

1. What must occupational therapists know about the transition to adulthood?
2. What programs are available to support the transition from school to work?
3. What are the indicators of a successful transition to adulthood?
4. How can occupational therapists use evidence-based practices to support individuals in transition?

In the United States, individuals with disabilities may receive a free and appropriate public education through the age of 21 years. For young people 16 to 21 years of age, education is viewed as a way to develop the knowledge, skills, and experience necessary to make the critical transition from school into a variety of adult roles. On leaving high school, young adults with and without disabilities, with their parents, make decisions about their next options, including postsecondary education, paid employment, volunteer work, establishing a home, and participating in meaningful occupations and healthy relationships. When a person has a disability, this transition becomes more complex and often requires timely planning and access to a variety of supports and services that begin during and should extend after high school.

The requirement to provide transition services from school to adult life was established in 1990 by the Individuals with Disabilities Education Act (IDEA; P.L. 101-476). The most recently amended version of IDEA (P.L. 108-446) states that

transition-related planning must begin for students with disabilities when they are 16 years old or earlier based on individual student needs (§ 614 (d)(1)(A)(i)(VII)). Students receiving transition-related planning and services may graduate or complete high school at around the age of 18 years with their peers who do not have disabilities. Others may continue to receive school-funded education and transition services through the age of 21. Because the legal requirement for special education and transition services ends on high school graduation, some individuals may choose to delay graduation so that they continue to receive these special education and transition services. High school exit decisions (before age 22) are based on individual student needs and goals as determined by the transition team.

Transition team is a term used throughout this chapter. The team is interdisciplinary, with team members from various professions, and may be interagency, with school employees and employees from nonschool community agencies. The transition team, sometimes called the individualized transition team, is responsible for the development of the student's Individualized Education Program (IEP) and subsequent transition services (§ 614 (d)). Regardless of the team's name, the goal remains the same, and all team members share responsibility for the student's achievement of positive post-high school outcomes.

The student is the most critical and central member of his or her transition team and is joined by an array of school and community professionals. When appropriate, the student's parent or guardian joins the team as an essential partner. It is the student's parents or other family members who usually accompany the student during the entire journey into adult life by providing essential support along the way. In contrast, professional members of the transition team are involved for only portions of the student's journey. When considered in this way, the need for professional members of the transition team to support family members in this process becomes evident.

Students who receive transition services must have a disability that fits one or more of the disability categories recognized by IDEA: intellectual disability; hearing impairment including deafness, speech, or language impairments; visual impairments (including blindness); serious emotional disturbance; orthopedic impairments; autism; traumatic brain injury; other health impairments; or specific learning disabilities (§602 (3)(A)(ii)). Furthermore, students with identified disabilities who receive specialized instruction (special education)

are automatically eligible for related services such as occupational therapy.

Occupational Therapy Contributions to Transition

Occupational therapy is included as a transition service when the transition team determines that occupational therapy can help the student access, participate in, and benefit from his or her specialized education and transition services. Regardless of the student's disability label, the occupational therapist's involvement with a particular student is based on that student's demonstrated or anticipated problems in performance and participation in education and transition-related activities and contexts. These contexts may include the high school classroom, a variety of in-school environments, public transportation systems, general community, home, internship placements, community job sites, and more.

Occupational therapists working in schools understand the educational performance and participation demands, opportunities, and challenges experienced by children and youth with disabilities. Of importance, they use conditional reasoning⁶⁵ to understand and, to some extent, anticipate how a student's disability may affect his or her transition to post-high school activities and roles, including postsecondary or vocational education, employment, and community living. The occupational therapist's positive, future-oriented view of students combines a commitment to student-centered services, collaborative teamwork, and achievement of performance and participation outcomes, making him or her a valuable addition to a student's transition team.

For example, the occupational therapist may analyze a student's internship site and work with the student's job coach to make recommendations to facilitate a student's successful job performance. The student and job coach continually inform the occupational therapist about the student's job performance to monitor the effects of the recommended modifications and ultimately to measure intervention outcomes. Importantly, occupational therapy outcomes completely align with the intent of IDEA and the goals for student participation in work and community, as defined by the transition team. In summary, occupational therapists provide interventions that support students in establishing new skills, transferring skills to new contexts and activities, and modifying contexts and activities to increase performance and participation and prevent new performance problems.

This chapter connects transition policy and evidence-based practices in a way that allows occupational therapists to

understand and articulate their role in the transition process and as members of a collaborative, interdisciplinary, and interagency transition team. A variety of student stories and examples are included throughout to illustrate further how occupational therapists work with transition-age youth. Occupational therapy, when added to the mix of transition services, can make a real difference in the lives of young people whose goals and dreams include some combination of post-high school employment, community living, further education or training, economic self-sufficiency, and social connections.³⁷

Intersection of Policy and Scientific Evidence

The federal mandate for comprehensive school to adult life transition services was issued in 1990 following years of study by the Office of Special Education Programs in the U.S. Department of Education.^{43,86} Although laws and regulations guaranteeing all children a free and appropriate public education have been in place since enactment of the Education for All Handicapped Children Act (1975; P.L. 94-142), outcome-focused research during the 1980s and 1990s revealed that educational results for youth with disabilities were disappointing at best. The extensive public investment in specialized education and related services was not consistently producing competent, well-adjusted, and self-sufficient adults. High rates of unemployment or underemployment, dependency, and social isolation characterized adults with disabilities who had been served by the special education system.^{28,45,51,85}

Although important in the shaping of federal transition policy, early outcome-focused research provided almost no guidance to education and related service professionals in identifying which specific transition practices were most likely to produce the best results for youth. Transition policy, as stated in IDEA (P.L. 105-17), specified system-level processes and expected post-high school outcomes, but did not specify practices to promote those outcomes.

A growing body of evidence has shown that transition services can improve employment and life satisfaction outcomes for individuals with disabilities who receive special education services.⁸⁶ Practices with moderate to strong research evidence are most likely to produce positive postsecondary outcomes and provide local school districts with greater confidence that they can meet the intent and letter of IDEA's transition provisions. Education and related service professionals working in transition may leverage these research and policy resources to develop and implement services that prepare youth to reach their adult life goals. See [Case Study 25-1](#).

CASE STUDY 25-1 Bright Futures in Focus

Debora Davidson is an occupational therapist who works with transition-age young adults who have disabilities. She became aware that many young adults with disabilities seemed to fall through the cracks of school and VR systems and struggled to succeed after they graduated from high school. These individuals did not get jobs despite their efforts, had difficulty

making friends, and had limited ability or knowledge about how to participate in their community. As an occupational therapist with over 35 years of experience in clinical, community, and educational settings, she realized that these young adults' futures were not going to improve with the current services available to them. She thought that an

CASE STUDY 25-1 Bright Futures in Focus—cont'd

innovative occupational therapy approach could help improve their prognosis and help them to engage and participate in life more fully.

In June 2011, Debora left a career in academia and founded Bright Futures in Focus to help meet this untapped need to serve transition-age young adults in and around St. Louis. Debora is the creative developer and provider of clinical services for Bright Futures. She founded the practice with her husband, Ken Bolyard (LCSW, MPH) who manages the business side of the practice. Bright Futures is a small business that is fee-for-service; clients and their families pay directly for her services (Bright Futures does not accept insurance). Fee-for-service helps decrease overhead costs and allows Debora to practice occupational therapy as she thinks is appropriate for the client. She is not subject to insurance restrictions on how or what she does with clients.

Bright Futures helps transition-age young adults attain education, work, and leisure goals. Debora provides instruction and coaching to improve their skills and locates places and activities that are a fit for her clients' unique abilities and interests. She works directly with clients in their homes, workplaces, and communities.

Debora works with individuals and families to develop a vision for their future that is exciting and attainable. She helps identify local resources and suggests or develops creative options. This process is always done together with her client to ensure that his or her needs are met. Debora and the client can work together to develop solutions for immediate, short-term, and long-term challenges. Debora created the Bright Futures Service Menu, which encourages clients to prioritize areas in which they would like help (Figure 25-1). Categories in the service menu include work, education, leisure, living,

Client Name:

Date:

Bright Futures Service Menu

Below are some examples of services that Bright Futures can provide. Please consider each item, and check the items that apply to you. Then, indicate priority by checking *high*, *medium*, or *low*.

WORK I would like to....	Low priority	Medium priority	High priority
Learn about skills for jobs I am interested in			
Create a resume			
Apply for jobs			
Volunteer for community agencies			
Learn about work habits and attitudes for keeping a job			
Practice the speaking skills for a job interview			
Explore different careers based on my interests, goals, and abilities			
Receive support or coaching on the job or volunteer site			
Have a consultant to work with my employer			
Start my own business			
Learn about workplace accommodations and/or job task modifications			
Other (please specify):			
EDUCATION I would like to....	Low priority	Medium priority	High priority
Organize my academic or work life			
Choose a course of study and/or institution			
Establish study habits needed for college			
Follow a schedule or routine			
Increase computer, email, or technology skills			
Use the internet to find information			
Use a planner or calendar to stay organized			
Better coordinate my educational services/ accommodations			
Find a peer mentor at my school			
Establish a transition plan for leaving or entering school			
Other (please specify):			

FIGURE 25-1 Service menu to prioritize goal setting.

Continued

CASE STUDY 25-1 Bright Futures in Focus—cont'd

LIVING SKILLS I would like to....	Low priority	Medium priority	High priority
Create a routine for daily living			
Live on my own			
Improve my self care or personal hygiene			
Use a bank account			
Take care of my home (chores, minor repairs, etc.)			
Do my own laundry			
Manage my own medicines			
Pay my own bills			
Cook my own hot meals			
Budget my money			
Use public transportation			
Learn to drive			
Plan a week of meals			
Work on childcare, pet care, of care of others			
Learn about assistive technology			
Modify my home environment to better suit my needs			
Other (please specify):			
SOCIAL/ LEISURE I would like to....	Low priority	Medium priority	High priority
Find friends to hang out with who share common interests with me			
Have fun activities that I do in my free time			
Find out about local social/leisure groups, programs, or clubs that interest me			
Plan a vacation			
Go on dates			
Develop my network of support			
Other (please specify):			
CITIZENSHIP I would like to....	Low priority	Medium priority	High priority
Register to vote			
Learn about my basic legal rights (relating to my disability, work, school, personal)			
Become more involved in my community			
Create a plan for what to do if stopped by the police			
Other (please specify):			
PERSONAL I would like to....	Low priority	Medium priority	High priority
Make healthier food choices			
Learn about energy conservation			
Make informed choices regarding sexual behavior			
Establish an exercise routine			
Set goals for myself			
Find a doctor who takes care of my health needs			
Find a lawyer to assist with long term planning or guardianship			
Find a counselor to help with my mental health needs			
Learn about how to disclose my disability in different situations (work, school, personal)			
Explore avenues for spiritual and/or religious expression			
Other (please specify):			

Bright Futures Service Menu <http://b-futures.com/> Debora A. Davidson, Ph.D., OTR/L

FIGURE 25-1, cont'd

CASE STUDY 25-1 Bright Futures in Focus—cont'd

citizenship, and personal skills. The service menu allows the client to help prioritize goals to work on in occupational therapy.

The client goes through the 57 different items on the service menu and prioritizes each as high, medium, or low priority, or the client might prioritize a goal that is not listed on the service menu. The service menu is useful to ensure that the client's priorities are addressed.

After the client fills out the service menu, Debora interviews the client and family and may choose to conduct a typical occupational therapy assessment if it can provide necessary information to help the client meet his or her goals. Often the client has had negative experiences with labels and the sense of defeat that can come with standardized assessments, so Debora may choose to base goals and treatment decisions on options from the service menu and client interview rather than a standardized assessment.

After she gets to know a client, Debora locates services, programs, or community opportunities that may meet the client's specific needs and preferences, and then she and the client test these new opportunities together. Debora matches clients with paid or volunteer work opportunities in the community and provides skilled job coaching and consultation to employers. She also helps clients locate and try out social activities until they are comfortable accessing these independently. When a client is denied services or funding, she serves as a diplomatic and tenacious advocate and assists

families in deciphering and completing complicated bureaucratic paperwork.

Bright Futures has a regular bowling night, free of charge, that clients are welcome to attend. This is an event that can occur in any weather, and clients are welcome to bring friends or family. It is a night of fun that offers natural opportunities to meet new people, work out transportation, practice social skills, and provide a small start to structuring a person's week. Bowling provides a topic for the young adult to talk about at family events and is an event that he or she can count on every week to meet new people, build existing friendships, and develop a hobby.

Bright Futures is different from traditional social service agencies, which offer clients a limited array of choices from which they must make a forced selection. Bright Futures starts by discovering what clients really want from life and then seeks to find ways to achieve those dreams. Debora meets with clients at times and places that are convenient to them and provides transportation to sites in the community to test out options for work, education, or social activities. She strives to use the natural resources found within the client's own community and family, promoting inclusion and a durable base of ongoing support. She facilitates clients' development of skills and habits needed for full participation and success. Clients let her know what they want to achieve, and they guide Debora's actions throughout their work together. The goal is to reach the bright future that the client desires.

Transition to Adulthood in America Individuals with Disabilities Education Act

The Individuals with Disabilities Education Improvement Act of 2004 (P.L. 108-446), known as IDEA, is the federal law most responsible for ensuring that children and youth with disabilities have access to publicly funded, individualized education, including school to adult life transition services. Initially passed in 1975, IDEA is the law responsible for the strong presence of occupational therapists in public schools. Foundational to the IDEA are the following core beliefs expressed by the Congress and written into the law:

Disability is a natural part of the human experience and in no way diminishes the right of individuals to participate in or contribute to society. Improving educational results for children with disabilities is an essential element of our national policy of ensuring equality of opportunity, full participation, independent living, and economic self-sufficiency for individuals with disabilities (§ 601(d)(1)(A)).

Beginning with the 1997 amendments to IDEA, participation of all students within the general education context became a central focus. Specifically, students with disabilities receiving specialized instruction (special education) were expected to participate and show progress in the general curriculum alongside their same-age peers without disabilities. This means that for students with and without disabilities, the general education

standards provide educational achievement and performance targets.

With specialized support, many students with disabilities can and will achieve the general education standards expected of all students. For other students with disabilities, steady progress toward general education standards is the expectation. IDEA's focus on student participation in general education has significantly raised the educational bar for the nation's children and youth with disabilities. The general education focus of IDEA challenges previously held views and practices of separate special and general education programs, staff, and curricula.^{22,43,86}

Accompanying the shift toward a single general education system, special educators and related service personnel, including occupational therapists, are similarly shifting their roles and activities to support students and their teachers better within a variety of general education and transition-related contexts. Collaboration with teachers, job coaches, employers, and others characterizes the evolving role of transition-focused occupational therapists who are expected to help students achieve postsecondary education, vocational training, employment, and/or community living outcomes. Figure 25-2 depicts a student who attends a university and also works at university swim meets.

Occupational therapists working under the auspices of IDEA must understand the overarching purpose of the law and its key provisions. The full text of the IDEA law and a variety of interpretive resources are readily available at the U.S. Department of Education website (see the Evolve website) and are

FIGURE 25-2 Intern timing college swimmers at practice.

essential reading for school-based occupational therapists. IDEA defines transition services as a coordinated set of activities for a child with a disability that:

(A) is designed to be within a results-oriented process that is focused on improving the academic and functional achievement of the child with a disability to facilitate the child's movement from school to post-school activities, including post-secondary education, vocational education, integrated employment (including supported employment), continuing and adult education, adult services, independent living, or community participation; (B) is based on the individual child's needs, taking into account the child's strengths, preferences, and interests; and (C) includes instruction, related services, community experiences, the development of employment and other post-school adult living objectives and, when appropriate, acquisition of daily living skills and functional vocational evaluation (§ 602(26)).

Section 504 of the Rehabilitation Act

Transition services may include reasonable accommodations under Section 504 of the Rehabilitation Act (as amended in 1998 by P.L. 93-516). Initially signed into law in 1973, Section 504 was among the first civil rights laws prohibiting discrimination on the basis of disability by any program or agency that receives federal funding. Section 504 defines individuals with disabilities as “persons with a physical or mental impairment which substantially limits one or more major life activities” (34 C.F.R. § 104.3 (j)(2)(i)). Subparts of the law prohibit discrimination in employment, building and program accessibility, schooling (preschool through secondary education), and post-secondary education (colleges, universities, community colleges, vocational programs).

Students who have disabilities but do not qualify for an IEP may be entitled to reasonable accommodations through Section 504. Occupational therapists are experts in identifying the need for and providing resources to create accommodations. The term *reasonable accommodation* means that an

FIGURE 25-3 Intern mopping a football team's weight room.

employer (or educational institution) must take reasonable steps to accommodate an individual's disability. Examples include installing grab bars in work or learning areas, purchasing assistive technology (AT) devices to support job or school performance, ensuring that online materials are presented in an accessible format, adding an entrance ramp, or providing specific job-related training (see the Evolve website). The term *reasonable*, although somewhat vague, is used in the law to protect employers from undue hardship when accommodations are needed or requested. The law recognizes that for some employers, the resources needed to provide accommodations for an individual employee who has a disability may exceed employer resources. Most accommodations, however, are low cost, which is outweighed by the benefit of having a motivated and reliable worker who happens to have a disability.

Prevention of disability-related discrimination is at the core of the Rehabilitation Act and Section 504, but the law also created a nationwide network of state vocational rehabilitation (VR) services to enable potential workers with disabilities ultimately to enter and be successful in the workforce. Vocational rehabilitation is supported by a blend of federal and state funding and provides needed employment and independent living support for adults with disabilities. An individual who is eligible for VR services works with a VR counselor, who can serve as an important member of a school-based transition team. The VR counselor is expected to work together with school personnel to plan for the student's future job-related education and training, job placement, and independent living. VR can provide qualified individuals with needed financial support for job training, job placement services, job coaching, postsecondary education, and independent living. In all cases, VR-supported services are outcome oriented, with community employment and improved self-sufficiency as the end goal. School-based occupational therapists may work closely with VR counselors on behalf of young adults with disabilities to optimize the match between the individual and available job or postsecondary education opportunities, recommend needed accommodations, and address community and independent living needs (Figure 25-3).

Americans with Disabilities Act

The Americans with Disabilities Act (ADA) of 1990 (amended in 2008; P.L. 110-325) is a civil rights law and, like Section 504 of the Rehabilitation Act, focuses on accessibility and nondiscrimination. Unlike Section 504, ADA protections

FIGURE 25-4 Intern delivering mail in clearly labeled bins.

extend beyond programs and services that receive federal funding. The ADA addresses access and discrimination in public and private schools, business establishments, and public buildings. The law also establishes clear accessibility standards for new building construction and public facilities. Occupational therapists who work with transition-age youth should become familiar with the ADA and its many provisions so they can assist employers and public facilities to eliminate barriers and provide reasonable accommodations for young adults with disabilities. [Figure 25-4](#) shows a student sorting mail. The occupational therapist has replaced the mailboxes with larger bins and labeled with larger signs to accommodate this student in visually organizing a mail-sorting task.

Cradle to College and Career

Cradle to College and Career (CCC) is a state-led initiative that emerged in the mid-1990s in Georgia, Maryland, and Oregon to improve outcomes for at-risk students. CCC has since spread in some form to most states as part of the P-16 (preschool to college graduation) movement.⁷⁹ The CCC concept creates an educational continuum beginning at birth (cradle) that supports a student's educational needs through graduation from college or other postsecondary program and career placement. See [Box 25-1](#).

CCC works to develop an integrated service delivery system that focuses energy and resources starting at an early age to long-term employment and life success. This focus on academic, employment, and independent living skills is important

BOX 25-1 Vision for Cradle to College and Career

- All youth have access to adequate and equitably funded quality early intervention and education that meets the diverse needs of families and children and fosters social, emotional, and developmental and educational readiness.
- Parents and students are strong stakeholders.
- Strong interagency agreements and collaboration with informal support networks are present.
- All children have the right to leave the pre-K–12 system with a diploma or credential meaningful to the individual.
- All youth are educated in a safe, supportive, and caring environment in which they feel connected and supported.
- All youth are involved in relevant and rigorous preparation activities that focus on twenty-first-century skills.
- All youth have their unique needs met and have the opportunity to be productive citizens, have choices about their outcomes, and have full access to and are involved in the community.
- All youth are engaged in meaningful, active learning school experiences that result in successful school and postschool outcomes.
- A comprehensive and coordinated system of services and supports is essential.
- All youth are working and developing to their greatest potential within an integrated, seamless lifelong system of services.
- Vocational rehabilitation is an integral, integrated, and early part of the team.

IDEA Partnership, 2013f. Retrieved August 5, 2014 from: <http://ideapartnership.org>.

for all students, but especially for students with disabilities. As the child grows and transitions between grade levels, these services and supports must grow and adapt with the student.³² It is never too early to focus school-based services on a student's transition to adulthood. Similarly, as students are encouraged to take responsibility for themselves and their life goals, outcomes improve.⁶⁷

The current transition system for students may involve different agencies, such as school districts, developmental disability boards, and state rehabilitation agencies, that function in silos and do not communicate well with each other.⁷³ In the CCC model, schools focus energy and effort to help students succeed as they transition from one grade to the next, from one school to the next, and from high school to a postsecondary program. A student who has access to services through a VR agency or community agency must have those services linked with the student's school curriculum. The goal of CCC is to have schools work with these employment agencies and employers so that the student has the tools necessary for employment and engagement in life.³³

Additional supports may be necessary to encourage students with disabilities or other at-risk students to continue with their education, rather than drop out of school. These supports may include services outside the traditional academic environment such as scouting, Big Brothers, Big Sisters, and volunteer experiences to provide the opportunity for students to develop many of the soft skills necessary to succeed in life that may be difficult to replicate in a typical academic setting.²⁰

CCC takes a lifelong view of the student to determine what skills the student will need to be successful in life.³³ The goal is for all transitions in a student's life to be purposeful to ensure that each academic year builds on the previous year's efforts. The student and his or her transition team focus on continuity and integration as the student moves in a coordinated fashion from grade level to grade level, from school to school, and from school to career.⁷⁸

CCC is promoted by the IDEA partnership, a group of more than 50 national associations, including the American Occupational Therapy Association (AOTA), who work together to improve outcomes for youth with disabilities.³⁴ The partnership seeks to build coordinated systems of service delivery that support student learning outcomes while reducing long-term costs.³⁵ In 2007, the estimated cost to taxpayers for someone who drops out of high school before graduating was more than \$240,000 over that person's lifetime in additional health care and welfare costs and in decreased tax revenues because of lower lifetime earnings.⁴¹ Those costs have certainly increased since 2007 in today's dollars.

Occupational therapists can play an important role in the CCC model because of the emphasis on community models and on collaboration among community agencies and schools. They are uniquely qualified to assess a student's occupational performance, design interventions within community contexts, and help students develop the skills necessary to be successful in employment and in life.

Common Core State Standards

The Common Core State Standards (CCSS) are a national curricula in English-Language Arts (ELA) and Mathematics that define the knowledge and skills that all students should master by the end of each grade level so they are ready for college and a career.¹⁶ CCSS were developed in response to the increase in the number of high school graduates who were not prepared for the rigor of college or were not adequately prepared to enter the workforce.¹⁴ CCSS have been approved and adopted by 45 states and are the first national curricula for the United States.⁵⁷

The National Governor's Association developed the Common Core to raise standards so that U.S. students remain competitive with students from other countries.¹ A benefit of one national standard instead of 50 different state standards is that the expectations for high school juniors in Ohio are the same as for those for high school juniors in South Dakota, so if a student moved from South Dakota to Ohio, the standards would remain the same. States and school districts remain free to write individual curricula to meet the CCSS.¹¹

The focus of the Common Core is to identify skills needed by twenty-first-century learners, with an emphasis on the application of content to real-world expectations.⁷⁴ Although it is important for students to learn their mathematics facts, the ability to apply them competently in everyday life is most essential (Box 25-2). U.S. business leaders and educational experts provided considerable input during development of the CCSS to ensure that high school students would be adequately prepared for the needs of the future workforce.

This emphasis on real-world expectations and college and career readiness is well aligned with the focus on high-quality, integrated, practical transition services for students with disabilities. Occupational therapists are well positioned to support

BOX 25-2 Expected Outcomes of Common Core State Standards

Graduates will do the following:

- Demonstrate independence.
- Build strong content knowledge.
- Respond to varying demands of audience, task, purpose, and discipline.
- Comprehend as well as critique.
- Value evidence.
- Use technology and digital media strategically and capably.
- Understand other perspectives and cultures.

FIGURE 25-5 Intern checking inventory in university laboratory.

students in this transition to college or career readiness. Public schools are a large employer of occupational therapists, but only 16% of school-based occupational therapists report that they work with adolescents and transition age-students.³⁷ Occupational therapists are well named and well suited to help individuals develop skills that lead to actual occupations. They offer expertise in areas essential in employment success, such as task analysis and matching the demands and abilities of the person, occupation, and environment. Figure 25-5 shows a young adult with high skills in following a written procedure, sorting, and categorizing who is working in a university laboratory.

Employment First

Employment First is a national movement that seeks to promote community-based employment in lieu of sheltered workshops as the preferred choice for individuals with disabilities.⁵² To accomplish this goal, Employment First proponents seek to change government funding structures and service delivery systems and policies so that community employment options are available and tax dollars are prioritized toward supporting community employment. Policy changes that foster community employment over sheltered work settings include government

BOX 25-3 Vocational Choices for Young Adults with Disabilities

- Internships to prepare for employment
- Supported employment
- Customized employment
- Self-employment
- Day program or sheltered workshop
- Community rehabilitation program
- Competitive employment and business models

Adapted from Wehman, P., & Brooke, V. (2013). Securing meaningful work in the community: Vocational internships, placements, and careers. In P. Wehman (Ed.), *Life beyond the classroom: Transition strategies for young people with disabilities* (pp. 310–338). Baltimore, MD: Paul H. Brookes.

FIGURE 25-6 Intern cutting tomatoes for a salad in dorm cafeteria.

funding for community employment services and Medicaid buy-ins attached to the person, instead of to the sheltered workshop. The buy-in allows an individual who receives federal disability or health insurance benefits to earn an income without the risk of losing government health insurance.⁶⁶ Individuals with disabilities and their families are empowered to make employment decisions that are best for them and that encourage community employment.

Given a variety of vocational choices for young adults with disabilities (Box 25-3), Employment First prioritizes community employment. The use of internships as a primary Employment First approach has consistently resulted in positive, community-based employment outcomes. For example, Project SEARCH is a 1-year transition to community employment program that combines on-site internships, job coaching, and an employment skills curriculum.²⁹ Students work 20 hours/week in an unpaid internship as they develop skills on the job and in the classroom-based employment skills curriculum. Students progress through three 3-month internships during the school year, often in their last year of public education (Figure 25-6). Students build their resumé, learn to use public transportation or drive, and practice job-searching strategies with the goal of interviewing for and obtaining a paid position at the conclusion of the Project Search experience.

FIGURE 25-7 Intern washing windows at a college football training facility.

Cincinnati Children's hospital developed the first Project SEARCH site almost 20 years ago, and, at present, Project SEARCH has established more than 250 sites throughout the United States and in four other countries.⁶⁰ Project SEARCH is typically a partnership between a school district and the state vocational rehabilitation agency. Many Project SEARCH sites are in health care settings, with the emphasis on finding jobs that are well suited for an individual's unique talents.

Research evidence has suggested that a history of internships improves employment outcomes.⁸⁰ Internships may be chosen to suit an individual's skills or to give an individual the opportunity to learn or develop new skills. The job coach learns the job from the employer and instructs the student in how to complete the job. As the student's ability grows, the job coaching fades until the student is completing the job independently. Figure 25-7 depicts a student who has become independent in window washing for the football team's training facility. The stated goal is that 90% of Project SEARCH graduates become employed at the conclusion of the program, and each year a number of the program sites reach at least that 90% goal.⁶¹ Figure 25-8 depicts a Project SEARCH graduate working at a university library.

Think College

Think College aspires to have individuals with intellectual disabilities attend college for the same reason that individuals without intellectual disabilities go to college: to decide on a

FIGURE 25-8 Intern shelving journals at a library.

career, make friends and establish connections, and improve their earning potential to “get a better job.”²⁶ These students have been in school with their typical peers since preschool; Think College wants to know why inclusion should stop after high school. Think College promotes postsecondary opportunities for individuals with intellectual disabilities, and currently these programs are in 214 different college and university campuses in the United States.⁸² Each program is different, but each offers students pathways for integration into typical campus life. Students enroll in courses, attend campus sporting and cultural events, use campus athletic and recreational facilities, and may live in campus housing. They may receive supports that are available to all students, such as those offered by the campus office of disability services or from their course instructors during typical office hours. Other students may receive additional supports, such as an academic coach or a study table specific to students in the Think College program.⁵⁴ Some programs offer additional life skills and vocational training to augment the academic program. The length of the programs varies from 1 to 4 years, and some students earn degrees or certificates. Some Think College programs are paid for by state vocational rehabilitation agencies or developmental disability funds. When public funds are not available, students and their families may choose to pay for tuition, room, and board.

Seamless Transition: Alignment of Outcomes

Two common goals of these transition programs—Cradle to College and Career, Common Core State Standards, Employment First, and Think College—are to raise expectations and improve long-term outcomes (e.g., schools, vocational rehabilitation, developmental disability) for individuals with disabilities. To achieve improved outcomes, the educational system, government developmental disability agencies and vocational rehabilitation agencies must work together, and transition planning must be in place throughout a student’s schooling. The concept of a seamless transition from high school to postsecondary education and career is designed to keep the young adult on track to achieve a successful employment outcome.¹²

One example of nonseamless transition is assistive technology (AT). In most states, the school districts that purchase

technology for students to use during high school require that the technology be returned when the student graduates. If that technology was beneficial to the transitioning student, doesn’t it make sense for the student to own that technology? Occupational therapists can consider VR as a better funding source for AT for use in employment because the device is owned by the student. It follows that cooperation and coordination between schools and VR for the purchase of needed technology can improve employment outcomes.⁷³

It is imperative that the transition from high school to postsecondary employment or academic pursuits is smooth and coordinated and that the student is well prepared for adulthood. Once a student receives his or her high school diploma, the federal mandate for educational and related services expires, and the youth moves into a system that may not have the same financial resources and expertise as that of the public schools.⁴⁹

Transition Outcomes

In 2011, the U.S. Office of Special Education Programs reported that 6,530,552 students with disabilities were served under IDEA, Part B.⁷⁷ Of these, 2,163,479 students were aged 14 to 21 years, and 644,694 were in their last year of school. Taken together, these data reveal that roughly one third of children eligible for services under Part B of IDEA may be thought of as being of transition age—that is, being 14 to 16 years of age (depending on locality) or older and having an IEP with measurable postsecondary goals and transition services. These data also reveal that about 10% of youth with disabilities will exit the public schools any given year.

What happens to youth with disabilities when they exit the public schools? Where do they go? What do they do? What services are available? Studies have shown that postsecondary outcomes experienced by youth in transition to adulthood vary widely; some students work and/or go on to postsecondary education, but others do not go on to postsecondary education or employment.

Transition from high school to postsecondary life is often complicated by the different and sometimes competing perspectives of the various stakeholders (e.g., student, teacher, parent, community organization) involved in transition.¹⁹ For example, special educators and related service personnel are likely to view transition to postsecondary education and/or competitive employment as the key markers of a successful transition. By contrast, vocational rehabilitation professionals (e.g., vocational counselors, job developers, job coaches) tend to emphasize the acquisition of competitive employment as the primary indicator of a successful transition to adulthood. Representatives from the state’s board of developmental disabilities focus on the living arrangements, health, safety, and welfare of individuals in transition. Parents and families may prioritize health, wellness, and happiness as the most important outcomes for their child in transition. Consequently, identifying agreed-on transition outcomes may require negotiation among the students, families, and professionals involved in the transition process. Often young adults thrive in job tasks with easily learned, concrete, repetitive steps and work environments that offer opportunities to interact with peers (Figure 25-9).

Occupational therapists who understand these differences can help students and families prepare for and navigate the intricacies of the transition process. Table 25-1 summarizes the

TABLE 25-1 Interdisciplinary Transition Teams and Outcome Orientations

Organization	Personnel Involved	Outcome Orientation—Transition Target
School district	Individualized education program team	Academics
Vocational rehabilitation (VR) agency	Community partners VR counselor	Postsecondary education and/or postsecondary employment
Board of Development Disabilities	Community rehabilitation provider	Employment
Family	Case manager Parent Caregiver Student	Health, wellness, and community living Health, quality of life, independent living skills, education, employment

**FIGURE 25-9** Intern preparing sandwiches for a university event.

different, and sometimes competing, perspectives of the stakeholders involved in the transition planning process.

Postsecondary Education Outcomes

For most adolescents and their families, matriculation to postsecondary institutions and, eventually, competitive employment remain the primary objectives of secondary education. In the context of transition outcomes, the term *postsecondary education* refers broadly to participation in three types of institutions: (1) 2-year or community colleges; (2) vocational, business, or technical schools; and (3) 4-year colleges. Understanding outcomes for youth with disabilities at these types of institutions is important for students, families, and professionals contributing to the transition planning and decision-making process.

After exiting high school, youth with disabilities pursue postsecondary education at rates lower than those without disabilities.⁵¹ The National Longitudinal Transition Study-2 (NLTS2) followed a representative sample of more than 11,000 high school students who received special education services in high school into early adulthood to determine educational, employment, and social outcomes. The NLTS2 revealed that 60% of young adults with disabilities enroll in postsecondary education within 8 years of leaving high school.⁵¹ By comparison, 67% of young adults without disabilities pursue

postsecondary educational opportunities in the years after high school. Young adults with disabilities matriculate to postsecondary institutions at different rates, depending on their primary disability category (Table 25-2). Enrollment in postsecondary education is lowest for individuals with intellectual disabilities (28.7%), multiple disabilities (32.8%), and autism spectrum disorder (43.9%). Furthermore, the results of the NLTS2⁵¹ indicate the following for youth with disabilities:

- They are more likely to pursue education at a 2-year institution than at a 4-year institution.
- They may take longer to matriculate to school.
- They may not consider themselves disabled by the time they enter postsecondary settings.
- They may require assistance requesting accommodations.

Postsecondary Employment Outcomes

Like postsecondary education, employment remains a key objective of youth in transition to adulthood. Employment is important for a number of reasons. Workers experience the socioeconomic benefit of earned wages and related benefits in terms of better health and quality of life. Interviews conducted as part of the NLTS2 indicated that young adults with disabilities were employed outside their homes at a rate of 60%.⁵¹ By comparison, 66% of young adults without disabilities reported currently working. Like the picture of postsecondary education, the employment figures vary as a function of disability (see Table 25-2). Employment outside the home was lowest for individuals with deafness-blindness (30.1%), orthopedic impairment (35.0%), autism spectrum disorder (37.2%), and intellectual disabilities (38.8%). Generally, young adults with disabilities tended to work fewer hours for lower wages.⁸⁶ They also tended to retain employment for shorter periods of time, often less than 12 months.⁵¹

Community Participation and Inclusion

As depicted in Table 25-1, employment and education are not the only outcomes considered by an IEP team engaged in the transition planning process. For example, an adolescent may consider the acquisition of independent living skills to be his or her highest priority. According to the NLTS2⁵¹:

- 19% of young adults with disabilities engaged in community-based activities beyond education and employment.
- 59% of young adults with disabilities lived independently within 8 years of exiting high school.
- 59% of young adults with disabilities had checking and savings accounts.

TABLE 25-2 Outcome Data for Young Adults with Disabilities*

Disability Category	Ever Enrolled in Postsecondary Education (%)	Employed at Time of NLT2 Interview (%)
Learning disability	66.8	67.3
Speech-language impairment	66.9	63.9
Mental retardation	28.7	38.8
Emotional disturbance	53.0	49.6
Hearing impairment	74.7	57.2
Visual impairment	71.0	43.8
Orthopedic impairment	62.0	35.0
Other health impairment	65.7	64.4
Autism	43.9	37.2
Traumatic brain injury	61.0	51.6
Multiple disabilities	32.8	39.2
Deafness-blindness	56.8	30.1

*Young adults (21-29 yr).

Adapted from Newman, L., Wagner, M., Knokey, A., Marder, C., Nagle, K., Shaver, D., et al.; National Center for Special Education Research (Eds.). (2011). *The post-high school outcomes of young adults with disabilities up to 8 years after high school: A report from the National Longitudinal Transition Study-2 (NLT2)* (Tables 2 and 19). National Center for Special Education Research. Retrieved August 5, 2014 from: <http://ies.ed.gov/ncser/>

- 77% of young adults with disabilities visited friends weekly outside of organized activities.
- 78% of young adults with disabilities had driving privileges.
- Many young adults with disabilities reported negative experiences, such as getting in a fight or having an encounter with law enforcement.

Participation in the meaningful activities of adulthood, such as education, employment, and community living, remains elusive for many individuals with disabilities. Recognition of these outcomes for a significant portion of young adults is the first step toward their remediation. Occupational therapists working in transition settings (e.g., schools, community) may help youth with disabilities prepare for life after high school by using evidence-based practices designed to improve these important outcomes.

Best Practices in Occupational Therapy

Federal education policy and universal commitment to civil rights and equal educational opportunity mobilized initial school to adult life transition efforts. Federal policies (e.g., IDEA) specify expected education outcomes and processes that must be followed by state and local education agencies to ensure that all children have access to a free and appropriate education. Policies, however, do not specify which research-supported practices are most likely to produce the desired outcomes.

The use of evidence-based transition practices is an expectation of the IDEA; that is, services must be based on “peer-reviewed research to the extent practicable” (§ 614 (d)(1)(A) (i)(IV)). Like special education, the occupational therapy profession is dedicated to the principles of evidence-based practice and the ongoing development of rigorous research that can lead to effective services and optimal outcomes for individuals, groups, and organizations.⁴²

In recent years, scholars and practitioners have agreed that a number of evidence-based practices increase the probability of

youth’s success in postsecondary life. Although some are more established than others, all may be considered occupational therapy best practices when working with youth in transition. Recommended transition practices include the following:

1. Early, paid work experience
2. Student involvement in transition planning
3. Emphasis on student’s social competence
4. Development of life skills
5. Use of assistive technology
6. Collaborative interdisciplinary and interagency teamwork

Early, Paid Work Experience

Work is one of the most fundamental human occupations. Identify, self-worth, health, socioeconomic status (SES), and quality of life (QoL) are strongly linked to one’s ability to work independently and earn a living wage.^{15,55} Beyond the functional and economic implications, work also provides a social-cognitive structure through which people interact with and experience the world.¹⁹ Engagement in meaningful work enables the development of social networks and self-efficacy, provides a sense of belonging and security, and contributes to overall health and quality of life. People who fail to acquire and/or maintain meaningful employment experience the parallel negative effects.⁶⁸

Work is important for individuals of all skill and ability levels. Unfortunately individuals with disabilities are employed at rates significantly lower than those of nondisabled individuals.¹⁰ In 2011, only 17.8% of individuals with a disability were employed, compared with 63.6% for individuals without a disability.⁹ The impacts of such unemployment or underemployment are significant. An estimated 21.7% of individuals with a disability (compared with 12.8% of individuals without a disability) live below the poverty line.⁸³ Therefore, individuals with a disability are less likely to be employed and more likely to live in poverty. It follows that individuals with disabilities who work are less likely to live in poverty and that employment is a path to socioeconomic independence for individuals with disabilities.^{10,83}

Employment is also strongly related to health and quality of life. Employment status (employed, unemployed) is known to influence health in nondisabled^{64,76} and disabled populations.^{48,56} These studies have suggested that employed individuals tend to experience better health than unemployed individuals. This relationship may be particularly true for individuals with disabilities. Because individuals with disabilities are employed at lower rates than those without disabilities, they may experience the effects of ill health to a greater degree than nondisabled individuals. Quality of life is similarly affected by employment status. That is, employed individuals tend to experience a higher quality of life than unemployed individuals.^{17,21,36,38,48,59,69}

Student engagement in paid work before his or her exit from high school is strongly associated with postsecondary employment⁵¹ and likely leads to the benefits described in the previous paragraph. Even for students who plan to pursue postsecondary education, the ability to maintain employment is considered a critical life skill that cannot be delayed until all formal education is complete.⁴⁶

Although secondary students secure paid work using a variety of strategies,⁷ students who have disabilities may lack the skills needed to access or use conventional job search strategies effectively. For these students, supported employment provides an important, evidence-based alternative.^{39,44,63} In supported employment, youth and adults receive on-the-job training and ongoing supports provided by a job coach to acquire and sustain employment in community businesses and organizations.

When an individual with a disability struggles to find or maintain employment through supported employment, the transition team may consider customized employment. As an alternative approach, customized employment “is a process for individualizing the employment relationship between a job seeker or an employee and an employer in ways that meet the needs of both.”⁸⁷ In this model, an employment specialist works with the client (individual with a disability) and prospective employers in the community to match the individual strengths and needs of the job seeker with the needs of the business. Often this requires negotiating the rearranging or combining of job tasks into a job that is customized for the individual with a disability.

Enabling youth who have disabilities to secure community employment that is meaningful and individually matched to their skills and abilities is among the most important achievements of transition teams. Youth can apply for and receive VR resources to help in securing employment; these resources can support the student’s job search and placement process or fund postsecondary education at a university, community college, or vocational training program as long as a career or job path is evident.^{3,47} If the goal is not building skills for eventual employment, VR agencies will not fund services.

A recent review of the transition literature⁴⁶ has identified a number of work-related behaviors and experiences that relate to successful postsecondary employment outcomes. Participation in work-study programs, vocational education classes, job internships, and mentoring experiences are all known to increase the likelihood of obtaining full-time employment after high school. When students are given opportunities to practice self-management skills, such as timeliness, orderliness, and cleanliness, they are more likely to succeed in the working

world. Students who learn to express their desire for work, actively pursue work, and obtain work during the high school years are likely to matriculate into postsecondary education and/or employment after transition. Occupational therapists working with transition teams can help facilitate positive outcomes by ensuring that postsecondary goals and services target these factors. See [Case Study 25-2](#).

Student Involvement in Transition Planning

Beginning at age 16 years (age 14 in some states), IDEA requires that a student’s IEP specifies measurable transition goals and needed services. Transition goals must be based on the results of age-appropriate assessments and should relate to postsecondary priorities in the areas of education, employment, and community living. Although IDEA requires that youth with disabilities be invited to IEP meetings when postsecondary goals are considered, actual participation of students with disabilities remains limited. Although almost 50% of students with disabilities provide at least some input at their most recent IEP meeting, only about 10% to 20% take leadership roles at the meeting.⁸⁴ This limited participation is of concern because a student’s ability to self-direct the IEP meeting and transition planning process strongly relates to positive postsecondary outcomes.^{46,86}

Over the past 2 decades, professionals, researchers, and other key stakeholders have developed a number of intervention techniques targeted at self-determination and designed to improve a student’s ability to participate in the IEP meeting and transition planning process. Self-determined students do the following: (1) demonstrate self-awareness and self-advocacy, (2) make choices and decisions, (3) problem solve when issues arise, and (4) achieve self-identified goals.⁸⁸ Occupational therapists working in transition to adulthood can contribute to the development of these important skills by deploying existing, evidence-based assessment tools and curricula.

Assessment that informs the transition planning process is optimized by the inclusion of tools that enhance a student’s ability to self-direct IEP meetings and make choices about postsecondary life. [Box 25-4](#) lists recommended self-determination scales that occupational therapists can use to enhance a student’s and team’s awareness of strengths, weaknesses, goals, and needs. An occupational therapist who uses these tools contributes rigorous data to the transition planning process. At the same time, use of these instruments may help a student increase his or her self-awareness of personal strengths, needs, goals, and priorities.

Assessment of self-determination skills is only part of facilitating student involvement in the transition planning process. In many cases, direct instruction is required to teach individuals with disabilities to become aware of their strengths and needs and advocate for services. A number of formal, evidence-based curricula exist for just this purpose. [Box 25-5](#) presents the information on available curricula. Occupational therapists interested in facilitating student participation in the transition planning process can incorporate these existing resources into their practice (see the [Evolve website](#)).

Emphasis on Student’s Social Competence

To transition from high school to postsecondary education or employment successfully, students must understand and adapt

CASE STUDY 25-2 Youth with High-Functioning Autism: Planning for Postsecondary Education

Sara, a 17-year-old adolescent girl with high-functioning autism, planned to enroll in a 4-year college following graduation from high school. She did well in academic classes; however, her performance was significantly compromised whenever her routines were disturbed. Moving between classes was especially difficult for Sara. She often lost track of time during classes and was startled by the school bell that signals students to transition between classes. Because the bell was disorganizing, Sara felt unprepared to transition to her next class, and her stress disrupted her routine of writing down her assignments, organizing her materials, and inserting her ear plugs before the hallways were filled with loud students. When Sara's routine was disrupted, her performance in the next class was negatively affected. To help her prepare for transitions between classes, Sara's occupational therapist downloaded and programmed a reminders application for Sara's iPhone. The app provided vibrotactile alerts based on a schedule developed by the user. The occupational therapist developed the following alert structure to help Sara transition:

Timetable	Alert Type	Associated Behavioral Cue
Passing Time		
1 minute before class starts	iPhone vibrates 10×	Finish walking to class.
Class Time		
5 minutes before class ends	iPhone vibrates 5×	Write down assignments.
3 minutes before class ends	iPhone vibrates 3×	Organize materials for storage or place into book bag.
1 minute before class ends	iPhone vibrates 1×	Insert ear plugs.

These alerts enabled Sara to move between her classes in an orderly and timely fashion and resulted in improved academic performance.

Sara volunteered with the local animal shelter after school, which was part of her senior service requirement that she and all of her classmates had to fulfill. She used a bus app on her iPhone to track when the next bus was scheduled to arrive to minimize her wait time in the cold. She also used a checklist on her iPhone that reminded her of her assigned tasks at the animal shelter. The most challenging task for Sara was answering the animal shelter phone. The shelter administrator instructed her to answer it politely, ask basic questions of the caller, and refer the caller to the correct person. Sarah recognized that by working on this challenging task she would improve her customer interaction skills and that these would be important for most future jobs. Together, Sara, her occupational therapist, and the animal shelter manager developed a checklist of tasks for Sara to carry out. Sara videotaped the manager answering the phone and role played the most common phone scenarios. Sara found it reassuring to watch the video before her shift answering the phone. Sara had regularly scheduled video calls from the occupational therapist to ensure that she felt comfortable in her job; Sara preferred video calling so that she could show her occupational therapist the new rescue dogs that had come to the shelter that week. Sara's favorite job at the animal shelter was to train new rescued dogs to walk on a leash because she knew that dogs that could walk on a leash were more likely to be adopted. Sara loved caring for the dogs at the shelter. Although some of the tasks at the shelter were challenging, she was highly motivated and continued to gain competence in her public and phone interactions, knowing that her work in the shelter was important to finding rescued dogs a real home.

BOX 25-4 Self-Determination Scales

AIR Self-Determination Scale*

Purpose

- Profile student's level of self-determination.
- Identify strengths and needs.
- Identify goals and objectives.
- Develop strategies to improve self-determination.

- Facilitate student participation in planning processes.
- Conduct self-determination research.

Online Resources

<http://www.ou.edu/content/education/centers-and-partnerships/zarrow/self-determination-assessment-tools.html>

ARC Self-Determination Scale†

Purpose

- Identify strengths and weaknesses of self-determination.

*Adapted from Wolman, J. M., Campeau, P. L., DuBois, P. A., Mithaug, D. E., & Stolarski, V. S. (1994). *AIR self-determination scale and user guide*. Palo Alto, CA: American Institutes for Research.

to new social environments. Social norms in employment and college settings are different from those in high school. These transitions can be difficult for many young adults and often pose serious challenges to individuals with disabilities, who may struggle with social competence.

Social competence refers to an individual's effectiveness in navigating interpersonal relationships with others at work, school, home, or public situations.⁶² Social competence is largely subjective in nature and often changes, given the context in which an event occurs. A socially competent person during a rock concert would look and behave differently from a socially competent person at an opera performance. A socially competent person realizes the different expectations and decorum at each event and changes the way he or she dresses, interacts with fellow concertgoers, and responds to the music to match the event's social norms. These expectations are highly dependent on the cultural context in which the actions take place and create a feedback loop for how one is to behave in a given situation.

Once the student understands the environmental demands of a situation, he or she must have adequate social and communication skills and manage the interpersonal demands required for that situation. These social demands can be quite complicated and overwhelming for students with disabilities, who are less likely to have had social opportunities to learn, practice, and develop social competence.⁵³

Occupational therapists can support a client's development of social competence by helping improve his or her social skills. This intervention focus is crucial because evidence suggests that students with disabilities who have higher levels of social skills are more likely to be employed than those who have lower levels of these skills.⁸⁰ Examples of interventions to enhance social skills follow a continuum from hands-on to advocacy, including direct instruction, peer awareness, involvement, and accommodation, and a positive climate of integration and encouragement.⁴

Occupational therapists provide direct interventions to help young adults develop social skills. Examples include training in the use of augmentative communication devices, tablet computers, and/or smartphones to improve communication output; participation in a group activities; use of social stories

to prepare students for novel situations; and teaching students to self-monitor their interactions with others.⁶ Peers can be effective in encouraging social participation. For example, providing peers with information about the student's disability, interests, and preferences can increase interaction between typical peers and students with disabilities.¹² The presence of trained peer mentors can increase the social participation of young adults with disabilities.^{2,72} In some cases, peers are more effective than adults in helping students shape behavior, and positive peer pressure can make a difference when other interventions do not. Peer mentoring can provide natural supports in the classroom, on the job, or in the field.

This increased interaction and friendships between those with an identified disability and those without a disability can help decrease discrimination and prejudice.²³ State legislatures in most states have amended laws to change the phrase *mental retardation* to *intellectual disability*, in no small part because of the efforts of a high school student.⁸¹ This movement started in Fremd High School in Palatine, Illinois, in 2007 when Soeren Palumbo pleaded with his high school classmates in a speech not to use the term *retardation* ("the r word") out of respect for his sister, who had an intellectual disability. This movement, which started at one high school in Illinois, has become an international force to fight discrimination against individuals with intellectual disabilities. Each year, on the first Wednesday of March, many schools and universities encourage integration by recognizing a national day to "Spread the Word to End the Word."

The physical and social environment can also be adapted or created to increase social participation of students with disabilities. For example, school, work, or social events should always take place in accessible environments. Classrooms, lunchrooms, and extracurricular activities should be integrated so that students with disabilities have the opportunity to socialize with their typical peers, rather than be in segregated environments. Social activities outside school are the focus of Best Buddies, an affiliate program of Special Olympics, which pairs an individual with a disability with a typical peer to encourage friendship.²⁶ Increased social participation provides additional opportunities to practice and refine social skills important to employment and social participation.⁸⁰

The climate of the school and work setting should be one of openness to diversity and the appreciation of differences. Teachers, therapists, paraprofessionals, job coaches, and other adults can encourage interaction between the student with a disability and his or her typical peers and co-workers. Inclusion of students with disabilities into all aspects of school, work, and social life helps raise expectations and create an environment in which differences are celebrated rather than excluded. Many organizations and employers have inclusion and diversity as part of their mission.⁵ Institutions that adopt a mission of inclusion establish policies and cultural norms that welcome everyone, regardless, of gender, race, age, religion, sexual preference, veteran status, or national origin. Individuals with physical, cognitive, or psychiatric disabilities must also be seen as part of this diverse rainbow for the benefit of the individuals, the organizations, and society.

Development of Life Skills

By the time a student with disabilities enters high school, educators and therapists, with family input, must make curriculum

decisions based on their vision for the student's post-transition outcome. For most professionals, this decision presents a choice between a traditional academic curriculum and a functional, life skills curriculum. A life skills curriculum is an alternative to the traditional academic curriculum designed to facilitate student development of skills necessary for success in adult life, such as the following:

- Activities of daily living (e.g., grooming, bathing)
- Community mobility and transportation (e.g., route finding, driving)
- Work skills (e.g., attention, endurance)
- Social skills (e.g., turn taking, carrying on a conversation)
- Self-determination (e.g., awareness, advocacy, problem solving)
- Functional writing and mathematics (e.g., completing a job application, writing a check)
- Independent living (e.g., budgeting, household chores)

Historically, this type of curriculum has usually been associated with students who have moderate to severe disabilities. In past years, many of these students on a functional curricular track were educated in isolation, away from peers without disabilities. Such practices conflicted with federal guidelines (IDEA 2004, NCLB 2001) that promote educating all students in natural environments and led to the stigmatization of the functional curriculum. Accordingly, the acceptability of a functional, life skills curriculum as a valid curricular choice is likely to vary across the country and among districts, cities, and states.

The functional curriculum is an important option for many young adults in transition. This is particularly true for students whose primary postsecondary target is employment and not education.⁸ Occupational therapists working in transition can help teams make curricular decisions by keeping the following information in mind⁸:

- All students, whether disabled or not, must learn and master independent living skills.
- A functional, life skills curriculum is a legitimate option for students with disabilities in transition.
- The functional curriculum may be more appropriate than an academic curriculum for some students.
- Occupational therapists have expertise in life skills interventions, including assistive technologies that promote independence in instrumental activities of daily living and can contribute to the functional curriculum.

Use of Assistive Technology

Technology is evolving at an exponential rate and holds great potential to assist students with disabilities as they transition into adulthood. Adolescents and young adults are avid users and consumers of technology and are considered to be digital natives who have been raised and educated with technology.⁵⁸ Other chapters of this text describe how occupational therapists use AT to improve participation (see [Chapter 19](#)). Wheelchairs, augmentative communication devices, environmental controls, and adaptive equipment can all help improve a person's ability to navigate and participate in life. Although these supports can certainly increase independence, they also can make an individual appear disabled and different from his or her typical peers. New technologies and platforms allow students to use AT without separating them from their peers.

Concepts of universal design for learning and accessibility mandates make commercially available technology useful in supporting students in transition. Smartphones, tablets, and computers have accessible features that many consumers have found to improve efficiency and productivity. Additional applications (apps) or programs can be added to customize a device to the individual's unique needs.

Students have hundreds of different smartphone and tablet computer options from which they can choose. The operating system, size of the device, and technologic capabilities all dictate the device's functionality. [Box 25-6](#) gives a brief overview of smartphones and tablets for occupational therapists to consider when they make technology recommendations.¹⁸

An advantage that tablets and smartphones have over other AT devices is that students who use this technology are using the same technology that their typical peers use, so these devices can actually become tools of inclusion. These devices can facilitate student success in academic, employment, and community engagement. For example, college students, with and without disabilities, use the following apps for their smartphones and tablet computers to support their academic success:

1. Map an app to find a college classroom.
2. Apps to audio or video record a professor's lecture can be synchronized to written notes.

BOX 25-6 Smartphone and Tablet Computer Options

Which operating system should I use?

- Android (Google) is often the least expensive device.
- iOS (Apple) has the most apps available to purchase.
- Windows (Microsoft Office) functions most like a typical computer operating system.

What hardware capability do I need?

- Amount of storage—devices with greater storage are more expensive.
- WiFi capability—will the student have access to a public WiFi network (open or closed) to be able to access the device's full capability?
- Data—will the student need the device in areas in which there is no access to a public WiFi network, and does a separate data plan need to be purchased?

What size device would be best?

- Would the use of a smartphone and a tablet cause confusion?
- Does the device need to be small enough to be kept in a pocket?
- Does the device need to be large to allow for reduced visual or fine motor capabilities?

Which built-in accessibility features will the student need?

- Does the device offer text to speech?
- Does the device offer speech to text?
- Does the device offer options for those with low vision?
- Does the device have accessible options for individuals with physical limitations?

Which apps should be purchased to make the most out of the device?

- What is the cost, and is it a one-time or ongoing cost?
- Does the app require access to the Internet to function properly?
- Does the app have an interface so it can be used on a variety of devices?

3. A built-in calendar with audio prompts can help the individual maintain the class schedule or study group meetings.
4. Reminder apps provide cognitive cues to complete assignments.
5. Spoken word to text apps help transcribe papers and assignments.
6. Text to voice apps can read assigned readings out loud.
7. Course-specific apps are available to help the student understand academic content in a different way than the professor presented it.

These devices are also useful in supporting students as they transition into competitive employment. Business is always increasing its reliance on information technology and adopting paperless workplaces. In the past, a teacher or job coach might have photographed job tasks and assembled them into a three-ring paper binder that described how to perform a particular job. These bulky binders are now being replaced by a tablet or smartphone with a series of photos or video checklist to help support a student in employment.²⁴ Other examples of how this technology can support employment include the following:

1. Remote job coaching. A job coach can make a video call to an employee to check on how work is progressing, and the student can show the quality of his or her work remotely.³¹
2. Telehealth. An occupational therapist can be brought in via video call (depending on state licensure requirements) to assess a task and help a student and job coach make adaptations to get the job done.¹³
3. Video modeling applications can support students as they move and learn to accomplish one task to the next on the job.⁵
4. Emotional support applications can be customized to allow students to center and calm themselves during stressful situations.⁶

Collaborative Interdisciplinary and Interagency Teamwork

Outcome-oriented, student-centered planning and services based on collaborative teamwork are at the center of high-quality transition services.⁸⁶ For transition-age students, this teamwork is accomplished by the IEP or transition team. As students with disabilities approach graduation from high school, all IEP planning and services must converge around the student's postsecondary goals and activities.⁴⁰

When representatives from nonschool agencies join the student, family members, teachers, and related service personnel on the transition team, the interdisciplinary team becomes an interagency team. Congress, when formulating IDEA, did not intend for schools to have sole responsibility for transition processes and outcomes. Interagency linkages became part of IDEA in 1990, indicating the expectation for shared responsibility across local education agencies and adult or community programs. Establishing interagency linkages, although challenging, can be an important benefit to students with disabilities who are preparing to exit the public education system.⁷⁵

On graduation or completion of public education programs, a student's IDEA-based entitlement to school-sponsored educational, vocational, and other services ends. In the place of one lead agency (the school system), a number of service

agencies, such as the state vocational rehabilitation agency, state departments of mental health and developmental disabilities, state brain injury programs, and postsecondary education or training programs, become responsible for providing services to individuals who qualify. Those who are no longer eligible for the school's transition-focused special education or related services become responsible for identifying where to obtain the ongoing services they need and for demonstrating their eligibility to receive those services.

Interagency responsibilities and linkages should be clearly stated in IEP documents developed by the transition team. Failure to initiate and formalize these connections during high school can result in the student missing opportunities to receive important services, coping with delays in receiving services, and potentially losing skills and motivation because of these delays and missed opportunities. The importance of strong interagency linkages cannot be overstated.

For transition-age students, collaboration is viewed as an effective way for a team to come together to help them plan for and achieve desired transition outcomes in the areas of postsecondary education, community living and recreation, and employment. Collaborative teams share a sense of purpose, with shared responsibility for student outcomes.^{27,71} An effective transition team is not simply a collection of individuals, each with a different set of skills. Collaboration should be evident during the planning of individualized transition services and documented in the student's IEP. Collaborative efforts and open communication are essential, given the variety of interdisciplinary team members representing the school's and community's interests.

Numerous formats exist to help the team identify potential transition outcomes.^{50,70} For example, the student and team may discuss a future that includes living in an apartment or home with others who are identified or chosen by the student, use of community services (e.g., transportation, shopping, banking) and amenities (e.g., joining a health club, attending public concerts), employment (e.g., full- or part-time employment, other productive volunteer work), postsecondary education (e.g., vocational training, university enrollment), and relationships. Not surprisingly, these are goals that most people, with or without disabilities, envision for themselves or their loved ones.

While establishing a positive vision for the student's future, the team also begins to consider the student's anticipated long-term needs for resources and supports that will enable the vision to become reality. For example, a young adult with significant disabilities may require long-term job support in the form of a job coach, who provides on-the-job training and other support needed to maintain employment. Another individual with high-functioning autism may require social and academic support or accommodations to be in place and operational at the selected university before the start of the school year.

This type of planning is often termed *person-centered*⁶⁰ and involves a group of individuals who know the student well and who have come together to engage in a positive, facilitated discussion focused on the student's future. Emerging from this discussion is a comprehensive understanding of the student's unique strengths and interests, effective supports and accommodations, and potential resources and opportunities that can be incorporated into the student's transition services.

Collaborative, group-oriented planning processes have been shown to be an effective approach to student evaluation and transition planning.³⁰

Summary

School-based interdisciplinary teams coordinate with community agencies to provide a range of essential services that promote positive postsecondary outcomes for individuals with disabilities. Occupational therapists understand the importance of work for fostering a person's sense of productivity, self-esteem, and self-determination and to create opportunities for social relationships and connections that support a high quality of life. Occupational therapists are well represented in the public schools, and yet only a relatively small percentage report that they work with transition-age students.³⁷ Occupational therapists have unique training to support individuals in transition and unique expertise on the interventions and tools needed to prepare youth and young adults to be successful in life and help them achieve that success.

The current educational and political environment has established higher expectations for postsecondary outcomes of students with disabilities. Full inclusion in postsecondary academic settings, employment, and full participation in life is the goal for all individuals with disabilities. Occupational therapists can help facilitate the successful transition of youth to adulthood. The following points summarize this chapter:

- Students with disabilities are entitled to receive transition services (e.g., special education and related services, including occupational therapy if the team determines a need) designed to help them achieve their postsecondary goals.
- In the U.S. public school system, a successful transition to adulthood is usually defined by matriculation to postsecondary education and/or employment.
- Key stakeholders, such as the student, parents, community partners, and advocates, may define additional important outcomes such as health, quality of life, friendships, and independent living skills.
- Occupational therapists are ideally positioned to provide evidence-based services to students in transition to adulthood.

CHAPTER

26

Intervention for Children Who Are Blind or Who Have Visual Impairment

Kathryn M. Loukas • Patricia S. Nagaishi

KEY TERMS

Certified low vision therapist	Blindness
Certified orientation and mobility specialist	Visual impairment
Certified vision rehabilitation therapist (CVRT)	Visual perception
	Visual information processing
	Compensatory skills
	Assistive technology

GUIDING QUESTIONS

1. What is the definition of blindness and visual impairment in children and youth?
2. Who are the members and what are the roles of the inter-professional team who may be involved with children who are blind or visually impaired?
3. How might visual impairment affect occupational performance?
4. What are the concepts and client factors related to occupational performance of children who are blind or visually impaired?
5. Which types of assessments might be utilized in the evaluation of a child who is blind or visually impaired?
6. How might theory guide practice when working with this population?
7. What evidence supports occupational therapy intervention with infants, children, or youth with blindness/visual impairment?

"I long to accomplish a great and noble task, but it is my chief duty to accomplish humble tasks as though they were great and noble. The world is moved along, not only by the mighty shoves of its heroes, but also by the aggregate of the tiny pushes of each honest worker."

—Helen Keller⁵⁸

Vision is the sense people use to gain understanding of the environment and the relationships among people, objects, and the surroundings. It serves as an efficient integrator of multi-sensory information that contributes to the development of perceptual abilities and concept formation.²⁰ We use vision to scan the environment (e.g., obtain information about distance,

movement, spatial relations) and to discriminate features of objects and symbols (e.g., size, shape, color, orientation of letters). Because vision plays an important role in developing relationships and associations between people and objects, children with visual impairment often have delayed language. They may exhibit delayed cognitive, motor, and perceptual skills and limited self-care, play, and social participation. Occupational therapists must understand the complexity and importance of vision because of the significant impact visual impairment has on development, occupational engagement, and participation.

This chapter defines key terms related to vision and the effect of visual impairment on occupational performance; also described are assessment and evaluation measures specific to understanding children and youth with visual impairment. A description of intervention goals and strategies for children and youth with visual impairments or blindness is presented in a case study illustrating how occupational therapy interventions meet the needs of children and youth with visual impairments across different life stages ([Case Study 26-1](#)).

Terminology

In a discussion of vision, it is important to differentiate between *sight*—the ability to discriminate small objects, which is measured as visual acuity (or the resolving power of the eye to see small detail at a specified distance [i.e., 20/20 acuity is considered normal])—and *vision*—the process of taking in, processing, and integrating visual and other sensory information to form a perception.⁶⁵

Scheiman describes an optometric model of vision comprising three interrelated components.⁶⁵ The first component consists of acuity, refraction, and eye health; the second component includes visual efficiency skills; and the third component involves visual information processing. See Table 26-1e on the Evolve website for a glossary of terms. Occupational therapy practitioners may intervene as related to each component. For example, children who exhibit deficits in acuity, refraction, and eye health may require accommodations and/or assistive devices to engage in daily activities. They may require intervention to learn to care for visual devices (e.g., glasses). Practitioners may also provide eye exercises and work closely with optometrists. The focus of occupational therapy intervention may be to enhance visual efficiency and information processing through a variety of structured visual activities.

The dynamic, complex system of visual skills, neural processing and integration, cortical interpretation, and adaptive visual-motor function develops through interactions with the world.⁷³

The authors wish to thank and acknowledge the scholarly work and reference updates performed by occupational therapy graduate student Tara Kaminski.

CASE STUDY 26-1 Visual Impairment Across Developmental Stages

This Case Study illustrates the evolving needs of children and youth with visual impairments and describes the role of occupational therapy. This case study applies occupational therapy concepts to intervention planning using the concepts and approaches described throughout this chapter and text to elucidate the process of occupational therapy when working with children and youth with visual impairments. The client is followed across the lifespan of childhood toward adulthood using client-centered and theoretically sound principles of intervention.

Early Childhood

Brooke was born prematurely at 32 weeks gestation, weighing 1500 grams at birth. As a result of lifesaving oxygen given to her in the neonatal intensive care unit, she had a condition called *retinopathy of prematurity*. This is a common reason for blindness or visual impairment in children in the United States.²⁹ Retinopathy of prematurity results from incomplete blood vessel development. As these vessels grow following premature birth, they can grow into the vitreous instead of the retinal surface. This process can pull on the retina and cause retinal detachment,²⁹ which was the case with Brooke. Her visual conditions included significant decrease in visual acuity at about 20/200 with corrective lenses, which corresponds to a diagnosis of legal blindness. Brooke had scarring of the retina and retinal detachment with loss of visual fields. Brooke was the oldest child of involved, concerned, and loving parents. The family lived in a small apartment outside of a small city.

Theoretical Foundation

The occupational therapy practitioner used a developmental frame of reference while integrating a dynamic systems and family-centered intervention.

Practice Setting

Early intervention (birth to 3 years of age).

Evaluation

The occupational therapist in early intervention received a referral from the pediatrician to evaluate Brooke. The evaluation began with an interprofessional arena assessment that included an occupational therapist, physical therapist, and speech and language pathologist. The team met and planned to evaluate Brooke using the Hawaii Evaluation and Learning Profile⁵² and Peabody Developmental Motor Scales.²⁵ The occupational therapy evaluation also included an occupational profile,⁴ home-based observations, and the Knox Preschool Play Scale.³⁹ The trio of therapists worked together as they met to interview the parent(s) and engage Brooke in playful interactions with toys and assessment objects in the therapy environment. The occupational therapist addressed areas of occupation in self-care and play with careful attention to the developmental, sensory, adaptive, and exploratory needs of the child.

Team-Based Intervention Planning

Following the evaluation, the team and family developed an individual family service plan. Using findings from the arena assessment, including those from the Hawaii Early Learning Profile and Peabody Developmental Motor Scales, observations, and interview, the team determined that Brooke had strong prelanguage and social skills. Brooke was developmentally delayed in her motor milestones and the team noticed that her parents tended to hold her versus letting her explore or move on her tummy or other positions on the floor. Cognitive development was also somewhat delayed. The team hypothesized that this was because of Brooke's inability to see objects with which to interact. The team developed goals related to play exploration, parent education, activities of daily living, rest and sleep, and sensory input. The State Center for the Blind was contacted so that services were initiated specific to the needs of children who are blind.

Description of Occupational Therapy Interventions

The occupational therapist provided family-centered intervention with Brooke, addressing concerns regarding sleep patterns by coaching them to extinguish use of sound during interruption of the night time sleep cycle.⁷⁸ The occupational therapist also addressed needs articulated by the mother regarding appropriate play in the home by bringing toys that had distinctive sensory features including tactile and auditory components. The practitioner modeled appropriate habits as she sang songs with hand motions to direct some routines such as eating and dressing; Brooke responded to this interactive, sensory motor approach. The occupational therapist used motor learning approaches (see [Chapter 7](#)) when a game challenged her emerging motor performance. Specifically, the practitioner provided short verbal directions with tactual cues as needed. The practitioner allowed Brooke to problem solve and play with a variety of toys, and the intervention occurred in the child's home (natural context). Further, the practitioner incorporated Brooke's love of stuffed animals into the games (meaning promotes motor learning).

To address development of childhood occupations,³⁵ the practitioner used an ecologic model, setting up an environment to promote Brooke's development of intrinsic motivation. This set up included a child-safe environment free of clutter or hazardous furniture with assorted climbing toys such as a slide, toys with tactile and auditory input, and a playhouse with play clothes, pretend food items, and other household objects. The team decided that the occupational therapy practitioner would serve as Brooke's primary therapist in early intervention services because her speech and language were strong and overall gross motor potential was evident. Working with the parents, the occupational therapist supported and encouraged healthy routines that facilitated development and adaptive functioning. The dynamic systems approach makes exceptions to strict developmental expectations. This approach includes working with the initial conditions of significant visual impairment while recognizing that Brooke may develop in some areas (such as language) much faster than others. Family-centered interventions

CASE STUDY 26-1 Visual Impairment Across Developmental Stages—cont'd

acknowledge the importance of family support and the home environment in services for young children (Box 26-1).

School-Age

Practice Setting

School-based practice.

Theoretical Foundation

The person-environment-occupation (PEO) model¹³ uses adaptation and compensation interventions and sensory processing frame of reference¹⁷ in an inclusive, interprofessional milieu. A remediative approach utilizing visual rehabilitation was also included in the program.

Occupational Therapy in the School Environment

As a school-aged child Brooke received occupational therapy services through the Individuals with Disabilities Education Act.^{76,77} Brooke also received services through the Department of Blind Rehabilitation, including a certified vision rehabilitation therapist (CVRT) who taught Brooke to read Braille as well as other skills specific to living with blindness. Brooke learned and practiced nonvisual cane mobility with a certified orientation and mobility specialist who saw her once per month.¹ In addition, Brooke had a classroom teacher each year as well as specialist teachers in areas such as art, music, physical education, and computers.³

Evaluation

The occupational therapist used observations in a variety of school contexts, an occupational profile, analysis of the occupations expected in school,⁴ the School Function Assessment,¹⁶ and the Sensory Profile School Companion¹⁸ to evaluate Brooke's school-based strengths, abilities, and adaptation needs. Formal school-based evaluations are necessary every 3 years, although goals and outcomes are documented quarterly.

Interventions for School Occupations

The occupational therapist used the PEO model to guide her thinking about the needs that Brooke had as a child with significant visual impairment/blindness. As a therapist who is consistently in the schools, the occupational therapist worked with the professionals in services for the blind to assure carryover of academic and mobility recommendations. First, the occupational therapist addressed Brooke as a *person*. Brooke was a person who sought sensory input and physical activity, particularly tactile and proprioceptive input. Brooke was also highly social, always talking and curious about the world around her. The occupational therapist influenced teachers and students to see Brooke as a person with many strengths and interests, as well as a child who is blind. Using the PEO model addressing the environment, the occupational therapist educated the school community regarding the importance of not having clutter in the halls and aisles of the classroom, as well as the importance of keeping physical obstacles in the same place. In collaboration with the CVRT, the occupational therapist implemented assistive technology such as voice-activated software to help Brooke with written work. Although Brooke was learning braille, the occupational therapist took

the lead in finding auditory books and resources for Brooke. To help Brooke refrain from self-stimulation during teacher-directed learning, the occupational therapist implemented use of a sensory box in which Brooke could find stimulating items with which to fidget. The occupational therapist developed a sensory diet for the classroom and specific playground activities whereby Brooke learned to participate independently on the equipment. The occupational therapist also adapted recess games such as kick-ball with a playground ball with jingle bells inserted for Brooke to kick as well as a designated buddy runner to assist her in the game.

Brooke and the art teacher collaborated to create art that had significant tactile properties so that Brooke could feel the art. Art projects included, for example, paper mache, hanger sculpture, and others after an in-service from the occupational therapist. Brooke fully participated in the school environment according to her performance capacity in the natural context of the school.

In addition, a remediation approach of vision rehabilitation targeted maximizing Brooke's residual vision. This approach utilized vision training and specific attention to factors in her limited visual field based on experience.⁷⁴ (See Research Note 26-1.) The occupational therapist was dedicated to individualized inclusive intervention approaches and developed activities to challenge Brooke to use the vision she had. The therapist also recommended environmental adaptations throughout the school to optimize her safety and participation.

Interventions to Promote Social Participation

The occupational therapist collaborated with Brooke to develop social participation and identity building occupations. Following the therapist's recommendations and consultation, Brooke actively engaged in occupations such as horseback riding, swimming, martial arts, and wrestling. After Brooke expressed the desire to know other children who were blind or had visual impairment, the therapist encouraged the family to increase social participation by sending Brooke to a camp for children who are blind or visually impaired. Brooke was delighted because all the activities at camp were adapted for children with blindness. Brooke enjoyed meeting other children who were blind. She was curious about how they adapted to various occupations. In addition, Brooke's parents found a support network to assist them to be effective parents of a child who is blind.

Transitioning to Adult Roles

Practice Setting

School, home, and/or community.

Theoretical Foundation

The Model of Human Occupation (MOHO)³⁸ psychosocial and developmental frames of reference.

Challenges in Secondary Education

As Brooke entered middle and high school she encountered new areas of developmental challenge, including social relationships and preparation for adult roles and responsibility. Brooke was reading Braille fluently and achieving "on grade level" in most classes; she was involved in sports on the

Continued

CASE STUDY 26-1 Visual Impairment Across Developmental Stages—cont'd

recreational and school team levels. Brooke began to self-advocate to meet her adaptive needs. Thus, the role of the occupational therapist changed to a consultant role and the practitioner supported Brooke's development of self and identity to prepare Brooke for independence as a young adult.⁴⁸

Evaluation of Secondary School Students

The occupational therapist evaluated Brooke's skills and abilities with the following assessments: Occupational Circumstances Assessment Interview and Rating Scale²⁶; Occupational Self-Assessment³⁸; interest and role checklists³⁸; Children Helping Out, Responsibilities, Expectations, and Supports (CHORES)¹⁷; and the Kohlman Evaluation of Living Skills⁴¹ to assess IADL skills. At age 16 she was also given the Transition Daily Rewards and Worries Questionnaire³² to fully address her needs in transition planning to adult life. The occupational therapist took a key role in helping Brooke transition to adult roles.³⁶

Occupational Therapy Intervention

Using MOHO as the model of practice, the occupational therapy practitioner addressed the area of *volition*, as she continued a strong relationship with both Brooke and her family. During the developmental years, she influenced Brooke's athletic abilities that began with her need for and interest in physical activity. She helped Brooke access the United States Association of Blind Athletes⁷⁵ to support

participation in athletics using the Access Sports Model.^{47,56} This model involves adapting sports targets and goals, boundaries and equipment, and/or rules. Recent legislation indicated that students with disabilities have the right to be involved in varsity and extracurricular sports, by the Disabilities Act and Interscholastic Sports,⁷⁶ which supported Brooke's motivational (volitional) involvement.

The occupational therapist consulted with the family and Brooke when examining *habitation*, to assure that she was involved in healthy routines and habits including chores and IADL activities at home and in the community to move toward independent or interdependent living. Brooke continued to work with both the CVRT and the certified orientation and mobility specialist to maximize experience, confidence, and access to the community. The occupational therapist collaborated with services for the blind to assure consistency and follow-through of recommendations and expertise. Brooke developed her own goals and took on key roles in IADLs, athletics, and school activities. The occupational therapist used the interest and role checklists to include the environment and performance capacity into her daily occupations. Brooke demonstrated some challenges in performance capacity owing to struggles with self-esteem, autonomy, and community participation, which the occupational therapist prudently addressed in intervention planning³⁶. Areas of occupation addressed included education, work, leisure, instrumental activities of daily living (IADLs), and social participation. See [Research Note 26-2](#).

BOX 26-1 Family-Centered Care

Factors Influencing Mothers' Learning

Overview: This study follows a paradigm shift away from clinic-based intervention and toward community and occupation-centered practice in early intervention. This qualitative study explored the relationship of 9 mothers and their child's occupational therapists in early intervention, specifically factors that facilitated learning. The themes that emerged included the role of parents as active partners versus passive observers and the importance of relationships and open communication in meeting the needs of mothers.

Effectiveness of Home-Based Early Intervention for Blind Infants and Preschoolers

Overview: This German study documented the positive effects of comprehensive early intervention with full-term blind children with high levels of parent involvement. The nonrandomized control trial included targeted intervention in spatial orientation, sensory awareness, and daily living skills. A specialist addressed the needs of 10 blind children with visits every 14 days for 2 years with 40 children in the control group. Children who received the specialized home-based intervention advanced in general development as compared with controls.

RESEARCH NOTE 26-1

Vision Rehabilitation

Tsai, L.-T., Meng, L.-F., Wu, W.-C., Jang, Y., & Su, Y.-C. (2013). *Effects of visual rehabilitation on a child with severe visual impairment*. *American Journal of Occupational Therapy*, 67, 437–447.

This single case study used a research design of ABA and AB to explore the brain changes of play-based specific vision rehabilitation techniques with a 6-year-old boy with severe visual impairment. The researchers implemented and measured the effects of a chromatic luminance discrimination program and fixation training through an online game activity. The outcomes were measured using evoked potential to evaluate neural activity in the primary visual cortex. Along with neurologic changes, the authors' results indicate that this programming helped the boy detect obstacles in his environment not noticed prior to the program. The functional and neurologic changes cited in this study suggest the ability to maximize residual visual functions through experience-dependent neuroplasticity.

RESEARCH NOTE 26-2

Behaviors Associated with Future Success in Employment and Education

McConnell, A. E., Martin, J. E., Juan, C. Y., Hennessey, M. N., Terry, R. A., el-Kazimi, N. A., et al. (2012). Career development and transition for exceptional individuals. *Hammill Institute on Disabilities*. Published online December 13; <http://cde.sagepub.com/content/early/2012/12/13/2165143412468147>.

McConnell et al. analyzed existing research on behaviors that favorably influenced successful secondary transition of students with disabilities to adult roles. Based on a meta-analysis of 83 studies, the authors found that behaviors associated with postschool education and employment included: (a) knowledge and actions regarding their own strengths and weaknesses (insight), (b) disability awareness, (c) employment and experience, (d) goal setting and attainment, (e) persistence and proactive involvement, (h) self-advocacy, and (i) supports and utilization of resources (p. 4). Implications for occupational therapy involvement in transition planning and development of interventions related to successful transition are significant. These include educational consultation, facilitation of independence in the community, advocacy, IADL training, social participation activities, and family support.

Visual skills include fixation, tracking/pursuits, saccades, accommodation, convergence, and binocular vision. In addition, stereopsis (binocular depth perception), form perception, and field of vision depend on the coordination of accommodation and convergence.⁷³ Visual and sensorimotor integration involves integration of visual skills with the other sensory systems (e.g., vestibular, proprioception, auditory, tactile) that enable the child to develop functional skills (e.g., orienting responses, protective reactions, spatiotemporal orientation, eye-hand and eye-foot coordination, perceptual skills, and academic skills). At the same time, sensorimotor functions support the development of visual skills.

Visual Impairment

For the purposes of this chapter, *visual impairment* is defined as the loss of or deficit in visual function (i.e., vision, visual perception, interpretation of visual input) owing to pathology or processing problems in one or more components of the visual system (e.g., structures of the eye, visual pathways, and the brain) that limits the individual's ability to engage in and participate in daily occupations. The leading causes of visual impairment in young children are cortical visual impairment, retinopathy of prematurity (ROP), and optic nerve hypoplasia.^{19,23,49} Other common causes include microphthalmia, anophthalmia, childhood glaucoma, retinoblastoma, and congenital cataracts, whereas less common causes include severe myopia, albinism, and nystagmus.¹⁹

Because the effects of visual impairment are evident in the acquisition of early milestones for occupation-based mobility, play, and hand function, children with visual impairments are

often referred for developmental evaluation and intervention by pediatricians. However, children with developmental disabilities (e.g., cerebral palsy, Down syndrome) are among the most likely to receive services from occupational therapists, and 50% to 66% of children with developmental disabilities also have a significant ocular disorder or visual impairment.^{49,54} Therefore occupational therapy practitioners who provide services to children with these diagnoses must recognize, understand, and address how the child's visual functioning influences occupational functioning.

In a national collaborative study that examined the developmental trajectories of a group of 186 children with visual impairment, children with visual impairment and co-occurring disabilities (e.g., intellectual disability [ID] or developmental delay) had lower developmental age scores, as measured by the Battelle Developmental Inventory, and showed a slower rate of development when compared with children with visual impairment who did not have ID, regardless of the levels of visual functioning demonstrated by the children.³⁴ The level of visual function was highly correlated with the presence of ID: more than half of the children with severe vision loss also had ID, whereas children with mild to moderate vision loss did not. Among the children with no ID, those with the least vision had significantly lower rates of motor and personal-social development when compared with those with the most vision. The degree of visual impairment, therefore, appears to be a factor in the development of these children, and those with better vision are more likely to have favorable developmental outcomes.³⁴

The degree of visual impairment, however, is only one variable that must be considered in the individual child's developmental trajectory.^{80,81} Some children with visual impairments function at least within the average range or even at the high end of developmental age norms for sighted children. Therefore the dynamic evaluation of occupational performance in relation to the demands (i.e., expectations and challenges) of the context in which the child with visual impairment functions and how these interactions change over time is presented as a more useful framework.⁸¹ Whether the child with a visual impairment is singly impaired or has multiple disabilities, occupational therapists view the child and family in relation to their ability to participate and engage in occupations and activities that are meaningful to their everyday lives.

Children with visual impairment are often identified in the first year of life and begin to receive services from local early intervention programs, which according to best practice serve children in natural contexts such as the home or daycare. Occupational therapy practitioners are part of the interprofessional team for children who are blind or visually impaired and may work with children in the neonatal intensive care unit, early intervention sites, home care, schools, specialty schools, transition programs, vocational sites, and children's hospitals or rehabilitation centers.^{15,54}

Developmental Considerations and the Impact of Visual Impairment

To evaluate the ability of children to engage in age-appropriate occupations and to design appropriate interventions, occupational therapists need to understand the development of the visual system and visual functioning. Vision is a quick, efficient integrating sense that allows immediate feedback and

appreciation of both near and distant information about the environment in multiple locations.^{37,72}

At 24 to 25 weeks' gestation, the major structures of the eye and the visual pathway to the level of the visual cortex are in place, but the eyelids are fused and the visual system remains immature.^{30,31} Therefore infants born extremely premature are at high risk for ROP because the retina and visual cortex undergo further maturation during the last trimester of pregnancy.³⁰ Although improvements in neonatal and ophthalmic care have resulted in improved visual outcomes for children with ROP,⁶⁷ children with extremely low birthweight may be at higher risk for visual impairments.^{68,69} By 24 to 28 weeks the eyelids are no longer fused and an immature visual response emerges, but the awake and sleep states are not well differentiated. By 30 to 34 weeks sleep and awake states become differentiated, the eyes may open, and brief visual fixation may occur. By 36 weeks the visual evoked response is similar to that of a full-term infant, and the awake state can be sustained for longer periods.³¹

At birth the infant's visual acuity is approximately 20/200 (i.e., the infant can see at 20 feet what an adult with normal vision can see at 200 feet); at 1 year, it is about 20/50, and by 2 years normal 20/20 acuity is present.²⁰ The maturation of the visual system in typical infants continues after birth and is a function of the transactions that occur between the infant and the environment and concurrent changes in the synaptic density of the visual cortex and other parts of the brain.³¹ Vision enables an infant to explore the environment and negotiate space, to learn about the properties of objects, to interact and communicate with caregivers, and to develop the visual-perceptual skills needed for more complex activities, such as reading and writing, and for play and self-care occupations. In addition, vision is major contributor to praxis, which allows an individual to organize ideas and actions and to anticipate, monitor, and adapt to the demands of the environment.^{64,68} Because many of the conditions that affect vision are congenital or have a prenatal etiology, a major system for processing and interpreting information is compromised at birth, with substantial impact on the child's subsequent development in all areas of occupation, including developing social relationships, self-care, play, activities of daily living, and academics.

Parent-Infant Attachment

Through engagement in the daily caregiving activities and routines of eating/feeding, bathing, sleep/rest, and playful interactions, the infant and the caregiver co-regulate their signals and responses, and each actively participates in these interactions. Through these interactions the infant and the caregiver develop their relationship; infant behaviors such as eye gaze and visual regard of faces, and the mother's interpretations of these behaviors, are important to this process. However, vision is not required for the basic infant behaviors that elicit caregiver responses, such as smiling and vocalizing or for infants to perceive the caregiver's responsive behaviors, such as vocalizing, cuddling, or feeding.⁸¹ Sighted infants and infants with visual impairments engaged in similar proportions of facial expressions that were considered meaningful by their mothers, including smiling.⁷

Indeed, positive and strong attachment relationships can occur in infants with visual impairment.⁸⁰ A caregiver who is coping with learning that the infant has a visual impairment

may have difficulty responding to the infant's cues, but at the same time the infant may display fewer behaviors that elicit positive responses from the caregiver, setting up a cycle of interactions that are out of sync or not mutually and emotionally satisfying. Furthermore, an infant who is visually impaired may be securely attached to a primary caregiver but have attachment behaviors that are different from those seen and expected in sighted children.²⁰ Vision loss itself is not necessarily a causal factor, but it may create a condition of risk for early social-emotional development and attachment.⁸¹

Sleep and Rest

Young children with visual impairment may experience sleep disorders that could impact the bedtime and sleep-wake routines in the household, their behavior, and performance.²⁰ One study examined the sleep patterns of two groups of toddlers with visual impairment ranging in age from 10 months to 39 months: one group without associated disabilities, and one group with associated disabilities.²² The investigators found that when compared with the control group of typical sighted peers, the children with visual impairment had more difficulty falling asleep and sleeping through the night (i.e., longer time spent awake and greater number of nocturnal awakenings), and the sleep behaviors were not related to the presence of associated disabilities. Thus it is important that occupational therapists consider the daily routines of the child and family, including sleep-wake cycles, as part of the evaluation and intervention processes. See [Research Note 26-3](#).

Exploration and Play

Vision provides children motivation to explore and seek out interactions with the physical and social worlds that contributes to the acquisition of perceptual motor skills and development across domains. Children with visual impairment, particularly those who have significantly decreased visual functioning, have a qualitatively different experience with, and level of affordances of, objects and people in their environment.⁷¹

Children with visual impairment often demonstrate delayed achievement of certain milestones, such as crawling and walking.³⁴ In a survey of 200 families, children with visual impairment demonstrated delayed gross motor development, with the most significant delays related to locomotion, such as cruising around furniture, walking independently, and negotiating stairs.¹¹ Among the subgroups in the sample, children with the least vision (i.e., light perception only or no light perception) had the poorest motor outcomes, followed by children with visual impairments who were born prematurely. A summary of selected studies comparing motor function, degree of visual impairment, and severity of co-occurring conditions is presented in Table 26-2c on the Evolve website.

Warren suggested that lack of vision may have an indirect rather than a direct effect on locomotion, because studies have shown significant variance among infants with visual impairment, with some achieving milestones for crawling and walking well within the normal range.⁸¹ Specifically, vision may serve as a motivator for infants to explore interesting sights out of reach, and perhaps more important is the extent to which infants are provided with opportunities and encouragement to explore and learn.⁸¹

RESEARCH NOTE 26-3

Recommendations for Sleep Problems in Young Children with Blindness

Mindell and DeMarco (1997) investigated 28 blind children ages 4 to 36 months regarding sleep habits as compared with a control group of 22 sighted children.⁵⁰ The authors hypothesized that children who are blind have significantly greater sleep problems because of difficulties with circadian rhythms. According to a standardized parent questionnaire, blind children had more sleep-related problems including bedtime behavior difficulties, longer time getting to sleep, wakefulness during the night, and overall less sleep time. The authors reported that parents of blind children were more likely to use conversation, sound, or reading when the child awoke, which may have promoted the awakened behavior. A corresponding single case study by Vervloed, Hoevenaars, and Maas⁷⁸ found that parents of a 4½-year-old girl with visual impairment had significant difficulty getting the child to sleep and keeping her asleep during the night.

The parents were instructed to use graduated extinction procedures of parental attention during awakened periods during the night. This included ignoring the disrupted sleep behavior during the night. The study also incorporated an improved bedtime routine of calming activities and discontinued physical play. Parents were encouraged to use behavioral practices for 30 days, including a graduated extinction of sounds while comforting the awakened child. Results indicated that the child had improved initiation and latency of sleep 3 months following behavioral treatment.⁷⁸

Implications for Occupational Therapy

- When children with blindness have difficulty sleeping, establishing behavior expectation may help to improve sleeping habits.
- Occupational therapists can recommend behavioral strategies combined with establishing routines to improve sleeping patterns.

Learning, Education, and Academic Performance

Children with visual impairment learn in a range of educational contexts, from general education settings to residential facilities. According to the Individuals with Disabilities Education Act^{76,77} most preschoolers with visual impairment are served in early childhood special education settings. Knowledge of the typical developmental processes is critical, not only for comparison with sighted children but to provide a context for professional decision making to determine developmentally appropriate evaluation and intervention.²¹ For example, children develop an understanding of the properties of the world and how things relate and work, develop logical thought and learn to problem solve, and also learn to regulate and organize executive functions such as memory, attention, and information processing. They learn by exploring and engaging in sensorimotor actions with objects, developing associations and affordances among objects, experiencing the relationship between self and others and objects in space, establishing perception and mental representations, solving complex problems,

and ultimately using symbolic representation and manipulation for abstract thinking. Children with visual impairment have unique needs that must be considered when examining the development of cognition, concept development, and language. For example, the occupational therapist provides opportunities for movement, tactile exploration, and sensory experiences to stimulate cognitive associations, concept development, and language. Modifications to the environment may be needed to allow children with visual impairments to fully experience learning.

Children with visual impairment may achieve developmental milestones at a different rate and sequence than sighted children; they may achieve some developmental milestones within the same typical range.²³ Cognition and communication often develop on a later schedule, depending on factors such as age at onset, degree of visual functioning, presence of other disabilities, and the nature of the child's experiences in different contexts. Many studies found no significant differences in the cognitive/learning and communication development or school performance of children with visual impairment when compared with normative samples of typical peers.^{27,42,60,61} This does not mean, however, that children with visual impairment who perform within the typical range based on standardized test scores do not have qualitative differences or needs that may affect occupational performance and require intervention.

For example, several studies reported cognitive functioning in the normal range among children with visual impairment, but some children displayed a pattern of differences in visual motor performance (see Table 26-2e on the Evolve website). In one study, although the mean scores for mental and motor development on the Bayley Scales of Infant Development II fell within the average range for a group of 54 young children with retinoblastoma (RB), visual motor performance differed relative to extent of RB (unilateral or bilateral).⁶¹ The children with bilateral RB had significantly lower mean scores for motor development (although still within the average range), and they were more likely to be referred for intervention to address visuomotor difficulties than the children with unilateral RB.

Potential unidentified visual deficits among older children who display academic problems also need to be considered. Goldstand, Koslowe, and Parush found that among a sample of 71 seventh graders (mean age of 12.7 years; 46 proficient readers, 25 nonproficient readers) in middle school in Jerusalem, more than half the group failed an optometric vision screening measure.³³ Nonproficient readers had significantly poorer visual efficiency skills when compared with proficient readers, suggesting that basic visual skills can be important to learning to read with proficiency.

These findings suggest that visual deficits may be common among school-age children and that many of these children are in school with uncorrected visual problems. Children with visual problems often have learning problems but may not receive accommodations, remedial intervention, or related services (e.g., occupational therapy, speech-language pathology). Screening for and recognizing visual problems among children who are struggling in school can be an important role for the occupational therapist, who can make a referral to a vision care specialist for comprehensive evaluation and diagnosis. Once a child with visual problems is identified, the occupational therapist can develop appropriate compensatory and instructional strategies, accommodations, and other supports to help the child access the curriculum and improve academic performance.

Use of Information from Other Sensory Systems

It is a common assumption that children with visual impairment compensate for the loss of vision through increased use or heightened performance of the remaining senses. It is important to remember, however, that the child who is visually impaired (i.e., from birth or early infancy) is in the *process* of building experiences that affect the developing brain and therefore must learn differently than do typical children. However, infants and young children with visual impairment do make sensory associations to form perceptions through their experiences, and if the remaining sensory systems are intact and the infant is otherwise healthy, the capacity to become competent and independent can be realized.⁶⁸ Furthermore, the research suggests that visual impairment does not have a negative impact on early development of tactile and auditory perception in that infants with visual impairment demonstrate basic discrimination abilities similar to those of sighted infants.⁸¹ As Glass noted, infants with visual impairment may have a heightened behavioral response to auditory stimuli.⁶²

Although infants with visual impairment discriminate and respond to caregivers' voices or touch, their ability to connect auditory input with external objects in a specific location and to use this information to reach for objects appears to take longer to develop.⁸¹ It is not a simple matter for an infant to know that a sound goes with a desirable object and locate it. Ross and Tobin posited that an infant may expend energy trying to interpret sounds at the expense of exploratory motor behavior.⁶²

The development of occupations that use fine motor skills depends on visual monitoring. Loss or distortion of visual input makes it more difficult for children to acquire these skills, although information from the tactile system can offer some compensatory strategies.⁶⁸ Children with visual impairment can manipulate objects to detect their form and shape, and therefore their concepts of objects are developed using haptic perception. In addition, their ability to coordinate reaching with sound depends on precise tactile system perception used for exploration and concept development⁴⁵ and the use of audition to locate an object in space. Although object concept behaviors in children with visual impairment are similar to those in sighted infants through the first year and a half, performance on tasks that involve complex spatial displacements that cannot easily be tracked by audition or touch is more difficult; therefore, spatial understanding may be more of a problem than object conceptualization for children with visual impairment.⁸¹

The use of remaining sensory systems does not substitute for the efficiency of the visual system in integrating the child's experiences, and therefore the child with a visual impairment takes longer to develop his or her conceptual understanding of the world.^{21,59} Learning is much more efficient for sighted children, who have the benefit of seeing the whole first and then discovering the different parts. As Fazzi and Klein explain, children with visual impairment must learn about things in parts based on different, discrete sensory inputs without seeing what the whole looks like first.²¹ In their example, a child with a visual impairment may experience something with a furry body, a wet nose and tongue, a moving tail, and loud barking and must then integrate these pieces of sensory information to

form the complete concept of "dog." Without adequate opportunities to experience all parts, the child's "picture" of the whole may be incomplete or inaccurate.

Although the child with visual impairment may gain specific information about an object's unique properties, the remaining senses do not necessarily provide him or her with sufficient information about the contexts in which the object exists.⁶⁸ For example, a child may learn about the cup he uses for drinking but may not come to understand for years that his plastic tumbler, his father's coffee mug, and the crystal wine glass used for special occasions are all variations of a class of objects used for drinking, especially if he has not had direct tactile experience with these items. If a child has limited experiences and does not have systematic introduction to objects in context, he or she will have a narrow range of schemes to work with, and these available schemes may not be fully validated by others.⁵⁹

Sensory Modulation

Children with visual impairment and blindness often demonstrate stereotypical or repetitive behaviors, such as hand flapping, eye poking, or self-rocking.^{84,85} However, occupational therapists need to be mindful that these behaviors are also seen in children with other conditions, such as autistic spectrum disorder, severe or profound intellectual disabilities, and other developmental disabilities. Therefore the presence of these behaviors (with the exception of eye poking) may not be due to blindness per se but rather to the underlying cause of the blindness, particularly in children with multiple disabilities. These stereotypic behaviors have been hypothesized to be sensory-seeking activities that may compensate for the vision loss, but another explanation may be that the behaviors emerge as a result of the severely limited repertoires of movement and behavior available to children with visual impairment.⁶⁸

Some children with visual impairment also present with behaviors that suggest tactile hypersensitivity, postural instability, or gravitational insecurity. That is, a child may withdraw his or her hand from an object or art media, may object to being touched, may be fearful of moving through space, or may be afraid to get on playground equipment such as swings or the jungle gym. The intensity of the child's responses in these situations varies, as does the degree to which the responses interfere with the child's ability to engage in everyday occupations. Children with visual impairment who present with these behaviors may have restricted interactions with the environment and fewer typical motor and manipulative experiences that allow them to develop postural control, gross and fine motor skills, and praxis at similar levels of competence and quality as those of typical sighted children.

To understand the reasons for specific behaviors, the occupational therapist carefully evaluates the child's behaviors. For example, a child who may appear to demonstrate tactile hypersensitivity may not truly have a sensory modulation disorder or generalized hypersensitivities, but rather may need additional cues and strategies for managing new tactile experiences. The child may tolerate other tactile experiences, such as being held or wearing clothing made of different fabrics, and once the child becomes familiar with the object or material, the "defensive" reactions no longer occur. This scenario is different from that in which a child consistently demonstrates tactile hypersensitivity even to familiar tactile experiences or exhibits strong

BOX 26-2 Postural and Motor Characteristics Seen in Children with Visual Impairment

Children with visual impairment may display the following:

- Overall low muscle and postural tone, including instability in shoulder girdle and hips
- Head tilted to one side (visual or auditory accommodations)
- Head forward or hyperextended, resting on neck
- Head movements (e.g., swaying)
- Maintaining a wide base of support when standing or when walking
- Tendency to move in straight planes (e.g., decreased trunk rotation)
- High guard posture when walking

reactions to tactile stimuli beyond what could be attributed to caution or hesitance.

Children with visual impairment whose motor experiences are limited may be fearful about moving through open space (e.g., crawling across the room, walking across the playground), moving on equipment such as tricycles or swings, climbing on play structures, or going down a slide. Children with visual impairment often display characteristic postural and movement patterns (Box 26-2) that may give the appearance of or contribute to movement challenges, depending on the demonstrated level of functioning. In addition, caregivers (e.g., parents, daycare staff, teachers) who are concerned about safety may become overprotective and prevent or restrict children with visual impairment from engaging in movement and exploratory activities and experiencing the bumps and bruises that go with them, thus transmitting their fear to the child.

The integrity of the child's other sensory systems contributes to his or her ability to explore and learn from the environment, interact with family members and others, develop play skills, and master activities of daily living. Without vision, the child must use vestibular, proprioceptive, and auditory information to orient to gravity, move through space, and maintain postural alignment.^{68,70} To integrate these sensory systems, the child must have opportunities to actively engage in and experience movement in a variety of situations.

Activities of Daily Living and Instrumental Activities of Daily Living

Children with visual impairment may have difficulty performing activities of daily living (ADLs), such as dressing and self-feeding. The impact of visual impairment on the development of locomotion, gross and fine motor skills, and praxis for play may also affect the child's ability to stand and lift the leg to put on a pair of pants, to direct the spoon to the plate to scoop up food, or to get into and out of the bathtub. In addition, if tactile hypersensitivity is present, the child's ability to engage in dressing, grooming, and toileting activities may be limited. If oral hypersensitivity is present, the progression to more textured foods and eating a variety of foods may be problematic. These reactions can disrupt daily routines for both the child and caregivers, as well as affect interactions with others and limit participation in learning activities at school. Negative

associations with these activities can have long-lasting effects on the child's relationships with others and on occupational performance. Occupational therapy practitioners play a key role in helping children and families develop positive routines.

As children grow older and move into adolescence, participation in instrumental activities of daily living (IADLs) such as meal preparation, care of pets, and use of communication devices (i.e., Braille writers), needs to be encouraged. Supports can include adapting the task (i.e., completing the task in a different manner), changing the environment (e.g., placing materials for meal preparation in the same place), and providing adaptive equipment or technology (e.g., enlarged-print, adapted computers). A variety of commercially made technology and readily available applications for tablets and personal computers exist that may benefit the child or youth with visual impairments. (See Chapter 19 and the Evolve website for examples and resources.) The occupational therapist considers the individual's skills and abilities, environment, and the task itself when developing an intervention plan to address IADLs.

Social Participation and Communication

Patterns of interaction and communication for young children with visual impairment and their caregivers differ from those of sighted children, but can fully develop in the absence of functional vision.⁸¹ The quality of social participation is influenced not only by the visual impairment but also the degree to which the child has acquired specific social skills. One study by Cabello and Verdugo examined the quality of social participation in different contexts (i.e., one-to-one, small group, and large group), for 64 children (4 to 18 years) with visual impairment based on teacher ratings of social skills.¹⁰ The investigators found that visual impairment was a significant predictor for the quality of one-to-one interactions along with verbal skills, body language, and recognition and expression of emotions, whereas intellectual disability and visual impairment were significant predictors for large group interactions, with verbal skills, body language, play skills, and cooperation skills as important factors.

Specifically, young children with visual impairment may experience difficulty initiating and sustaining play and social interactions with peers. Without visual information to size up the context of the interaction and to pick up cues to respond to or imitate actions, the child with visual impairment may not have strategies to support the fluid give and take of a play scenario or social interaction.²⁰ The child may need explicit facilitation using physical, tactile, and verbal cues to keep up with changes that are often unpredictable, such as when play partners move to a different part of the playground or switch from sand play to ball play. In addition, the child with visual impairment may need to rely on tactile and auditory means for social referencing, and typical peers may need assistance to understand that the child's physical contact or listening is not meant to be intrusive or nonresponsive.

As children grow older, the complexity of interactions increases, and the contextual aspects of language and communication become important. Vision plays a significant role in the interpretation of facial expressions and body language and in the imitation and sustaining of the give and take of these interactions. Making eye contact, imitating facial gestures, shifting gaze, and perceiving the contextual features of visual images are often not part of the repertoire or experience of

children who have vision loss at an early age.⁶⁸ The English language has many visual references that describe images, and Western culture expects individuals with visual impairment to communicate using the language of those who have sight.

Children with congenital visual impairment cannot “see” many features or qualities of objects such as a “red” button or “green” grass using the other sensory channels, nor can they see “a beautiful sunset” or “that one over there.” Consequently, they can only try to imagine what it means when such descriptors or phrases are used.⁶⁸ In addition, children with visual impairment may not demonstrate the animation and nuances of facial expression because they have not experienced seeing and imitating these expressions.

These social skills difficulties may affect the child’s ability to develop friendships or to fit in with the social demands and expectations of peers. When the occupational therapist, teachers, and family provide a range of opportunities and targeted strategies to support social development, these skills can fully develop and positively affect the child’s participation in school, recreation, and home activities.

Occupational Therapy Evaluation

In many respects evaluation of the occupational performance of children with visual impairment encompasses the same components as in evaluation of children with other disabilities. Participation in play, self-care, school activities, and preparation for work are areas of focus for evaluation depending on the age and needs of the child. Evaluation of the performance skills (e.g., motor, process, and communication/interaction skills) that support or limit the child’s ability to engage in specific activities in these areas, and the activity demands, client factors, and contexts in which the child performs these activities, is part of a comprehensive assessment. For example, a toddler with a visual impairment who has difficulty playing with toys may need evaluation of fine motor skills, tactile and proprioceptive processing, and postural control in sitting, with observations conducted in the home and day-care settings.

Standardized assessment tools for evaluating overall development in major domains (e.g., the Bayley Scales of Infant and Toddler Development, 3rd edition [Bayley III]⁹ or the Peabody Developmental Motor Scales, 2nd edition [PDMS-2]²⁵) should be used with caution because these measures were not standardized on children with visual impairment and the administration procedures do not include adaptations for this group. Therefore comparison of performance with that of sighted peers and use of the standard scores based on the normative sample are usually not appropriate. A few assessment tools (e.g., Battelle Developmental Inventory, 2nd edition)⁵¹ are both standardized and criterion-referenced and include administration instructions for children with motor or sensory impairments.

Criterion-referenced measures, such as the Hawaii Early Learning Profile (HELP) for infants and toddlers⁵³ and preschoolers,⁷⁹ or play-based assessment tools, such as the Transdisciplinary Play-Based Assessment, 2nd edition,⁴⁶ may be more useful because they yield a profile of individual strengths and limitations or concerns that can be used to formulate an intervention plan. In addition, tools such as the Oregon Project Skills Inventory, 5th edition,⁵ take into consideration what is

known about the unique developmental trajectories of certain skills (e.g., walking independently, reaching to sound) in children with visual impairment.

An assessment tool that specifically addresses the impact of visual impairment on quality of life for students with low vision has been developed and may be of interest to occupational therapists.¹⁴ This questionnaire was based on the Impact of Vision Impairment Profile developed for adults^{43,44,82} and consists of five domains: school/specialist instruction, social interaction, community, family, and vision impairment/peer interaction. The questionnaire is helpful in identifying needs and planning intervention and its items emphasize participation in routine school and daily activities relative to social interaction, academic success, orientation and mobility skills, community acceptance, and other social opportunities.

In some instances a child who has developmental delays or difficulties may be referred for occupational therapy but has not yet been diagnosed with a visual impairment. If a child shows signs or symptoms of a vision problem and a visual impairment is suspected, the occupational therapist can assist in the diagnostic process through screening or evaluation of oculomotor skills (e.g., visual tracking, fixation, shifting gaze), focusing skills (e.g., shift from near to far), and eye teaming or binocularity (e.g., strabismus). See Table 26-1. The occupational therapist may also measure the child’s visual perceptual skills (e.g., visual discrimination, visual spatial relations) and visual motor integration. Some developmental measures (e.g., Bayley III, HELP) include items that require visual attention, visual tracking, visual memory, and other vision-related areas.

Skilled observation and parent or caregiver questionnaires can be useful for gathering information about the child’s temperament, self-regulation capacities, sensory processing and sensory modulation behaviors, and interaction with caregivers. In addition, interviews with the parents, teachers, or other caregivers provide information about daily routines, contexts, expectations, and resources available to support the child’s participation in activities. As children get older the focus of the occupational therapy evaluation may involve collaboration with the special education or regular education teacher, education vision specialists (e.g., teacher for students with visual impairment or orientation and mobility specialist), and vision care specialists (e.g., developmental optometrist) to assess barriers in school and play settings and determine the need for adaptations for performing classroom activities, organization of desk space, or the use of assistive technology.^{40,55,57} For adolescents, the occupational therapist, in collaboration with teachers, vision specialists, and the family, evaluates the individual’s school, community, and work participation, in addition to leisure interests and activities. Case Study 26-1 shows the changing needs of the child and how occupational therapy services evolve over time.

Occupational Therapy Intervention

Occupational therapy for children who are blind or have significant visual impairment includes occupation-based, family-centered, developmental, visual rehabilitation, and ecologic approaches. As described in the previous sections, developmentally based oculomotor skills, visual alignment, acuity, and visual perception affect many areas of occupation.

TABLE 26-1 Signs and Symptoms of Visual Problems*

Category	Signs and Symptoms
Physical	- Eyes shake or randomly wander - Eyes are not able to follow moving object, face of parent - Pupils of the eyes are excessively large or small - Pupils of the eyes are not black; a cloudy film appears to be present - Eyes are not in alignment (e.g., they are crossed or turn outward) - Blurred vision or double vision - Sensitivity to light
Behavioral	- Needs to move closer to objects of interest; sits excessively close to the television - Squinting, eyestrain, frequently rubs eyes - Covers or closes one eye when looking at detail - Excessive head movement - Complains of discomfort or headaches when reading or doing close work - Turns or tilts head when looking at detail - Responds significantly better to objects on one side of the body than on the other - Avoidance of or becomes tired after close work - Poor attention span - Complains of moving print
Performance	- Appears clumsy or frequently bumps into objects when walking and running - Cannot find necessary items for activities - Difficulty learning left and right - Has trouble learning the alphabet, recognizing words, learning basic math concepts of size, magnitude, position - Difficulty with reading—reads slowly, skips lines, trouble with navigating page - Difficulty with drawing, copying, writing—alignment, accuracy, reversals, organization on page, etc. - Difficulty copying from board - Has trouble keeping up with assignments
Social	- Lack of interest in the environment - Anxiety, social isolation - Decreased self-confidence

*If a child shows any of the listed signs or symptoms, a referral to an eye care specialist is indicated.

Data from Takeshita, B. (n.d.). *Developing your child's vision*. Los Angeles: Center for the Partially Sighted; Scheiman, M. (2002). Optometric model of vision, parts one, two and three. In *Understanding and managing vision deficits: A guide for occupational therapists* (2nd ed., pp. 17-84). Thorofare, NJ: Slack; and Goldstand, S., Koslowe, K. D., & Parush, S. (2005). Vision, visual information processing, and academic performance among seventh-grade school children: A more significant relationship than we thought? *American Journal of Occupational Therapy*, 59, 377-389.

The outcome of occupational therapy intervention for children with visual impairment is to support participation in the daily contexts in which they function. For a 6-month-old premature infant with retinopathy of prematurity, for example, the occupational therapist may focus on establishing oral motor skills for feeding and self-soothing strategies for calming; other recommendations may include positioning strategies for feeding and caregiver-infant interactions and selecting toys that enhance the use of available vision, along with auditory and tactile channels. For a 10-year-old boy who has cerebral palsy with spastic hemiparesis and legal blindness (i.e., best corrected visual acuity of 20/200 or worse, or a visual field of 20 degrees or less in the better eye⁸³), the school-based occupational therapist may focus on enhancing self-care skills, establishing organizational skills for using desk space and completing assignments, devising strategies that support the use of low vision aids, and promoting social participation in games with peers with modifications and adaptations.

Occupational therapy frames of reference that are particularly useful for intervention with children who have visual impairments may include developmental, sensory processing, motor acquisition and motor learning, visual perception,

the Model of Human Occupation (MOHO), and person-environment-occupation-performance (PEOP) frameworks. Occupational therapy interventions with children and youth include emphasis on family-centered care, therapeutic use of self, therapeutic use of occupations and activities, consultation, and education. These approaches may be incorporated in different combinations and at different points during intervention in a dynamic process that changes based on the needs of the child and family, the progress and response to interventions, and the demands of the contexts involved.

The occupational therapist may be the primary practitioner for children who have visual impairments with other conditions; however, if the visual impairment is the primary or sole condition, it is more likely that an educational vision specialist (i.e., teacher of students with visual impairment, orientation and mobility specialist) is the primary interventionist, and the occupational therapist may provide consultation as needed. Generally the occupational therapist is a member of a team of professionals (e.g., general education teacher and/or special education teacher, educational vision specialist, speech-language pathologist, vision care specialist) who, along with the family, collaborate to identify the child's and family's needs and

develop an intervention program to address those needs with one or more individuals providing services.

The occupational therapy practitioner often provides services to achieve the following goals.

Develop Self-Care Skills

The occupational therapist may consult with and educate those who work with the child with visual impairment to identify skill levels and explain problems affecting the child's development of self-care skills. The occupational therapist may specifically address underlying foundations and specific skills needed to perform self-care tasks, and work collaboratively with the family and the team to incorporate behavioral or learning strategies to improve self-care performance. The practitioner may suggest adaptations or modifications to the environment, recommend specialized equipment, and incorporate strategies that support independence (e.g., placing a tactile cue in specific areas of clothing to distinguish front from back or to identify color; using a divided plate or the clock orientation to serve food items).

Enhance Sensory Processing, Sensory Modulation, and Sensory Integration

Developmentally age-appropriate activities and materials that provide tactile, auditory, proprioceptive, and vestibular input can benefit the child with visual impairment and enhance or promote development of body concept, postural control, and tactile discrimination for recognizing and manipulating objects, self-regulation, and spatial relation perceptions. Sensorimotor activities can also promote bilateral hand use and praxis. Suspended equipment, scooterboards, tilt boards, obstacle courses, and other movement or balance equipment are useful, but it is also important to provide interventions using playground equipment (e.g., slides, jungle gyms, tricycles, swings) in the natural settings in which the child functions on a regular basis (Figure 26-1). Safety must be maintained in the use of equipment, and, as appropriate, the child should be allowed to control the movement and amount of input within his or her range of adaptive responses.

The child with visual impairment does not see the approach of people and objects and may exhibit hypersensitivity to touch. In many instances children who have some or variable vision may have more difficulty with this than children with total blindness because children with some functional vision or low vision (i.e., best corrected visual acuity of 20/70 in the better eye^{28,83}) receive unpredictable visual input from light patterns and movements. For children with total blindness, the visual input is essentially consistent. Firm touch generally is better than light touch, which can be interpreted as painful or aversive. The child with visual impairment often is more comfortable and less defensive when a verbal cue accompanies or precedes the tactile cue.

Strategies to help children modulate their reactions to tactile input include activities that encourage the child to explore and play with various materials using graded textures (e.g., sand, dried lentils, beans, and rice), activities that include vibration or proprioceptive input, and incorporation of a sensory diet at home and in the classroom. Support of the child's sensory modulation may be needed before an activity that the child finds aversive, such as art time, sand play, or eating. The child with hypersensitivity may benefit from recommendations for

FIGURE 26-1 A child who is blind participates in equine assisted experiences.

clothing, sleepwear, and linens. Also, if oral hypersensitivity is a factor, strategies such as introduction of graded food and liquid textures and tactile/proprioceptive activities involving the mouth (e.g., using straws with thickened liquids; blowing activities with bubbles or whistles) can be implemented. During these activities, it is important for the child with visual impairment to experience contingent responses to his or her behaviors, taking into consideration individual needs and preferences, rather than being a passive recipient of adult actions (noncontingent experiences).¹² For example, a child should not experience tactile stimulation in isolation (e.g., rubbing of different textured cloths on the arms); rather, the tactile experiences should be provided in the context of real-life activities (e.g., using a nubby towel to dry oneself after a bath) so that the child associates tactile experiences with actions and events.

Enhance Participation in Play or Productivity Through Postural Control and Movement in Space

Providing a variety of movement experiences throughout the daily routines early in life is important. Caregivers can be encouraged to use different carrying positions or carriers while

FIGURE 26-2 A child with significant visual impairment sits on a therapy ball to give him desired sensory input and to develop postural control.

FIGURE 26-3 A child who has visual impairment enjoys time in the ball pool.

engaging in everyday activities so that infants experience movement (and vestibular and proprioceptive input) under secure conditions. Instead of passive prone positioning, in which motivation to lift the head is minimal, when visual impairment is significant, caregivers can be encouraged to engage in games that include tilting the child toward and away from them while talking to and having fun with the child, or positioning toys of interest in front of or to either side of the child and encouraging the child to reach for them.^{57,71} The occupational therapist and the orientation and mobility specialist can work closely to facilitate and establish the child's ability to move through space through the use of push toys and riding toys, and by moving over surfaces of different heights, density, firmness, and/or textures (See [Figures 26-2; 26-3; 26-4](#)). In addition, motor learning principles may be applied to provide children with opportunities to practice a variety of movement strategies during different play activities, with feedback on their performance and results of their actions.

Develop Occupation-Based Mobility Through Body Awareness and Spatial Orientation

Many of the aforementioned activities can also help the child develop body awareness and directionality. Obstacle courses

FIGURE 26-4 A child who is blind reads Braille and is assisted by professional services for the blind.

can teach the child spatial concepts such as left-right, up-down, over-under, in-out, beside, around, and behind. It is important to describe the movement or direction the child experiences to help him or her establish the association that will give meaning to the spatial concepts. Body awareness and spatial awareness

are critical components that contribute to the child's development of mobility and language.^{63,64,68,71}

Develop School-Based Tactile-Proprioceptive Perceptual Skills

The child with visual impairment needs to maximize tactile discrimination function to learn about the features and properties of objects; to adjust grasp according to the size, shape, and weight of an object; and to grade the amount of pressure, force, or speed needed to manipulate toys or to use tools. Tactile discrimination is also important for learning to read Braille. Finger painting, finding and identifying objects hidden in sand or beans or other media, and experiencing gradations of textures among everyday objects and materials, clothing, and surfaces are examples of activities that can increase tactile awareness and discrimination. In addition, manipulating objects and operating or using toys functionally (e.g., pushing buttons on a toy phone, playing with shape sorter toys with auditory feedback) helps children develop functional skills using tactile-proprioceptive and auditory information.

Children also need opportunities to explore and feel real-life objects to build multisensory associations and perceptions that ultimately become integrated and provide foundations for progression to more abstract representations (e.g., a real orange that is round, cold, fragrant, has an outside texture that can be peeled, can be separated into segments, tasted; a plastic orange and orange wedges used in kitchen and food play; a flat orange-shaped puzzle piece that fits into a puzzle board; a raised outline of an orange on paper for coloring). These experiences can help a child with visual impairment establish a mental image of the label "orange" and the color "orange" that is unique to each child based on characteristics that are meaningful to him or her.

Improve Manipulation and Fine Motor Skills

At first the world has to come to the child with visual impairment. A variety of toys and objects should be maintained within reach (e.g., tied to the crib, on the high chair or tabletop, on the floor). In addition, occupational therapists implement activities that promote general strength using upper extremity weight bearing.^{70,71} By assessing the sensory features of the toys or objects, the occupational therapist can select objects and media appropriate for the child's ability to process the information and develop manipulation skills. For example, the occupational therapist selects objects that vary in texture, or in texture and sound, or have multisensory features (e.g., sound, texture, flashing lights) and media that are typically available in school settings (e.g., sand, paint, glue, PlayDoh). Providing opportunities for the child with visual impairment to practice in-hand manipulation with activities that involve rotation and translation of small objects can improve the dynamic use of tools. Some of the activities described previously (e.g., that address sensory integration and hypersensitivity) can also be used for sensory preparation of the hands before manipulation of objects.

Maximize Use of Functional Vision

The occupational therapist should always facilitate the child's use of whatever vision is available to him or her during intervention and everyday activities. The more a child uses visual

pathways, the better vision develops.⁸ Visual awareness and discrimination activities, such as color or shape recognition and matching, are important for children with functional vision. Activities such as use of a flashlight in a darkened room for tracking games or localizing targets may also improve visual skills. The occupational therapist can also promote the child's use of low vision aids recommended by the vision care specialist such as large print books or magnifiers and any other assistive technology that may be appropriate (e.g., closed-circuit television, computers with special software).

Encourage Social Participation

Children with visual impairment are at a disadvantage in social situations, particularly at school, where typical children are active and often participate in a variety of physical games. It is difficult for children with visual impairment to signal their interest in playing with peers, and reliance on others to help them with these interactions limits their ability to experience social competence.^{20,37} It is important to provide the child with real-life activities, with specific instruction in social play, perhaps with one other child at first and then introducing other children as the child gains skills. Role playing, turn taking, and use of facial expressions with high affect and animation are strategies that can be used to facilitate social interactions. The child with visual impairment may need verbal or tactile cues to face people when speaking, to smile, and to maintain an upright posture with the head in midline. He or she must also learn to determine how others are reacting based on voices rather than gestures, facial expressions, or body language.

Strengthen Cognitive Skills and Concept Development

The child with visual impairment must consciously be taught to develop cognitive schemes that the sighted child picks up in a relatively casual manner. Concepts that cannot be touched or heard (e.g., clouds) need to be described and explained. To reiterate, it is beneficial to provide real-life, hands-on, multisensory experiences in a variety of meaningful contexts to help children with visual impairment establish the foundations for understanding concrete, functional, and abstract concepts.²¹

A variety of toys are available to help infants, toddlers, and preschoolers develop these skills. Toys that are of high interest and motivating can be incorporated to build intentionality, effective search strategies, and means-end understanding within everyday routines.²¹ In addition, shape sorters, form boards, simple puzzles, or blocks that provide auditory feedback (e.g., music, animal sounds) when inserted into appropriate openings or when connected are useful. The occupational therapists can help children with visual impairment to develop strategies such as using one hand to locate the opening tactually and placing the shape with the other hand. For older children these goals can be accomplished through games (e.g., to promote memory, classification, sorting) using different media and many simple craft activities. The unique abilities and limitations of the child must be considered in addressing goals.

These goals require the occupational therapy practitioner to educate and consult with family members, who should be encouraged to provide the child with visual impairment opportunities for engagement in activities as they would a child

without disability. Verbal and physical interaction should also be encouraged because the child may not always demonstrate behaviors that elicit interaction. Occupational therapists may consult with parents on ways to create a safe environment in which the child can play independently and make recommendations for adapting the environment to optimize independent functioning of the child.

Maximize Auditory Perceptual Abilities

The child with visual impairment must learn to identify sounds and their meanings and react to them appropriately. Sounds come from several basic sources: toys, speech, and the environment. Active, rather than passive, listening should be emphasized. Helpful activities include locating a variety of sounds in the environment, identifying sounds, and following directions from persons and recordings. In addition, the child with visual impairment must also use hearing as the primary distance sense and source for spatial information that guides his or her movement in the environment.⁶ Helping children with visual impairment to use one or two sound references in their environment (e.g., the clock ticking on the wall, a bell attached to the classroom door) will be useful to enable them to know automatically where they are and where they want or need to go in a given space. Incorporate mobile objects that have sound (e.g., balls with bells inside, toy cars that make sounds), encourage children to discover interesting sounds, and vary the volume. It is just as important for children with visual impairment to register soft sounds and to filter out irrelevant auditory information, so use of toys and activities should involve grading the intensity of sensory input accordingly to avoid overwhelming or distracting the child. Also important for the child with visual impairment is the development of echolocation skills.

Supporting the Transition to Adulthood

The adolescent with visual impairment may face significant challenges in selecting an appropriate occupation,⁴⁵ although with current technology, many more opportunities are available than in the past. Although individuals with visual impairment as a group may experience unemployment or underemployment, an appropriate match between the personality and talent areas of the adolescent and the occupational choice can lead to a successful and enduring career. Lack of exposure to vocational options is a problem that the occupational therapist can address through community orientation and various activities that provide the individual with a variety of prevocational experiences.

Many IADLs, such as cooking, cleaning, and recreation, become increasingly important as the child with visual impairment reaches adolescence. The American Foundation for the Blind (<http://www.afb.org>) provides a comprehensive list of aids and appliances that can help the adolescent with visual impairment engage in such activities.² These may include a sugar meter that dispenses half a teaspoon of sugar at a time, an elbow-length oven mitt that protects against accidental burns, kits for marking canned goods, and self-threading needles. Recreational and leisure activities such as games with braille cards, low vision cards, or board games (e.g., Scrabble, Monopoly) with braille markings are available. Because many adults with severe visual impairment lead sedentary lives, it is important to instill the benefits of physical activity early in

children's lives to promote healthy habits and routines. Organizations such as the United States Association for Blind Athletes (<http://www.usaba.org>),⁷⁵ Special Olympics (<http://www.specialolympics.org>), and community recreation programs offer sports and other physical activities in which children and youth with visual impairment can participate, train, and compete.

Specialized Professionals, Services, and Equipment for Children with Visual Impairment

Children with documented visual problems or who are suspected as having visual problems should have an examination by a pediatric ophthalmologist. Children with acuity, oculomotor, or eye alignment difficulties should also consider evaluation and treatment by a behavioral optometrist.²⁹ Occupational therapists screen for visual difficulties and provide intervention to remediate or compensate for visual impairment, in collaboration with a full medically based visual examination. Occupational therapy practitioners are uniquely trained in development and ecologic modifications for children with developmental disabilities affecting vision. However, when a child is blind or significantly visually impaired, unique and specialized technology, methodologies, resources, and supports requiring a level of specific education and training are needed. Personnel include certified low vision therapists, who evaluate and make recommendations regarding technologic supports; certified vision rehabilitation therapists (CVRT), who instruct people with blindness/visual impairment in compensatory skills and training including independent living, vocation, and education; and certified orientation and mobility specialists, who train people with significant visual impairment/blindness to access the community through nonvisual means, including the use of a white cane and leader dogs. Many of the professionals who provide services to people who are blind or visually impaired are certified in literacy braille through the National Blindness Professional Certification Board.¹ It is very important that occupational therapy practitioners recognize the need for these professionals and resources for the blind and refer children/families for these additional and essential services.

Children with severe visual impairments may rely on braille materials and talking books (e.g., those that can be listened to using devices such as compact disc and MP3 players) for their education. Braille is a system of six raised dots arranged in a cell to represent the letters of the alphabet, numbers, and words. It is produced on a special slate with a stylus or on a machine called a braillewriter. The system was developed by a young, blind French student, Louis Braille, in 1824, and was found to be more efficient than attempting to read the raised Roman alphabet. The complete Braille code consists of letters of the alphabet and contractions and words in short form.⁴⁰ Advances in technology now make it possible to use computer software and devices that incorporate Braille and/or audio formats. These devices can increase the amount and quality of written output and provide opportunities for interactive learning.

Various types of lenses are available for individuals with visual impairment, from the relatively common ones used to correct refractive errors to telescopic lenses (for viewing distant objects) and microscopic lenses (for viewing near objects) that

are used as low vision aids for certain types of vision problems. Hand-held magnifiers include those that have the lens in sturdy housing (i.e., stand magnifiers) that are placed directly onto the reading material and those that can be worn around the neck. Electronic magnification systems include closed-circuit television systems, hand-held cameras that interface with a display monitor, head-mounted systems with a camera and display unit in front of each eye, small electronic systems that combine a camera and display for portable use, and miniature LCD magnifiers.²⁴

Some occupational therapists are involved with low vision training (or vision therapy) to teach the child with visual impairment to use his or her available vision^{8,66} in collaboration with a low vision specialist (i.e., optometrist). This may involve specific activities recommended by the low vision specialist that address problems with accommodation, vergence, visual fixation and focusing, oculomotor skills, or other vision-related problems, many of which can be incorporated into the play-based or therapeutic activities that the occupational therapist already implements. In addition, practitioners may provide a variety of adaptations and accommodations, including adjusting the intensity, position, and type of light (illumination) in the environment; minimizing glare; enhancing or maximizing contrast between objects and background or surfaces; adjusting size of objects or print; changing the spacing and positioning of objects; using color selection; and adjusting the amount of time to complete tasks.¹⁹

Orientation and mobility training or instruction teaches basic skills and techniques for travel in the environment such as trailing, the human (sighted) guide technique, and protective techniques.⁴ In the *human guide technique*, the child who is blind takes the guide's arm and walks a half step behind and to the side of the guide to follow the guide's movements. For young children, an adapted grasp may be used, such as holding the guide's wrist (and progressing to the guide's elbow as the child gets older), or the child may hold the guide's index finger. This is preferred over the adult's holding the child's hand and pulling or leading the child. The human guide technique is safe and efficient and enables the child to interpret the guide's body movement (i.e., on uneven surfaces) and changes in direction.⁶ Specific verbal and tactual cues are incorporated to negotiate stairs or narrow passages or if the child with visual impairment needs to change sides.

Trailing is a technique whereby the child with visual impairment holds his or her arm at a 45-degree angle in front and to the side of the body to follow a surface (e.g., wall) with the hand. Trailing serves several functions, including protection during movement, as a method for gathering information and locating landmarks and destinations, and for alignment.⁶ The use of trailing can be enhanced when taught together with using a cane.

Echolocation is the ability to hear and interpret sound waves, which is important for orientation and travel in the environment.⁶ By using clear sound signals (e.g., a clap, tongue clicking, tapping, or a hand-held clicker) the child uses echoes produced to determine the location of objects and important features (e.g., size, general shape, density) and to detect buildings, play structures, doorways, stairs, and potential obstacles (e.g., poles, trees). Echolocation serves as a means to extend the reach of the cane to gather information at much greater distances. Some children with visual impairment develop

echolocation skills on their own without any instruction, whereas other children will need targeted intervention. The occupational therapist can collaborate with the orientation and mobility specialist to support recommended strategies that promote the development of echolocation skills.

Protective techniques can be taught to toddlers and preschoolers (depending on motor development, physical coordination, and attention span) and involve upper body and lower body techniques in which the arm is flexed with forearm held across the body with palm facing out at about shoulder height or at an angle in front of the face, or extended downward and diagonally across the body at the hip with palm facing the body. Another protection technique used in bending down to retrieve a dropped object is to extend the arm palm out in front of the head. The child with visual impairment can search for a lost object by touching the ground to establish a beginning point and then searching in an ever-widening concentric circle pattern. A technique for exploring a room involves searching the parameters of the room first, then mentally dividing it into grids to be searched methodically. This method can be used to introduce the child with vision impairment to a new classroom or new home set up. The use of landmarks and cues (e.g., the grass at the edge of the sidewalk) is beneficial for independent movement in the environment. These techniques help to protect against obstacles during movement, although the degree of protection is limited if it is the only technique used, and if used frequently the child may become fatigued.⁶ As with trailing, these techniques are more beneficial if used in conjunction with a long cane.

The orientation and mobility specialist is typically the one who teaches human guide, trailing, and protection techniques. However, occupational therapists, as well as caregivers and others who work with children with visual impairment, should learn the basic techniques to reinforce appropriate use that supports the child's interaction with the environment. *Cane technique* is a specialized procedure that requires training from a professional, but occupational therapists can promote skills and prepare young children with visual impairment for using a mobility device, particularly when co-existing conditions also affect mobility. The occupational therapist can recommend activities and provide intervention to improve balance, coordination, postural control, praxis, and prehension. The occupational therapist (and physical therapist) can also provide input and education regarding the advantages and disadvantages of the use of commercially available infant walkers or other apparatus (e.g., infant swings, jumpers) based on the postural, motor, and sensory processing of the child. Mobile toys, such as shopping carts, push toys with long handles, ride-on toys, or large balls, can be incorporated to provide movement experiences and serve as an early navigation tool as long as they are used with safety, function, and social acceptability in mind.⁶

The orientation and mobility specialist performs evaluations to determine a child's readiness for use of a cane. Various types of mobility devices are available, including long canes (e.g., with dual handles or dual grips) and polyvinyl chloride devices (e.g., with curved tips, rollers, or wheels). Specialists disagree regarding the introduction of cane use with preschoolers, arguing for and against early use; however, a child with visual impairment who is determined to be ready and is motivated to learn to use a cane will likely benefit from early introduction to its use and move toward independent mobility.

Summary

The process of occupational therapy is unique and individualized to each client. Children with blindness or who have visual impairment present with unique client factors, life challenges, and triumphs. Many children with developmental disabilities also present with visual problems. It is important that occupational therapy practitioners recognize and refer to vision professionals who are specifically trained in services for the blind/significant visual impairment when necessary. The occupational therapy practitioner utilizes occupation-based models as well as developmental and ecologic theoretical approaches to address occupational performance for children who are blind or visually impaired. The chapter's case study followed one client through childhood and three practice settings using occupational therapy interventions grounded in theoretical perspectives. Professional reasoning and specific occupational profiles and family-centered aspects of intervention planning help the occupational therapist to provide best practice with children who are blind or have visual impairment.

Summary Points

- *Visual impairment* is defined as the loss of or deficits in visual function (i.e., vision, visual perception, interpretation

of visual input) because of pathology or processing problems in one or more components of the visual system (e.g., structures of the eye, visual pathways, and the brain) that limits the individual's ability to engage in and participate in daily occupations.

- Visual impairment may interfere with a child's ability to engage in areas of occupation, which include play/leisure, eating/feeding, sleep/rest, self-care ADLs and IADLs, work/productivity, community mobility, and social participation.
- Occupational therapists collaborate with vision professionals including pediatric ophthalmologists, behavioral optometrists, certified low vision therapists, and certified orientation and mobility specialists. By understanding the important contributions of these professionals, occupational therapists make recommendations to assure children receive these essential services.
- Occupational therapy evaluation/intervention with children who are visually impaired or blind includes activities to promote development, sensory modulation, perceptual motor function, occupation-based mobility, and social participation. Full participation in life activities for people who are blind or visually impaired is the overarching goal.
- Occupational therapy practitioners using occupation-based models, including task and environment adaptation, promote the participation of infants, children, and youth with visual impairment or blindness.

CHAPTER

27

Autism Spectrum Disorder

Heather Miller-Kuhaneck

KEY TERMS

Cognitive Orientation to Daily Occupational Performance	Self-efficacy
Family-centered care	Social participation
Floortime	Social stories
Positive behavioral support	Sensory processing
Optimistic parenting	Sensory integration intervention
Parental stress	Applied Behavioral Analysis
Coping	Reciprocal Imitation Training

GUIDING QUESTIONS

1. What is autism spectrum disorder (ASD) and how does it impact the occupational performance of individuals?
2. How does ASD in one family member affect the entire family?
3. What is an occupational therapist's role in assessment and intervention in ASD?
4. How can occupational therapists assist families to improve the occupational performance of children with ASD as well as overall family functioning?

Introduction to Autism Spectrum Disorder

Autism spectrum disorder (ASD) is a neurologic disorder seen most commonly, but not uniquely, in boys. First described 70 years ago,¹¹⁰ according to the current *Diagnostic and Statistical Manual*, fifth edition (DSM-5), the symptoms of ASD cluster in two primary categories of functioning: social interaction and repetitive and restrictive behaviors.⁹ Symptoms may be evident at a young age, but diagnosis is typically made during the preschool years. With a wide diversity of potential symptoms of ASD and varying levels of severity, each child presents with a unique compilation of strengths and weaknesses that will impact occupational performance for the child and family in differing ways.

History of the Diagnosis

The diagnosis of ASD has a lengthy history. Authors have speculated that case reports from the 1700s and 1800s may document individuals who had autism.⁷³ However, the first

cases in the research literature were published in 1943 by Dr. Leo Kanner. Unfortunately for many families, Kanner considered the 11 individuals whom he labeled autistic to suffer from social withdrawal in response to poor parenting.¹¹⁰ This view, broadcast in a *Time* magazine article in 1960, suggested children with autism had a “cold” mother who was able to “defrost enough to produce a child”^{28,209} and even suggested “parentectomy,” a treatment in which children were removed from these rejecting and unfeeling parents. This flawed accounting of the role of parenting in autism persisted for decades. See Table 27-1e on the Evolve website for resources regarding the history of the diagnosis of ASD.

In the first two editions of the DSM^{4,5} ASD was not included as an accepted diagnosis, and individuals with ASD were often diagnosed with schizophrenia.¹¹¹ A diagnosis of infantile autism was defined under the umbrella term *pervasive developmental disorder* in the third edition of the DSM in 1980.⁶ The label was changed to autistic disorder in 1987.⁷ In the fourth edition of the DSM⁸ the diagnostic criteria for autism disorders were broadened.¹⁰ The umbrella term of pervasive developmental disorder included five individual categories: autism, Asperger's syndrome, Rett's syndrome, childhood disintegrative disorder, and pervasive developmental disorder—not otherwise specified. Researchers demonstrated that the boundaries around these categories were indistinct, and for many years researchers and professionals used the term “autism spectrum disorder” to describe the entire range of individuals who demonstrated behaviors associated with autism.

Recent Diagnostic Changes

The DSM-5⁴ made significant changes to the diagnostic criteria and labeling for ASD. For example, Asperger's disorder is no longer a distinct diagnostic label. These changes have been somewhat controversial, as parents and professionals worried about the impact of these changes on individuals who could lose their diagnosis if they no longer meet the new criteria for ASD.⁴⁹ It is possible that the new diagnostic criteria may exclude up to 40% of individuals previously diagnosed under the older criteria of the DSM-IV.¹⁴³ One addition to the DSM-5 ASD diagnosis is the inclusion of criteria regarding unusual responses to sensation, an area of assessment and intervention that has historically resided primarily within the profession of occupational therapy. The opportunities for occupational therapists to emerge as leaders on the health care team in this arena are substantial.²²¹ Box 27-1 includes information about the current diagnostic criteria in the DSM-5. The revisions to the diagnostic criteria over time have occurred in response to

BOX 27-1 Autism Spectrum Disorder**Diagnostic Criteria**

A. Persistent deficits in social communication and social interaction across multiple contexts, as manifested by the following, currently or by history (examples are illustrative, not exhaustive, see text):

1. Deficits in social-emotional reciprocity, ranging, for example, from abnormal social approach and failure of normal back-and-forth conversation; to reduced sharing of interests, emotions, or affect; to failure to initiate or respond to social interactions.
2. Deficits in nonverbal communicative behaviors used for social interaction, ranging, for example, from poorly integrated verbal and nonverbal communication; to abnormalities in eye contact and body language or deficits in understanding and use of gestures; to a total lack of facial expressions and nonverbal communication.
3. Deficits in developing, maintaining, and understanding relationships, ranging, for example, from difficulties adjusting behavior to suit various social contexts; to difficulties in sharing imaginative play or in making friends; to absence of interest in peers.

Specify current severity:

Severity is based on social communication impairments and restricted, repetitive patterns of behavior.

B. Restricted, repetitive patterns of behavior, interests, or activities, as manifested by at least two of the following, currently or by history (examples are illustrative, not exhaustive, see text):

1. Stereotyped or repetitive motor movements, use of objects, or speech (e.g., simple motor stereotypes, lining up toys or flipping objects, echolalia, idiosyncratic phrases).
2. Insistence on sameness, inflexible adherence to routines, or ritualized patterns of verbal or nonverbal behavior

(e.g., extreme distress at small changes, difficulties with transitions, rigid thinking patterns, greeting rituals, need to take same route or eat same food every day).

3. Highly restricted, fixated interests that are abnormal in intensity or focus (e.g., strong attachment to or preoccupation with unusual objects, excessively circumscribed or perseverative interests).
4. Hyper- or hyporeactivity to sensory input or unusual interest in sensory aspects of the environment (e.g., apparent indifference to pain/temperature, adverse response to specific sounds or textures, excessive smelling or touching of objects, visual fascination with lights or movement).

Specify current severity:

Severity is based on social communication impairments and restricted, repetitive patterns of behavior.

- C.** Symptoms must be present in the early developmental period (but may not become fully manifest until social demands exceed limited capacities, or may be masked by learned strategies in later life).
- D.** Symptoms cause clinically significant impairment in social, occupational, or other important areas of current functioning.
- E.** These disturbances are not better explained by intellectual disability (intellectual developmental disorder) or global developmental delay. Intellectual disability and autism spectrum disorder frequently co-occur; to make comorbid diagnoses of autism spectrum disorder and intellectual disability, social communication should be below that expected for general developmental level.

Note: Individuals with a well-established DSM-IV diagnosis of autistic disorder, Asperger's disorder, or pervasive developmental disorder not otherwise specified should be given the diagnosis of autism spectrum disorder.

research findings and to changing needs of the medical and scientific community. Although important, these modifications have also created difficulty in determining real changes in ASD prevalence over time.

Prevalence

Research indicates a rise in the prevalence of ASD. During the 1960s and 1970s, ASD reportedly occurred in as few as one per 10,000 children.³² Although it is likely that early prevalence studies drastically underestimated ASD rates,¹⁹⁰ research since the 1990s indicated a substantial increase. By 2007, the Centers for Disease Control and Prevention (CDC) reported one in 150 children with ASD, an increase from one in 166 just 2 years earlier.⁴² The Centers' figures suggested an average prevalence of one in 110 children in 2009¹⁸¹ and one in 88 in 2012.¹⁶ A national survey conducted by Kogan et al. (2009) reported a prevalence of one in 91 children 3 to 17 years of age, or 1% of the population. Most recently, a prevalence rate of 1 in 50 was reported.¹¹⁹

Causal factors for the change in prevalence are unclear, and many potential mechanisms require further exploration. However, regardless of causal factors, the current reported prevalence suggests that ASD is now the second most common developmental disability in the nation. The lifetime use of services by individuals with ASD therefore reflects a large public

health burden.^{32,37,163} The increasing prevalence suggests considerable public health implications, including societal and familial costs associated with raising and educating a child with ASD.^{74,83,153-155}

Occupational Performance in Autism Spectrum Disorder

Autism spectrum disorder may impact any and all areas of occupation but research suggests that certain types of occupational performance issues are more common than others.

Social Participation

Social issues are a hallmark of this disorder. Friendship and social inclusion requires different skills at different ages.⁵⁹ Very young children often imitate others to begin to form friendships,²²⁰ whereas preschoolers exhibit more advanced communication skills, positive affect, conflict negotiation, and pretend play to engage in friendships with peers.^{96,220} Older children and teens need shared activities, frequently sports related or online, and experiences away from adult supervision. Often children with ASD have difficulty with imitation, communication abilities, sharing similar interests with their peers, and playing with pretense and ideation. They may need supervision past an age when

typically developing children require direct adult contact. For many children with ASD, therefore, forming friendships can be extremely difficult. The child's verbal and social-cognitive skills influence his or her ability to form and maintain friendships.^{23,24} Although friendships of children with ASD can be both similar to and different from friendships between typically developing dyads, research suggests that children with ASD have limited friendships, may have trouble understanding what friendship means, and are lonely.^{22,40,126,129} The Internet and online gaming is often one way to help children with ASD and typically developing peers develop friendships.

As children with ASD become teens and adults, social participation difficulties can continue. Many teens and young adults are underemployed or unemployed and socially isolated; furthermore, resources and programs for this age group are few.^{206,207} Although many individuals desire and engage in romantic and sexual relationships, these can be difficult for some.^{38,39,204} Social skill difficulties, communication problems, and sensory processing issues can hinder the development of fulfilling romantic and sexual relationships.^{107,158,202} Some individuals do not understand appropriate courtship behaviors and may find themselves in trouble with the law for behaviors others consider dangerous or threatening. Limited research exists to guide professionals in determining the most successful interventions for this age group.²⁰⁸ Most communities lack resources and opportunities for socialization, employment, and dating for persons with ASD. (See Figure 27-5.) One cinematic depiction of these issues, *Mozart and the Whale*, heightens awareness of the relationship, friendship, and employment issues through a story of two young adults with ASD.

Play

Children with ASD do play, although their chosen play may appear atypical.^{56,198} Beginning in infancy, both extreme preoccupation with and unusual use of objects are noted.^{20,169,223-225} Uncommon use of objects may include unusual visual exploration, preoccupation with object features, limited flexibility and creativity in the use of objects, and repetitive use of objects.^{20,136,224} Many studies of children with ASD suggest that children engage in sensory exploration of objects beyond an age when sensorimotor play is expected^{223,224} and that they engage in more exploratory and sensorimotor play than typically developing children.⁵⁵ Children with ASD also perform differently in natural free play, with brief play episodes and frequent selection of solitary sensorimotor play and functional play.^{94,95}

Functional play consists of using objects as their form suggests, such as pushing a toy car, bringing a play spoon to the mouth, or pushing a train on a track. Although frequency of functional play seems similar in children with and without an ASD,⁴³ these groups differ in duration or the quality of the play.^{223,224} Children with an ASD, when compared with language or mental age-matched controls, spend less total time in functional play,¹⁰⁵ and functional play is reported to be less varied and more repetitive, as would be expected considering the diagnostic criteria of the disorder.

Studies support the idea that children with ASD have specific difficulty with generating flexible and novel ideas for play and engaging in play in a way that indicates spontaneity and pleasure.^{134,135} Symbolic play of children with ASD has been studied most extensively. Jarrold¹⁰⁴ provides a review suggesting children with an ASD are less likely to engage in pretend

play and spend less total time in pretend play. However, children with an ASD are capable of pretending,^{93,105,106} in particular when pretense is elicited or prompted by an adult.

Sleep

Children with ASD commonly exhibit problems with sleep. Sleep studies using parent report, sleep diaries, actigraphy (a measure of body movements during sleep), or polysomnography (a full sleep study with measurement of brain waves, heart rate, breathing, and movement) have led to findings supporting disordered sleep in ASD.¹⁸² Children with ASD tend to have difficulty falling asleep and staying asleep and often wake early.^{171,176,182,196} Studies suggest that these sleep disturbances are highly prevalent; between 40% and 73% of children with ASD are reported to have sleep difficulties.^{121,176,182} Eighty percent of the parents of children with autism and 60% of the parents of children with high functioning autism reported that their own sleep was disturbed because of their child.¹⁷⁶ Difficulties with settling to sleep at night or with night waking are often associated with problems with bedtime routines,^{171,182} and bedtime routines are difficult to develop.¹²⁸ Sleep problems in ASD have also been associated with other ASD symptoms as well as both internalizing and externalizing behavior problems,¹⁷¹ suggesting the importance of sleep for both children and parents.

Activities of Daily Living

Because self-care routines are patterned behavior, children with ASD often learn and perform many self-care skills independently.¹³⁰ However, researchers have documented delayed self-care performance in children with ASD. For example, in one study, 49% of the sample of children with ASD scored 2 SD below the mean on the WeeFIM and moderately low on the Vineland Adaptive Behavior Scales.¹⁰⁶ Parents report their child to have difficulties with feeding and toileting in particular.^{2,142} Children with ASD may have very limited diets, require special diets because of food allergies, or be placed on special diets by their parents.^{137,150,161} Parents of children with ASD also reported difficulties with oral care and dental visits.²⁰¹

Feeding, dental care, and toileting issues may relate, in part, to sensory processing difficulties. For those with sensory modulation issues, tolerating the sensory experiences that are characteristics of dressing, bathing, and toileting can create difficulty or reluctance to perform. Dressing requires toleration of fabric textures, the edges of sleeves rubbing on skin, the feel of elastic waistbands, and the rubbing of clothing tags on the back of the neck, for example. Bathing requires toleration of water temperature, the tactile experience of water moving over skin, the smell of soaps and shampoos, and the feel of towels or washcloths. In addition, washing one's hair may require leaning backward with one's eyes closed, a scary motion for someone with vestibular difficulties. Toileting requires the experience of wiping with toilet tissue, perhaps the feeling of water spray as the toilet flushes, and the noise of the flushing water.

Education

The educational needs of children with ASD are as varied as the children themselves. Given the wide range of ability, all that can be stated with certainty is that many children with ASD require accommodations to their educational program. These

accommodations may be necessary for the child to fully participate in academic tasks, classroom and social activities, and the school's sensory environment. Some children with ASD (e.g., those with average or above average IQ) are fully included in general education classrooms; others receive special education services; and the most involved may be placed in separate centers specifically designed for children with ASD. Even for children with typical cognitive ability, academic achievement may not match their intellects because of social difficulties and behavioral concerns.⁶⁹ Parents may need assistance in selecting appropriate educational placements for their child, and this can be very challenging decision.⁵⁴

Performance Patterns

Given that one of the characteristics of ASD is restricted and repetitive behaviors, it is unsurprising that children with ASD have specific needs for routine and predictability. These needs can have a significant impact on the development of family routines that work for the whole family. Families may have difficulty with various family routines, and participating in activities in and outside of the home can be particularly stressful or chaotic.^{15,141,193} Families may adopt highly structured home and mealtime routines to accommodate their children's rigid behaviors, and when engaging in activities outside the home, may adopt a model of extreme flexibility.^{53,130,193} Mothers report excessive planning to be one effective strategy,¹²³ and in general family activities often are scheduled to revolve around the needs of the child with ASD.^{4,53,193} The balancing act between the need for predictable routine for the child and excessive flexibility for other family members may be particularly difficult for some families. Some families may avoid social events and activities outside the home, resulting in social isolation.²²⁸

Performance Skills and Client Factors

Children with ASD can have difficulties with all of the performance skills, including communication, social, emotional regulation, motor, praxis,^{11,13,200,219} and sensory perceptual skills.^{140,212} Difficulties with sensory processing have been documented in individuals with ASD as early as 1943, when Kanner described individuals with fear of noises from machines, who repeatedly watched bowling pins fall, who sought out movement on swings, and who mouthed objects and flicked lights.^{27,110} described the first sensory-based hypothesis of autism whereby they believed children were overly sensitive and therefore developed defenses to the social world. In the 1960s, Rimland developed an underarousal hypothesis suggesting that the reticular activating system was functioning improperly, impairing the child's ability to learn through pairing current and past sensory experiences.¹⁸³ Atypical brain activity with electroencephalogram recordings suggests that physiologic overarousal in autism influences many autistic behaviors.⁹⁷ In addition, chronic arousal may lead to blocking of new stimuli and related gaze aversion.⁹⁸ Ayres¹⁴ identified common difficulties in sensory processing seen during her intervention with children with autism.

Current research suggests that a majority of individuals with ASD have various sensory processing and praxis difficulties that are present across the life span and highly variable across individuals.^{25,46,75,106,195} Personal accounts suggest that individuals with ASD can articulate the impact of sensory processing

difficulties on their daily lives.^{77,108,118} These sensory processing deficits may be linked to social difficulties and problem behaviors in the ASDs,^{17,91} motor and postural difficulties,¹⁵² academic performance,¹² adaptive behavior,¹⁸⁸ daily living skills,¹²⁷ and restricted and repetitive behaviors.^{44,109,222} Recent studies have also linked sensory reactivity to anxiety,^{45,81} suggesting that stress responses to daily typical sensation may be atypical in the ASDs and may relate to the development of anxiety.

Research illustrates processing issues that range between behavioral hypersensitivity and hyposensitivity, as well as neurologic hyporesponsiveness and hyperresponsiveness. Poor auditory filtering and sensory seeking are both commonly reported areas of difficulty with this population.^{12,127,213} The evidence appears strongest for hyporesponsivity in the ASDs.^{25,189,195} It appears that habituation is intact in individuals with an ASD, whereas orienting responses may not be, at least at young ages.^{21,130,195} Simple sensory recognition may be intact, whereas more complex sensory perceptual functions may not.¹⁵²

Although sensory processing dysfunction in general is not unique to the ASDs,^{21,165} specific patterns of processing may be unique. Specific sensory items have been examined to determine those that best discriminate individuals on the autism spectrum.^{19,21,112,133,188,213,222} These include overreactions to sounds; overreactions to touch, tastes, and smells; atypical visual exploration of objects; poor eye contact; and lack of response to name or the inability to orient to one's name. Other important behaviors in discriminating children with ASD include excessive mouthing of objects and social touch aversions.¹⁹

Motor skill difficulties were somewhat ignored for many years, because often motor performance was a relative strength for individuals with ASD. However, a growing body of research has documented the motor difficulties common in this population.^{29,200} Common motor concerns include poor gait, posture, balance, coordination, imitation, and praxis. Fairly consistent results suggest that imitative impairments are common in children with ASD.^{200,226} Some research suggests that imitative deficits may be one of the best discriminators between individuals with and without ASD,²⁰³ and the diagnosis of autism may be the best predictor of imitative deficits.²¹⁵ Children also demonstrate dyspraxia, that is, motor planning difficulty.^{57,66,139,157}

Individuals with ASD demonstrate specific difficulties with one type of executive function called *generativity*, which is a skill in generating novel or creative thoughts and actions.^{30,35,184} Poor generativity has been linked to difficulties with communication and repetitive behaviors, but occupational therapists well versed in sensory integration (SI) theory might also consider how these deficits reflect ideational praxis related to play skills and ADLs.

Family Impact

The considerable health care needs of a child with ASD, combined with the behavioral characteristics of the disorder, have a substantial impact on the entire family. Access to care varies by community, and in a survey of parents, 89% reported they were the primary case coordinator for the child with ASD.¹⁴² More than 25% of parents report that they spend more than 10 hours per week coordinating services for their child with ASD.¹²⁰ The difficulties of coordinating care and finding appropriate care can create a significant amount of stress for the family.

Consistently parents of children with ASD report higher stress levels when compared with the parents of children with other disabilities.^{153,159,194} In addition to the financial and access-to-care issues, other stressors associated with raising a child with ASD include significant and lengthy child-rearing needs and the need to have highly structured and regular routines that can restrict family lifestyle and create social isolation.^{31,48,53,128,194} Responses from the 2003-2004 National Survey of Children's Health indicated that parents of children with ASD, when compared with the parents of children with attention-deficit disorder or no disability, feel a greater burden of care for their child and a lower quality of life.¹³² These parents reported less community involvement, less attendance at religious services, and less child participation in organized events.

Mothers of children with ASD have reported the demands of child-rearing as overwhelming, nonstop, and often leaving them feeling powerless.⁵³ Maternal stress is related to child symptoms of dysregulation such as poor sleep, poor eating, and sensory sensitivity.⁴⁸ The problem behaviors in the child with ASD have been associated with higher levels of family stress; specifically, maladaptive behaviors are likely to disrupt family socialization by limiting the ability of the family to participate in social events.^{48,84,88,103,210,211} Mothers of children with ASD with more common or severe restrictive repetitive behaviors or poorer adaptive behaviors report greater perceived negative impact.³¹

Mothers of children with ASD tend to carry the majority of the child-rearing burden and, therefore, often report greater levels of stress than fathers. Mothers also report a lower quality of life and poorer physical and mental health than fathers.^{3,78,85,86,88} Older research that focused specifically on mothers of children with ASD found a fairly consistent stress profile in the mothers, regardless of their culture, geographic location, and age and functioning of their child with ASD.¹¹⁷

In addition to parental effects, research documents that having a sibling with a disability can impact sibling relationships.¹⁴⁴ Interactions between brothers and sisters provide children with their first socialization experiences, and the sibling relationship is a unique interaction that provides opportunities for social development. Sibling relationships are often the longest-lasting of all human relationships. In the ASD population, the importance of the sibling relationship increases because of the potential role of the sibling as a future caregiver. It is important to encourage and promote the development of positive, meaningful, and caring sibling and family relationships. It is also important for the coping and resiliency of the whole family that all family members are included. Sibling relationships within the family are complex and many factors interact to predict how well typically developing siblings adjust to a sibling with ASD in the family.¹⁴⁶

Siblings report a variety of difficulties related to living with a sibling with ASD.¹²² Some of the issues for typical siblings include loneliness, jealousy in relation to unequal parental attention, difficulty in understanding varied rules for behavior for each sibling, aggression from the sibling with ASD, and the possible need to take on a caretaking role for their sibling with ASD. However, research also shows that most siblings of children with ASD are well adjusted and may learn prosocial and positive behaviors from the experience.¹⁴⁴

The Role of Occupational Therapy in Autism Spectrum Disorder

Best practice places the occupational therapist within a well-functioning and cohesive multidisciplinary team focused on assisting the family of a child with ASD as well as the child. Each team may have slightly different divisions of functions, and the role of an occupational therapist may overlap somewhat with that of a physical therapist, speech therapist, behaviorist, or teacher. Families value the contribution of occupational therapy practitioners and parents report that occupational therapy intervention is the third most commonly used intervention for individuals with ASD; intervention for SI dysfunction, also commonly provided by occupational therapists, is ranked fifth.⁹⁹

Evaluation

The occupational therapist's evaluation of the child with ASD includes an occupational profile and assessment of occupational performance¹¹; however, characteristics of ASD may require alternative assessment strategies, such as alternative communication methods. Information may need to come primarily from a parent or caregiver and through observation. Specific observational strategies to attempt to understand the importance of meaning behind unusual child behaviors may be most successful in understanding the child's occupational performance.¹⁹⁸

Occupational therapists may experience difficulties using certain standardized norm-referenced assessments with this population because of child problems with communication, attention, motivation, or behavior.^{1,116} Adaptations of standardized assessments frequently required to engage the child include allowing the child to become familiar with the therapist and the testing area before beginning, providing breaks between tasks, allowing parental presence, using motivators and rewards for task completion, limiting eye contact or verbal interaction, providing additional time to process verbal requests, or changing the order of item administration regarding preferred and nonpreferred tasks. Any scores obtained following modification of standardized procedures must be considered only estimates of ability, and any reports should clearly indicate which modifications were made to procedures and why.

A variety of tools have been developed specifically for children with ASD, particularly for screening or diagnosis. See [Table 27-1](#) for an overview of potential assessment tools that may be used in evaluation of a child with ASD. Therapists should be aware that many of these tools are designed to find problems and difficulties; therefore, therapists must also be careful to take time to determine the child's strengths and abilities.

Occupational therapy evaluations must focus on function as well as determining the cause of the child's difficulties. Identifying what is currently working for the child and family can inform specific interventions for performance difficulties. For example, finding that a child has strong visual skills and ability to read written instructions may lead the therapist to suggest using clearly written instructions, perhaps with photos, to prompt the child through difficult tasks in the home or classroom. See [Box 27-2](#) for specific classroom assessment considerations. (See [Figure 27-6](#).)

The therapist collaborates with the family to determine which issues and difficulties are priorities for the family.

TABLE 27-1

Specific Assessment Tools Used with Children at Risk for or with Autism Spectrum Disorder

Tool Name	Authors	Publisher and Website	Type of Tool and Areas Assessed
Modified Checklist for Autism in Toddlers (MCHAT)	Robins, Fein, & Barton	Available online for free, http://www2.gsu.edu/~psydlr/Diana_L._Robins_Ph.D._files/M-CHAT_new.pdf ; http://www2.gsu.edu/~psydlr/DianaLRobins/Official_M-CHAT_Website.html	Screening for ASD in toddlers 16-30 months
Screening Tool for Autism in Toddlers and Young Children (STAT)	Stone & Ousley	Vanderbilt University, http://stat.vueinnovations.com/	Screening for ASD 24-36 months
The First Year Inventory (FYI)	Baranek, Watson, Crais, & Reznick	Information available through UNC School of Medicine, http://www.med.unc.edu/ahs/pearls/research/development-of-the-first-year-inventory	Screening for 12-month-old infants to identify those at risk of ASD
Childhood Autism Rating Scale (2nd ed.) (CARS-2)	Schopler, Van Bourgondien, Wellman, & Love	WPS http://portal.wpspublish.com/portal/page?_pageid=53,265699&_dad=portal&_schema=PORTAL	Diagnostic test for ASD
Gilliam Autism Rating Scale (3rd ed.) (GARS-3)	Gilliam	WPS http://portal.wpspublish.com/portal/page?_pageid=53,70079&_dad=portal&_schema=PORTAL	Diagnostic test for ASD
Autism Diagnostic Observation Schedule (2nd ed.) (ADOS-2)	Lord, Rutter, DiLavore, Risi, Gotham, & Bishop	WPS http://portal.wpspublish.com/portal/page?_pageid=53,288914&_dad=portal&_schema=PORTAL	Diagnostic test for ASD
Autism Diagnostic Interview—Revised (ADI-R)	Rutter, Le Couteur, & Lord	WPS http://portal.wpspublish.com/portal/page?_pageid=53,70436&_dad=portal&_schema=PORTAL	Diagnostic test for ASD and also used for research and intervention planning
Developmental, Dimensional and Diagnostic Interview (3di)	Skuse, Warrington, Bishop, Chowdhury, Lau, Mandy, & Place	Institute of Child Health, University College London http://www.ixdx.org/3di-index.html	Computer-based diagnostic test for symptoms of ASD. The authors suggest that the 3di is similar to the ADI-R but focuses on current behavior and therefore has high levels of agreement with ADOS
Diagnostic Interview for Social and Communication Disorders (DISCO)	Wing, Leekam, Libby, Gould, & Larcombe	Centre for Social and Communication Disorders http://www.autism.org.uk/our-services/diagnosing-complex-needs/the-diagnostic-interview-for-social-and-communication-disorders-disco.aspx	Diagnostic schedule for ASD and helps with assessment of individual needs
Autism Treatment Evaluation Checklist (ATEC)	Bernard Rimland & Stephen M. Edelson	Autism Research Institute http://www.autism.com/index.php/ind_atec_survey	Checklist/questionnaire completed by parents, teachers, or caretakers
Autism Screening Instrument for Educational Planning (3rd ed.) (ASIEP-3) (This includes the Autism Behavior Checklist)	Krug, Arick, & Almond	Pro-Ed http://www.proedinc.com/customer/productview.aspx?id=4217	Norm-referenced assessment to identify ASD and assist in planning educational programs
Assessment for Mothers of Children with Autism (AMCA)	Lewis, Ujcic-Snyder, Rider, & Fisher	Available through http://www.misericordia.edu/images/ot/AMCA.pdf	Interview guide for mothers of children with ASD, in relation to their stressors and coping strategies
The Motivation Assessment Scale (MAS)	Durand	Available online from http://store.monacoassociates.com/masenglishbundle.aspx For a sample one filled out with a case, see http://fba-behaviorsupport.wikispaces.com/file/view/motivation+assessment+scale.pdf	A Likert scale that examines a child's motivations for particular behaviors

Watling (Eds.), *Autism: A comprehensive occupational therapy approach* (3rd ed.). Bethesda, MD: AOTA Press.

BOX 27-2 Important Considerations for Evaluating the School Environment for a Child with Autism Spectrum Disorder

- What are the expectations for this child in the classroom/school? Consider the different expectations for the teacher, parent, other professionals, and the child's peers. If there is a problem with classroom performance, whose problem is it? (Is this issue bothering the child or the teacher?)
- What does the student want to participate in at school?
 - Social activities (school dances, pep rallies, organized sporting events)
 - Recreation (recess, physical education, playground, art)
 - Communal activities (assemblies, field trips, eating in the cafeteria)
 - Creative activities (orchestra, band, chorus)
 - Civic activities (school paper, student government, school clubs)
 - Academic (labs, library)
- Is the child participating in the activities he or she desires? If not, what is getting in the way?
- Does the student have friends in the classroom or school? If not, what is hindering the development of friendships?
- How much choice is available throughout the day? How much is the student allowed choice in his or her activities and use of time?
- How predictable is the day? Does the child know the schedule and routine? How often does the routine change and how much notice is there when a change will occur?
- How does the child's performance and behavior change, based on time of day or classroom activity?
- Are there any problem behaviors in the classroom that are disruptive to the child, the classroom activities, the teacher, or peers? If so, which interventions have already been tried? What is the teacher's perception of what initiates the problem behavior?
- How are instructions given to the child in the classroom? How well are they followed?
- How is this child able to communicate or demonstrate that he or she is learning the academic content?
- Does this child use peers as a model for behavior or learning of academic content?
- How does the child respond to the classroom sensory environment?
- What are the sensory characteristics of the lunch room, playground, and gym (noise, lighting, seating, physical proximity, and number of peers), and what is required of the child socially in those settings?
- How does the teacher manage fire drills and other safety drills? What are the school lockdown procedures for a student with special needs?

The occupational therapist asks about what is working for the family and what they love and enjoy about their child. The team considers the family's perspectives, acknowledging that the family members may have very different needs and feelings about the diagnosis.¹⁶⁷ For certain children with ASD, safety or escapism is a concern, but this concern may not be voiced unless the therapist asks specific questions about the child's behaviors in unsafe environment (e.g., crossing the street, at the grocery store). **Box 27-3** lists important questions to ask a parent about a child with ASD during an evaluation. Best practice is to presume parental competence, caring, and intelligence at all times.

BOX 27-3 Important Questions to Ask Families During an Evaluation

- What are your most pleasurable interactions with your child? Why?
- What do you love most about your child?
- What do you consider to be the strengths of your family? What works well?
- What have you already tried that works best for you?
- What routines do you have in place for your family? Are they working? With which routines are you having difficulties?
- How do you participate in family celebrations and holidays?
- Do you have any concerns for your child's safety?
- Are you satisfied with your ability to communicate and interact with your child?
- Does your child participate in decision making? How? (if age appropriate)
- If your child has siblings, what is their relationship and do you have any concerns? How do they play and interact together? How do you handle sibling conflicts?
- Do you feel satisfied with your ability to be social with others or are you feeling isolated in any way? Do you have or need respite care?
- Which interventions or accommodations have you already tried that didn't work? Why do you think that was?
- What information do you feel you need about your child?
- Are you satisfied with the services you have received so far?

From Miller-Kuhaneck, H., & Britner, P. A. (2013). A preliminary investigation of the relationship between sensory processing and social play in autism spectrum disorder. *OTJR: Occupation, Participation and Health*, 33(3):159–167.; Watling, R. (2010). Occupational therapy evaluation for individuals with an autism spectrum disorder. In H. Miller-Kuhaneck & R. Watling (Eds.), *Autism: A comprehensive occupational therapy approach* (ed. 3, pp. 285–304). Bethesda: AOTA Press.

Family-Centered Practice

Family-centered practice stems from a set of beliefs and attitudes that value the uniqueness of every family and recognize the reality that the family is the constant in any child's life. Collaboration and family choice are key principles of family-centered care. Optimal functioning for any child occurs in a family that is supportive and involved in the child's care, and to provide the best care, the strengths and needs of all family members are considered.¹¹³

To communicate with families in ways that support and encourage their involvement and ability to make informed decisions about their children, the occupational therapist considers how communication reflects interpersonal power.^{72,179} Expert power is the power that comes with having knowledge and skill that another does not have, and informational power comes from one person influencing another with logical information. If the caregiver changes because the occupational therapist is an expert and must know best, the occupational therapist has exerted expert power. However, if a caregiver changes because he or she has listened to the therapist and then made a decision for himself or herself, the occupational therapist has used informational power effectively. Occupational therapists working with children and families must strive to empower families to develop their own knowledge, strengths, and problem-solving abilities rather than fostering ongoing need of us and our knowledge and skill.

Coaching is a method to use informational power in a model of family-centered care. As described in Chapters 5 and 11, in coaching, the occupational therapist observes, listens, and guides the parent to learn skills helpful in managing and/or promoting skills in the child. The information is shared in such a way that allows the parent to consider it fully and make his or her own decision. Occupational therapists who listen carefully, use more indirect verbal behaviors, and allow family members to express their thoughts and feelings³⁶ support collaborative communication. A strategic tenet of a family-centered approach is that professionals listen actively to families and acknowledge and address families' concerns and needs. Reflection of feelings is an important skill during active listening and assists families in clarifying their concerns. By accepting families' feelings and demonstrating acceptance they may become better able to accept their own feelings. In addition, praising, encouraging, and accepting family ideas allow families to become more involved in their child's therapy and care.³⁶

Another important skill in family-centered practice is to share information as one is gathering it. Particularly during initial meetings with the family, the parents may have little understanding of the role of occupational therapy. As the occupational therapist is asking questions of the family during an evaluation, it can be very helpful to also explain *why* the questions lead to understanding their child's behaviors. As the family learns more about the team's clinical reasoning, the family becomes better at providing relevant information spontaneously. In addition, occupational therapists can help families learn how to create natural learning opportunities in their day-to-day lives⁶²; these successes should enable and empower, improving parental self-efficacy.^{60,61} These approaches are consistent with a strengths-based approach that parents report they desire.¹¹⁴

Interventions

Occupational therapists working with children with ASD provide interventions for all areas of occupation. Because multiple chapters in this text discuss specific intervention options for pediatric occupational therapy, this section highlights intervention methods and strategies common in ASD. Interventions described in this text for social participation (see Chapter 12), self-care (see Chapters 15 and 16), educational performance (see Chapters 10, 18, and 23), play (see Chapter 17), motor skills (see Chapters 7 and 8), assistive technology (see Chapter 19), and dealing with problem behaviors (see Chapter 13) often apply to children with ASD. Clinical guidelines for the treatment of ASD have also been published (Table 27-2).

The interventions for ASD generally fall into one of two categories, adult directed and compliance based or naturalistic and more child directed and playful. Children with ASD often do not appear motivated to do the learning tasks typical of school and child growth and development. Often the activities that they are motivated to do appear strange and unusual to typically developing peers and adults. Therefore professionals need to decide whether to approach the child from a position of gaining compliance with the "work" that needs to be done or to try to achieve learning through more playful means using the child's inherent preferences.

Specific Intervention Approaches

An abundance of intervention approaches are purported to help with symptoms and behaviors of ASD. As part of our role

helping families gather the information they need to make decisions, occupational therapists must be aware of these approaches and the evidence that supports or refutes them.¹⁶² It is beyond the scope of this chapter to fully review each one, but the informed occupational therapist working with a child with ASD should feel comfortable describing these interventions and providing a family with resources to consider their purpose, effectiveness, safety, and costs (Table 27-3). A few of the approaches most commonly used by occupational therapists are highlighted in the following.

Applied Behavior Analysis

To date, many interventions used with children with an ASD are based on theories of external motivation crafted within the behavioral framework initially developed by Pavlov, Watson, and Skinner primarily through the study of animal behavior.^{82,71,197,217} These early theories focused on drives as the guiding force behind human behaviors.⁵² In behaviorism, the belief is that learning occurs through a change in behavior brought about by external experiences. Behavior can be

TABLE 27-3 Interventions for Children with Autism Spectrum Disorder

Intervention Name	Web Link	How Used in Occupational Therapy
Reciprocal Imitation Training (RIT)	http://www.ncbi.nlm.nih.gov/pmc/articles/PMC3686149/	Occupational therapists can use imitation to increase engagement and interaction with a child with ASD. This is particularly useful when a child is avoiding the therapist or disengaged. The occupational therapist imitates the child until the child makes some indication of connection or interaction (a look, touch, smile). For evidence of the efficacy of this type of approach, see http://psychology.msu.edu/autismlab/publications.html . The evidence for imitation models is considered to be emerging.
Relationship Development Intervention (RDI)	http://www.rdiconnect.com/pages/Home.aspx	Focuses on coping with change, being more flexible, and integrating information from multiple sources. There is currently minimal evidence of efficacy, but research is occurring. The evidence for relationship-based models is considered to be emerging.
Treatment and Education of Autistic and related Handicapped Children (TEACCH)	http://www.teacch.com/	Occupational therapists can incorporate many of the visual support strategies into their sessions. See Eikeseth ⁶⁷ ; Mesibov & Shea, 2010 for information about the research that has been completed to examine the efficacy of this program. Efficacy is unclear at this time but one review suggests it was beneficial for improving motor skill and cognition (see http://www.effectivehealthcare.ahrq.gov/ehc/products/106/656/CER26_Autism_Report_04-14-2011.pdf). TEACCH is considered an emerging approach.
Early Start Denver Model	http://www.autismspeaks.org/what-autism/treatment/early-start-denver-model-esdm	Occupational therapists can use strategies from this model that focus on joint attention and shared interaction using a naturalistic applied behavioral approach. Well-designed studies of the Early Start model have documented effectiveness in improving IQ, language, and autism symptoms (Dawson et al., 2010). Also see http://www.effectivehealthcare.ahrq.gov/ehc/products/106/656/CER26_Autism_Report_04-14-2011.pdf . This model is considered established.
Miller Method	http://millermethod.org/	Occupational therapists can use many of the strategies to increase attention (i.e., carefully adding to the number of steps needed to achieve a desired goal or using raised surfaces to enhance attention to mobility). There is minimal evidence regarding the efficacy of the program in its entirety.
The Son-Rise Program	http://www.autismtreatmentcenter.org/	Focuses on using the child's inherent motivations to engage and interact and on helping parents be optimistic and hopeful while helping their child to learn and achieve. Very playful approach and open to including sensory-based therapy. There is currently no published evidence of efficacy for this program. See http://www.autismtreatmentcenter.org/contents/reviews_and_articles/research_project.php .

TABLE 27-3 Interventions for Children with Autism Spectrum Disorder—cont'd

Intervention Name	Web Link	How Used in Occupational Therapy
Social Communication, Emotional Regulation and Transactional Support (SCERTS)	http://scerts.com/index.php?option=com_content&view=article&id=2&Itemid=2	SCERTS is a comprehensive model to be used with a team. Occupational therapists are part of this team and are involved in the emotional regulation portion of the intervention. SCERTS can be readily combined with many other of the interventions, although it is considered to be most different from ABA. Evaluation of the SCERTS model is ongoing. See http://www.scerts.com/docs/SCERTS_EBP%20090810%20v1.pdf and http://ies.ed.gov/funding/grantsearch/details.asp?ID=978 .
Pivotal Response Training (PRT)	http://www.koegelautism.com/	Occupational therapists can use specific strategies such as providing choice, using task variation, rewarding attempts, and using natural reinforcers in play-based sessions. PRT specifically teaches responsivity to multiple cues and the occupational therapist can incorporate this into activities such as visual-perceptual-motor tasks (i.e., "Can you find the big, round, one? Can you find the smooth, red one?"). See http://education.ucsb.edu/autism/documents/EmpiricalSupportforPRT-ExpandedVersion.pdf for information about studies related to PRT. PRT is a well-studied approach to treatment for ASD and is considered an established approach.
Animal Assisted Therapy (AAT)	Pet Partners (formerly the Delta Society) http://www.petpartners.org/	Animals may be calming for individuals with ASD and may help increase language and social interaction. They can be used in occupational therapist sessions if the occupational therapist is trained in this approach (see Nimer & Lundahl, ¹⁶⁴ and Sams, Fortney, & Willenbring. ¹⁹¹

From Miller-Kuhaneck, H., & Gross, M. (2010). Alternative and complimentary interventions for the autism spectrum disorders. In H. Miller-Kuhaneck & R. Watling (Eds.), *Autism: A comprehensive occupational therapy approach* (3rd ed). Baltimore: AOTA; Watling, R. (2010). Behavioral and educational approaches for teaching skills to children with an autism spectrum disorder. In H. Miller-Kuhaneck & R. Watling (Eds.), *Autism: A comprehensive occupational therapy approach* (3rd ed.). Bethesda, MD: AOTA Press; also see <http://www.autismspeaks.org/what-autism/treatment> for summaries of many of the approaches above and <http://www.nationalautismcenter.org> for a national report that reviews autism interventions.

explained based on external events and behaviors and it can be modified through manipulated environmental consequences called *reinforcers* through classical or operant conditioning. Learning is defined as a change in observable behavior. Interventions based on behavioral theories are highly adult directed, focus significantly on compliance with adult demands, and often are completed in one-to-one instruction without peers. Behavioral interventionists give little consideration to the child's internal motivations for learning, the urge for mastery or competence, or the need for autonomy and choice. Although critics of these approaches^{100,199} have voiced concerns, behavioral approaches have demonstrated effectiveness.^{67,71,174,217} Applied behavior analysis (ABA), in particular, discrete trial training, is supported and considered to be an established approach that is commonly used by many on the health care team of a child with ASD. In ABA, the antecedents and consequences for a behavior are manipulated to influence the behavior. In very simple terms, ABA rewards desired behaviors while ignoring undesirable behaviors or providing undesirable consequences for undesired behaviors. Both positive and negative reinforcement makes the behavior more likely to occur, but positive reinforcement is the application of something pleasurable usually, whereas negative reinforcement is the removal of something unpleasant. Two types of negative reinforcement are escape and avoidance. Differential reinforcement occurs when a behavior is reinforced in some settings or situations and not

in others. Reinforcement is provided in specific schedules developed by a behavioral specialist, following a functional behavior analysis or assessment. Discrete trial training (DTT) is a very specific type of ABA in which targeted skills are taught in repetitive trials using the same antecedents, behaviors, and consequences.

Positive behavioral support (PBS) is a behavioral approach developed in the 1980s based on ABA but in response to criticisms of some older ABA programs. Positive behavioral support is considered to be proactive rather than reactive in terms of problem behavior, more individualized, more respectful of an individual's right to choose activities, and better generalizable to daily life settings.⁹⁰ Positive behavioral support considers the environment in which the behavior occurs, and practitioners of PBS seek to understand the purpose of the behavior for the individual. Then once the purpose is determined, a problem-solving approach is used to find solutions for the behavior. The overall process for PBS is to establish goals, gather information about the behavior from a variety of people, analyze the patterns of the behavior, develop a plan to prevent the problem from occurring, and respond consistently if it does, and then gather data and monitor effectiveness of the plan.

Occupational therapists may use principles of ABA during intervention sessions such as assessing the functions of specific behaviors and rewarding appropriate task performance. Specific strategies used in therapy in addition to reinforcement may

include prompting, shaping or chaining, and fading out (see [Chapters 15 and 16](#)). Occupational therapists may use token economy systems, sticker charts, or food rewards. They may incorporate the child's typical learned commands during intervention activities. Occupational therapists also assist in determining appropriate reinforcers with the child's team and may use this approach to gain child compliance with adult-directed activities to enhance learning of specific skills.

The Cognitive Orientation to Daily Occupational Performance Approach

The Cognitive Orientation to Daily Occupational Performance (CO-OP) approach¹⁷⁵ is an intervention approach designed by occupational therapists to assist children in mastering skills to achieve the performance goals they have set for themselves in collaboration with the occupational therapist. Cognitive Orientation to Daily Occupational Performance has demonstrated effectiveness for children with high-functioning ASD.¹⁸⁷ Cognitive theories of learning consider additional characteristics of learning that cannot be readily observed such as memory and attention. Cognitive and cognitive-behavioral approaches stress observational learning and consider the individual's internal motivations for learning as important to achieving behavioral outcomes. The CO-OP approach uses cognitive behavioral and motivation theories to guide the intervention principles. The objectives are the learning of new skills and the generalization or transfer of those skills into everyday life. Children and therapists collaborate to develop goals and then use a problem-solving, occupational therapist-guided executive function strategy termed "Goal-Plan-Do-Check." The first two steps answer the following questions for the child: What do I want to do? and How am I going to do it? Then the child tries to do the task or skill and observes how well it works. The therapist assists and collaborates throughout the process, by using child-centered assessment to assist the child in developing his or her goals and determining if the child has the motivation, knowledge, and competence to achieve the chosen goal. The therapists also discuss and refine the plan or cognitive strategies the child will use to learn the skill and achieve the goal, models strategy use, and provides feedback for performance. The therapist then works with the child to examine and consider his or her own performance and teach self-evaluation (see [Chapter 10](#)). Recent studies suggest that for children with ASD who have the language and cognitive capacity to participate in this approach, it may be effective and successful.¹⁸⁵⁻¹⁸⁷

Occupational Therapy-Sensory Integration (Ayres Sensory Integration) and Sensory Strategies

Ayres Sensory Integration Theory¹⁴ suggests that all learning and development is based on a foundation of multisensory integration within the brain that often develops in children through play. Therefore occupational therapist-SI intervention uses a play-based approach. Sensory strategies developed through an understanding of occupational therapist-SI theory include modifying tasks and environment to enhance a child's comfort or toleration of an activity or experience, to improve their ability to attend and engage with others, or to alter their arousal level to provide a better platform for learning to occur. Sensory strategies can be thought of as quick fixes or over-the-counter remedies that may at times be implemented by teachers or parents with consultation from occupational therapists,

whereas long-term clinic-based occupational therapist-SI intervention is believed to alter neurologic processing through brain plasticity and should be provided by a well-trained therapist who can provide the approach with fidelity to the principles. (See [Chapter 9](#) for more information on occupational therapist-SI and sensory strategies in occupational therapist intervention with children.) (See [Figure 27-1 C](#).)

Occupational therapists are the experts in the intervention of sensory issues and families with children with ASD seek out occupational therapists for this expertise.⁹⁹ Treatment for sensory issues may be of primary importance in this population as they may be related to sleep problems,¹¹⁵ difficulties with self-care,¹⁰⁶ problems with dental hygiene,²⁰¹ educational performance,¹² problem behavior,^{166,214} and family occupations.¹⁵ Knowledge of SI theory allows occupational therapists, through activity analysis, to provide suggestions and modification to a variety of tasks in the home, school, and community to allow a child to have greater comfort with, and engagement and participation in, a variety of occupations.

Floortime and the Developmental, Individual Differences, Relationship-Based Model

Developed by Stanley Greenspan, MD, a psychiatrist who worked closely with and valued occupational therapy, Floortime is a family-centered intervention approach with strategies that can easily be incorporated into naturalistic or play-based occupational therapy sessions. Three primary strategies include following the child's lead/joining in his or her world, challenging creativity and spontaneity, and expanding interaction to include sensory motor skills and emotions.

The Developmental, Individual Differences, Relationship-Based (DIR) model is a comprehensive program that considers the child's emotional developmental level, their unique strengths and needs, and their preferences. Through parent-implemented strategies, children progress through six developmental stages of self-regulation and interest in the world: intimacy, engagement and falling in love, two-way communication, complex communication, emotional ideas, and, finally, emotional and logical thinking. Occupational therapists can use the strategies of playful blocking, using child preferences in play to increase engagement and using one's own playfulness to improve interaction. Individual differences including unique sensory processing styles are considered. The parent-child relationship is encouraged and strengthened through the playful activities of Floortime. Floortime intervention therefore is a specific child-directed playful approach with the caregiver that is part of the DIR comprehensive model. The evidence for relationship-based models is considered to be emerging.¹⁷⁰

Other Common Strategies

A multitude of other approaches are used with children with ASD. Many are included in [Table 27-3](#) and are helpful to use within an occupational therapy session.^{147,149,218} They exemplify the "therapeutic use of self" through playful child-therapist interactions.¹⁴⁹ Each session may incorporate different strategies to meet the goals for that session or activity, and it is unlikely that the therapist will use all of the strategies. The therapist's skill in careful observation and choosing which strategies work with each child within specific situations is paramount. See [Box 27-4](#) for particular strategies and when to use them.

BOX 27-4 Specific Strategies for Occupational Therapy Sessions**Improve Engagement and Interaction,
Reduce Fear or Anxiety**

- Imitate the child and wait for the child to initiate interaction via eye contact, touch, or moving into closer physical proximity (reciprocal imitation training [RIT]¹⁶⁰)
- Alter the therapist's proximity to the child^{149,160}
- Reduce use of direct eye contact
- Alter the therapist's pace both motorically and verbally (ASI¹⁴⁹)
- Alter the therapist's voice volume or intonation (ASI¹⁴⁹)
- Use musical or sing-song vocalizations or word pronunciation that the child finds humorous¹⁴⁹
- Use preferred objects, colors, or movements within therapy tasks. For example, hide a favorite object within Theraputty or place it on top of something to encourage climbing, under something to encourage digging, or inside something to encourage fine motor skills like opening or unbuttoning. Be sure the child sees where the object went and, if necessary, make sure that he or she will be able to get it back quickly to avoid distress and difficult behaviors. This should be a fun game. (TEACCH, PRT, RDI, DIR, SCERTS, ASI, Miller Method)
- Interact playfully (DIR, RDI, ASI, RIT, SCERTS, and others), make work into play¹⁴⁹
- Create fun problems to be solved. For example, "Oh no, the pig (stuffed toy) is trapped in the mud, you have to help him get out. How can we save him?" (DIR, RDI, ASI, RIT, SCERTS, and others)
- Sing familiar songs and leave out the last word, to encourage the child to vocalize to fill in where you have omitted the word

**Improve Behavior and Task Completion,
Reduce Fear or Anxiety**

- Use objects, visual cues, or schedules to help the child predict what will come next or what will happen. Provide a visual schedule that indicates how many times a particular action or behavior is expected. For example, place five magnetic coins on the table to be placed in the container. When the five are done, this activity is done. (TEACCH/SCERTS)
- Use the prompts that are familiar to the child (ABA)
- Know and use the child's preferred reinforcers throughout occupational therapy "work" (ABA)
- Provide clear boundaries regarding areas of the intervention space so that it is clear which type of activity occurs in each area (TEACCH)
- Provide choices or choice boards, visual schedules, or other visual materials to aid in understanding what is to be done (TEACCH)
- Provide written instructions for a child who can read (TEACCH, ABA, SCERTS)

Improve Comfort, Reduce Fear and Anxiety

- Carefully grade the introduction of novelty into a session (ASI)
- Attend to the sensory environment and the child's response (including facial expression, nonverbal responses) to the sensory environment (ASI)

- Alter lighting, noise, smells (ASI)
- Provide opportunities for deep pressure and proprioception through active play (ASI)

Improve Motor Skills/Praxis

- Create fun obstacles or challenges that encourage the movements that are therapeutically desired (e.g., require motor planning, bilateral coordination and sequencing, relate to functional goals) while engaging the child in a preferred activity of his or her choice (ASI, DIR, RDI, RIT, SCERTS, and others)
- Climb, walk, or crawl on raised surfaces to increase attention to motion. For example, climb across a wide balance beam or a horizontal ladder at 2 to 3 feet off the ground (with mats and pillows for safety and hand holding if needed). (Miller Method, ASI)
- Gradually increase motoric sequences that are completed before a desired event or object is provided. For example, place a favorite toy (or a puzzle piece) in a zip lock bag to be opened. Then wrap it in a wad of tin foil inside a zip lock bag to be opened. Then put it in a closed Tupperware, wrapped in tin foil, and inside a zip lock bag. Then in a closed Tupperware, wrapped in tin foil, inside a zip lock bag placed up a ramp, up a ladder, or through a tunnel. (Miller Method)
- Alternate preferred sensory activities with more challenging motor tasks (ASI)
- Sing about the motor activity you are doing using familiar tune. For example, using the tune of "Mary Had a Little Lamb," or "Row, Row, Row Your Boat," you can sing about Johnny's going to climb that ramp, or push, push, push that cart gently down the hall.

Improve Play and Ideational Praxis

- Use realistic props to begin to introduce role play (fireman's hats, dress-up clothing that is realistic)
- Use movie characters and stories to begin to introduce pretend play
- Promote imagination in your sessions (What would an animal look like if it were part zebra and part frog?)
- Have the child help you create a game out of unusual materials ("What could we play with this cup, this small ball, and this stuffed animal?")
- Have the child help you build an obstacle course or sensorimotor activity (ASI)
- Discuss the ways you can use certain objects based on their properties (affordances). ("Look, this is round. It can roll. These are all square shaped and they can stack. What could we do with this object?") (ASI)
- Try to add to current ideas with prompting. ("Can you think of another way to do that? How many different ways can you do that?")
- Take turns between imitating the child and having the child attempt to imitate you. Use silly motions, vocalizations, and sequences to be playful (RTI, DIR, ASI, RDI).

Specific Interventions for Areas of Occupation

Sleep

Behavioral interventions, medications, melatonin, and herbal treatments are often used for sleeping problems in children with ASD.⁷⁶ Occupational therapists combine behavioral and sensory strategies when problem solving with families who have children with poorly regulated sleeping routines. In particular, they consider the sensory environment in which sleep occurs in relation to the sensory issues of the child and the options available for providing appropriate sensation to improve sleep. Some children will need sensation to be reduced to sleep successfully, whereas others may need enhanced sensation to sleep. For most children, calming sensations are more steady and consistent and include deep pressure, neutral warmth, soft or dim sounds and lighting, and slow easy motion. Alerting sensations may include louder, brighter, more rapidly changing, or more intense sensations. Therefore to assist with sleep the auditory environment can be altered with the use of music, a white noise machine, ear plugs, or extra padding and draperies to dampen sounds. The visual environment can be altered by adding or removing wall hangings, changing patterns on drapes or bedding, providing glow-in-the-dark stars on the ceiling, using a night light, sleeping with an eye mask, or changing the colors in the room. The tactile environment can be altered by using softer bedding such as flannel or velour or heavier bedding and blankets that provide more pressure; changing sleep clothes to try different fabrics or sleeve and leg lengths; sleeping with or without socks; and providing warm baths, massage, or back rubs before bed or while falling asleep. The vestibular system can be engaged by sleeping on a waterbed or vibrating mattress or by using a rocking chair and rocking slowly before bed. For some children, chewing gum before brushing teeth and going to bed can be relaxing and help them to become calm for sleep.

Behavioral strategies can promote sleep.¹⁵⁶ These include, for example, unmodified or graduated extinction. In unmodified extinction parents put the child to bed at the appropriate bedtime and then ignore the child until morning (monitoring for safety). This process is meant to eliminate the reinforcer of parental attention for crying, screaming, or other bedtime behavior issues. In graduated extinction the parent ignores the behaviors at bedtime for a certain amount of time before checking on the child. The goal is for the child to develop self-soothing skills in order to fall asleep by him- or herself.

The occupational therapist can collaborate with the team and family to create consistent bedtime routines to improve sleep. Routines can include a bath, massage, and other calming activities (see [Figure 27-1A](#)).¹⁵¹ Parents may move bedtime closer to the child's naturally established time to fall asleep and then gradually move bedtime earlier and earlier until the child is able to fall asleep at the desired bedtime. Another strategy is to remove the child from bed for a brief period of time if he or she does not fall asleep.

Extinction programs may be difficult for parents of children with ASD to follow and may need to be combined with reinforcement, for example the Excuse Me Drill.¹²⁵ First the parent teaches the child to fall asleep in the environment in which the parent wants the child to sleep (likely the child's own bedroom). Parental presence is allowed at this time, as is back rubs, rocking, singing, and so on. Next, the parent begins to

reinforce appropriate bedtime behavior with their attention. In very brief bouts initially, the parent removes him- or herself with the statement, "Excuse me, I need to _____, but I will be right back to check on you." The parent then quickly returns, praising for being good and staying quietly in bed. The duration and distance of the parent's removal is then gradually increased until the child is able to fall asleep independently in his or her room.

Activities of Daily Living and Instrumental Activities of Daily Living

Children with ASD can benefit from behavioral, cognitive, motor, and sensory strategies to improve their ability to independently perform activities of daily living (ADLs) and instrumental activities of daily living (IADLs). In addition, families often benefit from consultation to improve their use of structure and routine to assist in these endeavors.

Dressing, bathing, and toileting skills, once learned, may become established routines that children with ASD perform independently. However, for some children with motor or cognitive difficulties, learning these skills can be difficult. If cognitive issues or the development of habits and routines are the concern, visual supports and assistance for sequences may be helpful.¹³⁰ Learning from video demonstration that can be repeated many times may facilitate ADL performance. Families may need assistance with developing consistent routines to follow in the home. For children with motor delays, the occupational therapist can use motor learning strategies, the CO-OP approach, or occupational therapist-SI activities to improve praxis. For those with behavioral resistance to specific ADL tasks, implementing a behavior plan and reinforcing appropriate ADL behaviors might be most important. Behavioral approaches matched to the child's cognitive and communication skills can increase toileting independence (see [Chapter 15](#)).

For children with sensory difficulties, modification of tasks to increase comfort, reduce fear, and allow engagement in activities can help families manage their morning and evening routines with less stress. For example, a child may be more likely to learn to wipe if allowed to wear plastic gloves, or he or she may tolerate a bath or washing hair at the sink better than a shower. In addition, occupational therapist-SI may improve the related sensory issues and dyspraxia.

Feeding and eating can often be an area of difficulty for children with ASD because of their insistence on sameness and their sensory sensitivities. Occupational therapist interventions apply both behavioral and sensory strategies to address limited diet. Interventions can include changes to the feeding environment (see [Figure 27-1B](#)), changes to positioning the child at the table, creating a consistent feeding routine that works for the family, altering food choices based on sensory characteristics, modifying foods based on their sensory properties (texture, taste, smell) or oral motor requirements, reinforcing positive feeding behaviors, and using visual supports to promote ease of transition to the mealtime environment.⁹¹ When using a behavioral approach, the occupational therapist might work toward increasing tolerance through repeated but gradual exposure or through food chaining (working toward acceptance of a nonpreferred or target food by starting with a preferred food and then presenting foods with one similar property to the prior accepted food in the chain). When using an SI

FIGURE 27-1 **A**, An important role for occupational therapists is to help families develop bedtime routines to promote sleep. **B**, Children with ASD can be picky eaters, but interventions using sensory and behavioral strategies can improve their ability to eat a wider variety of foods. **C**, Outpatient occupational therapy using ASI is highly valued by families to help children with ASD improve sensory processing and praxis. **D**, In naturalistic studies of play, children with ASD were more likely to approach adults who were smiling more and were inviting and playful. **E**, The occupational therapist can assist the family in creating meaningful shared family occupations.

approach, the occupational therapist reduces sensory sensitivities generally using deep pressure and proprioceptive activities and may first try to incorporate chewier foods or those that provide greater proprioceptive input to the oral area.

Using sensory processing and behavioral strategies, occupational therapists also provide strategies to assist families in managing oral care and visits to the dentist.^{124,173} Dental visits are challenging sensory experiences in multiple sensory modalities, and many dentists are not well versed in managing children with special needs. Once the child's sensory preferences and difficulties are determined, the occupational therapist can give parents suggestions to try before and during oral care and dental visits to make the experience more comfortable for the child. In particular, children with sensory defensiveness may need supports to manage the touch to the face and tastes inside the mouth that are associated with dental hygiene and care, for example, the texture and grittiness of the tooth or polishing paste, and the toothbrush, dental tools, x-ray materials, or gloved fingers in the mouth. At the dentist's office, the child also must tolerate the dental chair reclining; bright lights shining directly into the face; the smell of the glove materials or the taste of the glove in the mouth; the paste taste or smell; the sounds of the dental equipment, especially the polishing brush, suction, and high speed hand pieces; as well as the unexpected office noises such as intercoms, door alarms, and beeps. Additionally, the hygienist's or dentist's face is often covered with a mask. Wearing a mask highlights the eyes and covers the mouth, an area that many with autism look at when speaking with others, as they often avoid direct eye contact. The occupational therapist may recommend to the parent or perhaps directly to the dental professional any of the following to help the child manage this experience:

- Use verbal preparation.
- Give a set time limit that the input will occur (i.e., "We are going to do this until the count of 20").
- Provide a timetable or a visual indication of when the procedure will be done. Ask dental staff to refrain from highly scented cleaners and air fresheners in the office area.
 - Place the chair in the fully reclined position before the patient gets into the chair, to avoid the backward motion.
 - Allow the patient to listen to music over headphones.
- Use as little touch to the face as possible. Use firm deep touch rather than light touch.
- Ask which sensory experiences (e.g., lighting) are most difficult and discuss with the family and dental staff what can be altered.
- Have the child wear the heavy x-ray vest during the entire appointment to provide extra weight and deep pressure
- Have the caregiver do oral deep pressure or vibration in the form of electric toothbrush, mini-massager, or rubbing with a toothette before the appointment.

Education

Autism spectrum disorder often adversely impacts a child's performance in academics; however, students with ASD respond well to educational settings that provide supports and accommodations tailored to meet their individual needs. Students with ASD may benefit when classroom tasks and environments are modified to improve their engagement and reduce

problem behaviors. The modifications may occur in the form of academic alterations, visual supports, technological supports, behavioral supports, social supports, sensory-based modifications and strategies, or motivational supports. Teachers report that they use a multitude of strategies in the classroom for children with ASD.⁸⁹ Although the primary person responsible for the educational content is the teacher, an occupational therapist using activity analysis can provide valuable information about modifications to assist the teacher and support the student.

Academic Alterations

In a classroom that allows for differentiated curricula, teachers can determine through assessment the student's learning style or learning preference and then teach to that strength. Assessments such as the VARK (see the Evolve website) can help with this determination for students who can complete it. Concepts can be taught either through visual means, auditory means, or kinesthetic or movement methods. Tiered instruction allows teachers to teach a concept in a variety of ways and allows for multiple methods of assessment for the student to demonstrate that the concept has been learned. Additionally, content may be modified to reduce the cognitive load and enhance learning, for example, by breaking the content into smaller "chunks." The social aspect of learning can be removed for some. For example, for a young child, instead of learning the alphabet in the classroom with peers, he or she may better learn from a video of the teacher teaching about the letters, perhaps using preferred characters or puppets.

Visual Supports

Visual supports can include pictures, visual or picture schedules, choice boards, pictorial communication methods, signs, maps, timers, clocks, watches, and items as simple as checklists or written instructions for those who can read. Visual supports can also include boundaries around areas and signs or labels to explain which activity is supposed to happen in that area of the classroom. Visual supports may be real objects; for example, an occupational therapist could provide an orange and a banana when asking the child to make a choice, or can be symbolic, such as a toy banana or a line drawing or a picture of a banana. For schedules or choice boards, the items can be presented either horizontally or vertically, are often laminated for durability, and may be attached with Velcro onto a board or card. Visual supports are used to enhance communication and understanding and often help ease transitions by allowing some predictability for a child who has difficulty in knowing or understanding typical routines. They may be used to show when to start and finish an activity or to explain the sequence of multiple activities. Visual supports can help explain requirements of tasks to enhance a child's ability to complete activities. They can be used also to help identify emotions or mood, provide reminders, and teach new skill sequences. Autism Speaks has created a toolkit for parents and providers for visual supports and other accommodations for help in daily life.

Technologic Supports

Technologic supports can include devices such as communication systems, iPhones, or iPads with apps to help with academic tasks or social interactions. Technology such as computer games may assist with promoting peer interaction in the classroom. Calculators can assist those with difficulty with math skills. Those who have difficulty with handwriting may benefit

from technology for keyboarding. Others may be able to use and benefit from voice recognition software, whereas still others without speech may be able to use technology for communication through speech-generating devices. (See the Evolve website for a list of preferred apps.)

Social Supports

Social supports can include but are not limited to social skills groups, peer mentoring programs, integrated play groups, scales and thermometers for emotional regulation, and assistance or guidance at recess and other less structured social times at school.⁹¹ The occupational therapist can help facilitate games or activities at recess that will include the child with ASD and then use recess time or a social skills group at another time to teach appropriate and specific needed social skills. Peer modeling can be used for observation of appropriate behaviors and can then be reinforced using appropriate behavior plans. Occupational therapists can also be involved in school-wide programs for acceptance of difference and/or disability awareness (see Figure 27-4).

Social Stories

Developed by Carol Gray,^{79,80} social stories are a teaching technique for children with ASD. They are individually written descriptions about what to expect during typical life events, individualized for each child to target specific areas of need for that child. The stories are written to create understanding and to share information, not to change behavior. They have been found effective in multiple studies to date.^{33,47,168,178,205}

A social story should describe rather than direct and is written to support the child in learning about an event or a specific situation. The story has an introduction, body, and conclusion and must answer “wh” questions (i.e., who, what, where, when) about the event or behavior. The story should answer questions about what others know as well. It can be written from either first or third perspective, but with younger children, it should be written using “I.” The story includes descriptive sentences, important affirmative sentences, and perspective sentences as appropriate. The story should have limited directive sentences.

Descriptive sentences state the facts. For example, one may write, “My name is _____. There are boys and girls in my class. The teacher’s desk is in the front of the room. The boys and girls sit in chairs.” If describing a timed event, there needs to be a way “out” if the time changes. For example, instead of writing, “I have gym class every Tuesday,” one should state, “On most Tuesdays I have gym class.” (Some Tuesdays there might be an assembly.) Instead of specifying, “I go home on the bus at 3:15,” a social story would read, “I usually go home on the bus at 3:15.” (Some days the bus might have a flat tire and be late.) Perspective sentences reflect what other people know, think, or feel. They might read, “My mother knows when it is time to go to school,” “My teacher knows when it is time to go to lunch,” or “The teacher will like it if I listen to her when she talks.” Directive sentences remind the child of what he or she should be doing or what should be happening. They must be stated in such a way that the child will not “fail” the story if he or she is unable to do what it says. For example, one should read, “I will try to sit in my chair,” rather than, “I will sit in my chair.” Affirmative sentences indicate a shared value or opinion in culture. They are used only if the adult is sure they are true for the child. An example might be, “It is polite to raise my hand before speaking.” Cooperative

sentences describe what others will do to try to help the child. For example, a story may read, “Mom and Dad will try to remain calm while I learn to use the toilet.” In a social story, the practitioner describes the situation twice as much as telling a child what to do. They must be literally correct, using “usually” and “sometimes,” and mentioning changes in routines. The stories can have pictures and titles. Titles are often best expressed as questions that the story will help answer. For example, a title may be “What do children do when they ride the bus?” or “What will we do at Bob’s house?” Stories can be very short (five sentences) or longer for older children. Sample social stories are available online (see the Evolve website) and there are also books for sale that provide stories for common problem events such as riding the bus.

Behavioral Supports

Therapists help to develop and support implementation of positive behavior programs in the classroom and specific behavior plans with appropriate reinforcers for the child. One of the best approaches to promote good behavior is a positive behavior plan for the classroom. Classrooms should have clear rules that promote the positive learning environment the teacher and class desire, and the behaviors desired are encouraged by positive consequences for completion such as earning free play time. Consequences for rule violations start mild and become more and more severe as the offense is repeated. Often for a child with ASD more intensive intervention is required. Typically there will be a functional behavioral analysis completed to determine the cause or the reason for the behavior. Next a behavior plan will be put in place that addresses the cause of the behavior. Occupational therapists may or may not be involved in the creation of the plan, but will likely assist in following it with the child.

Sensory Supports

Occupational therapists often provide sensory diets and sensory strategies for children with ASD in the schools. Although perhaps more difficult to implement than highly structured and standard programs, sensory diets should be individualized for the child and strategies should be implemented throughout the day based on the child’s behaviors and needs, as opposed to designated by the clock. Therapists also need to be clear which frame of reference they are using when they provide sensory strategies. Sensory interventions respect the child’s preferences and are not methods of desensitization to force tolerance of uncomfortable sensory experiences. The sensory strategy should not be used as a reward for good behavior if the therapist is using an SI frame of reference. However, therapists also need to be aware of the potential for sensory strategies to become an unintended reward for poor behavior, if every time the child acts out in class, he or she gets pulled out to do a preferred sensory activity.

The classroom environment is frequently brightly lit, with additional visual stimulation provided by items hanging on the walls and individuals moving about the room. Learning activities frequently provide additional touch inputs, movement experiences, and even smells. Classrooms that are noisy with poor acoustics have been associated with reduced attention, concentration, and academic performance. Individuals with ASD may react with a range of behaviors to uncomfortable stimuli, from avoidance to violent physical aggression.¹⁴⁵ Therapists can make recommendations to improve the match between student sensory preferences and classroom sensory

FIGURE 27-2 Sensory strategies in the home or classroom may promote better regulation of behavior and attention.

FIGURE 27-3 Sensory strategies such as those that can be used in a school or home can help a child to regulate his or her behavior and learn to explore and tolerate new experiences.

environments, knowing that certain aspects of the sensory environment cannot be modified, for example, acoustics in older buildings. In those cases, other features may be modified, for example, a child could wear ear plugs or headphones in noisy environments that cannot be altered. The therapist must use knowledge about the child's sensory preferences and needs gained through evaluation and collaborate with the teacher to adapt the environment and tasks to allow the child his or her best possible performance (see [Figures 27-2 and 27-3](#)).

Motivational Supports

Motivational supports are used to increase the child's participation in educational activities the child finds undesirable. A playful and creative therapist may often gain more compliance with tasks such as writing, cutting, or using a ruler when the child's preferences are included in the task. For example, a child who loves John Deere tractors can complete matching tasks to match letters he or she needs to learn by finding them in the tractor catalog. A child who loves green frogs can be given green markers to use to write with and can write stories about

FIGURE 27-4 Peer supports can be helpful in engaging the child with ASD in play and educational activities.

frogs. A child who is passionate about trains can learn to cut squares or circles by creating trains made of colored paper as the final outcome. An additional motivational support often used by occupational therapists is providing choices between activities whenever possible.

Play

Areas of play and imitation are understudied, even though they are considered areas of core deficit in the ASDs.²²⁷ However, a variety of intervention methods, for example, Floortime (DIR) or occupational therapist-SI, are purported to improve play in individuals with ASD. Video modeling appears to have efficacy for increasing play and interactions, play initiations, reciprocal pretend play, and independence in toy play.^{92,138,172,180} Peer-mediated interventions and specifically a model called Integrated Play Groups has demonstrated effectiveness in a variety of small studies, primarily using single-subject designs.^{229,230} Multiple single-subject design studies have indicated efficacy using Reciprocal Imitation Training (RIT), as applied by parents and practitioners, for developing play skills.¹⁰⁰⁻¹⁰²

A variety of studies have examined individual aspects of interventions important to the development of play skills. Use of choice, the use of preferred sensory toys or perseverative interests, the frequent variation of task demands, and the incorporation of ritualistic behaviors into interventions promote play behaviors.^{18,41,58,192,216} In naturalistic studies of play, children with ASD were more likely to approach adults who were

FIGURE 27-5 It is important to help families find meaningful occupations in the community for children and teens with ASD. **A**, This young boy volunteers with his mother at a local animal shelter each week. **B**, This young adult sings and plays lead guitar at local clubs and bars at his own shows and on open mike nights.

smiling more and were inviting and playful. Adult sound effects appeared particularly enticing.¹⁶⁰ There are also benefits when an adult imitates the child with ASD. Children with ASD respond to being imitated with greater responsiveness, more eye contact, and improved play.^{50,51,68,70,160} Even brief imitative sessions can produce beneficial results.⁸⁷ These studies as a group demonstrate the importance of choice, preferred interests, affect, and the sensory properties of toys and activities to promote improved behavior and motivation, reduce the need for adult guidance or redirection, and increase interaction in children with ASD (see [Figure 27-1D](#)).

From the limited research, it appears that play deficits can be remediated by a variety of means. Occupational therapists can implement strategies in their sessions from many of the approaches into their playful work with children with ASD. Children with ASD may respond best, however, to playful adults and in particular to adults who imitate them at least some of the time.

Additional Intervention Concerns

Safety

Occupational therapists can assist the family in managing escapism and other safety issues through problem solving, activity analysis, and often through the use of technology. Depending

on the situation, families with the financial means can install a variety of window and door alarms to alert them to the possibility of the child leaving the home. Yard fencing may be an option for some as well. GPS tracking is another option. For families with limited financial means, simple low tech solutions, such as more difficult locking mechanisms or the use of Velcro and bells to alert family members to windows or doors or cabinets being opened, can be helpful. Bed tents can provide relatively low cost relief for families of children who wander during the night. Special harnesses and mechanisms can prevent children from removing themselves from their seatbelts or child seats. Household cleaners or medicines may need to be put into different containers and kept in locked cabinets. Similar methods may be needed for knives and other sharp kitchen utensils. On some stoves the knobs may be removable. Autism Speaks has developed a list of safety products for families of individuals with ASD (see the Evolve website for a link to safety products).

Coping and Self-Efficacy

As stated, parents of children with ASD are often stressed; therefore, an important role for the occupational therapist working with a family and child with ASD may be helping the family cope. The most commonly used model of coping, the transactional model,¹³¹ guided research for more than 20 years.

FIGURE 27-6 A, B, A child with ASD with special strengths in visual construction and creativity in design. An important role for occupational therapists is finding out about a child's strengths and preferences during evaluation, so that these can be used in intervention.

This model applied to parenting proposes that coping is a dynamic process, whereby following a parent appraisal that an event is stressful, the parent's coping is influenced by his or her personality, the resources available, the situation in relation to additional stressors, and the availability of coping responses. In this model, coping responses are not inherently good or bad or useful. The effectiveness of a coping response depends on the match between the actual stress and the response that is chosen to address it. Personality factors do play into coping effectiveness and psychological well-being. However, research suggests that certain coping responses may be linked to mood states.¹⁷⁷ For example, coping responses that were more active, such as problem-focused coping, finding and using social support, engaging in positive reframing, and compromise, were associated with a more positive daily mood, whereas coping responses such as escape, blame, withdrawal, and helplessness were associated with a more negative daily mood. Other researchers found similar results, suggesting that positive reframing is an important coping strategy for improving mental health, whereas coping strategies that could be called avoidance are associated with depression and anger.²⁶

Mothers report that their coping strategies include gaining information, planning and organizing effectively, making time for their own personal needs (i.e., "me time"), and reframing the experience in a positive light, noting the joys and benefits of having a child with ASD.^{123,128} Many of their reported

strategies were active ones according to the preceding model, those that will help their mood and well-being. Therefore occupational therapists can assist in family coping by helping families gain or gather the information they need about ASD and intervention approaches.¹²³ Therapists who remain current with the latest information, research, policy changes, and clinical guidelines can also assist parents in making effective decisions about their child's care. Therapists can assist parents in creating organizational or planning methods that work for their family. Occupational therapists can assist the family in finding appropriate respite care or in developing parent-to-parent networks to share the work and allow for individual time. They can become knowledgeable about local resources for family fun and outings that are ASD friendly such as special movie nights where the theater volume is turned low and the lights are left on slightly, and malls that have initiated special times for children with ASD to visit with Santa during the holidays.

Occupational therapists can also improve parental self-efficacy by using informational power to help parents learn how to parent their child. By sharing knowledge of activity analysis, natural learning opportunities, and sensory processing, occupational therapists can empower parents to feel confident and capable of handling situations as they arise in the community, their home, or anywhere. Parents can be taught to use skills of activity analysis to attempt to understand a problem behavior for their child in the community, considering the requirements

of the activity they are being asked to engage in and the environment in which they are doing so. Parents can learn to consider the sensory environment, the novelty, and the cognitive challenges provided by the activity to help prepare their child. In addition, by teaching some aspects of activity analysis, parents can learn to more readily use the natural learning opportunities provided in their day-to-day activities, to promote desired skills for their child without taking time to specifically “work” on a skill in isolation. For example, parents can be taught to look for natural opportunities during their day in which the task at hand requires a specific cognitive or motor skill or a specific social emotional behavior such as waiting, sharing, or taking turns.

Research suggests that “optimistic parenting” of a child with ASD may be quite important in managing early behavioral difficulties and keeping them from growing into larger problems.⁶³⁻⁶⁵ Cognitive behavioral interventions to support parental optimism and provide positive behavioral supports (knowledge and ways to manage behaviors) appear to be successful in helping those families who need the help the most.⁶⁵ Parents need to feel able to manage their child’s behavior and need to feel confident about their ability to be in the community and handle the judgments and poor behavior of others who lack understanding of ASD.

Summary

Autism spectrum disorder is a complex condition with a unique profile for each individual, and its symptoms impact multiple aspects of occupational functioning. Occupational therapists will likely address play or leisure, self-care, sleep, education, all areas of performance skills, and performance patterns,

although emphasis shifts according to the practice setting and the age of the child. For some children with substantial behavioral difficulties, significant supports and intense interventions are required, whereas for other children who are high functioning, the primary focus may be enhancing social skills across a broad range of social situations. Whether or not ASD is severe, the entire family is affected. Practicing family-centered care, occupational therapists use their knowledge, expertise, and informational power to enhance families’ ability to manage the difficulties and challenges that an ASD diagnosis can bring, while focusing on the family’s strengths to help the family cope and engage in meaningful family occupations (see Figure 27-1E).

Summary Points

- Autism spectrum disorder may impact all aspects of occupational performance, but in particular social participation is often most greatly affected. Sensory issues are a common concern as well.
- A child with ASD may alter the dynamics and relationships of the entire family, and parents are often stressed and need assistance to enhance their competence, self-efficacy, and coping skills.
- Occupational therapists assess the strengths of a child with ASD and the areas of concern for the family and child and provide family-centered care to promote occupational functioning of the whole family.
- Interventions for ASD commonly include behavioral supports, sensory supports, cognitive and social supports, and the use of a variety of specific strategies and approaches that motivate the child with ASD, reduce fear and anxiety, and improve behavior, skill, and engagement.

Neuromotor: Cerebral Palsy

Patty C. Coker-Bolt • Teresa Garcia • Erin Naber

KEY TERMS

Motor control	Functional electrical stimulation
Hemiplegia	Gaming technology
Quadriplegia	Physical agent modalities
Botulinum toxin therapy	Rehabilitation robotics
Complementary and alternative medicine	Flexible and rigid taping
	Adaptive recreation

GUIDING QUESTIONS

1. What are clinical characteristics associated with the different types of cerebral palsy (classification and distribution in body)?
2. How do the primary and secondary impairments associated with cerebral palsy contribute to functional limitations?
3. How are current theories of motor control applied to interventions for children with cerebral palsy?
4. How does impaired muscle tone influence activity and participation in children diagnosed with cerebral palsy?
5. How are rehabilitative and compensatory approaches applied in comprehensive services for children with cerebral palsy?

Introduction

The term *cerebral palsy* (CP) describes a group of developmental motor disorders arising from a nonprogressive lesion or disorder of the brain.⁶ Associated damage to one of more areas of the brain may lead to paralysis, spasticity, or abnormal control of movement or posture. Although the injury to the brain is considered static, the pattern of motor impairment changes over time, often affecting development in all daily occupations of childhood.^{3,4} The motor disorders associated with cerebral palsy can be accompanied by disturbances of sensation, cognition, communication, and perception and by a seizure disorder.^{3,4} The lesion or damage in the brain may cause impairment in muscle activity in all or part of the body. Cerebral palsy typically affects the development of sensory, perceptual, and motor areas of the central nervous system. As a result, the child has difficulty integrating the information that the brain needs to correctly plan and direct movements in the trunk

and extremities that are used in everyday interactions with the environment. The muscles are activated in uncoordinated and inefficient ways and are unable to work together to create smooth, effective motion.^{4,8}

Prevalence and Etiology of Cerebral Palsy

Cerebral palsy is the most prevalent cause of persistent motor dysfunction in children, with a prevalence of one in 500 births to three in 1000 births.^{4,28,39} The prevalence of cerebral palsy has remained stable since the 1950s, although prenatal and perinatal care has improved dramatically over the last 4 decades.⁴⁵ Societal costs for persons diagnosed with CP are substantial, and estimates of total lifetime expenditures are estimated as high as \$11.5 billion.^{11,37} Average lifetime expenditure per child could exceed \$900,000 above ordinary costs of raising a child.^{11,37}

The diagnosis of CP is approximately 1.5 times more common in males and is higher among non-Hispanic African American children and children from low to middle income families.³² According to the United Cerebral Palsy (UCP) foundation, approximately 800,000 children and adults in the United States live with one or more symptoms of cerebral palsy.⁴⁸ The origin of brain injury may occur during the prenatal, perinatal, or postnatal period, but evidence suggests that 70% to 80% is prenatal in origin.^{3,4,28} The nervous system damage that causes CP can occur before or during birth or before a child's second year, the time when myelination of the child's sensory and motor tracts and central nervous system (CNS) structures occurs rapidly.

It is increasingly apparent that CP can result from the interaction of multiple factors, and in many cases, a single cause cannot be identified.⁴ Prenatal maternal infection, premature birth, low birth weight, and multiple pregnancies have been associated with cerebral palsy.²⁸ Prenatal factors may include genetic abnormalities or maternal health factors such as stress, malnutrition, exposure to damaging drugs, and pregnancy-induced hypertension. Some gestational conditions of the mother, such as diabetes, may cause perinatal risks to the developing infant; prematurity and low birth weight significantly increase an infant's chance of acquiring a cerebral palsy diagnosis.⁴⁴ Medical problems associated with premature birth may directly or indirectly damage the developing sensorimotor areas of the CNS. In particular, respiratory disorders can cause the premature newborn to experience hypoxemia, which deprives brain cells of the oxygen needed to function and survive. Typical postnatal causes of cerebral palsy include conditions

BOX 28-1 Risk Factors Associated with the Development of Cerebral Palsy**Prenatal**

- Genetic disorders
- Maternal health factors (e.g., chronic stress, malnutrition)
- Teratogenic agents (e.g., drugs, chemical exposure, radiation)
- Placental disruption (inability of the placenta to provide the developing fetus oxygen and nutrients)
- Lack of growth factors affecting fetal growth in utero (e.g., hormones, insulin, proteins)
- RH blood type incompatibility between mother and infant

Perinatal

- Prenatal conditions (e.g., toxemia secondary to maternal diabetes)
- Medical problems associated with prematurity (e.g., compromised respiratory and cardiovascular systems, intraventricular hemorrhage [IVH], periventricular leukomalacia [PVL])
- Multiple births
- Low birth weight

Postnatal

- Severe and untreated jaundice shortly after birth
- Infections (e.g., meningitis, encephalitis, chorioamnionitis)
- Alcohol or drug intoxication transferred during breastfeeding
- Hypoxic ischemic encephalopathy (HIE)—prolonged loss of oxygen during the birthing process
- Trauma during birth or shortly after^{3,4,28}

that result in significant damage to the developing CNS such as hypoxic ischemia encephalopathy resulting from lack of oxygen to the brain. Postnatal causes include infections or exposure to environmental toxins. **Box 28-1** lists risk factors associated with cerebral palsy.

Practice Models to Guide Interventions for Children with Cerebral Palsy

Because children diagnosed with CP have difficulty with postural control and movement against gravity, therapists frequently use *motor control and motor learning concepts* to guide intervention of children with movement disorders. The ability to regulate movement is complex and emerges from the interaction of the child, the task, and the environment. A child generates movement to meet the demands of the task being performed in a specific environment. For example, a child selects specific movements to use a spoon to eat a bowl of soup while sitting at the kitchen table with family. The selected movements are influenced by the child's ability to feel, hold, and manipulate a spoon; the task (e.g., type of soup, size of bowl, type of spoon); and the environment (e.g., how the child is sitting, who is present at the table, environmental sounds). In everyday life, a child performs a variety of functional tasks requiring simple to complex movements. Theories of motor control and motor learning are discussed in more detail in [Chapter 7](#).

Dynamic systems theory poses that movement is complex and multidimensional systems work in coordination to influence functional movement.³⁰ A good example of this is breathing,

which involves linking biomechanical and musculoskeletal systems (muscles in trunk, chest, and back) to respiratory function. The head remains stable because of postural support from the trunk and pelvis, demonstrating a linkage between the function of breathing and the control of head, trunk, and pelvis. This theory suggests that impairments of any one structure (e.g., the hand or shoulder) may have significant impact on multiple systems in the body. For example, a child with CP may have shortening of elbow flexors and loss of range of motion in the ankle. This may influence the child's ability to move his or her body in an efficient manner or generate coordinated complex movement to complete a functional task (e.g., put on a shirt). In addition, dynamic systems theorists hypothesize that functional movement is influenced by psychological, environmental, social, and physical characteristics of the child in the context in which a task occurs.

Several strategic principles of dynamic systems theory include a child's ability to self-organize motor actions through repetition and practice, thus creating new patterns from refinement of motor actions. The child's physical characteristics, activity demands, and environmental factors can influence the child's functional movement. For example, a child with CP may have underlying muscle weakness or abnormal muscle tone that limits his or her ability to sustain movement against gravity.³⁰ Environmental supports, such as a prone stander, can allow standing. Motor behaviors move through states of stability and instability, especially when a child is learning a new motor action. Periods of instability, or transition states, are when new forms of movement are most likely to occur.³⁰ [Chapter 7](#) provides an in-depth explanation of dynamic systems theory as it relates to the development of functional performance.

Reflex-hierarchic models hypothesize that motor development is based on central nervous system maturation. Motor development is "wired" in the brain, and an infant's first movements reflect lower level brain centers (i.e., the brainstem) before cortical brain functions mature allowing more controlled movement. Although this theory lacks evidence as a basis for intervention,^{40,41} certain therapeutic techniques, such as the Masgutova Neurosensorimotor Reflex Integration (MNRI) method, are based on the reflex-hierarchic theory and are sometimes used for children with cerebral palsy. The MNRI method assumes that motor reflex patterns play a subordinate role in the maturation of more complex motor reflex schemes (e.g., rolling over, sitting up, crawling) and that integrating reflexes can improve functional movement. A recent systematic review of interventions for children with CP concluded that interventions focused on meaningful goal-directed activity results in better outcomes than a focus on performance components (e.g., reflex). This systematic review did not support the use of MNRI.^{40,41} Consequently therapists selecting to use this approach should carefully monitor child progress and short-term outcomes to determine benefit. Most often occupational therapists use the tenets of these practice models in combination, dynamically, and tailored to meet individual needs.

Sensorimotor Function in Children with Cerebral Palsy

Posture, Postural Control, and Movement

To understand the functional movement problems that develop in children who have cerebral palsy, the occupational therapy

practitioner must be familiar with the ways that people typically control their bodies and execute skilled movements. The term *posture* describes the alignment of the body's parts in relation to each other and the environment. The ability to develop a large repertoire of postures and change them easily during an activity depends on the integration of automatic, involuntary movement actions referred to as the postural mechanism. The postural mechanism includes several strategic components:

- Muscle and postural tone
- Emergence of righting, equilibrium, and protective extension reactions
- Developmental integration of early, primitive reflex movement patterns
- Intentional, voluntary movements against the forces of gravity
- The ability to combine movement patterns in the performance of functional activities

Righting reactions and equilibrium reactions allow individuals to maintain upright posture with dynamic stability. When the head is out of alignment with the body, righting reactions realign the head with the body. An individual uses equilibrium reactions or balance reactions when the body's center of gravity is moved over the base of support. Equilibrium reactions are coordinated responses of trunk, neck, and extremities as the individual moves in and out of different postures. When righting and equilibrium reactions are not sufficient to regain an upright posture, individuals use a protective extension reaction (i.e., they automatically reach outward from their bodies to catch themselves or prevent a fall). A protective response requires the motor ability to quickly extend an extremity (i.e., arm or leg).

Atypical Movement Patterns in Cerebral Palsy

Children who have CP demonstrate difficulty achieving and maintaining stable posture while lying down, sitting, and standing because of impaired patterns of muscle activation.^{3,4} Poor postural alignment and stability result from the CNS's decreased ability to control co-activation and reciprocal innervation of select muscle groups. Co-activation of muscle, or simultaneous contraction of agonist and antagonist muscle groups, provides stability around a joint and stability of body posture. Reciprocal innervation in muscle groups occurs when excitatory input directs the agonist muscle to contract while inhibitory input directs the antagonist muscle to remain inactive.^{28,44} These reciprocal innervations allow for extremity and trunk movement. Children who have CP may develop abnormal movement compensations and body postures as they try to overcome these motor deficits to function within their environments. Over time, movement compensations and atypical motor patterns create barriers to ongoing motor skill development. Instead of freely moving and exploring the world, as children with a normally developing sensorimotor system do, children who have CP may rely on primitive and automatic reflex movement patterns as their primary means of mobility (Boxes 28-2 and 28-3).^{4,5,28}

Muscle tone is the force with which a muscle resists being lengthened; it can also be defined as the muscle's resting stiffness. It is tested by an occupational therapist's passive stretch of the muscle from the shortened to the lengthened state as the occupational therapist feels the resistance offered by the muscle to the stretch. A child's ability to perform sequential

BOX 28-2 Sensorimotor Problems in Children with Cerebral Palsy

1. Abnormal muscle tone
 - Hypertonicity—increase in resting state of muscle
 - Spasticity—velocity-dependent increase in muscle tone (occurs with active or passive movement)
 - Hypotonicity—decrease in resting state of muscle
 - Fluctuating—muscle tone changes between hypertonic and hypotonic
2. Persistence of atypical and abnormal primitive reflexes
3. Atypical righting, equilibrium, and protective responses
4. Poor sensory processing
 - Decreased processing of vestibular, visual, and proprioceptive information
 - Limited body awareness and body scheme
5. Joint hypermobility or joint stiffness
 - Reduced limb stability and poor co-contraction across joints
 - Reduced joint movement
6. Muscle weakness and poor muscle co-activation
7. Delays in typical progressing of motor movement and motor skills affecting adaptive function

BOX 28-3 Examples of Primary and Secondary Impairments in Children Diagnosed with Cerebral Palsy

Primary Impairments	Secondary Impairments
Muscle weakness or hypotonicity	Contracture in a joint (e.g., elbow, wrist, hip, knee, ankle)
Muscle tightness or hypertonicity	Poor or unsteady gait or mobility
Spasticity	Impairment of visual processing, hearing, or speech
Involuntary movement	Difficulty with bladder and bowel control
Weakness of eye muscles	Intellectual disability, learning disabilities
Abnormal muscle tone in facial musculature	Problems with breathing because of postural difficulties and weakness in trunk muscles
Impaired sensation in affected limbs	Skin integrity—increased risk of pressure sores
Possible seizure disorder	Difficulty in feeding, eating, and swallowing

movements is supported by muscle tension (stiffness) and elasticity during the movements. Muscles must have sufficient tone to move against gravity in a smooth, coordinated motion. Emotions and mental state, including levels of alertness, fatigue, and excitement, can also influence muscle tone. Normal muscle tone develops along a continuum, with some variability among members of the typical population. The muscle's qualities of contractility and elasticity are necessary for immediate, consistent responses to the elongation and contraction experienced during movement, such as during co-activation. Muscle tone

allows muscles to adapt readily to the changing sensory stimuli during functional activities. Decreased muscle tone, or hypotonia, can make a child appear relaxed and even “floppy.” Increased muscle tone, or hypertonia, can make a child appear stiff or rigid. In some cases of CP, an infant may initially appear hypotonic, but the muscle tone may change to hypertonia at 6 or 7 months.^{4,5}

Classification and Distribution

Cerebral palsy can be classified by the location of the lesion in the CNS and by distribution of abnormal muscle tone in the trunk and extremities. Involvement of one extremity is commonly referred to a *monoplegia*, upper and lower extremities on one side of the body as *hemiplegia*, both lower extremities as *paraplegia*, all limbs as *quadriplegia*, and all limbs and head/neck as *tetraplegia*. Cerebral palsy is also classified by the nature of the movement disorder according to four main types: (1) spastic, (2) dyskinetic, (3) ataxic, and (4) mixed (Table 28-1).^{4,28}

Children with spastic CP demonstrate hypertonia and muscle spasticity. Spasticity is defined as a velocity-dependent resistance to stretch.³⁸ Resistance to range of motion will either increase with speed of force or will increase with quick movement. The effects of spasticity are often associated with clonus, an extensor plantar response, and persistent primitive reflexes. As a child with spastic CP attempts to move, muscle tone increases and then rapidly releases, triggering a hyperactive stretch reflex in the muscle. Spasticity is associated with poor control of voluntary movement and limited ability to regulate force of movement. Distribution of spasticity can be monoplegia (rare), diplegia, hemiplegia, quadriplegia, or tetraplegia.

In dyskinetic CP, movement patterns are classified as athetoid, choreoathetoid, and dystonic, which generally affect the entire body. A child with dyskinesia exhibits excessive and abnormal movement, and often when initiating movement in one extremity, atypical and unintentional movements in other extremities result. The child with athetosis exhibits slow, writhing, involuntary motor movements in combination with abrupt, irregular, and jerky movements. Children with pure athetosis demonstrate a fluctuation of muscle tone from low to normal with little or no spasticity and poor co-activation of muscle flexors and extensors.

Children with choreoathetosis have constant fluctuations from low to high with jerky involuntary movement that may be seen more proximal to distal. Dystonic movements are sustained twisted postures that are absent at rest and triggered by movement (action). The movements follow a similar pattern,

and these repetitive postures support the diagnosis of dystonia (unlike choreoathetosis, in which movement fluctuations are random).

The third type of CP, ataxia, is characterized by poor balance and coordination. Children who have ataxia may show shifts in muscle tone, with quadriplegic distribution, but to a lesser degree than those with dyskinesia. Children with ataxic type CP are more successful in directing voluntary movements but appear clumsy and show involuntary tremor. They have considerable difficulty with balance, coordination, and maintenance of stable alignment of the head, trunk, shoulders, and pelvis. These children may have poorly developed equilibrium responses and lack proximal stability in the trunk to assist with control of hand and leg movements.

Children with CP who often show combinations of high and low muscle tone problems are classified as the mixed type. Those who have spastic CP move their extremities with abrupt hypertonic motions but may also exhibit marked hypotonicity in their trunk muscles. The distribution for mixed type CP is typically quadriplegic.

Hand Skills and Upper Extremity Function

Children with CP demonstrate problems with upper limb function resulting from abnormal muscle tone and decreased ability to maintain a stable posture when attempting functional tasks.^{28,29} Efficient performance of the arm and hand depends on proximal control and dynamic stability of the trunk and shoulder girdle. Children with CP demonstrate weakness in the shoulder girdle, may have contractures in their elbow, forearm, wrist, fingers, and thumb caused by hypertonicity, or may move the arm and hand in synergistic patterns, lacking the ability to isolate single joint movements. Postural instability can affect upper extremity movement also, as children with CP may need to use their upper extremity to support upright postures against gravity. When the upper extremity is fixed and used to help stabilize and compensate for trunk weakness, the arm and hand cannot be used for functional tasks (e.g., functional mobility such as pulling self from sit to stand or playing with toys at the midline of the body while challenged to sit unsupported).

Associated Problems and Functional Implications

Children with CP manifest primary impairments that are the direct result of the lesion in the CNS. Primary impairments are those that are an immediate and a direct result of the cortical

TABLE 28-1 Classification of Cerebral Palsy

Type of Movement Disorder	Area of Body Involved	Prevalence
Spastic	Diplegic: legs > arms	32%
	Quadriplegic: all four extremities	24%
	Hemiplegic: one-sided involvement, arm > leg	29%
	Double hemiplegic: both sides; one greater than other, arms > legs	24%
Dyskinetic	Choreoathetoid	14%
	Dystonic	
	Athetosis	
Ataxic		<1%
Mixed (percentages included above)		

CASE STUDY 28-1 Evaluation and Classification: Ben

Ben is a 9-month-old infant referred for occupational therapy services because of developmental delay. His mother is concerned that he is “not moving like his older brother was at this age.” At 9 months, he recently learned to sit independently but has difficulty rolling because of “tightness” in the left arm and leg. The occupational therapist completed a thorough evaluation including formal and informal assessment of body structure and function and developmental skills. She administered the Grasping and Visual Motor Integration subscales of the Peabody Developmental Motor Scales-2 (PDMS-2) and the Alberta Infant Motor Scales (AIMS). On each of the assessments, Ben scored below average when compared with typical age peers. He did not reach and grasp with his left arm and did not bring both hands to midline to play. He did not use both hands to hold a sippy cup and his mother reported difficulty putting on shirts and pants because

of tightness in Ben’s left arm and leg. During the occupational therapist’s clinical observation of Ben’s movement during play, she noticed that he exhibited limited control of left arm and leg movement when transitioning out of sitting, rolling, or reaching for objects. He did not use his left arm for protective reactions forward or sideways. She also noticed that his eyes were not aligned and his left eye appeared to drift laterally.

After her evaluation, the occupational therapist discussed the results of her evaluation with the referring pediatric neurologist. The neurologist ordered a magnetic resonance imaging (MRI) test to identify possible central nervous system lesion(s). The results of the MRI revealed that Ben has a lesion affecting the right primary motor cortex and internal capsule, and the neurologist confirmed a diagnosis of spastic left hemiplegic cerebral palsy.

lesion in the brain. Because the lesion occurs in immature brain structures, the progression of the child’s motor development may appear to change, causing secondary impairments (see [Box 28-3](#)). Normal nervous system maturation shifts control of voluntary movement to cortical brain areas. The child who has CP exhibits some changes in movement ability that result from the expected progression of motor development skills, but these changes tend to be delayed relative to age and often show much less variety than those seen in the typically developing child. See [Case Study 28-1](#).

Children with CP develop secondary impairments in systems or organs over time because of the effects of one or more of the primary impairments.^{3,45,46} These secondary impairments may become just as debilitating as the primary impairments. Although the initial brain injury is unchanging, the results or the secondary impairments are not static and change over time with body growth and attempts to move against gravity.^{4,8,28} When playing or in functional activities, children with CP move in atypical patterns that may become repetitive and fixed. The repetition of the atypical movement patterns prevents children with CP from gaining full voluntary control of their movements and can lead to diminished strength and musculoskeletal problems. The combination of impaired muscle co-activation and the use of reflexively controlled postures may lead to future contractures in the muscle, tendon, and ligamentous tissues, causing the tissues to become permanently shortened. Soft tissue changes can lead to contractures and possibly bone deformities; they can also cause spinal and joint misalignment.

In addition to the risk for joint contractures and deformities and spinal or joint misalignment, children with CP are at risk for skin breakdown and decreased bone density. Children in wheelchairs, who maintain sitting or lying for extended periods or who cannot independently shift their weight, risk skin breakdown. Children who are most vulnerable may sit with their body weight pressure on body prominences for prolonged time periods. Children in wheelchairs also experience decreased time standing or ambulating, negatively influencing the strength of the individual’s bones. Children diagnosed with CP may have decreased bone mineral density and are vulnerable to pathologic fractures.³⁵ Occupational therapy practitioners provide

opportunities for children with CP to maintain upright positions and bear weight in a variety of positions. This can be accomplished by providing children with adapted seating, such as specialized seats, prone or supine standers, and toys that promote weight bearing (e.g., scooters).

Children with CP may experience additional problems such as seizures and other medical conditions not directly related to the child’s movement disorder. When postural muscles are weak, breathing can be compromised. Abnormal posture and weak muscle activity may compromise cardiac and respiratory functions and prevent these systems from working efficiently. The resulting low endurance and fatigue can influence the child’s capacity for activity. The occupational therapy practitioner monitors each child’s physical endurance and plans therapeutic goals to increase strength and endurance.

Cognition and Language

Because CP is caused by a focal brain lesion, language and cognition may or may not be affected, depending on which areas of the brain are affected (e.g., frontal lobe, temporal lobe). Lesions affecting the frontal lobe may affect the child’s cognitive abilities, including attention, organization, problem solving, inhibition, and judgment. Lesions affecting both the primary motor and temporal lobes may affect language and speech development. Because speech requires complex movements of oral/facial structure and requires control of breathing, children and adults diagnosed with CP may have various problems with speech and language. These potential problems include decreased speech production, poor articulation, and decreased speech intelligibility. *Dysarthria* is the term used to describe a disorder of speech production secondary to decreased muscle coordination, paralysis, or weakness.

In addition to speech production disorders, children who have cerebral palsy may have changes in the quality of their voice resulting from decreased strength or control of respiratory and postural muscles. Because CP has the potential to affect areas of the brain outside of the motor system, children who have CP can have decreased expressive and receptive language skills. This means they have difficulty processing language-based information or producing responses. All of

CASE STUDY 28-2 Assistive Technology to Aid Communication: Antoine

Antoine is an 8-year-old boy with a history of a seizure disorder and athetoid cerebral palsy. He uses a power wheelchair for all mobility and an augmentative communication device for communication. He attends elementary school, where he is placed in an age-appropriate classroom with accommodations and related services, including physical therapy, occupational therapy, speech-language therapy, and assistive technology. Antoine's continuous body movements make it difficult for him to complete fine motor tasks, including accessing his communication device to communicate with his teacher and friends. He gets frustrated when he knows the answer to a question but cannot communicate it to his teacher and classmates in a timely manner. He has difficulty with fine motor tasks and it takes additional time for him to complete classwork.

Antoine's therapy team discovers that a head stick helps to improve his access to his communication device and that using his head, versus his hand, is a faster and more efficient way for him to access his communication device and a word processing program on the computer. The occupational therapist worked with his art teacher to fasten a holder for tools such as a paintbrush to his head stick. Now Antoine is able to creatively express himself through a variety of media, including paint and pastels, which do not require a lot of pressure when drawing. Antoine also seems to have improved success in using the device when he grasps the armrest of his wheelchair, so his occupational therapist tries mounting a bar on his tray for him to push into to improve his trunk stability.

these potential impairments can have a significant impact on the child's participation in age-appropriate activities with peers, understanding of and response to directions, making his or her needs known, and managing his or her own care. A child's cognitive and linguistic skill level is considered when developing goals and potential outcomes (Case Study 28-2).

Sensory Functions

Children with CP may have visual or sensory impairments. Visual impairments such as blindness, uncoordinated eye movements, and eye muscle weakness affect as many as 50% of children who have CP. Children who have more severe CP are more likely to have visual impairment.²⁷ Regardless of the functional level of a child, vision should always be taken into consideration during fine motor tasks, play, and activities of daily living completion. Vision plays an important role in timing of grasp and release, manipulating objects, orienting materials, making eye contact, and finding needed items. Children with visual impairments may use postural adaptations, such as a head tilt or changes to the angle of gaze, to compensate for visual deficits. These deficits may be oculomotor in nature, meaning their eye muscles do not move smoothly or in sync or may move involuntarily. The term *strabismus* refers to the eyes not being aligned because of muscle imbalance. Functionally, strabismus may cause difficulty with attending to visual tasks. The child may have decreased convergence or divergence, decreased depth perception, or double vision. Other terms describing misalignment of the eyes include exotropia (one eye drifts temporally), esotropia (one eye drifts nasally), hypertropia (one eye drifts upward), and hypotropia (one eye drifts downward). *Nystagmus* refers to the eyes constantly moving in a repetitive and uncontrolled way. Functional issues associated with nystagmus include reduced acuity, difficulty fixating on a target to maintain balance, reduced target accuracy when reaching or grasping, compensatory head movements, or posturing to compensate for visual deficit.

In addition to oculomotor impairments, children may have deficits in the way the brain processes visual information. Without proper processing, a child may not understand the spatial relationships among objects, be missing part of the visual

field, or not identify a partially hidden item, such as his or her coat in a closet.

Auditory reception and processing deficits have an impact on 25% of individuals with CP.²⁸ Hearing loss with both conductive hearing loss and sensorineural hearing impairments may occur if a child has been affected by a congenital nervous system infection.

Both vision and hearing should be tested regularly for children with CP.

Children with CP may have difficulty processing tactile and proprioceptive information (e.g., fingertip force regulation during object manipulation).²³ Children with CP may also demonstrate tactile hypersensitivities (e.g., overreacting to touch, textures, and changes in head position), causing some children to become visibly upset when handled or moved by others. When children have multiple sensory processing problems, they may have difficulty understanding and responding to the social and physical elements of their environments. Oral tactile sensitivity may be associated with abnormal oral movement patterns. Children may have aversion to certain food textures, causing disorganized oral motor control and problems coordinating chewing, sucking, and swallowing. Those with severe problems in this area may be surgically fitted with a percutaneous endoscopic gastrostomy (PEG) tube for feeding. Occupational therapy practitioners must consider a child's sensory limitations and strengths when setting intervention goals. The practitioner considers which sensory experiences are likely to improve occupational performance.

Assessment

Clinical observation of the child's occupational performance provides the occupational practitioner with data on factors influencing the child's muscle tone, reflex activity, gross and fine motor skills, sensory systems, cognition, perception, and psychosocial development. Clinical assessment data create a "picture" of the child's functioning and indicate his or her strengths and weaknesses. Observation of a child completing simple tasks such as putting on a shirt, transitioning from a

TABLE 28-2 Selected Upper Limb Assessments for Body Structure, Function, and Activity for Children with Cerebral Palsy

Assessment	Age	Domain and Activities
Melbourne Assessment of Unilateral Upper Limb Function (MUUL) ^{16,42}	5-15 years	Assessment of impairment and activity limitations in the upper extremity. Examiner administers 16 items that involve reach, grasp, release, and manipulation. Each item is scored according to specific criteria to rate quality of range of motion, accuracy, fluency, and dexterity, yielding a maximum possible raw score of 122.
Quality of Upper Extremity Skills Test (QUEST) ^{21,47}	2-13 years	A criterion-referenced observational assessment measuring 34 items in four domains (dissociated movement, grasp, weight bearing, and protective extension). Scores from each domain are summed and converted to a percentage score.
Jebson Taylor Test of Hand Function (JTTHF) ¹⁹	6-17 years	A clinical evaluation of speed and dexterity of upper limb tasks. The seven timed subtests vary in complexity and use everyday objects to assess how a child uses grasp and release in daily tasks.

TABLE 28-3 Selected Participation and Quality of Life Measures for Children with Cerebral Palsy

Outcome Measure	Age	Domains and Relevant Items
Cerebral Palsy Quality of Life (CP QOL)—Child ⁴⁹	4-12 years Parent report; Child report 9-12 years	66 items 1. Social well-being and acceptance 2. Participation and physical health 3. Functioning 4. Emotional well-being 5. Pain and impact of disability 6. Access to services 7. Family Self-report: 53 items
Cerebral Palsy Quality of Life (CP QOL)—Teen ¹⁹	12-18 years Child report	72 items 1. Well-being and participation 2. Communication and physical health 3. School well-being 4. Social well-being 5. Access to services 6. Family health 7. Feelings about functioning

chair to the floor, opening containers, or playing with age-appropriate toys helps the occupational therapist identify atypical postures and movements that may be limiting functional abilities. Early identification and intervention of atypical postures may minimize the use of compensatory and dysfunctional movements, which could lead to secondary impairments and decreased functional abilities for children with CP. During therapy sessions, the occupational therapist facilitates mature and typical movement patterns to promote progress in typical developmental milestones.

Thorough assessment data are essential when working as part of a service delivery team. Selection of assessment measures may be based on several factors, including the child's age, setting (e.g., home health, school system, community), and the caregiver's and child's specific concerns about functional limitations. Table 28-2 provides information on specific classification systems and assessments commonly used for children diagnosed with CP. Two assessments are designed specifically to measure quality of life and overall participation in children with CP (Table 28-3). Functional classification systems include the

Gross Motor Function Classification System (GMFCS) and the Manual Ability Classification System for Children with Cerebral Palsy (MACS) (Tables 28-4 and 28-5).

The occupational therapy practitioner uses assessment information, including parent concerns and priorities, to formulate goals that match the child's needs, developmental performance, and potential outcomes. Examples include increasing a child's ability to participate in a classroom writing activity and teaching family members adaptive techniques so that they can bathe or feed a child with greater ease. Goals for the adolescent might address accessing public transportation or learning ways to perform homemaking skills. See Box 28-4 for sample goals.

Occupational Therapy Interventions

The occupational therapy practitioner plans and implements interventions to promote function and independence in children with CP. Practitioners may work one-on-one with the

TABLE 28-4 Gross Motor Function Classification System

Level	Description of Functional Abilities
Level I	Walks without limitations. Performs gross motor skills like running and jumping but speed, balance, and coordination may be impaired.
Level II	Walks with limitations. This includes on uneven surface, inclines, stairs, long distances, or in crowds or confined spaces.
Level III	Walks using a hand-held mobility device. Walks on even surfaces, indoors and outdoors with an assistive device. Children may use manual wheelchair for long distances.
Level IV	Self-mobility with limitations. Child may use powered mobility or require assistance from a caregiver. May walk short distances with a mobility device but relies primarily on wheeled mobility.
Level V	Transported in a manual wheelchair. Child has no means of independent mobility and relies on caregiver for all transportation needs.

From Palisano, R., Rosenbaum, P., Walter, S., Russell, D., Wood, E., & Galuppi, B. (1997). Development and reliability of a system to classify gross motor function in children with cerebral palsy. *Developmental Medicine & Child Neurology*, 39, 214–223.

TABLE 28-5 Manual Ability Classification System

Level	Description of Functional Abilities
Level I	Handles objects easily and successfully. At most times, handles objects with both hands. The child may have limitations in the ease of performing manual tasks requiring speed and accuracy. However, any limitations in manual abilities do not restrict independence in daily activities.
Level II	Handles most objects but with somewhat reduced quality and/or speed of achievement. The child may avoid certain activities or the activity will be achieved with some difficulty. The child develops ways of performing some manual activities that do not usually restrict independence in daily activities.
Level III	Handles objects with difficulty; needs help to prepare and/or modify activities. The child's performance is slow and achieved with limited success regarding quality and quantity. The child cannot perform certain activities and his or her degree of independence is related to the supportiveness of the environmental context. Activities are performed independently if they have been set up or adapted.
Level IV	Handles a limited selection of easily managed objects in adapted situations. The child performs parts of activities with effort and with limited success. Requires continuous support and assistance and/or adapted equipment, for even partial achievement of the activity.
Level V	Does not handle objects and has severely limited ability to perform even simple actions. Requires total assistance.

The Manual Ability Classification System (MACS) for children with cerebral palsy: Scale development and evidence of validity and reliability. *Developmental Medicine and Child Neurology*, 48, 549–554.

BOX 28-4 Sample Occupational Therapy Goals

Self-care	Child will don pullover shirt with minimal assistance, 100% trials. Child will use adaptive spoon to eat soft solid foods with modified independence.
Play	Child will show improved postural control to engage in 15-minute play activity while sitting unsupported at table with minimal physical support from occupational therapist.
Recreation	Child will successfully participate on an adaptive community sports team with same-aged peers, per parent's report.
Fine motor	Child will write first name from memory with no errors, 80% of trials. Child will isolate right index finger to successfully access games on iPad, 4 out of 5 trials.

child, lead groups of children with similar goals, or take a consultative role in assisting caregivers with problem-solving adaptive tools and strategies to encourage the child's independence. They can work with children in a variety of settings, including school, home, and the community. A recent comprehensive review of interventions used with children with CP⁴⁰ found the following interventions to be supported by current evidence, including adaptive equipment training, casting and orthotics, constraint-induced movement therapy, functional and goal-directed therapy, and bimanual training. These interventions, as well as an overview of additional interventions that occupational therapists may select to address the functional goals for children with CP, are provided in this section. The use of specific practice models is highlighted.

Adaptive Equipment Training

A variety of adaptive devices and equipment can assist a child with CP to complete activities of daily living (ADLs), instrumental activities of daily living (IADLs), play, and educational tasks. These devices serve to modify or control some of the

CASE STUDY 28-3 Feeding and Adaptive Equipment: Brian

Brian is an 11-year-old boy who was born at 35 weeks' gestation by emergency cesarean section. He was had global developmental delays with hypotonia and was diagnosed with quadriplegic cerebral palsy and neurodevelopmental disability.

He quickly becomes fatigued during self-feeding, and requires assistance with spoon feeding to obtain adequate nutrition. His mother reports that she often feeds him at home so he is able to eat much more quickly. She reports that he is easily distracted when eating.

During an occupational therapy assessment, Brian grasped a toddler spoon with large handle as well as a bent-handled spoon with large handle. He switched hand dominance, but performed best when using his left hand. He required moderate to maximum assistance to scoop thick foods from a scoop bowl and minimal assist to transport foods to his mouth without spilling.

Brian required repeated tactile and verbal cues to close his lips around the spoon and use his top lip to clear the spoon. He prefers to “dump” food into his mouth. He exhibited tongue thrust movements to move food laterally and posteriorly for swallowing. No coughing or choking was observed.

Brian used a straw to drink thin liquids from a juice box, but he had difficulty creating a tight seal with his lips and lost small amounts of liquid when drinking. The occupational therapist suggested an adapted straw with a larger opening to make it easier for him to drink.

Brian made gains in his ability to clear the spoon with his top lip when he was given assistance to stabilize his lower jaw and verbal cues to use his top lip to clear the spoon. He made improvements in his ability to move food from the bowl to his mouth without spilling. See [Chapter 14](#) for additional information on feeding interventions.

degrees of freedom required for children to engage in daily activities. The occupational therapist selects a device that matches the child's motor needs while simultaneously considering his or her sensory functioning (including vision, auditory, and sensation), the environment in which it will be used, and the child's position when using it (standing, sitting, or in his or her wheelchair or bed). Other considerations are the child or family's ability to transport the adaptive equipment, the set up needed to use it, and the ease of cleaning the device.

The occupational therapist may work with interdisciplinary team members when determining the child's needs. For example when selecting a communication device for a child with quadriplegic CP and cortical visual impairment, an occupational therapist may work with a low vision therapist and speech-language pathologist to select the most appropriate device and determine the most efficient way to access the device and the optimal position to mount the device for ease of visual scanning. The occupational therapist may recommend adaptive utensils during mealtime to compensate for limited grasping patterns or nonskid material to control the child's plate on the tabletop. Dressing tasks can also be modified to optimize the child's safety, efficiency, and independence.

A large zipper pull on jeans or pants may be recommended for a child with diplegic CP and limited fine motor coordination ([Case Study 28-3](#)). The occupational therapist practitioner should become familiar with a diverse group of assistive devices so that equipment recommendations consider all occupational performance concerns and the family's financial resources. It is also common for occupational therapists to fabricate assistive devices from common household materials or splinting materials ([Case Study 28-4](#); [Figure 28-1](#)).

Casting, Orthotics, and Splinting

Splinting or casting can be used to improve hand function, prevent joint contracture, improve hygiene, or relieve pain in a specific joint. Splinting may also be used to reduce unsafe behaviors in a child with self-injurious behaviors. Splints and orthotics can support the arm in a functional position to improve performance in activities of daily living (see

[Chapter 29](#)). Serial static splints and casts are designed to lengthen tissues and correct deformity through application of gentle forces sustained for extended periods of time with the goal of reducing tightness or spasticity in a selected muscle group. Splints are remolded and casts replaced at intervals that allowed for the muscle tissue to respond to the lengthened position. The biomechanical effects of splinting and casting relate to changes in the length of muscle and connective tissues, which can reverse the effects that occur when a muscle is maintained in a shortened position. Splinting to lengthen tight and contracted muscles in children with CP is best if applied continuously for periods greater than 6 hours.⁵⁰ Casting has additional biomechanical and neurophysiologic effects, although the exact neurophysiologic effects of casting on spasticity are not well defined at this time. It is theorized that inhibition of muscle contractions allowing lengthening of muscle tissue results from decreased cutaneous sensory input from muscle receptors during the period of immobilization. The effects of neutral warmth and circumferential contact also are believed to contribute to modification of spasticity ([Figure 28-2](#)).³²

Splints can also be used to meet the goals of the child or parent. For example, a splint may be fabricated to isolate a child's index finger to access a touch screen device or communication system. Splints have been used to compensate for hand deformities preventing the ability to grasp eating or writing utensils. Splints may also be used to aid in the ability to drive a power wheelchair such as a wrist support that allows a child to access the joystick control. Temporary splints are also fabricated by therapists to prevent movement from the hand to the mouth when children exhibit self-injurious behaviors or attempt to pull out feeding tubes, intravenous lines, or tracheostomy tubing. A systematic review of splint use in children with CP reported that splinting when combined with an active therapy program³² can have positive effects on function. The use of splinting alone without use of other complementary interventions does not have evidence of efficacy. When an occupational therapist determines that a child would benefit from wearing an orthosis or cast, he or she needs to educate parents as to the purpose and goals for the orthosis, provide instructions for donning, doffing, and cleaning, and

CASE STUDY 28-4 Adaptive Equipment to Improve Self-Care Skills: Nathan

Nathan is a 14-year-old boy with spastic quadriplegic cerebral palsy and normal cognition. He uses a power wheelchair. His posture is poor and he has impaired righting equilibrium and protective responses. He requires a chest strap and lateral supports on his wheelchair to assist with postural alignment and upright seating in his chair. His dynamic unsupported sitting balance is poor and his static sitting balance on the edge of his bed is fair but requires close supervision. Fine motor skills are significantly impaired with limited grip strength; his left hand is more affected than his right. Nathan has not received occupational therapy services since he was 10 years old when he and his family decided to take a break from services and explore adaptive recreational activities and aquatic therapy. Recently (at 14) he requested to return to services to become more independent in self-care. His family also recently purchased a computer tablet for him and he is interested in finding applications that will help him control his environment. At his initial evaluation the occupational therapist conducted the Canadian Occupational Performance Measure (COPM)³³ with Nathan. He identified his most important occupational performance problems as doffing his shoes, completing simple meal preparation, turning on his bedroom lights, and completing written work for school assignments. During the evaluation the occupational therapist determined that his power wheelchair was the safest place for him to complete ADLs since it offered him the best postural support.

Occupational Therapy Goals

1. While sitting with trunk supported and using adapted equipment, Nathan will successfully doff shoes within 1 minute.
2. Nathan will follow four-step instructions to prepare a simple meal with intermittent verbal cueing by the therapist.
3. Using a tablet programmed for environmental control placed on his power wheelchair, Nathan will successfully turn lights on in rooms at home, 100% of trials.
4. Nathan will dictate all appropriate school reports using adaptive word processing program with supervision and set up only.

Over the course of his 12-week admission, the occupational therapist tried and evaluated various adaptive equipment training. To increase independence in lower extremity dressing, Nathan attempted to use a reacher and long-handled shoe horn with good success. By the end of the 12 weeks, Nathan successfully unstrapped his foot supports, untied his shoes, and, using a long-handled shoe horn, doffed them. He continued to require assistance with doffing his ankle foot orthoses (AFOs) but was making progress toward independence with the strategies and adaptive equipment provided by his therapist.

To address simple meal preparation activities, the occupational therapist suggested use of an adapted cutting board that secured food and use of a rocker knife. Positioning his chair to the side of the counter to retrieve materials with his stronger arm was also beneficial. With a consult from an assistive technology specialist Nathan and the occupational therapist explored tablet applications for environmental control and found one that controlled the lights, his television, and his DVD player. The occupational therapist fabricated a mount with a Loc-Line modular hose system that allowed him to easily reposition his computer tablet or push it out of the way when not in use. The assistive technology specialist also recommended text-to-speech software and agreed that the most effective position for him to dictate school reports was in his chair, where he had the best breath support. Nathan worked with the occupational therapist to learn how to use the software and his speech-language pathologist was consulted for strategies to improve his articulation. At the end of the 12 weeks the occupational therapist reassessed his progress through structured observation and re-administered the COPM. Nathan reported improved performance and satisfaction with his performance on all the performance goals identified at admission, with the greatest change noted on meal preparation tasks. Because of his progress the occupational therapist reduced visits to one-time monthly consultative sessions for the next 6 months.

determine an optimal wearing schedule that fits the family's routines.

Constraint-Induced Movement Therapy

Constraint-induced movement therapy (CIMT) is an evidence-based intervention for children with hemiplegia that targets the functional use of the child's affected upper extremity through engagement in intensive practice, shaping and grading of targeted movements, and restricting use of the unaffected, stronger upper extremity. Children with hemiplegia often show "developmental disregard"²⁰; that is, they learn to ignore the involved arm because it is inefficient. Therefore use of the involved arm is negatively reinforced despite the function that may be available. The goal of CIMT is to reverse this effect. Constraint-induced movement therapy developed out of basic

experimental psychology research by Edward Taub and his colleagues on sensory contributions to motor learning in primates.⁴³ Constraint-induced movement therapy was initially used in the rehabilitation of patients post stroke and then developed as an intervention for children. Multiple case reports, cohort studies, and randomized control trials have reported the effectiveness of this intervention technique.^{1,7,10-13,31}

Current implementation of CIMT varies, but all programs have three essential features: (1) some method of constraint of use of the unimpaired upper extremity; (2) intensive, repetitive practice of motor activities, for up to 6 hours per day, for 2 to 4 weeks; and (3) shaping of more complex, functional motor acts by identifying the component movements of a targeted task and rewarding actions that are successive approximations to the task. The literature reports a variety of constraining devices and wearing schedules, including mitts, casts, splints,

FIGURE 28-1 Example of a pre-fabricated wrist and thumb support with thermoplastic insert for a child with hemiplegia. (Photos courtesy of Kennedy Krieger Institute.)

FIGURE 28-2 An example of sensory exploration during modified CIMT.

and slings. Use of constraining devices may be intermittent and they may be removed at certain times of the day or after massed practice trials are completed, or they may be applied continuously, allowing for practice and generalization of skills throughout the child's day for a set period of time.^{7,31}

Constraint-induced movement therapy can be defined as either a signature CIMT or modified CIMT (m-CIMT). A signature CIMT approach has five essential components,

including (1) constraint of the unaffected upper limb, (2) a high dosage of repetitive task practice (3 to 6 hours of therapy per day over several consecutive days), (3) the use of shaping techniques, (4) therapy provided in a natural setting, and (5) a transition or post-CIMT program to maintain gains acquired during CIMT program.⁴³ A typical signature approach provides massed practice and shaping of more mature motor movement for at least 2 consecutive weeks (14 to 21 days, dosage equal to 42 to 128 hours) by a professional with an understanding of rehabilitation techniques to improve motor function (*Case Study 28-5*).

Modified constraint-induced movement therapy (m-CIMT) is defined as constraint of the stronger or less affected upper limb combined with less than 3 hours per day of therapy. Most of the five essential elements of the signature approach are provided, but with modifications, including variation in where the therapy is provided (e.g., clinic or camp versus individual treatment at home) or a variation in the dosage of therapy (e.g., less concentrated, may be more distributed over several days or weeks).⁴³ Massed practice may be provided by a professional with training in CIMT, but not necessarily an occupational or physical therapist^{14,15} (e.g., parent, daycare worker, camp counselor). Unlike occupational therapists in adult settings, pediatric therapists using CIMT embed repetitive task practice in daily functional and play activities (*Figures 28-3 and 28-4*).^{14,15} Research questions remain about appropriate dosage, optimal age for treatment initiation, and optimal repeat intervention intervals.⁴³

CASE STUDY 28-5 Constraint-Induced Movement Therapy: Logan

Logan is a 3½-year-old boy with hemiplegic cerebral palsy. Until he was 3 years old he received home-based services through an early intervention program. When he turned 3, he began outpatient occupational therapy services once a week. Logan's goals included increased arm strength such that he maintains a quadruped position for a minute, full arm extension to push his arm through his shirt sleeve, and pulling up his pants with both hands. Another goal is to grasp toys with his right hand and carry toys with both hands.

Occupational Therapy Goals

1. Logan will show improved upper extremity strength to play in a quadruped position for up to 10 minutes with no physical cue required from the therapist.
2. Logan will be able to push both arms through sleeves of long sleeve shirt with minimal assistance from therapist or caregiver, 100% of trials.
3. Logan will pull pants up from knees to waist after toileting with minimal assistance from therapist or caregiver, 80% of trials.

Logan participated in a constraint-induced movement therapy program at an outpatient clinic. Logan attended a program for 3 hours a day and wore a continuous cast on his unaffected, stronger arm. Activities that are motivating such as carrying a bucket loaded with balls and picking up cars and putting them on a race track are done at a high level of repetition. Imaginary play activities, such as pushing his affected arm through dress-up clothes, help him generalize these new skills to play and ADL tasks.

CASE STUDY 28-6 Functional Electrical Stimulation: Ava

Ava is a 17-year-old girl with hemiplegic cerebral palsy affecting her left side. Ava is learning to drive and has worked with a driver rehabilitation specialist to adapt her mini-van. As training progressed, Ava reported that she had difficulty opening the car door with her left hand when holding her backpack or her textbooks in her right hand. The occupational therapist developed a strengthening program for Ava's left hand grip and an electrical stimulation program for her left wrist extensors. Ava's electrical stimulation device was pre-programmed with the help of the therapist. During the

intervention session, Ava took a photo with her camera phone of electrode placement on her left forearm. During occupational therapy, Ava demonstrated placing the pads in a correct location and collaborates with the occupational therapist to develop a list of activities to complete during electrical stimulation, which was 4 days per week for 20 minutes at home. Activities include playing games on a touch screen tablet positioned on a vertical surface, waxing her car, yoga positions in prone, and writing on a vertical surface.

Physical Agent Modalities

Various modalities target increasing muscle length and strength and reducing spasticity in children with CP to improve a child's functioning in play, ADLs, IADLs, and academics. These intervention modalities include electrical stimulation and hot/cold therapy. Heat may be used in conjunction with a stretching program to improve muscle length and reduce pain. Electrical stimulation can be used to strengthen antagonist muscles, re-educate muscles, target pain reduction, improve coordination, increase range of motion, and reduce spasticity (Case Study 28-6).^{6,51} Electrical stimulation is most effective when used with a functional activity, such as combing hair when stimulating the biceps or releasing toys into a container while stimulating wrist extensors. Use of neuromuscular electrical stimulation when applied with intensity can improve upper limb range of motion and strength, especially when paired with dynamic splinting.⁵¹ Occupational therapy practitioners should defer to their state regulatory boards regarding guidelines for application and training requirements for using physical agent modalities (PAMs). Some states may require a physician prescription before administration. Risk for burns is an important consideration, and contraindications such as cancer apply. Practitioners should complete advanced training in physical agent modality application before using PAMs.

Therapeutic Taping and Strapping

Two types of therapeutic tape are used in rehabilitation. Therapists use *rigid tape* to limit movement around a joint or to protect a joint during functional movement, while flexible, elastic *kinesiology tape* is used to facilitate improved movement patterns.⁵²

Kinesiology tape is applied directly to a child's skin and works by increasing stimulation to cutaneous mechanoreceptors that facilitate muscle contraction or inhibition (Figure 28-5). The elastic properties of the tape can also be used to reposition joints to a more appropriate alignment. Four major functions of kinesiology tape are to (1) support a weakened muscle, (2) improve circulation, (3) reduce pain, and (4) improve joint alignment.⁵² Published evidence to support or refute the use of taping interventions is minimal at best and is often reported in small case studies or cohort studies without controls.^{17,52} A recent case study reported significant improvements on sit-to-stand performance of a child with CP after application of elastic tape to lower extremity muscles.¹⁷ Another

FIGURE 28-5 A screen shot of robotic device software.

report by Footer²⁶ examining rigid taping techniques found no improvements in postural control in a sample of 18 children with quadriplegic CP. Because of potential skin sensitivities in children, it is always important before taping a full joint, to apply a small "test" strip to the child's skin to check for negative reactions to the properties of the tape. Advanced training in kinesiology and rigid taping applications is available through continuing education courses.

Positioning, Handling, and Neurodevelopmental Treatment

Occupational therapy practitioners often employ neurodevelopmental treatment (NDT) techniques of therapeutic positioning and handling to assist children with CP to optimize their independence with functional tasks. Occupational therapists determine the safest and most efficient positioning and handling techniques to facilitate completion of ADLs and IADLs. They recommend and select wheelchairs, standers, activity chairs, commode or bath chairs, and side-lyers to aid in completing play and ADL tasks. The occupational therapist makes recommendations for positioning, seating, and mobility in collaboration with interdisciplinary team members from rehabilitation engineering, speech-language pathology, and physical therapy depending on the complexity of the child and his or her needs. For example, an occupational therapist may suggest a reclined bath chair with a seat belt to support a child with quadriplegic CP and poor head control during bathing. A

school therapist may suggest a slant board and foot support to improve posture during writing tasks for a child with hemiplegic CP.

In addition to positioning in preparation for tasks, therapeutic handling can affect a child's tone throughout the body to assist with efficient muscle activation for movement. As a preparatory technique, handling techniques such as imposed rotational movement patterns, slow rocking, and bouncing facilitate or inhibit the child's muscle tone and enhance arousal level. Often children with CP have poor body awareness and a limited ability to anticipate postural changes required for movement or anticipatory control.³⁰ Facilitated weight bearing and weight shifting can build strength, improve co-contraction, and improve postural symmetry and alignment in children with CP. For example, an occupational therapist working with a child who tends to move in an extensor pattern may facilitate sustained flexion of the trunk and slow trunk rotation in sitting and knee flexion in quadruped in preparation for sitting in a chair for mealtime.

A practitioner may also train a parent to complete these activities with the child before dressing. If the child has high tone and his or her muscles are stiff, positioning and handling techniques may facilitate movements required for dressing and self-care tasks. Improved passive knee flexion reduces the burden of care on the caregiver while donning a child's pants. Evidence to support this intervention is mixed as recent studies have not been able to isolate the effect of treatment to this intervention.⁹ Neurodevelopmental treatment research shows conflicting findings and results are difficult to interpret because researchers used a variety of outcome measures; few studies were randomized; and samples included participants with a wide range of functional abilities.^{9,40}

Community Recreation

Children and teens with disabilities are at risk for limited participation in recreational and leisure activities,⁸ and youths with physical disabilities experience two to three times the activity limitations that are experienced by children with other chronic conditions.³⁹ In addition, children with disabilities are more restricted in their participation compared with their peers. Their leisure activities tend to be limited; they attend fewer social engagements and spend less time in quiet recreation than their typically developing peers.⁴⁶ Children with disabilities tend to be involved with more informal versus formal recreation activities and participate less in physical and skill-based activities.^{33,34} Occupational therapy practitioners can assist children with CP in accessing adaptive recreation options. Children's recreation and leisure participation can be divided into formal activities (e.g., structured activities with rules and often a leader) and informal activities (e.g., child-initiated, unstructured activities).³⁴ Occupational therapists can assist in identifying preferred formal and informal leisure and recreational activities for children with CP and also can assist in the modification of specific activities to meet the needs of the child both at home and in the community. For example, an occupational therapist may suggest the use of a tee stand for a child with hemiplegia to participate on a softball team with his or her peers or may provide a universal cuff to allow a child to participate in playing a video game at home. Occupational therapists may also guide families to appropriate community

organizations that provide recreational activities for children with disabilities.

Complementary and Alternative Medicine

The National Center for Complementary and Alternative Medicine defines *complementary and alternative medicine* (CAM) as "a group of diverse medical and health care systems, practices, and products that are not generally considered part of conventional medicine."³⁸ Conventional medicine is practiced by holders of M.D. (medical doctor) or D.O. (Doctor of Osteopathic Medicine) degrees and by their allied health professionals such as physical therapists, psychologists, and registered nurses. Over the past several years, the use of CAM approaches, including yoga, has become more popular. According to the 2007 National Health Interview Survey, which gathered information on CAM use among more than 9000 children aged 17 and under, nearly 12% of the children had used some form of CAM during the past 12 months. The top five most commonly used forms of CAM therapy included natural products, chiropractic and osteopathy, yoga, and homeopathic treatments. Majnemer and colleagues³⁶ reported that 25% of the 166 adolescents with CP surveyed in their study currently use or had used some form of CAM. The most popular of these was massage. Some occupational therapy practitioners with training in these methods or advance certifications may use CAM to help children with CP engage in leisure activities to improve overall quality of life. Ultimately occupational therapists are responsible for the safety of their patients and use their clinical judgment and the best available evidence to determine use of these intervention techniques to complement service delivery.² Complementary and alternative medicine approaches commonly used by occupational therapists include guided imagery, myofascial release, yoga, and meditation.²

Robotics and Commercially Available Gaming Systems

Robotics is an emerging technology to enhance motor and cognitive performance in children diagnosed with CP. These devices typically employ robotic arms, joysticks, or other controllers to measure the patient's performance on the targeted movement. Early studies demonstrate that children using robotic devices in therapy sessions are motivated and make positive gains.^{24,25} *Rehabilitation robotics* is the use of robotic devices to restore or improve function for a person with a disability. Robotics can be part of a prosthetic, used as an assistive device for some functional task, or used therapeutically to achieve a high level of repetition of movement patterns. Therapeutic robotics may be used to achieve massed practice during a therapy program. Because most devices have settings that progress and challenge movement patterns and strength, the occupational therapist can select the level of challenge most appropriate for the child.

Robotic devices range from large stationary devices with both gross and fine motor components to glove-based systems with small sensors (see Figures 28-6 and 28-7 for examples of different devices). Most robotic devices are connected to a computer so that the child can receive feedback from the game graphics on a screen or monitor (see Figure 28-6). Figure 28-7

**CASE STUDY 28-7 Gaming Technology: Aiden**

Aiden is a 7-year-old boy with diplegic cerebral palsy. He walks with Lofstrand crutches and is working on simple snack making and lower body dressing sitting on the side of his bed. His family has a Wii gaming system at home. Although he has some trouble keeping up with his brother during outdoor play, they are evenly matched when playing these games at

home. His occupational therapist develops adaptations to the Wii and makes it part of his home exercise program. With these adaptations, the Wii offers Aiden a recreational activity that also promotes arm and hand coordination and strength (see [Figure 28-7](#)).

**CASE STUDY 28-8 Medical Interventions and Orthotics: Chloe**

Chloe is a 10-year-old girl with spastic quadriplegic cerebral palsy and cognitive delay. Chloe has limited finger extension and significant wrist flexion contracture. Her mother reported that she recently had difficulty thoroughly washing Chloe's hands, especially her left palm. A stretching home program was trialed for 6 weeks with no changes in Chloe's functional ability to open her hand. After discussing intervention options with the physiatrist and occupational therapist, Chloe's mother agreed to botulinum neurotoxin injections to Chloe's thenar eminence and wrist flexors in conjunction

with serial splinting for 2 hours during the day and all night splint wear for the next 12 weeks. Two weeks after the injection her mother noticed a significant change in the muscle tone of her left hand. Her hand was more relaxed, making it easier for her mother to open her hand for hygiene tasks and to don her splints. In addition to splinting, the therapist recommended activities to encourage hand opening, such as movement to songs that required hand opening, releasing a ball into a container, and tossing a ball to her service dog.

shows adaptations that allow children with limited hand function to use a robot arm or access gaming technology. Research on the effectiveness of robotics for children with CP is limited. One study reported that use of robotic training with children with hemiplegia demonstrated improved range of motion and coordination of the upper limb.²²

Gaming technology refers to the use of commercially available video game systems in the clinical environment in ways that are integrated with planned therapy. In recent years, a number of gaming devices that require gross motor activity to successfully operate have become commercially available and are quickly being incorporated into clinical rehabilitation programs. Research on use of these devices in rehabilitation is limited to case reports. In one report, an adolescent with spastic diplegia showed positive changes in mobility, postural control, and visual perception after using the Nintendo Wii for 11 sessions (see [Case Study 28-7](#)).

Use of robotics and gaming technology should be selected with caution. When choosing a device or gaming system, an occupational therapist considers multiple factors. The child's age and cognitive ability suggest his or her capacity to follow directions and play games associated with the device. The size of the child's arm and hand may prohibit his or her use of a robotic device that was created for adult use. Baseline level of motor function helps determine the level of additional support or adaptations a device may require for the participant to hold the device. Visual perceptual capacities may pose a challenge or add additional frustration to game play. Games with high contrast or solid backgrounds may be easier for the child to see. During intervention, occupational therapists monitor for compensatory movements that could cause repetitive use injuries and provide breaks at regular intervals. The occupational therapist is responsible for monitoring muscle fatigue and providing the appropriate challenge based on the child's performance. Robotics, virtual reality, and commercially available gaming systems may complement an occupational therapy plan of care

because they motivate the child and provide additional opportunities for massed practice.

Medical Based Interventions

Physicians may prescribe pharmaceuticals, recommend surgeries, or apply specific medical interventions for children and youth with CP. Medical interventions are often used in conjunction with occupational therapy to maximize the effect. Children with spasticity may benefit from medications that reduce muscle tone. Baclofen is a medication that may be dosed orally or injected into a pump that delivers the medication directly into the cerebrospinal fluid. Baclofen reduces muscle tone throughout the person's body.

Botulinum neurotoxin, commonly called Botox, is a more specific approach to reducing tone, with injections delivered directly to a spastic muscle. The injection of the toxin causes paralysis of the targeted muscle by blocking acetylcholine release, which is necessary for muscle activation and contraction.^{18,40} Botulinum injections typically take a week to demonstrate an effect that lasts for 3 to 4 months.^{18,40} A child is restricted in the number of injections he or she can receive each year. Risks include the medication "bleeding" into other muscle groups, especially in areas like the hand and thumb in which children's muscle bellies are small. Injections can be paired with serial casting or splinting to maximize gains in range of motion. Evidence for the use of these injections is limited, and, as with many interventions, this technique is often paired with other techniques, making it difficult to conclude that the treatment effect is only from the injections ([Case Study 28-8](#)).

Over time and with growth, children with moderate to severe spasticity may experience increasing muscle and tendon tightness, contractures, joint dislocation (particularly at hips), and other joint problems. Orthopedic surgeries can help to ameliorate these issues when more conservative treatment such as splinting is not effective. Surgeries include tendon transfers,

muscle releases, and osteotomies. In tendon transfer surgery, the insertion of a muscle is moved to change the action the muscle produces. For example, a child with weak or paralyzed hand musculature may have a wrist muscle moved to the finger flexors to assist with grasp. Other types of soft tissue surgery include muscle releases or lengthening. These procedures lengthen or release tight muscle tissue to allow increased

movement of a joint. Often done in conjunction with soft tissue surgery, osteotomies are procedures in which the bone is lengthened or shortened to improve its alignment. All of these surgeries involve a period of immobilization initially, followed by early movement and occupational therapy to strengthen and promote the function made possible by the structural changes (Case Study 28-9).

CASE STUDY 28-9 Lower Extremity Tendon Transfer Surgery: Owen

Owen is a 7½-year-old boy with hemiplegic cerebral palsy and age-appropriate cognition. Owen was born at 27 weeks' gestation and had a grade 4 intraventricular hemorrhage. A magnetic resonance image revealed periventricular leukomalacia. Owen has right-sided weakness and spasticity. Recently Owen demonstrated increased tightening of his right lower extremity muscles and a leg length discrepancy with his right leg shorter than his left. Owen's balance was negatively affected by this shortening, and, subsequently, he was experiencing more trips and falls. At school Owen's occupational therapist and physical therapist noticed increased difficulty managing stairs, keeping up with his peers when walking to and from assemblies, and safely transferring in the bathroom. Owen's occupational therapist discussed adaptations with his teacher, recommending that he move his seat closer to the door and white board to decrease the length of the classroom he had to traverse and letting him leave early to walk to assemblies with a partner peer to minimize his risk of falls. After receiving training from the school occupational therapist, a classroom aide began supervising him for safety in the bathroom and provided contact guard assist as needed during toilet transfers.

His outpatient occupational therapy goals focused on bimanual coordination for fastener completion. His outpatient occupational therapist recommended that Owen position himself in long sitting on the floor against a wall while he played preferred video games at night or while doing his occupational therapy home exercise program to encourage lengthening of his hamstrings. During intervention sessions, she engaged Owen in dynamic yoga poses (such as the downward facing dog pose) that encouraged upper extremity weight bearing with hamstring and lower extremity extension. Despite these interventions and adaptations, with each growth spurt, Owen continued to experience tightening of his hamstrings and heel cords.

Occupational Therapy Goals

1. Owen will use two hands to fasten four (½-in) buttons on shirt, 80% of trials.
2. Owen will use two hands to fasten zipper on jacket, 100% of trials.

After consultation with the psychiatrist and orthopedist, his family and medical team decided he would undergo right hamstring and heel cord lengthening surgery. After 2 days in the local children's hospital where the surgery was performed, Owen was transferred to a pediatric inpatient rehabilitation hospital where he received occupational therapy 3 times per week and physical therapy 6 times per week. Owen received medical orders to bear weight as tolerated on his right lower extremity. He wore a knee immobilizer on the right side; his

foot and ankle were casted for 4 weeks after the surgery. His occupational therapy goals included transferring to the toilet with distant supervision, standing and performing ADLs sink-side with distant supervision, and donning his pants with supervision and adaptive equipment as needed. During occupational therapy sessions, the occupational therapist developed strategies for him to dress and bathe himself while he wore the cast and knee immobilizer. He continued to work on right upper extremity weight-bearing activities and well as fine motor activities in long sitting and standing. During physical therapy sessions he worked on sitting and standing balance, gait training, and stairs. After 2 weeks at inpatient rehabilitation, he returned home, where he received home-based occupational therapy and physical therapy services one time per week. The occupational therapist worked with Owen's caregivers to help transfer him into and out of the bathtub safely and trained them in the use of a tub bench. The practitioner worked with Owen to retrieve his clothes from his dresser and closet safely and efficiently while using a walker. The occupational therapist helped Owen prepare a simple snack at his kitchen counter to work on functional balance and practice adaptive strategies such as safely moving ingredients across counter surfaces. A home teacher provided by his school district visited two times per week to review his missed school work.

After his cast was removed, Owen returned to outpatient occupational therapy one time per week and received outpatient physical therapy three times per week. In addition to his previous goals to improve his hand skills for fastener completion, his outpatient occupational therapist added the goals of donning his new ankle foot orthosis (AFO) independently and completing all ADLs and IADLs independently while standing.

Occupational Therapy Goals

1. Owen will don elastic waist pants using adaptive equipment and modified independence, 100% of trials.
2. Owen will don AFOs independently within 2 minutes, 100% of trials.

After 4 weeks of outpatient therapy, Owen demonstrated improved standing balance and performed all ADLs and transfers safely and independently. With support of the special educator, he completed most of his missed schoolwork. With permission from his parents, the outpatient occupational therapist discussed the progress he made with the school-based therapists. Owen continued with outpatient physical therapy for the next 6 weeks in after-school sessions to work on his gait pattern. He was discharged from outpatient occupational therapy with a home exercise program.

Summary

Cerebral palsy is a condition that encompasses a group of postural control and movement disorders associated with pre-, peri-, or postnatal neurologic impairment. Occupational therapists play a vital role in helping children who have CP increase their occupational performance, functional independence, and participation in home, school, and community activities. Grounded in an understanding of motor control theory and motor skill development, occupational therapists apply positioning and handling methods to improve children's function and interaction with the environment. Occupational therapy interventions include techniques to develop postural control, righting and equilibrium reactions, and improve controlled arm and hand movement in functional daily activities. Occupational therapists can recommend and instruct children and their families in the use of assistive devices and specialized equipment to enable children with CP to engage in purposeful activities that match their occupational roles and interests.

Summary Points

- Cerebral palsy is a disorder of movement and posture associated with impairments in motor and sensory systems.

Occupational therapists should consider the dynamic interplay among these systems, the impact of the environment, and the demands of the task when evaluating and providing occupational therapy intervention.

- The Gross Motor Function Classification System (GMFCS) and the Manual Ability Classification Scale (MACS) are assessments designed to quantify the level of motor function in children with CP.
- A thorough assessment of a child with CP includes both clinical observation during engagement in functional tasks (e.g., dressing) and evaluation using scales that quantify limitations in movement, activity function, and overall participation.
- Current evidence suggests that functional and goal-directed training, constraint-induced movement therapy, bimanual training, fitness training, home exercise programs, and occupational therapy following botulinum toxin injections are effective occupational therapy interventions for children with CP.⁴⁰
- Positioning, casting, and orthotic programs help to minimize muscle tone's adverse effects on joint alignment.
- An occupational therapist may work in conjunction with several medical specialists, including a physical therapist, speech-language pathologist, neurologist, orthopedist, or physiatrist, to provide complementary intervention after a surgical or medical procedure.

Pediatric Hand Therapy

Jenny Dorich • Karen Harpster

KEY TERMS

Activity modifications	Joint tightness
Congenital differences	Kinesiology tape
Cryotherapy	Mirror therapy
Desensitization	Physical agent modalities
Dynamic splints	Sensory re-education
Energy conservation technique	Serial cast
Joint protection strategies	Static progressive splints
	Tendon tightness

GUIDING QUESTIONS

1. How do occupational therapists who specialize in pediatric hand therapy apply occupational therapy frames of reference to evaluation and intervention?
2. How do the assessment and evaluations used by occupational therapists in a pediatric hand therapy setting guide intervention planning?
3. What are the common diagnoses and associated impairments treated by pediatric hand therapists?
4. What interventions do occupational therapists implement with children who have upper extremity impairment?
5. How do occupational therapists in pediatric hand therapy apply interventions to achieve desired clinical outcomes?

The American Society of Hand Therapists (ASHT) defines the scope of hand therapy as “the art and science of rehabilitation of the upper limb, which includes the hand, wrist, elbow and shoulder girdle.”²² Hand therapy is a specialty area of practice for occupational therapists working in the pediatric setting. Occupational therapists who specialize in hand therapy have the combined knowledge of upper extremity development as well as the specialty skills of a hand therapist. Therapists are integral members of multidisciplinary care teams that include hand surgeons, nurses, physician assistants, and cast technicians. In some cases social workers, psychologists, or other medical specialists may also be members of the care team. Team members work closely together to coordinate and provide care to maximize a child’s upper extremity function.

Occupational therapists specializing in pediatric hand therapy provide services to three broad categories of conditions in children and youth:

1. Congenital differences of the hand or arm
2. Upper extremity impairments resulting from an underlying disorder (e.g., cerebral palsy [CP] or rheumatoid arthritis)
3. Injuries of the arm or hand

Each type of upper extremity condition requires different considerations in designing and delivering an intervention plan as described in this chapter. In the sections that follow, assessment tools and methods, common diagnoses, and general intervention considerations for these diagnoses are explained. Conceptual frameworks, principles, and interventions with examples to illustrate intervention applications are presented.

Assessment

The International Classification of Functioning, Disability and Health (ICF)^{42,106} guides the therapist’s assessment of upper extremity function. The ICF defines and classifies body functions and structure, activity, and participation, incorporating contextual factors including personal and environmental factors. Occupational therapists select formal and informal assessments to evaluate these three ICF categories.

Frames of reference and conceptual principles used by hand therapists to guide assessment and the development of the plan of care include developmental, motor skill acquisition, rehabilitative, and biomechanical. These frames of references and the underlying concepts and principles used by pediatric hand therapists are explained in [Table 29-1](#).

Operating with these frames of reference in mind, occupational therapists complete a comprehensive evaluation involving an interview, chart review, and administration of formal and informal assessments. Assessment varies according to the cause, type, and acuity of the hand condition.

The occupational therapist obtains background information from child/family interview, chart review, and clinical screening. The background information includes the following:

- A complete medical history regarding the reason for referral to occupational therapy and prior history relating to the referral
- Information regarding the child’s overall health status
- Developmental history
- Information regarding other medical teams currently working with the child and the plan of care of these teams
- Family concerns and priorities that have direct impact on the child’s plan of care

Knowledge of the family’s and child’s concerns regarding the child’s condition is paramount to guiding the occupational

TABLE 29-1 Frames of Reference and Conceptual Principles Used by Hand Therapists to Guide Treatment

Age-appropriate tasks	Selecting task and environmental demands appropriate to the child's developmental levels across domains promotes successful performance.
Active learning	New skills are developed through active experimentation, experience, and repetitive practice with a variety of strategies available to perform the task. The motor skills should be challenging and at the just-right challenge level. When appropriate, the child should practice the entire task to enhance learning.
Use of purposeful, functional activities	Learning is improved when the child is performing a purposeful, functional activity rather than a repetitive, nonpurposeful task. Function activities motivate children (as opposed to repetitive, nonpurposeful activities) leading to improved performance.
Feedback to promote generalization	Providing feedback helps the child understand the results of his or her movements. Feedback should transition from feedback from the occupational therapist to internal feedback and self-evaluation by the child as the child starts to master a skill.
Practice in a variety of contexts	Varying contexts of practice will enhance the development of flexible strategies and generalization of learning to multiple environments. Learning in natural environments during daily routines is preferred.
Compensatory and/or adaptive strategies considering person, environment, occupation	The occupational therapist provides compensatory and/or adaptive strategies for patients with persistent upper extremity difficulties (e.g., chronic pain, decreased range of motion). The occupational therapist considers the context(s), activity demands, and the child's performance patterns when making adaptation and/or compensatory techniques.
Motivation	The occupational therapist considers the child's values and roles and the context in which the task will be performed to motivate the child.

therapist's plan of care. The family and child inform the occupational therapist of specific concerns regarding the child's functional skills and how the child's upper extremity impairment is impacting the child's participation in life roles. Factors such as family resources and the family structure may impact the plan of care. For instance, a family may not have the availability to come to therapy appointments as frequently as recommended by the referring practitioner, or the child's family members may not be available to provide hands-on assistance with the child's home program activities.

When the occupational therapist obtains the knowledge of these variables during the evaluation, he or she is able to develop a plan of care that is feasible within the context of the child's life.

The family's ability to cope with the child's hand condition may influence the plan of care. For example, families may be experiencing depression, anxiety, or feelings of guilt for their child's hand impairment, especially in cases of brachial plexus birth palsies (BPBP) and congenital hand anomalies.^{14,49} In this situation the occupational therapist may need to coordinate support for the family from other disciplines. In trauma cases, background knowledge of the circumstances surrounding the trauma can help the therapist be sensitive to psychosocial factors associated with the trauma. For example, the injury could be the result of self-injurious behavior or an accident in which a loved one may have been lost.

Information about the child's roles and occupations are gathered through parent and child interview. Specifically, the occupational therapist inquires about play, school, work, volunteer activities, hobbies, and interests as the context for intervention. For example, children who engage in competitive sports or music often place higher demands on their extremities and require occupational therapist-directed conditioning after an injury to return to their prior level of activity.^{31,84,95,117}

Initial Screening and Assessment

Each category of hand conditions carries unique considerations that influence the plan of care. These considerations can affect the timing of intervention, the intensity of therapy services, the members of the care team who are actively involved in the child's care at a particular point in time, and the level of communication needed among the occupational therapist, the child/family, and the care team. With all categories of upper extremity impairment it is essential that therapists perform a thorough assessment of the child's overall health in addition to the specific impairment for which he or she is referred to therapy. Occupational therapists also screen for any past upper extremity surgery or injury, as either could influence the expected outcomes for the current episode of care. For example, a child may have a previous joint fusion at the wrist; therefore, improved wrist range of motion (ROM) would not be an expected outcome of therapy and, furthermore, would contraindicate wrist ROM exercises. Following are specific components of the initial assessment that occupational therapists should consider specific to each category of hand condition.

Congenital Differences of the Hand or Upper Extremity

Congenital differences of the hand are a common feature of some childhood syndromes, such as VACTERL and Fanconi anemia. When a child is referred to occupational therapy for evaluation and intervention for an upper extremity congenital difference, the occupational therapist should screen the child's overall health status. When a child's congenital hand difference is one of several health concerns, the status of the child's overall health can affect the timing of therapeutic and/or surgical interventions related to the child's hand impairment. A child with congenital hand differences is also more likely to have delays in fine motor, bilateral coordination, and/or functional mobility than a child who was otherwise healthy and sustained

an injury to the hand. Therefore, a screening of early developmental milestones and fine motor skills is advised so that the occupational therapist may identify if a need for additional therapy services (such as physical therapy) exists.

Underlying Disorder Affecting the Upper Extremity

Just as with congenital differences in the hand, it is not uncommon for children who are suffering from a systemic disease process that affects their upper extremity, such as CP, to have delays in meeting early developmental milestones. Occupational therapists globally screen the overall gross and fine motor skills of young children with medical conditions that are affecting the upper extremity to identify if a referral for developmental therapy is needed.

Acute Injury (Finger Fracture or Wrist Pain)

For children with acute injuries, the occupational therapist screens for the nature of the injury because certain types of trauma are more likely to develop secondary infection, for example, bite wounds.³⁰ The occupational therapist may be the first provider to see early signs of an infection and need to consult with the referring practitioner to coordinate care in such cases. Additionally a child with a traumatic injury may have been hospitalized and received prior care for the injury. A thorough medical history will reveal any previous care received for the injury and the outcomes from that treatment.

Clinical Assessment

When administering a comprehensive assessment, occupational therapists review the child's medical chart and interview the parents to guide the strategic elements and priorities of the assessment process. The following sections describe the components of an occupational therapy assessment in pediatric hand therapy.

Pain

Many children who are referred to hand therapy have pain. The occupational therapist screens for pain in the initial evaluation

and continues to reassess pain throughout the course of care. The therapist uses the child's level of pain to guide the treatment plan. Additionally, the ongoing assessment of pain helps to guide the therapist in the progression of interventions used to achieve desired goals. For example, if a child is participating in occupational therapy following a finger fracture and having significant pain while completing active ROM exercises, the occupational therapist may wait until the child is experiencing less pain before introducing passive ROM or strengthening exercises.

To assess the location, quality, frequency, and intensity of the child's pain, the occupational therapist asks the child to point to where he or she is experiencing pain. The occupational therapist asks questions to gauge if the pain is diffuse or localized. This information can help the occupational therapist determine the appropriate intervention(s), as well as pertinent clinical findings that are reported to the referring clinician. When developmentally appropriate, the occupational therapist asks the child to describe his or her pain (i.e., sharp, dull, aching, burning, shooting, or hurting). The child's responses can provide insight into the correct diagnosis. For example, tendonitis is often characterized by a sharp or shooting pain when using the upper extremity; generalized, aching joint pain is more typical in arthritis.^{81,112} The occupational therapist also asks the child how often and when the pain occurs. For example, the child may experience pain while performing specific activities or during certain periods of a day. Knowing the specific pattern of presentation guides the occupational therapist's recommendations for intervention. The intensity of pain can be quantified using a variety of self-report scales listed in Table 29-2. Quantifying the child's pain is most valuable in determining the usefulness of therapeutic intervention to decrease pain. The occupational therapist uses a pain scale appropriate to the child's age and cognition.

Occupational therapists also ask questions to determine which strategies the patient and/or family have found helpful for managing the pain. Knowledge of all aspects of the child's pain guides the occupational therapist to determine the most appropriate intervention(s) to reduce and manage the child's pain.

TABLE 29-2 Pain Scales

Pain Scale	Purpose/Description/Age Range
Faces Pain Scale—Revised (FPS-R) ^{12,38,41,98} Oucher ¹⁰	Therapist uses a card that has faces to describe pain. There are six faces and each face represents a number from 0, 2, 4, 6, 8, 10. Age range: 4-16 Consists of two scales developed for children to rate pain level. (1) The scale for younger children consists of six pictures of face to indicate pain intensity. The photographic scale should be used if the child is unable to count to 100 by ones or tens, if the child is unable to identify which of the two numbers is larger, or if the child can indicate a preference for using the photographic scale. (2) The scale for older children consists of the numbers from 0 to 100. The numeric scale should be used if the child can count to 100 by ones or tens and can identify which of any two numbers is larger. There are five versions of the Oucher scale, based on ethnic background. Age range: 3-12 years ^{10,11}
Visual Analog Scale (VAS)	The patient rates his or her pain using a visual representation of faces. Age range: 7 years to adult ^{20,57}
Numerical Rating Scale	The patient rates his or her pain on a scale from 0 to 10 where 0 is no pain and 10 is the worst possible pain. Age range: 6 years to adult ^{3,111}

Tenderness

The occupational therapist screens for specific patterns of tenderness when a child reports pain. If the child reports pain as occurring in a specific location of the upper extremity in response to a clinician's manual examination, then the child is reported to have tenderness. A variety of special tests are used to assess specific patterns of tenderness in the upper extremity to identify possible underlying structural concerns, such as ligamentous tear or inflamed tendon sheath. An example of a widely used assessment for tenderness is the Finklestein's test for De Quervain's tendonitis.²⁸ The reliability of upper extremity special tests is low^{64,87,95}; therefore, they should be used in conjunction with special tests. The clinician considers the child's reported symptom pattern and strength assessment to determine the most accurate clinical presentation.

Skin

The occupational therapist performs visual inspection of the skin at the evaluation, the start of treatment, and following therapeutic interventions. The skin's appearance provides information as to what therapeutic interventions may be necessary and how well a child is tolerating specific interventions.

If the child has undergone surgery or is recovering from a traumatic injury, he or she will likely have a healing wound or scar and require therapeutic intervention for wound or scar management. Children may also have skin color changes that can reflect circulatory compromise, indicating the need to change or discontinue intervention. In addition, occupational therapists monitor skin integrity regularly when providing interventions such as therapeutic taping or splinting. Children may require a different intervention or a modification in splint design if compromised skin integrity is noted. Occupational therapists should monitor children who report excessive pain or hypersensitivity for trophic changes because complex regional pain syndrome could be a concern warranting consultation with the referring physician.

Skin assessment is reported in subjective terms. When skin is noted to have compromised integrity, the following terms apply:

1. Color: red, white, blue, mottled (i.e., blotchy), or bruised
2. Quality: moist or dry
3. Temperature: cold or warm
4. Texture: calloused, macerated (i.e., moist, soft, and separated), or lacerated (i.e., cut)

The occupational therapist may also report if the skin has a rash or an abrasion.

When a child's skin has a wound or scar, the occupational therapist performs assessment at each treatment session to determine the effectiveness of interventions being used for wound and scar management. Wound assessment includes notation of wound location, size, color, stage of healing, and exudate (i.e., drainage). Therapists closely monitor wounds for signs of infection (redness and edema in the wound bed and/or purulent [i.e., containing pus] drainage that is in excess of the inflammatory stage of wound healing) and notify the referring provider when they observe signs of a possible infection. When assessing a scar, the occupational therapist describes whether it is raised or flat, the size, height, location, pliability, and color. When a scar appears to be hypertrophic (raised or extending beyond the borders for the initial wound), and a

formal assessment is needed, the occupational therapist may use the Vancouver Scar Scale (VSS) to measure changes in the four main scar characteristics (pigmentation, vascularity, pliability, and height).⁵

Edema

Edema is most common in cases of joint or tissue inflammation, such as arthritis or tendonitis, and in traumatic injury or post-surgical management of the upper extremity. Occupational therapists may document edema using subjective terms, including:

- Amount: trace, minimal, moderate, severe
- Quality: brawny (i.e., swollen and hard), pitting (i.e., swelling in which an indentation persists after pressure is applied to skin and the pressure is released)
- Location: anatomic description of the area edema is covering

More formal measurement of edema is recommended if (1) the amount of edema present is significant enough to limit the child's ROM or function, and (2) the child would benefit from treatment interventions focused on controlling the edema. Location of edema dictates the measurement tool to be used. When the edema is localized to one or a few joints, circumferential measurements are most appropriate. Edema that covers the dorsum of the hand is best measured using the figure-of-eight method.⁶¹ In the figure-of-eight method, the occupational therapist wraps a tape measure through the palm of the hand and over the dorsum of the hand in a figure-of-eight pattern as depicted in [Figure 29-1](#). When the edema is more

FIGURE 29-1 Figure-of-eight method for measuring edema on the dorsum of the hand.

FIGURE 29-2 Assessment of hand edema with a volumeter.

diffuse (i.e., throughout multiple joints in the hand and/or distal arm), the most accurate measurement is obtained using a volumeter (Figure 29-2).

Sensation

Occupational therapists assess sensation to detect abnormal sensory patterns that require therapeutic intervention. Assessment of sensation is important when peripheral nerve damage is reported or suspected or in cases in which extreme vascular changes have occurred. Information regarding a child's sensation is obtained through family interview, clinical observation, the wrinkle test, and other standardized assessments:

Patient and Family Interview

The occupational therapist asks the child and family about the pattern, quality, and presentation of sensory symptoms. Different patterns are indicative of specific clinical conditions. For example, if a child referred with wrist pain reports that the pattern of symptoms occurs primarily in the thumb, index, and middle finger at night and when typing or playing the piano, the occupational therapist may suspect possible median nerve compression (i.e., carpal tunnel syndrome).

Clinical Observation

The occupational therapist also observes how the child uses the arm and hand during functional tasks. The occupational therapist may note a child with normal active range of motion in the index and middle finger avoids using the index finger with fine motor tasks and instead uses the ring finger for pinch grasp.

FIGURE 29-3 Two-point discrimination assessment of hand sensation with the Disk-Criminator.

In this case, impaired sensation in the index finger may be causing this preferred pattern. For young children who are unable to explain their symptoms, the occupational therapist observes functional hand use to assess sensory function.

Wrinkle Test

The wrinkle test involves placing the child's hand in warm water for 30 minutes. When a child has peripheral nerve impairment, fingertip wrinkling is absent or diminished as compared with the unaffected hand. When sensory impairment improves, the typical wrinkling pattern returns. This is a particularly effective way to assess the presence of sensation in a child who is not able to report sensory symptoms.

Formal Assessment Tools

Two-point discrimination testing is used to assess the level of discriminative touch impairment. Therapists may use a standardized tool for assessing two point-discrimination, the two-point discriminator (Figure 29-3).²¹ Occupational therapists also use Semmes Weinstein Monofilaments (SWM) to evaluate touch discrimination. Semmes Weinstein Monofilaments (Figure 29-4) are used to quantify the level of abnormal sensory discrimination and pattern of impairment. To perform two-point discrimination or sensory assessment with SWM the child must be able to reliably report the sensory information he or she is feeling. When using the Disk-Criminator, he or she reports whether one or two points are felt when touching the fingertip. With SWM, the child must point to indicate whether or not and where he or she felt the monofilaments.

FIGURE 29-4 Assessment of hand sensation using Semmes Weinstein Monofilaments.

For both assessments, the child must also feel at ease enough in the treatment setting to close his or her eyes while the test is being administered. When performing these assessments, the child places his or her hand palm facing up and the tester alternates touching the fingertips with the testing instruments. Two-point discrimination is highly related to the sensory function required to perform certain fine motor tasks.⁷² Over time, reassessment with SWM can document the progression of returning sensation.⁸ For a child with sensory impairments, the interpretation scale for SWM aids in identifying the specific level of impairment and in intervention planning. Children who have sustained a nerve injury are good candidates for using this assessment tool.

Muscle Tone

Children who have an underlying neurologic disorder typically have abnormal muscle tone in their affected upper extremity. Muscle tone should be assessed through the function and feel of the upper extremity in all patients. The occupational therapist notes and describes the child's muscle tone. Generally tone is described as normal muscle, diminished (or low) muscle tone (hypotonicity), or high tone (hypertonicity). For example, a child who has spastic quadriplegic CP may have low muscle tone in core muscles and high muscle tone in his or her elbow flexors, pronators, wrist, and finger flexors. With children who have CP, the occupational therapist may use the Hypertonia Assessment Tool (HAT) to classify the type(s) of upper extremity hypertonicity.⁴⁵

Range of Motion

Hand therapists complete a gross assessment of upper extremity AROM, including shoulder, elbow, forearm, wrist, and digits.

If limitations are noted in active range of motion (AROM), the therapist completes goniometric assessment of the limited ranges.^{79,89} When only one of the child's upper extremities is affected, goniometric assessment of the unaffected upper extremity can be performed to use as a guide for the child's potential ROM and to establish plan-of-care goals. If there are no precautions that preclude assessing passive range of motion (PROM) (e.g., a recent fracture) and the child tolerates passive stretch, the occupational therapist also assesses the PROM in joints in which the child has AROM limitations. The occupational therapist notes the location and intensity of any pain the child reports during ROM assessment. This is particularly useful in cases of arthritis or other conditions in which pain is a primary symptom.

Limitations in ROM can be caused by joint tightness, tendon tightness, or scar adhesions. Occupational therapists may use the following techniques to determine if underlying factors are limiting ROM. If a child presents with similar measurements for AROM and PROM in the particular movement plane for the joint, he or she may have joint tightness. For example, a child with joint tightness in the proximal interphalangeal (PIP) joint would have 40 degrees of active PIP flexion and only 40 to 45 degrees of passive PIP flexion in the same digit. When a child has tendon tightness, the available AROM and PROM at a joint vary depending on the position of joints that are more proximal to the joints being tested. Tendon tightness may occur in the intrinsic or extrinsic muscles of the hand or both. One example of tendon tightness is extrinsic flexor tightness of the finger flexors that flex the PIP and distal interphalangeal (DIP) joints of the fingers, in which case the available AROM for PIP and DIP extension decreases as the angle of wrist extension increases.

Range of motion for the child who has sustained injury or undergone surgery can be limited when scarring adheres to soft tissue structures, such as the flexor tendons, and results in tightness. When scar adhesions limit joint ROM, the child will have a significant limitation in AROM at a joint while having near normal PROM at the same joint. Gaining a complete understanding of the biomechanics underlying the limitation in the ROM guides the occupational therapist in determining the appropriate intervention plan.

When a child presents with full PROM in a joint but limited AROM, he or she has muscle weakness. For example, the child may have full passive supination but active supination only to 30 degrees. In this case the difference between PROM and AROM can reflect weakness of the muscle group (in this example, there is weakness in the supinator and/or biceps) or hypertonicity of the antagonist muscles (in this example, the pronators) that is the underlying cause of the limitation in AROM.

Standardized Assessment Tools

Occupational therapists may use standardized assessment tools, patient-reported outcome measures, and individualized performance measures throughout the intervention. Self-report and/or individualized performance measures (Table 29-3) are often used at the start of intervention to guide the plan of care. Additionally, standardized assessments (Table 29-4) may be used with patients who are surgical candidates (e.g., patients with spinal cord injury [SCI] or CP) to determine if surgery is

TABLE 29-3 Patient-Reported Outcomes

Patient-Reported Outcome Measures	Purpose/Age Range/Administration Time
Disabilities of the Arm, Shoulder, and Hand (DASH) ^{2,34,71}	Assesses physical function and symptoms in patients with musculoskeletal disorders of the upper extremities. It is a self-report questionnaire with 30 items. Patients rate the first 21 items related to everyday tasks from 0 (unable to perform) to 4 (no difficulty in performing); the last 9 items are related to symptoms rated from 0 (extreme) to 4 (not at all). Age range: 18 and over
Quick DASH ⁷¹	Similar to the DASH; assesses activity of daily living; only 11 items with 2 optional four-item modules that are scored separately. Age range: 18 and over
Pediatrics Outcomes Data Collection Instrument (PODCI) ^{59,68,70}	Assesses upper extremity function, transfers and mobility, sports participation, pain and comfort, global function, and happiness with physical condition. Used with children with pediatric musculoskeletal conditions; each domain listed above is rated with a numerical score from 0 to 100. Age range: 19 and under
Pediatric Quality of Life Inventory (PedsQL) ^{67,107}	Assesses health-related quality of life in healthy children and children with acute and chronic health conditions. Age range: 2-18 years. Administration time: 5 minutes

TABLE 29-4 Standardized Assessments of Upper Extremity Function

Standardized Assessments	Purpose/Ages/Administration Time
Box and Blocks ^{65,84}	Assesses unilateral gross manual dexterity. The patient moves as many blocks as possible from one side of the box to the other within 60 seconds. The patient does this with both left and right hands. A higher score indicates higher dexterity. Age range: 6 years and older; administration time: 2-5 minutes
Jebsen-Taylor Hand Function Test ^{19,102}	Assesses a variety of hand functions used in activities of daily living. There are seven subtests, including writing, turning over index cards, picking up small items, simulated feeding, stacking checkers, picking up large objects, and picking up large, heavy objects. Tests are completed with both hands. Administration time: 30-45 minutes
9-Hole peg ^{86,96}	Assesses finger dexterity. The patient picks up the pegs one at a time and puts them into the holes in a square board as fast as he or she can. The patient performs the test with both hands. Age range: 18 years and up. Administration time: 5 minutes or less

a good option for achieving the child and family's goals for improved function. Standardized assessments also may be used before and after an intervention to examine the efficacy of the intervention.

Unstructured Clinical Observations

Unstructured observation of the child while engaged in age-appropriate and meaningful activities provides the occupational therapist with an understanding of how effectively the child uses the impaired upper extremity. This may be particularly helpful to occupational therapists who are working with young children who are not able to report their functional skills and limitations or children who exhibit signs of neglect with the affected upper extremity. The occupational therapist observes how the child spontaneously uses his or her affected upper extremity during play and functional tasks to determine if skills are age appropriate. For infants and toddlers, it is helpful to assess the child's use of the upper extremity during functional mobility while assessing gross motor skills (e.g., weight bearing through the upper extremity for positional changes).

Observing how the child positions and initiates use of the affected arm can provide the occupational therapist with insight into the child's true function in the affected arm. Occupational

therapists observe the appearance of the child's affected arm, how the child holds the affected arm, and how the child spontaneously uses the affected arm for play or self-care activities. Observations such as the affected hand being less groomed than the unaffected (e.g., nails trimmed on the unaffected and long on the affected) or the child holding the affected arm in a protected position of shoulder adduction and internal rotation with the elbow flexed and hand held at the torso are indications that the child is protective of the affected arm and avoids using it.

For children with congenital differences of the upper extremity and other conditions affecting upper extremity function, such as CP or an SCI, it is helpful to assess the type and efficiency of the grasping patterns used. The occupational therapist documents if the child can use a pinch grasp, spherical grasp, mass grasp, or any adaptive grasping patterns, such as a scissors grasp (i.e., grasping using finger adduction) (Figure 29-5). The occupational therapist assesses the child's lateral and/or palmar pinch to determine the child's capacity for tasks requiring a pinch grasp. When children have significantly limited thumb function, they may use an adaptive scissors grasp. The occupational therapist identifies which fingers the child uses for a scissors grasp and notes the efficiency of the grasp pattern. For instance, a child born with no thumb may

FIGURE 29-5 Example of a child using a scissors grasp of index finger and middle finger to fine motor prehension.

use a scissors grasp of the index and middle finger. This preference to use the radial side of the hand for activities requiring fine motor dexterity suggests that the child is a good candidate for a pollicization (i.e., transplantation of the digit to the location of the thumb) of the index finger. On the contrary, children who use a scissors grasp of the ring finger and small finger stand to gain less function from an index finger pollicization given their preference for ulnar grasping patterns. The occupational therapist specifically evaluates whether or not the child can demonstrate a mass digital grasp and spherical grasp. A child with limited thumb function may have limited or no spherical grasping pattern present and have difficulty with activities that require active thumb palmar abduction, such as holding a ball in the hand. The occupational therapist determines the child's overall capacity for functional grasp with the affected hand and which factors may be limiting functional performance.

For children with a history of typical upper extremity function who acquired an injury or condition affecting the arm or hand, the occupational therapist interviews the child and family to determine the child's prior level of upper extremity function. As the child engages in play or self-care tasks, the occupational therapist can observe how the child uses the affected upper extremity. Children can be highly adaptable in devising ways to work around their limitations. For example, the child may have switched to using the nondominant hand for writing, self-care, and play skills and may report minimal functional limitation yet not be returned to the baseline level of function. This provides the occupational therapist knowledge of the child's current level of function with the affected arm or hand as compared with his or her baseline performance to guide long-term goals.

Ongoing Assessment

Ongoing assessment is a component of each therapy appointment. If the child persists with ROM or strength limitations, the therapist may formally assess performance each session. Additionally, the therapist informally assesses the quality of hand function and grasping patterns at each session. Patient-reported outcome measures and goal setting assessments are completed within the first one to two sessions and periodically

through the duration of the intervention to assess progress toward goals.

Intervention Principles and Strategies

The guiding frames of reference and combinations of interventions an occupational therapist uses in treating children with upper extremity impairment (see [Table 29-1](#)) varies depending on the underlying cause of the impairment, the child's cognition, the child and family's goals, and the occupational therapist's assessment of the upper extremity impairment. When pain is present (which is typical in most traumatic injuries or post-surgical cases), interventions to minimize pain are employed so that the child may be able to gain enough comfort to participate in therapy activities aimed at improving his or her upper extremity function. In addition, interventions directed at restoring or optimizing ROM are regularly used by occupational therapists with a wide variety of diagnoses. Once ROM has been maximized, interventions such as strengthening or fine motor skills training are employed to refine hand function. As the occupational therapist plans the intervention approach to take with a child, the therapist almost always incorporates the person-environment-occupation model.⁵⁸ To do so, the occupational therapist determines the occupation(s) that is important to the child and in which the child is having difficulty. The occupational therapist completes a task analysis to observe the child's performance patterns, determine his or her strengths and weaknesses, and observe the environment in which the child will be performing the task. The occupational therapist then provides the most appropriate intervention to ensure the child performs the task at the highest level of independence possible.

The following sections will discuss common interventions utilized in a pediatric hand therapy practice.

Pain Management

Pain management is often essential for children recovering from an acute upper extremity injury or with joint inflammation. Pain management is the first step toward helping a child progress toward functional goals. If the child experiences pain during the course of therapeutic interventions without relief, the occupational therapist consults with the referring practitioner or refers the family to a pain specialist.

Occupational therapists assess the child's pain to identify the most appropriate interventions to minimize or eliminate pain. Pain that occurs or increases with specific activities can be managed through activity modifications. Pain that is associated with significant inflammation in the arm or hand may improve with edema management and splinting or periods of rest to relieve pain until the inflammation subsides.

For children who are postoperative or have experienced an upper extremity trauma, pain is a typical part of the recovery process that diminishes over time. One of the most effective pain management strategies for cases of upper extremity trauma is the occupational therapist's gradual progression of therapeutic activities. For example, pain management could be as simple as the occupational therapist grading the aggressiveness of stretching and strengthening to ensure the patient is experiencing only low level discomfort. In postoperative cases or upper extremity trauma, scarring may contribute to pain with

movement. Scar management strategies and static progressive splinting can improve tissue elasticity, resulting in less pain at the region of the scar.

A variety of physical agent modalities are used for pain management. Although the majority of pediatric hand therapy patients do not have pain significant enough to require the use of a modality, physical agent modalities are effective tools for pain management.

Physical Agent Modalities

Physical agent modalities (PAMs) employ a physical property, such as temperature, sound, or electricity, to achieve a specific therapeutic benefit.⁹⁹ Physical agent modalities are infrequently used in a pediatric hand therapy practice as compared with an adult population; however, when used, superficial thermal agents and electrical modalities are the most commonly applied. Ultrasound, a PAM that relies on the conversion of sound to produce a deep thermal heat, is not advised in children who are skeletally immature because it may harm growth plates in the bone.⁷

Superficial Thermal Agents

Superficial thermal agents include both heat modalities and cryotherapy (i.e., the therapeutic application of cold). See [Table 29-5](#) for an overview of superficial thermal agents.

- Heat is typically used to achieve increased tissue extensibility or to relieve pain. Heat can also help to temporarily decrease muscle spasticity.⁹⁶ Before using a heat modality, the occupational therapist should screen for contraindications. Heat modalities should not be used in the presence of untreated infection or acute edema, immediately following vessel or nerve reconstruction, over newly placed skin grafts, or in regions of sensory impairment or malignancy.⁹⁵ Additionally, fluidotherapy and paraffin are contraindicated when a wound is present in the region to which the modality would be applied.

- Cryotherapy is most commonly used when acute inflammation is present to relieve pain and tissue inflammation. Contraindications for using cryotherapy include children with Raynaud's disease, open wounds, acute vessel or nerve reconstruction, or sensory impairment.⁹⁵ Whereas heat is usually applied at the start of a treatment session to prepare the tissue for therapeutic intervention, cryotherapy results in the tissue contracting and the patient experiencing stiffness following application of the modality. As a result, cryotherapy is usually applied after the therapy session to alleviate or minimize tissue inflammation and pain.

Electrotherapeutic Physical Agent Modalities

Electrotherapeutic PAMs used with the pediatric population include neuromuscular electrical stimulation (NMES) and transcutaneous electrical nerve stimulation (TENS).

Neuromuscular electrical stimulation has two primary treatment applications in the pediatric population: (1) to increase strength of a specific muscle or muscle group and (2) to train a muscle or muscle group to perform a specific movement. Neuromuscular electrical stimulation is most commonly used in pediatric hand therapy to improve strength. In such cases, a gain in AROM may also be achieved at the joint controlled by the muscle group as the increased strength allows for the muscles to pull the joint through a greater arc of motion.

Common conditions that can benefit from application of NMES to improve strength and increase AROM include injury to the nerve at any level (spinal cord, brachial plexus, or peripheral nerve) and conditions in which central nervous system damage has resulted in abnormal muscle tone and movement patterns in the upper extremity (e.g., CP or traumatic brain injury). When a child has sustained an injury to the nerve, the regrowth rate is 1 inch per month. As a result, significant atrophy occurs in the muscles innervated by the nerve distal to the site of injury. When an injured nerve begins to regenerate, the occupational therapist observes trace movements in the

TABLE 29-5 Superficial Thermal Agents

Modality	Treatment Form	Description	Clinical Application
Moist heat	Heat	Delivers heat through the application of hot packs and multiple layers of toweling placed on a specific region of the upper extremity	Can be paired with a sustained stretch of a joint to achieve tissue elongation; can be replicated at home
Paraffin bath	Heat	Applies heat by child dipping his or her hand into heated paraffin wax	Can apply to the wrist and distal upper extremity; commonly used for pain management with arthritis
Fluidotherapy	Heat	A dry heat medium that is similar to a whirlpool. A fluidotherapy machine is filled with Cellux, ground corn cobs that are similar to sand in texture; the fluidotherapy unit blows these particles around the extremity placed in the unit to deliver heat.	The child may perform AROM during a fluidotherapy treatment; useful tool for desensitization
Ice packs	Cryotherapy	Delivers cold by placing ice packs on a specific region of the upper extremity	Can be replicated at home
Ice massage	Cryotherapy	A piece of ice is applied in a continuous pattern of movement (massage) directly over a specific region of the upper extremity	Particularly effective for tendonitis ⁶²

affected muscle or muscle groups. Once signs of returning motor function are observed, NMES can be used to help strengthen the atrophied muscles. When a child has a diagnosis of CP or traumatic brain injury with associated upper extremity motor impairments, NMES can be used to strengthen a weak muscle group. A common motor impairment in children with CP and upper extremity hemiparesis is muscle spasticity in the wrist and finger flexors that results in posturing (i.e., holding the affected upper extremity in wrist flexion with weakened grasp pattern). Neuromuscular electrical stimulation can be used to strengthen the weaker wrist extensor muscles, resulting in improved grasp from increased active wrist extension.

Neuromuscular electrical stimulation may also be helpful in retraining specific muscle groups. Sometimes following an injury a child will present with an imbalance in muscle groups resulting in compensatory upper extremity movement patterns. A common example is a wrist injury in which a child has significant weakness of the wrist extensors following immobilization. A common compensatory pattern for wrist extension is the use of the extensor digitorum communis to extend the wrist; that is, the child uses the muscle group that hyperextends the metacarpophalangeal (MCP) joints when he or she extends the wrist. To reduce this compensatory pattern of using a finger extensor muscle to activate wrist extension, NMES is applied on the wrist extensors with the child maintaining his or her fingers in a composite fist and extending the wrist (Figure 29-6).

Neuromuscular electrical stimulation can also be used for muscle retraining following a tendon transfer. Tendon transfers can restore or improve active muscle function in children with CP or a nerve impairment that results in permanent motor loss. For example, a child who has weak wrist extensor muscles may have a wrist flexor muscle(s) transferred to improve the power of wrist extension. Once the transfer has healed and is ready for strengthening, NMES can promote retraining of the wrist flexor to work as an extensor muscle.

FIGURE 29-6 Neuromuscular electrical stimulation may be used to strengthen and retrain the wrist extensors (versus the extensor digitorum communis [EDC]) to extend the wrist. The child keeps the fingers in a composite fist to prevent the EDC from extending the wrist.

TENS is also used to manage pain. The majority of children in pediatric hand therapy have pain that resolves as they are healing; however, some children are unable to engage in a therapy program or use their affected upper extremity because of increased pain. When a child is having pain as a primary concern, TENS may be applied to the region of reported pain. The pain control experienced with TENS occurs primarily while the child is wearing a TENS unit.²⁷

Splinting

Splinting has a wide variety of applications in pediatric hand therapy. The styles of splints most commonly used with the pediatric hand population include soft splints, static splints (splints that prevent motion in the affected joints), static progressive splints (splints that are serially modified to increase the joint angle), and dynamic splints with movable components that apply a force to a specific joint(s) for the purpose of moving that joint(s). The splints may be used for protection of the hand or arm during acute phases of healing, resting or supporting a joint for pain relief, positioning a joint for improved function, increasing ROM, or prevention of deformity in the upper extremity. When splints are used for protection (Figure 29-7), they are typically used following an injury or upper extremity surgery. A wide variety of splinting styles is used for this purpose, and the specific type and style of splint is determined by the type of injury or surgery and the specific motions that need to be prevented.

Splinting for pain relief most often occurs to treat acute pain and/or inflammation. Children with tendonitis in the upper extremity (e.g., De Quervain's tendonitis) or with a flare of arthritis symptoms in the arm or hand may benefit from splints

FIGURE 29-7 An ulnar gutter splint is an example of a protective splint. It is applied to protect a fracture of a digit or metacarpal in the ulnar two digits.

to rest the affected structures (e.g., joints/tendons) until their acute inflammation begins to resolve, which helps to relieve their pain.

Splints are used to improve function for children who have a condition affecting their joint stability or joint mobility. The style and type of splint appropriate for improving joint mobility is dependent on the child's specific limitations. For example, children with significant joint laxity leading to joint instability in the thumb may benefit from a splint that supports the first carpal metacarpal joint and thumb metacarpal phalangeal joints. The stability of the splint allows the child to stabilize other fingers against the thumb for improved pinch grasp and radial grasp control (Figure 29-8).¹⁰⁴ Additionally, children with congenital conditions, post-trauma, or systemic conditions may have limitations in joint mobility related to nerve and/or muscle impairment. Splinting in cases in which joint mobility is limited can help prevent deformity. In this case, the splint serves to position the joints in a plane in which movement is limited or missing. For example, a child with low radial nerve palsy may have no active wrist or MCP extension of the digits and no active radial abduction of the thumb until the nerve regenerates. A radial nerve palsy splint can support the wrist in extension and provide dynamic support to the digits holding them in extension while the hand is at rest and pulling them back into extension after active digit flexion. In this case the splint improves function for active grasp and release with the

FIGURE 29-8 A McKie splint is one style of splint that provides stability to the metacarpophalangeal joint of the thumb for improved fine motor function.

affected hand and prevents flexion contractures until active movement is restored.

Splints are used to improve ROM and correct deformity in cases of joint contracture or tendon tightness. Both static progressive splinting and dynamic splints may be appropriate to improve ROM.⁶⁰ (Both of these types of splints are discussed in following section.)

The following are styles of splints used in pediatric hand therapy:

- Occupational therapists make soft splints with neoprene or other soft material. Soft splints may be used to position the upper extremity to prevent contracture, especially in premature or young infants who are not using their upper extremities purposefully. Soft splints provide support to a joint to decrease pain or improve joint position for function. Additionally, a variety of prefabricated soft splints with or without rigid support can be ordered from vendors.
- Static splints are those that prevent motion in the affected joints. For example, a wrist and thumb spica splint immobilizes the MCP joint of the thumb, the first carpal metacarpal joint, and the wrist.
- Static progressive splinting is the application of static splint with serial adjustments to reposition the splint to change the joint angle. Static progressive splinting is used when mobility is limited by joint tightness with a soft end feel (i.e., mild to moderate resistance to passive motion in the direction of ROM limitation). An example is a static progressive elbow extension splint (Figure 29-9). Children lacking full elbow extension may be fitted with an elbow splint to increase the range of elbow extension. Children typically wear this splint when sleeping to allow for AROM and functional use of the affected arm when awake. The hand therapist routinely readjusts the splint to increase the angle of elbow extension over time. While any style of custom-fabricated splint can be serially adjusted to change the angle of positioning, prefabricated static progressive splints are also available.

FIGURE 29-9 When a child has limited elbow extension a static elbow extension splint can be used to improve range of motion. The splint is positioned at the child's end range of extension and the child wears the splint when sleeping. The splint is readjusted for increased extension at future visits to gradually increase the stretch and the child's active elbow extension.

FIGURE 29-10 An example of a dynamic splint to increase proximal interphalangeal (PIP) joint flexion. The child turns the dial to gradually increase the PIP flexion stretch while wearing the splint

- Dynamic splints include components that apply a dynamic force to a joint. Dynamic splints often assist a child with a motion that is absent or very weak, for example, a splint that assists with MCP extension when a child has radial nerve palsy. Additionally, dynamic splints are also used to apply light sustained force to increase joint mobility (Figure 29-10) at a joint that is limited in active motion secondary to joint tightness. Dynamic splints can be fabricated by the occupational therapist or can be prefabricated.

Casting

Occupational therapists fabricate casts to achieve specific treatment goals. Serial casting is used to increase joint mobility and tissue extensibility for improved ROM in the child's affected upper extremity, typically when the child presents with joint tightness. Serial casting (Figure 29-11) is similar to static progressive splinting in that a series of casts are applied, with each cast increasing the angle of the affected joint(s) to obtain the desired arc of movement. The serial cast is typically applied permanently until the child returns for the next cast to be applied. A serial cast can be formed as a bivalve cast that is removable in cases in which the child may require some time out of the cast. Serial casting is an established practice to gain increased mobility following Botox or phenol injections and to

FIGURE 29-11 Serial cast for elbow extension. At each visit a new cast is applied in an increased extension stretch.

decrease muscle spasticity in children who have movement limitations.^{6,13,52,82}

Casting is also used for children participating in constraint-induced movement therapy (CIMT). The constraint cast is applied to the less affected upper extremity to require the child to use the affected arm and hand during functional tasks. Constraint-induced movement therapy is most often implemented with children with hemiparesis resulting from conditions such as CP or a brachial plexus palsy and decreased spontaneous use of their affected arm and hand. Occupational therapists use different protocols for wearing constraint casts, including both removable and nonremovable casts.^{24,39,76}

Kinesiology Tape

Kinesiology tape (KT) can be used to facilitate or inhibit specific muscles or muscle groups to decrease pain, improve ROM, enhance muscle activation, and/or relax specific muscles. It is an elastic, waterproof tape that was first used in sports therapy and has more recently been applied in the practice of pediatric hand therapy. The tape is latex-free and designed to allow skin to breathe. Kinesiotaping can enhance lymphatic drainage and improve blood flow to decrease inflammation.⁵⁰ Kinesiotaping can also improve the biomechanics of a joint; for example in the shoulder, more than one piece of KT can be used at the shoulder with tape in one region acting to inhibit specific muscles and another piece of tape placed to activate weakened muscles.^{44,53,105} Studies evaluating the effectiveness of KT in treating shoulder pain in individuals with impingement syndrome showed that patients treated with KT at the shoulder had more immediate pain relief^{53,105} and faster functional gains⁵³ compared with individuals treated without KT.

The occupational therapist may use KT to improve shoulder kinematics, particularly for children who have joint hypermobility, hemiparesis, or shoulder pain. In children with neuromuscular conditions, such as CP or SCI, KT has been found to improve postural control and upper extremity function and provide stability and joint alignment.^{43,115} It is also used to improve the activation and strength of the weaker muscle

FIGURE 29-12 The child in this picture has hemiplegic cerebral palsy and weakness of the wrist extensors. The kinesiology tape is applied to facilitate the wrist extensors.

groups (Figure 29-12). The authors of this chapter have found KT to be beneficial in improving muscle activation and joint stability at the shoulder, forearm, wrist, and fingers. Children may wear KT for 3 to 5 days before a new tape application is required, and family members can be instructed in how to apply tape. The tape may be cut in specific patterns and applied in a variety of ways. The occupational therapist cuts and applies the tape in a particular pattern depending on the functional goals. Adverse effects of KT such as skin irritation¹⁰⁵ and muscle soreness¹ have been reported to occur infrequently (<5% of subjects). Occupational therapists may apply a small test strip of tape on the child's skin to determine if the child has adverse skin response to wearing the tape. Occupational therapists may consult *Kinesio Taping in Pediatrics: Fundamentals and Whole Body Taping*⁵⁰ for instructions on how to cut and apply tape to achieve the specific outcome desired. Therapists can obtain certification in kinesiointaping.

Child and Family Education: Activity Modification, Joint Protection, and Energy Conservation

Activity Modifications

Occupational therapists commonly use and educate the child and family about activity modifications, joint protection

strategies, and energy conservation techniques for children. These strategies are often used with children who have pain that limits functional use, ROM deficit, strength impairments, or fine motor impairments in their upper extremities.

Activity modifications are adaptations made to an activity or tool in order to increase the child's ability to perform the activity or use the tool independently.⁹¹ Using the person-environment-occupation model, the occupational therapist completes a task analysis to identify the most appropriate activity modification for the task in question. Examples of activity modifications include modified sports equipment or instruments, adapted writing utensils, assistive technology, and adaptive devices such as buttonhooks or pediatric-sized sock aids.

Joint Protection Strategies

Joint protection strategies are techniques used to decrease pain caused by the amount of strain placed on a joint during a task or the amount of work a muscle group must perform to complete the task. The occupational therapist explains the purpose and importance of joint protection strategies and interviews the child and family to determine which activities trigger joint pain. The occupational therapist reviews the child's day and pattern of symptoms to help identify the most beneficial technique(s). The occupational therapist often demonstrates the strategy and then has the child and/or family perform the strategies in the clinic setting to ensure correct application.

Energy Conservation Techniques

Children experiencing fatigue limiting their function, for example, those with systemic conditions such as juvenile idiopathic arthritis or Duchenne muscular dystrophy, often benefit from energy conservation strategies. As with joint protection strategies, the occupational therapist's interview with the child and family helps to identify the child's activity demands. The occupational therapist also observes how the child performs specific activities identified as difficult or contributing to fatigue. The occupational therapist then educates the family and child on strategies used for energy conservation and helps them develop a plan for applying the strategies.

Wound Care

Pediatric hand therapists must be knowledgeable about wound care when working with children after a surgery or a traumatic upper extremity injury. Often nurses and members of the medical team manage wound care in the child's early recovery; however, sometimes children begin therapy almost immediately after surgery when pins or sutures are in place. Therefore, the occupational therapist should be knowledgeable of the pin and wound care strategies desired by the referring physician and provide family education on wound care.

In cases of significant trauma to the dermis with wound healing through tissue granulation such as abrasions in the arm or hand from shearing injuries, the time for healing often lasts several weeks and continues into the rehabilitative stages; therefore, the occupational therapist is integral in providing wound care. Similarly, when the child has a skin graft, healing requires an extended period of time. The occupational therapist monitors the health and healing of the wounds and grafts and may be involved in providing direct wound care. Skin graft

precautions include avoiding sheer force over new grafts (which can be caused by edema control garments or splints) and avoiding compression that could compromise blood flow to the graft.

Scar Management

Almost all children with healing wounds in the arm or hand benefit from scar management techniques. Scarring can limit ROM, may cause pain, and can be a cosmetic concern. Once the postsurgical rehabilitation protocol allows the child to perform ROM in the joints affected by scarring, ROM exercises can be implemented to restore mobility. Scar massage is used with scars that limit AROM in a joint, lack pliability, are thick, extend the borders of the wound, or are a cosmetic concern.

Pressure on scars is an effective strategy to improve tissue extensibility and cosmesis of scars. A variety of scar pads and compressive materials are available to occupational therapists. Often, for small, minimally raised scars, compression with a soft material, such as Velfoam donned under a splint, tape, or compressive wrap, is sufficient to promote healing.⁹⁰ For scars that are more severe in terms of size or diminished pliability, a variety of specialty products are available (Figure 29-13). Occupational therapists may use gel scar pads cut to cover the region of the scar or make a custom-molded scar pad from elastomer products in combination with a splint or compressive wrap to provide adequate compression.⁵¹ Typically, these interventions are implemented when the child is sleeping so that the upper extremity is free for functional use during the day. In cases of burns to the upper extremity or skin grafts, a period of using custom-sized compression garments is necessary for optimal scar management.⁹

Edema Control

Occupational therapists use edema control strategies when children have swelling following surgery or an upper extremity injury. Positioning and AROM are two of the most effective

edema control strategies.⁹⁷ A common positioning strategy for edema is to keep the arm and hand resting above the heart. Families with young children often report that this is difficult to implement with young children because of high activity levels and resistance to prolonged periods of sitting. Occupational therapists also teach children and/or family members AROM exercises to reduce edema. Young children often respond best to performing grasp and release activities AROM exercises in an elevated position a few times throughout the day. Older children can be taught to avoid prolonged periods of full elbow extension of the affected upper extremity until edema begins to subside and, when cleared by the physician, to regularly perform AROM exercises.

When edema is moderate to severe or not responding to positioning and AROM, the occupational therapist can use compressive wraps and retrograde massage to control edema.⁹⁷ Coban wrapped distal to proximal on a digit (Figure 29-14) or compressive finger sleeves (available in sizes for larger children) can be effective in decreasing digital edema. Compressive sleeves are also available in graded sizes that can be donned over the wrist or proximal upper extremity for edema control. Retrograde therapeutic massage techniques (i.e., specific massage patterns, moving distal to proximal, to mobilize edema out of the extremity) also may be used in cases of persistent edema.¹⁰⁸

Splinting is used for edema control when the swelling is associated with joint inflammation or the child is acutely ill and has limited ability to perform AROM exercises. Edema associated with systemic conditions, such as juvenile idiopathic arthritis and systemic lupus erythematosus (SLE), may improve with medication, and splinting may not be necessary. For children who experience tenosynovitis, a localized inflammation along a tendon sheath, resting the specific tendon group through splinting can reduce the inflammation.¹⁰¹ Children who are medically fragile and have upper extremity edema (e.g., a child in hospital intensive care unit recovering from septic shock and vascular compromise to the hands) may benefit from splinting to alleviate edema.

FIGURE 29-13 An example of an elastomer scar pad that a child wears when sleeping to improve scar pliability.

FIGURE 29-14 An example of a Coban wrap on the digit to decrease edema the finger.

Desensitization and Sensory Re-education

Desensitization and sensory re-education are two interventions occupational therapists use for children experiencing sensory impairments. Occupational therapists use desensitization strategies to reduce hypersensitivity (i.e., over-responsiveness to sensory stimulation) and facilitate the child's use of the affected arm in everyday functional activities.⁹⁴ Hypersensitivity can occur after an injury, especially if a nerve was involved. It may also occur spontaneously or after a minor injury, such as a sprain or strain to the wrist. A child may be hypersensitive to temperature, textures, and/or various grades of touch pressure. The occupational therapist desensitizes the area by using graded exposure to the types of sensory input to which the area is sensitive.¹⁸ Using play-based activities may increase a child's tolerance for desensitization activities, especially in younger children (Figure 29-15). Behavioral reinforcement strategies can also be used to improve compliance with desensitization home program activities for children who are less motivated by play-based activities.

Sensory re-education is used when a child is experiencing sensory return after a nerve injury. The occupational therapist exposes the upper extremity to a variety of sensory activities to improve sensory discrimination. Sensory re-education is appropriate to begin when a child has a Semmes Weinstein grade of monofilament 6.65 or better.⁹⁵

FIGURE 29-15 Children who have hypersensitivity can perform grasp release of a sensory medium or find toys hidden in a sensory medium for desensitization of the extremity.

Range of Motion Exercises

Pediatric hand therapists frequently use active, active-assistive, and PROM exercises. Occupational therapists working with children who sustained an injury or had upper extremity surgery must be familiar with the specific postsurgical protocol for progressing ROM exercises. The structures injured or repaired dictate which form of exercise is least stressful on the repair. For example, a commonly used protocol for children with flexor tendon repairs involves avoiding AROM in the early rehabilitation phase while performing passive digit flexion exercises to preserve joint mobility.⁹⁵ Therapy for upper extremity fractures begins with AROM and progresses to PROM when the referring clinician indicates fracture healing can withstand the more aggressive force.¹⁸

Blocking exercises (Figure 29-16) are useful when the patient demonstrates difficulty with PIP and/or DIP flexion and/or extension. This type of exercise allows for more force to be transferred to the PIP and DIP joints to achieve greater active pull at the joint. Static progressive stretches (Figure 29-17) can be used when the referring physician clears the child for PROM. To improve ROM for a child with joint or tendon tightness, static progressive exercises are often the most effective.⁶⁹

Developmental stage and personality of the child are considered when determining activities for improving ROM. Young children rely on a family member(s) to perform active assistive range of motion (AAROM) or PROM exercises. Young children respond best to structured play activities designed to achieve active movement within the desired plane. For example, a child who needs to work on shoulder flexion and elbow extension can perform finger painting on an easel. Most school-age children can be instructed in performing a set of specific exercises and can follow through with visual and/or written instruction.

FIGURE 29-16 With a proximal interphalangeal (PIP) joint blocking exercise the therapist supports the metacarpophalangeal in neutral extension while the child flexes the PIP joint.

FIGURE 29-17 A flexion wrap is a static progressive exercise where the digit is wrapped into a light flexion stretch with Coban. After the child has become comfortable with the stretch, another wrap of tape is applied pulling the digit into slightly more flexion.

Strengthening

Occupational therapists grade a strengthening program from light to challenging. For the lightest form of strengthening the child might start with isometric exercises without resistance and then progress to isometric exercises with resistance for an increased challenge. Isotonic exercises may also be performed without resistance and progressed to include resistance in the form of weights or resistive bands. Occupational therapists must ensure that there are no contraindications to strengthening before progressing a child to strengthening exercises. Children with a rheumatic disease and in a stage of active joint inflammation should refrain from strengthening until the inflammation is resolved. Similarly, children recovering from surgery or an upper extremity injury must have sufficient healing to withstand resistive force to the arm and hand.

Play-based activities or exercises involving holding sustained positions may be the most effective to achieve strengthening for young children. For example, a 10-month-old recovering from brachial plexus birth palsy can strengthen his or her shoulder muscles by reaching to throw a ball into a container placed above shoulder height or by activities in quadruped.

Reducing Muscle Tone

When a child presents with hypertonia (i.e., high muscle tone) in the affected upper extremity, the occupational therapist's intervention plan should include activities to decrease the muscle tone/spasticity. Decreasing muscle spasticity helps the child gain control of movement in the upper extremity. Weight bearing through the affected arm and hand can decrease muscle spasticity.⁸³ Neuromuscular electrical stimulation can also be used to decrease spasticity in a specific muscle group; however, reduction in spasticity is only seen during application of the NMES.^{4,37} Additionally, splinting with a night-resting hand splint following Botox injections has been shown to decrease muscle spasticity.⁴⁸

Fine Motor Skills and Bimanual Coordination

Following reconstructive surgery of a congenital anomaly or a traumatic injury to the hand, occupational therapists focus on maximizing functional grasp patterns. When a child has fine motor impairment as a result of a recovering nerve injury or a chronic progressive condition, occupational therapists use supportive splints, activity modifications, and assistive equipment to maximize fine motor impairment. If nerve function is restored, then therapy may progress to fine motor skills training.

When children have hemiparesis resulting in limited bimanual coordination skills, occupational therapists may use CIMT and sensory-based activities to promote increased awareness and use of the affected upper extremity. Bimanual skill training activities are also effective in maximizing functional performance.³²

Mirror Therapy

Mirror therapy (MT) is a novel therapeutic intervention first introduced by Ramachandran⁸⁹ to decrease phantom limb pain (PLP) in individuals with amputations. Since that time, MT has been reported to be effective in decreasing pain^{66,73} and restoring function⁷⁴ in individuals with complex regional pain syndrome. Mirror therapy also has been found to improve motor and sensory function¹¹⁴ in adults with hemiparesis after cerebral vascular accident. Gygax et al. found that children with hemiplegia achieved improved hand strength and functional ROM after 3 weeks of daily bimanual training using MT and achieved improved pinch strength after 3 weeks of daily bimanual training without the mirror.³⁵ Although MT is still in its infancy as an established intervention, it has promise to improve motor control and function in children with hemiparesis. Additionally, MT appears to have the potential to decrease pain and improve quality of life and function in children with phantom limb pain and complex regional pain syndrome.¹¹⁴

Interventions for Specific Conditions

This section describes the common diagnoses treated by pediatric hand therapists and presents intervention strategies for each diagnostic type.

Congenital Differences of the Upper Extremity

Although congenital differences of the hand or arm occur only in 0.2% of births,²⁹ they are not an uncommon diagnosis referred to a pediatric hand therapist. Upper limb development begins at 4 weeks' gestation and is complete by 8 weeks, so the majority of congenital defects of the arm and hand occur during this time of prenatal development. In addition, trauma in utero, such as vascular compromise or amniotic bands, may also result in congenital impairments of the upper extremity and typically occurs in the third trimester of prenatal development.⁹⁵

A variety of classification scales for upper extremity congenital differences has been introduced through the years. At present, the classification developed by the International

TABLE 29-6 Embryologic Classification of Congenital Anomalies

Classification	Description	Examples
Failure of formation • Transverse • Longitudinal	Specific upper limb anatomy does not develop entirely or is entirely absent	Radial longitudinal deficiencies, ulnar longitudinal deficiencies, transverse growth arrest, phocomelia
Failure of differentiation	Characterized by a disruption in the development of the digits, metacarpals, carpals, digital or interdigital spaces	Camptodactyly, clinodactyly, syndactyly, Apert syndrome, clasped thumb, synostoses
Duplication	Specific structures in the hand are duplicated	Thumb polydactyly, supernumerary digit on ulnar side of the hand, mirror hand
Overgrowth	Enlargement in the skeletal and soft tissue structures that occurs in the digits	Macroductyly
Undergrowth	An underdeveloped hand or absent digits	Brachydactyly
Congenital constriction band syndrome	An amniotic band wraps around the upper limb resulting in varying levels of limb abnormality distal to the level of the band	
Generalized skeletal abnormalities	Conditions in which defects of the upper extremity accompany multiple skeletal variations	Arthrogryposis, Marfan's syndrome, VATER syndrome, achondroplasia

Federation of Societies for Surgery of the Hand (IFSSH) (Table 29-6) is the most widely accepted classification scale.^{16,63,102}

The occupational therapist provides conservative management and postsurgical rehabilitation in children with congenital differences of the hand and arm. Only 10% of congenital upper extremity differences require surgery; therefore, the occupational therapist's role is most often conservative.²⁹ Conservative interventions focus on preventing further deformity and maximizing function and include splinting, activity modifications, therapeutic taping, and assistive equipment training. Postoperative treatment can include any of the following: splinting for positioning and protection, wound management, and scar management in the early stages of recovery. As the child heals, the occupational therapist's focus is on improving ROM, coordination, fine motor skills, and strength. In some cases, activity modifications and adaptive strategies are also used postsurgically to optimize function. See Case Study 29-1 for an example of intervention for a child with congenital differences that required surgical interventions.

Upper Extremity Impairments Caused by an Underlying Disorder

A child's upper extremity impairment can be caused by a number of underlying disorders, including neurological disorders (e.g., CP), neurodegenerative conditions (e.g., spinal muscular atrophy), rheumatic conditions (e.g., systemic lupus erythematosus), and connective tissue conditions (i.e., Ehlers Danlos syndrome). The following sections describe intervention considerations, goals, strategies, and progression for each of these conditions.

Neurologic Conditions

Children with CP or traumatic brain injury (TBI) often have associated upper extremity impairment as a result of the damage to the central nervous system. These children present with hypertonia (or, less often, hypotonia) in one or both upper

BOX 29-1

Manual Ability Classification System Levels

Level 1	Handles objects easily and successfully. At most limitations in the ease of performing manual tasks requiring speed and accuracy
Level 2	Handles most objects, but with somewhat reduced quality and/or speed of achievement. May avoid some tasks or use alternative ways of performance.
Level 3	Handles objects with difficulty. Needs help to prepare and/or modify activities.
Level 4	Handles a limited selection of easily managed objects in adaptive situations. Requires continuous support.
Level 5	Does not handle objects and has severely limited ability to perform even simple actions. Requires total assistance.

From http://www.macs.nu/files/MACS_identification_chart_eng.pdf.

extremities. A variety of therapeutic interventions may be appropriate for conservative management strategies to achieve optimal hand function or prevent deformity in these populations. The goals of therapy vary depending on the child's impairment level. For children who have the skills to manipulate objects with their affected upper extremity(ies) (Manual Ability Classification System [MACS] levels I to III), intervention strategies aim to improve functional performance. Box 29-1 shows the MACS levels. Intervention strategies can include neuromuscular retraining, serial casting, splinting, and/or CIMT, which focuses on improving sensory awareness and spontaneous use of the affected arm and hand. Intervention goals for children who do not engage in manipulating objects with their upper extremities (MACS levels IV to V) are often to prevent deformity and modify or adapt tasks.

CASE STUDY 29-1 Surgical Reconstruction and Postoperative Therapy for Hypoplastic Thumb

In the following case study consider:

1. How does assessment for an infant with a congenital difference of the hand differ from the assessment of an older child?
2. How does intervention progress and what clinical parameters and family considerations and preferences guide the progression of treatment?
3. What functional differences does the child achieve following surgical reconstruction and postoperative therapy?

Connor, an 8-month-old infant, was evaluated by the orthopedic hand surgeon secondary to keeping his right thumb in his palm. The hand surgeon diagnosed him with a mild right hypoplastic thumb and referred him to occupational therapy for range of motion (ROM), splinting, and fine motor skills. The hand clinic is located 1 hour away from Connor's home. During the initial occupational therapy evaluation, the therapist interviewed the family to identify the family's concerns and priorities and assessed Connor's ROM during play-based activities. The occupational therapist noticed that Connor displayed no active palmar abduction and exhibited thumb extension to neutral when attempting to grasp with his right hand, but otherwise kept his thumb flexed in his palm. The occupational therapist:

- Fit him with a nighttime wrist and thumb spica splint with the interphalangeal joint included in full extension and thumb in palmar abduction.
- Instructed his family in passive ROM exercises for thumb extension and palmar and radial abduction.
- Provided home program activities to promote grasping toys placed in the first web space (e.g., grasping trike handle between thumb and index finger) and pinch grasp (e.g., turning book pages, picking up finger foods with a pinch grasp, and picking up small toys using thumb).

Two weeks later, the family reported that he was tolerating his night splint well and displaying no change in active ROM (AROM) during the day. The therapist fit him with a soft neoprene hand-based short opponens thumb splint for day wear to promote palmar pinch grasp by stabilizing the thumb in abduction.

Connor did not return to therapy again until he was 14 months old secondary to social factors within his family. At this time he displayed improved AROM in his right thumb but continued to hold his thumb flexed in his palm during inactivity. He had outgrown his daytime splint; therefore, he was fitted with a new neoprene hand-based short opponens splint and the family was educated in activities to promote spherical and pinch grasp for a home exercise program. Over the next 3 months, he continued to improve the AROM in his right thumb during play but only while wearing the splint. His monthly occupational therapy sessions consisted of splint modifications to accommodate for growth, activities for right thumb active pinch grasp, and AROM in extension and abduction.

At 18 months of age, Connor continued to display improved right thumb function when wearing the soft splint, but kept his right thumb resting in his palm when a splint was not applied. He needed to wear the splint to pick up finger foods with a palmar pinch grasp or attempt to hold a toy (such as small ball) with an open fist web space. Connor's

family decided to return to the orthopedic hand surgeon and opted for surgical reconstruction of his right thumb. The surgeon performed a tendon transfer for right thumb opposition and a web space deepening to promote palmar abduction of the thumb and a collateral ligament reconstruction of the right thumb metacarpophalangeal (MCP) joint for increased stability of the thumb MCP joint. Connor was placed in a cast for 4 weeks after surgery and then referred to occupational therapy for postoperative therapy.

Connor was 22 months old at the time of his postoperative occupational therapy evaluation. He had a thick, raised scar in his first web space (i.e., space between his thumb and index finger) from the web space deepening and trace edema in his first web space and thenar region. He displayed a functional arc of right thumb AROM in all planes aside from not having active interphalangeal joint flexion of his right thumb. An elastomer scar pad was fashioned with the right thumb positioned in palmar abduction and the family was instructed to don it at night. The occupational therapist instructed his family in scar massage and home program activities for pinch grasp and opposition of thumb to each fingertip in his right upper extremity, including playing games to incorporate pinch grasp such as puzzles and playing with smaller toys such as small zoo animals.

Connor's family missed an appointment and returned 1 month following the occupational therapy postoperative re-evaluation. They reported that Connor continued to keep his thumb resting in neutral to slight adduction when he was not using his right hand to hold or manipulate items. The occupational therapist recommended weekly occupational therapy for right thumb AROM and fine motor skills; however, the family opted for every other week visits.

During the next 2 months, the therapist used kinesiotape to support the thumb in abduction for the first month. She used neuromuscular electrical stimulation (NMES) for training the adductor digiti minimi, the tendon transferred to perform thumb abduction. The family was educated in (1) home program activities (focusing on palmar pinch and opposition), (2) kinesiotape application, and (3) NMES. The family performed home program activities for right thumb AROM while Connor received NMES one to two times per day. He also wore tape continuously during the first month of home program activities, discontinuing it after a month per the therapist's recommendation because he was noted to have improved palmar abduction. Connor also continued with the night scar pad for his first web space that positioned the thumb in palmar abduction throughout this time.

Approximately 3 months after surgery, Connor displayed palmar abduction and opposition with his right thumb and no longer held his right thumb resting in flexion or adduction. Connor demonstrated a functional spherical grasp and palmar pinch in his right thumb. He learned to use his right hand to hold a marker for coloring and maintain grasp on the handle bar of a riding toy with an open first web space. He was discharged from therapy and all formal home exercise program activities were discontinued because his scar was flat and pliable and he displayed good right thumb function and AROM.

TABLE 29-7 Upper Extremity Surgeries for Children with Neuromuscular Impairment of the Upper Extremity

Type of Procedure	Description of Procedure	Example	Goal of Procedure
Tendon transfer	The origin of a muscle is left in place and the insertion is re-routed	Example: Green transfer (flexor carpi ulnaris [FCU] to the extensor carpi radialis or extensor carpi brevis)	To improve active motion in a specific plane. For a Green transfer the goal is to improve active wrist extension
Joint fusion	The two bones of the joint are surgically fused through surgical fixation of the bones across the joint	Wrist fusion First CMC fusion	To stabilize a joint for improved function or to improve or preserve skin integrity (ex. first CMC fusion to keep the thumb out of palm)
Tenotomy	A tendon is released from its insertion	FCU release	To release a specific tendon that is placing a very strong pull on a joint into a plane that limits function
Tendon lengthening	The length of the tendon is surgically advanced to decrease tendon tightness	Flexor tendon lengthening	To allow for improved active joint motion For example, in a flexor tendon lengthening of the long finger flexors, the patient may have improved active digit extension for increased active release of grasp

When children with CP experience muscle spasticity changes, for example, as is sometimes related to growth, they may incur secondary orthopedic impairments, including joint contractures and muscle imbalances limiting functional capacity. Surgical procedures, such as tendon transfers, joint fusions, tendon releases, and tendon lengthening (Table 29-7) are sometimes completed to improve function or correct contractures. The occupational therapist uses specific postsurgical rehabilitation protocols to guide the timing of interventions in relation to healing. In the early recovery period, the occupational therapist may fabricate splints for positioning and improving ROM, as well as educate the patient and family on scar management strategies and healing. Intervention progresses to include ROM exercises, functional skills training, and strengthening as appropriate for the surgical intervention performed.

Children with an SCI affecting C5-C8, T1 have limited arm and hand function. When an SCI is incomplete, the child may regain upper extremity function for several years as the nerves regenerate.⁸⁸ In the early phases of rehabilitation, the occupational therapist often fabricates splint(s) to prevent deformity and promote function. As the child's recovery reaches a plateau, the child may be a candidate for surgical procedures to maximize hand function. Surgical procedures, typically nerve grafts, tendon transfers, or joint fusions, are often used to restore active elbow extension, tenodesis grasp, and lateral pinch.^{40,54,56}

Specific postsurgical rehabilitation protocols for SCI are used to guide the timing of interventions in relation to healing. Similar to CP and TBI patients, in the early recovery period, the occupational therapist may fabricate splints for positioning and improving ROM, as well as educate the patient and family on scar management strategies and healing. Intervention includes ROM exercises, functional skills training, and strengthening as appropriate for the surgical intervention.

Neurodegenerative Conditions

Children with degenerative neuromuscular conditions, such as Duchenne muscular dystrophy (DMD) or spinal muscular

atrophy (SMA), are typically referred to therapy when their mobility and upper extremity function begin to deteriorate. Occupational therapists use splinting to preserve ROM and educate the family in stretching programs and positioning strategies to maximize function, improve comfort, and limit joint deformity. Additionally, activity modifications and assistive equipment are recommended to optimize functional independence.

Rheumatic Conditions

Pediatric rheumatic conditions encompass a wide variety of autoimmune conditions that can affect joint and soft tissue of the upper extremity. Juvenile idiopathic arthritis (JIA), SLE, and scleroderma are some of the more common diagnoses. The treatment strategies for children with pediatric rheumatic conditions are determined according to the child's stage of disease process and level of functional impairment. Intervention goals for children with active joint inflammation (i.e., joint pain and swelling) focus on limiting joint injury, preserving mobility through AROM exercises, managing pain, and enhancing function. Therapy for children with no signs of active joint inflammation and controlled disease process includes stretching for joints with limited mobility and strengthening. Because rheumatic conditions are characterized by intermittent flares in the disease process, the occupational therapist works closely with the medical care team to know the state of the child's health to guide the intervention plan. Family education on activity modification, joint protection, and energy conservation techniques remains important during all stages of the condition.

Ehlers Danlos Syndrome

Ehlers Danlos syndrome (EDS) is a genetic condition characterized by a collagen deficiency causing increased soft tissue elasticity and global joint hypermobility. Children with EDS experience joint pain and fatigue.¹¹⁰ Frequently, children with EDS also have associated comorbidities, such as sleep difficulty, headaches, gastrointestinal dysmotility, and postural orthostatic

tachycardia syndrome (POTS), requiring a coordinated care team to manage their multiple medical concerns. It is not uncommon for it to take years before a child is diagnosed with EDS,⁹³ yet the child may have endured joint pain and fatigue for several years. Therefore a hand therapist may be the first to identify or question the possibility of the diagnosis of EDS.

Whether or not the diagnosis is the primary reason for referral to a hand therapist or just suspected by the therapist, the intervention strategies for children with EDS are the same. Because of the increased joint mobility and tendency toward end range joint hyperextension, their joints are more predisposed to micro trauma, which presents as arthralgia (i.e., joint pain)⁷⁵ and sometimes localized joint swelling. Children with EDS are more likely to have pain with sustained repetitive use of their upper extremities such as while writing or playing a musical instrument. Occupational therapists use activity modifications and joint protection strategies to decrease joint strain and pain. These children may have altered proprioceptive registration⁹² and benefit from proprioceptive training exercises (Figure 29-18) to learn the feel of the joint end range without going into hyperextension. Often these children use excessive force with grasp patterns on writing tools and place strain on

FIGURE 29-18 One example of a proprioceptive retraining exercise an occupational therapist may use is depicted. The child is learning to gauge the amount of pressure exerted when holding a writing instrument by performing tip-to-tip pinch with Theraputty and keeping the joints in flexion versus hyperextension while producing only enough force to make a small indentation in the putty.

the finger and thumb joints. Strengthening the wrist and hand muscles and adaptive writing strategies (Figure 29-19) can improve success with writing. When children continue to show joint instability, they may benefit from external supports, such as splints (Figure 29-20) or therapeutic taping, to provide joint support and limit positions that strain the joints.⁷⁵

Upper Extremity Injury

Acquired impairments of the upper extremity are the result of a trauma that results in injury to one or more of anatomic

FIGURE 29-19 A Twist and Write pencil is one adaptive writing utensil that can decrease the strain on the interphalangeal joints of the hand with writing.

FIGURE 29-20 An Oval-8 splint placed at the distal interphalangeal (DIP) joint to prevent pain in the DIP joint that occurs with hyperextension of the index finger DIP (a common phenomenon with EDS) when writing.

substructures of the upper extremities. Brachial plexus birth palsy is type of trauma that is commonly seen in infants who are referred to therapy. Toddlers and older children can acquire injury to one or multiple structures in the upper extremities, such as the bones, nerves, or other soft tissue structures.

Brachial Plexus Birth Palsy

Brachial plexus birth palsies (BPBP) are typically the result of a shoulder traction injury (shoulder dystocia) at the time of delivery. The incidence of BPBP is 0.38 to 3 per 1000 births in the United States.^{85,116} The mildest form of injury is neuropraxia, stretching of the nerve fibers. With neurapraxic injuries, the healing resolves without surgical management and typically within 2 to 3 months. When the injury involves axonal damage (axonotmesis), the nerve regenerates at the rate of 1 mm/day. When the nature of injury is axonotmesis, recovery may be incomplete and may require surgery to maximize function of the affected extremity. When the trauma has resulted in an avulsion of the cell body from the axon (neurotmesis), the nerve does not regenerate and surgery is necessary to attempt to restore nerve function. A noninvasive diagnostic test does not exist to determine the type of nerve injury in infants with BPBP, so clinicians closely monitor motor recovery to determine the need for surgical reconstruction.

Brachial plexus birth palsies can present in a variety of patterns. When the entire brachial plexus has been injured, the child's entire extremity is flaccid. This occurs in approximately 20% of patients.²³ However, the most common presentation is Erb's palsy, comprising about 38% to 73% of patients.²³ In Erb's palsy the C5/C6 nerve roots are damaged; therefore, the child has good hand function but limited shoulder function. In the classic position of the upper extremity in Erb's palsy, the arm is held with the shoulder internally rotated, elbow extended, forearm pronated, and wrist flexed.

In children with BPBP, therapy is necessary during the first few months to preserve ROM and prevent deformity. The occupational therapist also educates the family in positioning to promote the child's progression through normal developmental milestones and in sensory stimulation to the affected upper extremity to enhance sensory perception and prevent neglect of the affected upper extremity (i.e., the habit of avoiding use of the upper extremity).⁷⁷ Approximately 66% of BPPBs have complete recovery with full restoration of the upper extremity by 12 months of age, requiring therapy during this period.⁷⁷ The child's returning function should be monitored closely during the first several months because the pattern of recovery indicates whether early surgery (at around 4 to 6 months of age) is necessary.

A variety of surgeries may be performed to optimize recovery and enhance function in children with BPBP. The child's pattern of recovery helps determine which surgery is most appropriate. A nerve graft surgery, performed at around 3 to 4 months of age, is common for a child who exhibits no return in muscle function distal to specific damaged nerve roots of the brachial plexus. Surgeries such as tendon transfers, muscle releases, rotational osteotomies, and/or muscle grafts may be necessary to increase the upper extremity function for a child with incomplete recovery. These surgeries can take place over several years in the child's life and the child may benefit from occupational therapy following each surgery to promote recovery and maximize function.

Upper Extremity Fractures

Fractures can occur in any bone or multiple bones in the upper extremity. Fractures of the distal radius are the most common fracture in children.⁷⁸ Children are more likely than adults to sustain forearm shaft fractures, often fracturing both the radius and the ulna.⁷⁹ Fractures of the bone shaft take longer to heal and are more susceptible to reinjury than fractures at the epiphysis, such as distal radius fractures. As a result, fractures of the forearm are typically casted longer than a distal radius fracture. Fractures of the carpal bones are rare in children; among carpal bone fractures, the scaphoid is the most frequently fractured.¹⁷ Metacarpal fractures are more commonly found in children over the age of 8 and are typically the result of a fight or sport injury.¹¹³ In the fingers, fractures of the third phalanx are the most common and tend to heal well without the need for therapy.¹¹³ Fractures elsewhere in the digits, especially if they are interarticular (i.e., in the region of the joint), are more likely to require therapy.³³ Elbow fractures, more so than fractures elsewhere in the upper extremity, may have associated nerve palsies as a result of trauma to the nerve.⁴⁶ If the elbow requires immobilization for more than 2 to 3 weeks, a child is likely to have joint stiffness and require therapy to regain mobility. Children who have an associated nerve palsy require occupational therapy interventions to address the deficits associated with the palsy. Generally, humeral shaft fractures, unless they have associated radial nerve palsy, heal well without the need for therapy.²⁵

Overall, the majority of children who sustain upper extremity fractures do not require therapy. When fractures have associated trauma, such as nerve palsy, therapy may begin before the child has had his or her cast removed. Therapy goals include improving hand function and preventing deformity. If a child has hypersensitivity and/or allodynia (i.e., pain in response to a nonpainful stimulus such as a cotton ball or wind on the skin) following a fracture, early therapy is indicated to prevent complex regional pain syndrome (CRPS). Fractures that require surgery for fixation and interarticular fractures are more severe and more likely to require therapy to restore joint movement.¹¹³ Children who avoid using their upper extremities or affected digits after sustaining fractures can benefit from therapy to restore optimal function in the affected upper extremities.

Children wear a cast or splint until the fracture has begun to heal. For children with complex fractures or nerve damage, AROM begins immediately after the cast is removed. Therapy can progress to include PROM and light strengthening as the physician indicates adequate bone healing. If the child experiences persistent stiffness, the occupational therapist may use static progressive or dynamic splinting to improve joint mobility. The occupational therapist must check with the referring care provider to ensure that healing has progressed and is sufficient to apply the force of the mobilization splint ([Case Study 29-2](#)).

Tendon and Ligament Injuries

Tendon injuries in the hand and arm can occur as the result of a laceration, a trauma that ruptures the tendon from its insertion, or a complex upper extremity trauma (e.g., crush injury). Most tendon injuries require surgical repair and a period of immobilization for healing before therapy is initiated. An exception is a mallet finger, which is an injury to the terminal extensor tendon in the digit. If treated acutely, mallet fingers

CASE STUDY 29-2 Upper Extremity Trauma: Case Study

In the following case study consider:

1. How does assessment for an upper extremity trauma advance over the course of intervention and what does it entail?
2. How does intervention progress and what clinical parameters guide the progression?
3. What role does the family have in the intervention plan, including completion of home programming?

Emily, a 4-year-old right hand-dominant girl, sustained a right supracondylar elbow fracture when she fell from monkey bars. She required closed reduction and percutaneous pinning of the fracture site and was casted 4 weeks after her surgery. Two weeks after her cast was removed she was referred to an occupational therapy because she was not using her affected arm. During her initial evaluation the occupational therapist assessed right upper extremity range of motion (ROM), sensation and grip strength and interviewed the family to identify their priorities and the child's roles and occupations. The following limitations were noted.

1. Range of motion:

Active Range of Motion	Flexion	Extension
Right elbow (affected upper extremity)	110	-15
Left elbow	135	+15

She also was lacking right thumb active palmar abduction and interphalangeal joint flexion and active flexion of the distal interphalangeal joints of the index and middle fingers. Passive range of motion (PROM) of the joints described in the preceding were within normal limits.

2. Diminished light touch sensation and report of constant tingling in her right thumb
3. Muscle atrophy in the thenar eminence and region of the first and second metacarpals
4. Grip strength of 3 pounds on her right as compared with 10 pounds on the left
5. Report of avoiding use of her right upper extremity for dressing, writing, and play

Emily was to attend kindergarten soon, and her mother was concerned that she would have difficulty writing and coloring with her right hand.

At the time of her evaluation, the occupational therapist instructed Emily and her mother in a home exercise program to be performed two times per day, including active ROM (AROM) and PROM and desensitization activities (massage

and touching her right arm with different textures). Emily returned to therapy once per week for reassessment of her functional status, ROM, and sensation and progression of her home exercise program. Emily continued to avoid use of her right arm during functional tasks and had difficulty with coloring and writing in school. The occupational therapist fabricated a constraint cast for her left upper extremity. She continued to complete her home program activities for ROM and desensitization and used the constraint cast as much as possible throughout the day. At a 2-week follow-up visit, reassessment revealed that Emily had made small improvements with AROM and resolved hypersensitivity and limitations in sensory discrimination. She was using her right arm to assist with dressing, but not for writing or donning her sock. Additionally, she had decreased grip and pinch strength in her right arm as compared with the left. Therefore hand strengthening with extra soft putty for grip and pinch were added to her established home program for ROM; desensitization activities were discontinued.

She continued to return every 2 weeks for reassessment and evaluation of her home program activities. Six weeks later she displayed improved sensory return, as evidenced by prehension using opposition of her thumb to the tip of her middle finger instead of a palmar pinch grasp. Sensory assessment using Semmes Weinstein monofilaments revealed deep pressure (SW = 6.65) sensation only in her distal volar index finger and loss of protective sensation (SW = 4.56) in her thumb and proximal volar index finger. Emily and her mother reported continued functional limitations with holding a pencil/crayon and donning socks and pants with her right upper extremity. The therapist taught Emily how to hold a pencil using modifications (1-inch diameter foam pencil grip) and increased the level of resistance of putty for hand strengthening on the home program.

One month later, Emily displayed improved sensation to SW = 4.56 (loss of protective sensation) at the tip of her index finger, so she was taught to perform sensory re-education activities for stereognosis and touch localization as part of her home program.

Emily continued with monthly visits to progress her home exercise program for strengthening and sensory re-education until she was 8 months from her date of injury. At discharge she fastened buttons and zippers with her right upper extremity and she used a dynamic tripod grasp for writing/coloring with no reports of fatigue or difficulty completing her school work. Her Semmes Weinstein scores improved to normal sensation. She exhibited age-appropriate patterns and strength with her right grip and pinch.

will often heal through a period of splinting or casting.⁸⁰ The occupational therapist must follow very specific rehabilitation protocols to guide the intervention progression for tendon injuries.

Each joint in the upper extremity has ligaments that connect the bones to form the joint. These ligaments are critical for providing joint stability. Ligament injuries in children may occur in the hand, wrist, or elbow and are typically sports

injuries or are the result of a fall.⁵⁵ When a ligament is injured, the joint often becomes painful, edematous, limited in ROM, and can be unstable, depending on the degree of ligament tear. If the ligament tear is a minor injury, meaning only a small portion of the ligament is torn, it is treated conservatively with a period of immobilization. More severe injuries, in which a large percentage of the ligament is torn or the ligament is completely ruptured, require surgical repair followed by

TABLE 29-8 Typical Presentation of Upper Extremity Nerve Injury and Recommended Splints

Nerve Involved	Pattern of Motor Impairment	Recommended Splints
Radial nerve	Absent or weakened: forearm supination, wrist extension, MCP extension, and thumb radial abduction	Thumb spica splint or wrist cock up splint; Benik radial nerve splint; Robinson Inrigger (adult sizes only)
Median nerve (high lesion)	Absent or weak: pronation, wrist flexion, digit flexion of the PIPs and DIPs of the IF and MF, thumb palmar abduction and opposition, thumb flexion	Thumb spica with thumb in palmar abduction
Median nerve (low lesion)	Absent or weak: thumb palmar abduction and opposition	Thumb spica with thumb in palmar abduction or short opponens splint
Ulnar nerve	Absent or weak intrinsic muscles resulting in claw positioning of RF and SF	Anticlaw splint for SF and RF (Note: If the child has MN injury, the claw deformity will also be present in the index, middle, ring, and small fingers and the anticlaw should include all four digits)

IF, Index finger; MF, middle finger; RF, ring finger; SF, small finger.

immobilization. Ligamentous injuries that are surgically repaired are more likely to require therapy to restore function than conservatively managed ligament injuries. When the child has persistent pain, joint stiffness, and/or limited function, occupational therapy is indicated.

Nerve Injuries

Primary nerve injuries are those that result from a lesion directly to the nerve, such as a laceration at the wrist severing the median nerve or a traction injury to the brachial plexus. Anatomic compression of a nerve can also result in symptoms of primary nerve injury. Carpal tunnel syndrome, which is rare in children, is compression of the median nerve as it passes under the carpal ligament. The ulnar nerve and the radial nerve also have anatomic sites of possible compression neuropathy.

Secondary nerve injuries occur as the result of an upper extremity trauma causing nerve injury. For example, the radial nerve wraps around the shaft of the humerus and may be injured by a humeral shaft fracture. Similarly, compartment syndrome is a condition in which the fascia in the arm has extreme swelling. If compartment syndrome is not surgically managed in its most acute state, the compression from the swelling can cause nerve compression or even necrosis of the nerve. When an injury to a peripheral nerve occurs in the upper extremity, a specific pattern of motor and sensory impairment occurs. Table 29-8 outlines the pattern of motor impairment and types of splints that may be used during the rehabilitation of peripheral nerve injuries in the upper extremity.

Upper extremity nerve injury can also result from a systemic process. Some systemic autoimmune conditions, such as SLE, can have associated neuropathy. Nerve damage in the arm and hand may also be the result of drug toxicity to the nerves. This can result from chemotherapy or other strong medications that children with a systemic disease process may need to take.

A child who has upper extremity nerve impairment will have loss of motor function and sensation in the innervation pattern of the nerve following the path of the nerve, distal from the site of nerve insult. Occupational therapists use ROM exercises and splinting to preserve joint mobility until AROM begins to return. Often children with nerve injuries experience pain and hypersensitivity in the affected upper extremity. In these cases

occupational therapists use desensitization techniques. Occupational therapists may also use sensory retraining strategies, NMES, and strengthening in the rehabilitation of upper extremity nerve injuries.

Complex Regional Pain Syndrome

Complex regional pain syndrome (CRPS) is characterized by pain, specifically allodynia, and hyperalgesia (i.e., abnormal pain sensitivity such that an individual rates pain at a higher rate than typical for the pain stimulus). The extremity may also be edematous and have trophic changes, such as skin color changes and changes in nail growth and appearance. In progressed stages of the condition, bone density can decrease. Complex regional pain syndrome is classified as type I and type II; type I does not have an associated nerve injury and type II follows an injury to the nerve.³⁶

Children with CRPS often guard against use of their affected extremities. Early therapy is recognized as a critical aspect of disease management.^{47,103} Traditionally, intervention strategies included the use of weight bearing, desensitization, AROM exercises, and pain management strategies. More recently therapists have found mirror therapy^{15,26} and graded motor imagery^{73,74} effective with this patient population. An integrated approach of medical, psychological, and therapeutic care is most effective for recovery.^{47,100,109}

Summary

Occupational therapists specializing in hand therapy use concepts and principles from developmental, motor skill acquisition, rehabilitative, and biomechanical frames of reference to guide assessment, intervention planning, and intervention. This chapter described the specific principles, strategies, and modalities for common upper extremity conditions that are used by occupational therapists specializing in pediatric hand therapy.

- Common conditions that receive occupational therapy intervention include: (1) congenital differences of the hand or arm, (2) upper extremity impairments caused by an underlying neurologic or systemic disorder, and (3) injuries of the arm or hand.

- Occupational therapists working in the pediatric hand therapy setting gather information from chart review of the medical history, child/family interview, and formal and informal assessment to guide intervention.
- In selecting an intervention the occupational therapist considers the child's developmental stage, child/family goals, the desired clinical outcomes established from the therapist's ongoing clinical assessment, and the category of hand impairment.
- Pain management is an important aspect of therapy that can have priority in the intervention sequence.
- Occupational therapists implement a wide variety of interventions for children with upper extremity conditions. These include physical agent modalities, splinting, casting, kinesiotape, mirror therapy, and activity modifications. Occupational therapists also support wound care, edema control, and scar management. An intervention session may include activities that promote sensory re-education, ROM, strengthening, manipulation, and coordination.
- Pediatric hand therapy involves a high level of coordination with surgeons, physicians, nurses, other therapists, potentially social workers, and always family members.

CHAPTER

30

Trauma-Induced Conditions

Amber Lowe • Patti Sharp • Carrie Thelen • Beth Warnken

KEY TERMS

Spinal cord injury	Multidisciplinary team
Traumatic brain injury	Acute care
Rancho Levels of Cognitive Functioning	Intensive care
Burn injuries	Rehabilitation
ASIA International Standards for Neurological Classification of SCI	Community reintegration

GUIDING QUESTIONS

1. What are some examples of trauma-induced conditions in children and youth? What is the incidence and pattern of these conditions?
2. What is the impact of trauma-induced conditions on occupational performance of children and youth?
3. What are the roles of the occupational therapist across the continuum of care for specific conditions?
4. What are some examples of occupational therapy interventions at each stage of care?
5. How do therapists use therapeutic relationships, grief management, and caregiver education to assist children and youth who have experienced trauma?
6. Who are the members of a multidisciplinary team and what are the roles of specific members?

Introduction

The role of the pediatric occupational therapist to facilitate participation in age-appropriate occupations holds true when working with children with complex medical conditions from traumatic events, including any incident that causes significant injury. When a child experiences trauma, the family must adjust to and cope with differences in their loved one. Changes may range from minor deficits to significant changes in personality, appearance, and/or abilities. Regardless of the nature of the trauma or its resulting medical conditions, the therapist must be prepared for heightened emotions and rapidly changing needs of the child and caregiver post-trauma. Post-trauma, a child may receive rehabilitation services across a continuum of care, including the intensive care unit (ICU), acute care, inpatient and outpatient rehabilitation, and community reintegration services. The role of the therapist may change frequently

according to the child's medical and psychosocial status. The occupational therapist's approach is determined by the child's injuries, his or her developmental stage, and the family's educational needs and priorities. This chapter describes occupational therapy services for the common trauma-induced conditions of spinal cord injury, traumatic brain injury, and burn injury.

This chapter presents background on each condition and foundational information relevant across diagnoses and the continuum of care, including therapeutic relationships, caregiver grieving, caregiver education, and multidisciplinary teamwork. Intervention, including preparatory methods, purposeful activity, occupation-based intervention, and education, are explained and illustrated. The chapter explains the stages of care with condition-specific information at each stage.

Spinal Cord Injury

The incidence of pediatric spinal cord injury (SCI) in the United States is an average of 1.99 times per 100,000, indicating approximately 1455 new injuries every year.¹²⁴ From the age of 3 years,¹²⁵ boys are more than two times as likely to experience SCI as girls.¹²⁴ The most common cause of pediatric SCI is motor vehicle accident;¹²⁴ other traumatic causes of SCI include violence, falls, and sports injuries. Non-traumatic causes of spinal cord lesion include spinal tumor, spinal procedure, or disease process such as transverse myelitis. Usually an injury is at a cervical, thoracic, or lumbar level and may be multilevel, either continuous or noncontinuous.

More than other age groups, younger children are likely to have SCI at the upper cervical level (C1-3) because of their disproportionately larger head size and ligamentous laxity.¹²⁵ Compared with other age groups, they are also more likely to experience SCI without radiographic abnormality because of greater ligamentous laxity; that is, sudden displacement of the spinal column can cause SCI without damaging vertebrae or ligaments.^{53,125} After SCI, children may experience changes in muscle tone, decreased sensation, weakness, and/or paralysis below the level of injury, which is identified by the corresponding vertebra. Common medical complications include pain, latex allergy, muscle spasticity, pressure ulcers, spine deformity, hip deformity, low bone density, poor temperature regulation, autonomic dysreflexia, and decreased cardiovascular, respiratory, bowel, and bladder function.^{53,125} Autonomic dysreflexia is a dangerous physiological response to noxious stimuli below the level of the SCI that causes symptoms including increased blood pressure. Until adolescence, children with SCI

experience deep vein thrombosis¹²⁵ and heterotopic ossification⁵³ less commonly than adults with SCI.

The level of a child's injury informs a therapist as to which muscle groups and dermatomes may be affected. Children with lower-level injuries affecting their leg function have paraplegia, whereas children with higher-level injuries affecting their arms and legs have quadriplegia or tetraplegia. The *Reference Manual for the International Standards for Neurological Classification of Spinal Cord Injury* from the American Spinal Injury Association (ASIA) provides ASIA Impairment Scale (AIS) classification of injuries based on motor exam of 10 muscle groups and sensory exam of 28 sensory points.⁸³ For example, if no sensory or motor function is preserved in the sacral segments (S4-S5), the injury will be classified as AIS A, or complete, which is associated with the most severe injuries (Figure 30-1). This classification can help an occupational therapist to determine the extent to which muscle groups and sensation below the level of injury are affected and predicts neurologic outcome, with a better prognosis for less severe injuries.¹²⁸ Of note, the exam may be less reliable with some children because of their ability to follow directions or precision of responses.⁵³ Depending on the injury classification and other variables, such as medical stability and cognitive function, children with SCI have varied levels of physical function. Their function determines the extent to which they require adapted methods to participate in meaningful occupations. A child with a complete, high-level cervical injury (e.g., C2) may require a ventilator for respiratory support and have more dependent mobility needs than those with lower level injuries; he or she may use head or pneumatic switches to drive a power wheelchair and access assistive technology, including environmental controls. Environmental controls use switches or a computer interface to allow the child to operate devices or appliances, such as turning on a light or changing the channel on a television. Children with lower-level cervical injuries (e.g., C5) may be able to use hand controls instead. Children with thoracic injuries often have sufficient upper extremity strength and trunk control to self-propel manual wheelchairs and use standard methods to control their environments. Children with incomplete injuries may be able to resume functional ambulation independently or by using assistive devices.

Traumatic Brain Injury

Brain injuries are classified as traumatic when the injury is caused by an external force. Other causes of acquired brain injury include but are not limited to stroke, anoxia, arteriovenous malformation rupture, brain tumor resection, seizure activity, seizure foci resection, infections such as meningitis or encephalitis, and metabolic disorders. Because of the numerous mechanisms in which a brain injury may occur and the varying ways in which different types of brain injuries may present and recover, this chapter's focus is on traumatic brain injuries.

Typical causes of traumatic brain injury (TBI) include falls, motor vehicle accidents, sports-related injuries, nonaccidental trauma, and gunshot wounds. According to the Centers for Disease Control and Prevention (CDC), approximately 1.7 million people sustain a traumatic brain injury each year.⁴³ Statistics have shown that young children aged 0 to 4 years, teenagers aged 15 to 19 years, and seniors over the age of 65

are the most likely age groups to incur a traumatic brain injury. Furthermore, between the years 2002 and 2006 the CDC reported that almost half a million children aged 0 to 14 years were admitted to the emergency department because of traumatic brain injuries.⁴³

Traumatic brain injuries are classified as mild, moderate, or severe and can result in deficits ranging from minor to debilitating. The Glasgow Coma Scale¹²⁰ provides an objective measurement of consciousness on a scale from 3 to 15 using observations of eye opening, verbal output, and motor responses and is used to help classify the severity of brain injuries. A mild brain injury is defined as a loss of consciousness for less than 30 minutes, a Glasgow Coma Scale score between 13 and 15, and post-traumatic amnesia that lasts for less than 24 hours.^{33,79} A moderate brain injury is defined by a loss of consciousness from 30 minutes to 24 hours, a Glasgow Coma Scale score between 9 and 12, and possible observable findings on an electroencephalogram (EEG), computed tomography (CT), or magnetic resonance imaging (MRI) scans. A severe brain injury is defined as a loss of consciousness lasting more than 24 hours, a Glasgow Coma Scale score between 3 and 8, and possible significant findings on EEG, CT, or MRI scans.^{33,79}

Beyond severity of injury, the functional deficits that result from brain injury are also dependent on location of injury and whether the injury was localized or diffuse. Typically children who have sustained a severe global brain injury, such as a diffuse axonal shear injury or anoxia, tend to have less optimal functional outcomes than children who have a smaller, more localized area of injury.^{30,63,114} Pre-morbid factors such as family socioeconomic disadvantage, behavioral issues, and poor academic performance can also influence long-term functional outcomes of children who have sustained a TBI.^{84,114} Brain injury can cause deficits in cognition: attention, language, processing speed, memory, sequencing, and pragmatics; physical functions: strength, muscle tone, sensation, and gross and fine motor skills; and behavior: emotions, behavioral regulation, social adjustment, and psychological functioning.⁵

It is helpful to use the Rancho Levels of Cognitive Functioning^{54,99} when determining the occupational therapy goals and interventions for a child who has incurred a traumatic brain injury. This assessment tool describes the progression of recovery following a traumatic brain injury. The eight levels define behaviors typically observed at each stage of recovery (Table 30-1).

Using the Rancho Levels as a guide, the occupational therapist critically appraises the child's cognitive level and uses activity analysis to select and implement interventions to advance the child to the next functional level of recovery. Each child and each brain injury is unique; therefore, the rate of progression through the eight stages of recovery varies greatly. Furthermore, a child may plateau for a period of time before progressing, or, in some cases, he or she may plateau and never progress to a higher level of functioning.

Burn Injury

Approximately 450,000 individuals require medical attention for burn injuries each year.^{3,93} More than half of that number is comprised of children under the age of 18, with approximately 30,000 requiring hospitalization for burn injuries.³¹ The

Muscle Function Grading

- 0 = total paralysis
 1 = palpable or visible contraction
 2 = active movement, full range of motion (ROM) with gravity eliminated
 3 = active movement, full ROM against gravity
 4 = active movement, full ROM against gravity and moderate resistance in a muscle specific position
 5 = (normal) active movement, full ROM against gravity and full resistance in a functional muscle position expected from an otherwise unimpaired person
 5* = (normal) active movement, full ROM against gravity and sufficient resistance to be considered normal if identified inhibiting factors (i.e. pain, disuse) were not present
 NT = not testable (i.e. due to immobilization, severe pain such that the patient cannot be graded, amputation of limb, or contracture of > 50% of the normal range of motion)

Sensory Grading

- 0 = Absent
 1 = Altered, either decreased/impaired sensation or hypersensitivity
 2 = Normal
 NT = Not testable

Non Key Muscle Functions (optional)

May be used to assign a motor level to differentiate AIS B vs. C

Movement	Root level
Shoulder: Flexion, extension, abduction, adduction, internal and external rotation	C5
Elbow: Supination	
Elbow: Pronation	C6
Wrist: Flexion	
Finger: Flexion at proximal joint, extension	C7
Thumb: Flexion, extension and abduction in plane of thumb	
Finger: Flexion at MCP joint	C8
Thumb: Opposition, adduction and abduction perpendicular to palm	
Finger: Abduction of the index finger	T1
Hip: Adduction	L2
Hip: External rotation	
Hip: Extension, abduction, internal rotation	L3
Knee: Flexion	
Ankle: Inversion and eversion	L4
Toe: MP and IP extension	
Hallux and Toe: DIP and PIP flexion and abduction	L5
Hallux: Adduction	S1

ASIA Impairment Scale (AIS)

A = Complete. No sensory or motor function is preserved in the sacral segments S4-5.

B = Sensory Incomplete. Sensory but not motor function is preserved below the neurological level and includes the sacral segments S4-5 (light touch or pin prick at S4-5 or deep anal pressure) AND no motor function is preserved more than three levels below the motor level on either side of the body.

C = Motor Incomplete. Motor function is preserved below the neurological level*, and more than half of key muscle functions below the neurological level of injury (NLI) have a muscle grade less than 3 (Grades 0-2).

D = Motor Incomplete. Motor function is preserved below the neurological level*, and at least half (half or more) of key muscle functions below the NLI have a muscle grade ≥ 3 .

E = Normal. If sensation and motor function as tested with the ISNCSCI are graded as normal in all segments, and the patient had prior deficits, then the AIS grade is E. Someone without an initial SCI does not receive an AIS grade.

** For an individual to receive a grade of C or D, i.e. motor incomplete status, they must have either (1) voluntary anal sphincter contraction or (2) sacral sensory sparing with sparing of motor function more than three levels below the motor level for that side of the body. The International Standards at this time allows even non-key muscle function more than 3 levels below the motor level to be used in determining motor incomplete status (AIS B versus C).

NOTE: When assessing the extent of motor sparing below the level for distinguishing between AIS B and C, the **motor level** on each side is used; whereas to differentiate between AIS C and D (based on proportion of key muscle functions with strength grade 3 or greater) the **neurological level of injury** is used.

Steps in Classification

The following order is recommended for determining the classification of individuals with SCI.

1. Determine sensory levels for right and left sides.

The sensory level is the most caudal, intact dermatome for both pin prick and light touch sensation.

2. Determine motor levels for right and left sides.

Defined by the lowest key muscle function that has a grade of at least 3 (on supine testing), providing the key muscle functions represented by segments above that level are judged to be intact (graded as a 5). Note: in regions where there is no myotome to test, the motor level is presumed to be the same as the sensory level, if testable motor function above that level is also normal.

3. Determine the neurological level of injury (NLI)

This refers to the most caudal segment of the cord with intact sensation and antigravity (3 or more) muscle function strength, provided that there is normal (intact) sensory and motor function rostrally respectively. The NLI is the most cephalad of the sensory and motor levels determined in steps 1 and 2.

4. Determine whether the injury is Complete or Incomplete.

(i.e. absence or presence of sacral sparing)
 If voluntary anal contraction = No AND all S4-5 sensory scores = 0 AND deep anal pressure = No, then injury is **Complete**. Otherwise, injury is **Incomplete**.

5. Determine ASIA Impairment Scale (AIS) Grade:

Is injury Complete? If YES, AIS=A and can record ZPP (lowest dermatome or myotome on each side with some preservation)

Is injury Motor Complete? If YES, AIS=B

(No=voluntary anal contraction OR motor function more than three levels below the motor level on a given side, if the patient has sensory incomplete classification)

Are at least half (half or more) of the key muscles below the neurological level of injury graded 3 or better?

NO $\downarrow$ AIS=C
 YES $\downarrow$ AIS=D

If sensation and motor function is normal in all segments, AIS=E
 Note: AIS E is used in follow-up testing when an individual with a documented SCI has recovered normal function. If at initial testing no deficits are found, the individual is neurologically intact; the ASIA Impairment Scale does not apply.

TABLE 30-1 The Rancho Levels of Cognitive Functioning and Typical Behaviors

Rancho Level of Cognitive Functioning	Description of Typical Behaviors
Level I : No Response	• Demonstrates no response to external stimuli
Level II: Generalized Response	• Demonstrates generalized body responses to external stimulation
Level III: Localized Response	• Demonstrates localized responses to external stimuli
	• May follow some basic commands
Level IV: Confused, Agitated	• Demonstrates confusion and agitation
	• Begins to participate in more basic activities of daily living with maximal assistance
Level V: Confused, Inappropriate, Non-agitated	• Demonstrates continued confusion
	• Needs step-by-step instructions for completion of self-care skills
	• Tends to persevere on certain ideas or actions
Level VI: Confused, Appropriate	• Demonstrates confusion due to memory deficits
	• Follows daily routines with supervision or minimal verbal cues
	• Exhibits improved attention to functional tasks
	• Easily distracted by environmental stimuli
	• Emerging insight into physical deficits
	• Impulsive with actions and speech
Level VII: Automatic, Appropriate	• Emerging independence with routine tasks, functional activities
	• Poor insight into true physical and cognitive capabilities
	• Demonstrates inflexibility with thought processes and actions
Level VIII: Purposeful, Appropriate	• Realizes the physical and cognitive impact injury
	• Compensates for deficits to independently complete daily tasks
	• Demonstrates more appropriate problem-solving skills
	• Illustrates improved learning abilities

Rehabilitation of pediatric spinal cord injury: from acute medical care to rehabilitation and beyond. *Journal of Pediatric Rehabilitation Medicine: An Interdisciplinary Approach*, 2, 13–27; Rancho Los Amigos National Rehabilitation Center. (2011). The Rancho Levels of Cognitive Functioning. Retrieved April 13, 2013 from http://www.rancho.org/Research_RanchoLevels.aspx.

majority of pediatric burns (60%) are caused by kitchen or bathroom scalds, whereas 25% are caused by flame, 10% by contact with hot objects or tools, and the remaining 5% by electrical or chemical interactions.⁹ Skin has two layers: the epidermis, which is thin and contains no blood vessels, and the dermis, which contains blood vessels, nerves, hair follicles, sweat glands, and fat and is responsible for cell production. The severity of complications resulting from burns is directly related to the depth of injury (Table 30-2). Burns are considered to be first degree or superficial when damage is caused only to the epidermis, second degree or partial thickness when damage enters the dermis, and third degree or deep partial or full thickness when the majority or entire dermis is damaged.

Tissue injury causing damage to deeper layers of the skin requires longer healing time and often requires surgical intervention, therefore increasing risk of infection. Burns that destroy the dermal layer of the skin most often require skin grafting, which presents risk of abnormal scar development. Sheet grafting occurs when an area of healthy skin is shaved off and placed over a same-sized wound. The healthy area is called the donor. Donor sites are similar to superficial partial thickness injuries. They generally heal within 10 to 14 days and are very painful. Donor sites may also scar. Meshed grafting is used to cover large wounds. This is when the donor skin is run through a machine for perforation so that it can cover a wound larger than the donor area. It is necessary for covering wounds when donor skin is minimal, for example, with large, full-body burns. Meshed grafting can be expanded two to nine times the original size, and the spaces in the mesh heal within 7 to 14 days.

The “waffled” appearance is permanent; therefore meshed grafting is generally only used when absolutely necessary and rarely on faces or hands. For those injured on a large portion of their body with minimal donor skin, temporary wound coverage can be provided through allograft, or donor skin from a cadaver or animal, which acts as a biologic dressing and remains in place for 2 to 3 weeks. When the allograft is rejected by the body, autografting must be completed, which uses the child’s own skin from an uninjured donor site on his or her body. As stated, all of these grafting procedures have a high risk of developing problematic scars.

Abnormal scar development is the cause of functional and aesthetic problems that arise from burns. With recent advances in burn care, survival rates have increased for all age groups, resulting in an increased need for effective rehabilitation. Collagen fibers that make up the skin are typically arranged in a linear fashion. When the dermal layer is damaged severely, the collagen fibers that make up the skin are overproduced and realign in a disorganized manner during the healing process, causing abnormal scarring. These hypertrophic scars are red, raised, thick, and tight in appearance. The incidence of hypertrophic scar development following burns is 67% to 90%, with increased prevalence in children and those with darker pigmented skin tones.^{2,13,32,42,51,59} Unmanaged hypertrophic scars have both physical and psychosocial repercussions, including joint contracture leading to decreased function, chronic wounds and pain, social stigma associated with visible disfigurement, and overall decreased quality of life.^{12,15,18,37,58,62,68,81,105} The optimal outcome for treatment of burn scars is restoration of

TABLE 30-2 Burn Depth and Intervention Implications

Degree and Thickness	Depth	Characteristics	Examples	Therapeutic Considerations
First: superficial	Epidermis	Pain, redness, itching	Sunburn	• Heals within a few days • Generally no intervention required • Monitor need for scar massage
Second: superficial partial thickness	Dermis—superficial papillary region	Pain, blistering, swelling; brief contact with burn agent	Brief contact with scalding water or curling iron, friction—road rash	• Will require heal time of 1-2 weeks • Will need scar massage and AROM • Monitor need for PROM, pressure therapy, and/or splinting
Deep second: deep partial thickness	Dermis—deeper reticular region	Relatively painless, white, leathery; significant contact with burn agent	Fire, significant contact with scalding water, friction—contact with moving treadmill	• Will likely need grafting or will require heal time of 3+ weeks • Will need PROM, scar massage, pressure, splinting, and re-teaching of skills with respect to pain and temporary limitations in joint ROM
Third: full thickness	Full dermis and/or hypodermis (muscle, bone)	Insensate, charred black or gray; prolonged contact with burn agent	Electrocution, explosions, contact with flammable chemicals, house fire entrapment	• Will need grafting, amputation, and/or complex surgical intervention • May need PROM, scar massage, and pressure depending on nature of surgery • Will likely need postoperative splinting • Will require re-teaching of skills, compensatory strategies, and/or prosthetics

tissue aesthetics and function as close to normal skin as possible. The therapist's role, as described in the following sections, is crucial during the period of active scar formation, i.e., first year following injury.

Therapeutic Relationships

Therapeutic relationships are instrumental to support the psychosocial well-being of children and their families in post-trauma care. Families may feel helpless following trauma, unfamiliar with their child's medical complications and the medical system. The therapist should assess the caregiver's readiness to learn and provide an appropriate level of information, facilitating the caregiver's increased confidence in making medical decisions and participating in his or her child's care.²⁴ Occupational therapists should assess and consider caregiver readiness, because encouraging caregiver participation or presenting too much information before the caregivers are ready may overwhelm them and decrease their confidence. To empower caregivers to fully participate on the medical team, occupational therapists educate caregivers using family-friendly language and methods of instruction.¹⁴ Hands-on education may offer caregivers a sense of involvement, responsibility, confidence, and role fulfillment.

In addition to engaging with caregivers, the occupational therapist uses developmentally and cognitively appropriate strategies⁵ to build rapport with the child. Children are often frightened and anxious in hospital settings; expressions of friendliness such as laughter and smiling may go a long way in building trust. If a therapy intervention is uncomfortable or

difficult, the occupational therapist may promote continued rapport development by validating the child's feelings and providing him or her with age-appropriate methods for coping with the stressful situation. Another strategy is to incorporate the child's premorbid interests into therapy activities. The occupational therapist may further build trust by educating the child on the medical condition, precautions, or procedures using developmentally appropriate language. The occupational therapist who describes what he or she will be doing to a child with a low level of consciousness acknowledges the child's experience and demonstrates respect. Once the child and caregivers feel comfortable in the medical setting and trust the care team members, they become more engaged in the rehabilitation process.⁵

It is important to be mindful of the often contrasting perspectives of the health care professionals and the family. The health care team is likely meeting the child after he or she has been injured; therefore, their view of recovery progression is based on the child postinjury. In contrast, the child's and caregivers' perspectives are based on the child before his or her injury, a child to whom they want to return. Although the care team, child, and caregivers all hope to achieve recovery as close to preinjury status as possible, it is important to recognize that the child and family members have a different perspective on progress.

Grief Management

Traumatically injured children and their families experience a variety of emotions and social issues. Psychologist Ken Moses

suggests impairment “shatters the dreams” a caregiver has for his or her child’s future.⁸⁷ The subsequent grieving process includes states of anxiety, denial, guilt, anger, and depression. “They must go on with their lives, cope with their child as he or she is now, let go of lost dreams, and generate new dreams.”⁸⁷ Moses suggests that dreams are shattered repeatedly at each stage of typical development. He conceptualizes the grieving process as dynamic, noting that caregivers may transition through grieving states in any order, rather than in a sequence, and sometimes repeat states. Every caregiver’s grieving process is unique. An occupational therapist may support caregivers, acknowledge the grieving process, and gently promote progress toward desired outcomes. Two ways to promote progress are providing sensitive education and collaborating with caregivers on the occupational therapy plan of care.

Caregiver Education

The health care team must consider the family’s grieving process to determine appropriate timing for delivery of delicate education topics.¹¹⁵ The traumatically injured child and caregivers may be in a fragile emotional state; it is important for the occupational therapist to meet the family “where they are” in the grieving process. The occupational therapist may be cautiously hopeful with caregivers and the child, finding a careful balance between squandering hope and promising the potentially impossible.¹³² The occupational therapist may also acknowledge children’s and families’ frustration with lack of knowledge about prognosis because there is likely not a clear-cut expected treatment outcome. It is important for the occupational therapist to continuously monitor the family’s readiness to progress education.

One approach to education involves a self-management structure. The intent of self-management is to ultimately empower the child and/or caregiver to manage care responsibilities. Using this approach, the occupational therapist initially discerns the caregiver’s priorities and confidence in his or her ability to manage the child’s condition.²⁴ The occupational therapist then continually assesses the caregiver’s ability to carry out health care recommendations¹⁴ and supports the caregiver’s ability to problem solve barriers.

Multidisciplinary Team

A coordinated, multidisciplinary team is comprised of health care professionals from different disciplines who are in regular collaboration with one another and the family to ensure the provision of consistent, goal-directed care.¹ This approach is essential to positive outcomes in the rehabilitation of children with trauma-induced medical conditions.^{1,19,23,26,47,70,93,115,126} Professionals from each discipline develop their own treatment plans for the child, and close coordination is necessary to ensure the plans correspond with one another. Over the course of the child’s recovery and according to the child’s needs, certain disciplines may hold more responsibility than others for determining the course of the treatment plan. A therapist must approach team members proactively with concerns about a child’s care plan. For instance, in some stages the therapist may interact with the child more frequently than the physician. In

this case, the occupational therapist may inform the physician regarding barriers to progress, such as pain levels requiring pharmacologic management. Furthermore, to meet the complex needs of the child post-trauma, occupational, physical, speech, and recreational therapists need open dialog and routine collaboration, which may include transdisciplinary practices (i.e., appropriate reinforcement of each other’s disciplinary goals). For example, the occupational therapist may focus on self-care while reinforcing mobility and communication, the respective primary goals of the physical therapist and speech-language pathologist. A unified approach to the child’s general care plan promotes the safety of the child, models consistency of care provision among caregivers and care providers, prevents the delivery of conflicting information, and facilitates the child’s ability to carry over restored skills to various contexts.^{46,47,132}

The individual therapists on the care team may change as the child progresses from one stage of care to another, further emphasizing the importance of care coordination.¹²⁹ Thorough and timely team communication supports a smooth transition of care from one practitioner to another. Consistency throughout the continuum of care provides the child and caregiver with a sense of security during potentially stressful transitions.^{23,115,129}

Post-Trauma Occupational Therapy Interventions

Provision of care for children post-trauma is complex and dynamic, with each child and caregiver presenting a multitude of therapy needs. To ensure holistic care and support progress, the occupational therapist uses different but intimately intertwined intervention types, including preparatory methods, purposeful activity, occupation-based intervention, and education. The occupational therapist uses preparatory methods to remediate client factors, including the injured body structures and impaired body functions. As occupational therapy intervention, preparatory methods must lead to purposeful activities or occupation-based interventions.⁴ The therapist uses purposeful activities and occupation-based interventions to rehabilitate the child’s participation in meaningful occupation. Both caregivers and children require educational intervention including supports and problem solving. Specific interventions post-trauma may change throughout the continuum of care (Table 30-3).

Post-Trauma Continuum of Care

Children post-trauma receive occupational therapy intervention across a continuum of care with different needs at each stage. These stages may include the intensive care unit (ICU), acute care, inpatient rehabilitation, outpatient rehabilitation, and community re-integration. Continuous assessment in each stage may include body structures (e.g., skin); mental functions, sensory functions, and pain; neuromusculoskeletal and movement-related functions (e.g., passive range of motion, strength, muscle tone, endurance, coordination); and skin functions. Although the specific interventions used may vary based on the specific trauma and resulting deficits, fundamentals for each recovery stage apply to all children’s intervention

TABLE 30-3 Interventions Through the Pediatric Post-Trauma Continuum of Care

Stage of Care	Preparatory Methods	Purposeful Activities and Occupation-Based Interventions	Education	Safety Notes
Intensive care unit	- Positioning - ROM - Splinting - Soft tissue mobility - Wound care - Sensory stimulation - Medical consultation regarding medication for pain and arousal	Promoting sleep/rest with low stimulation environment	- Education on diagnosis - Education on role of occupational therapist - Hands-on education on caring for child	- Precautions - Monitoring vitals
Acute care	- Positioning - ROM - Splinting - Soft tissue mobility - Wound care - Sensory stimulation - Scar massage - Pressure therapy - Medical consultation regarding medication for pain, arousal, and spasticity	- Trunk control work - Strengthening - Endurance - Neuromuscular re-education for coordination - Adaptive equipment training	- Education on DVT and orthostatic hypotension prevention - Education on exercises to be completed outside therapy - Education on therapeutic equipment/strategies	- Precautions - Monitoring vitals - Prevention of orthostatic hypotension
Inpatient rehabilitation	- Positioning - ROM - Splinting - Soft tissue mobility - Sensory stimulation - Scar massage - Pressure therapy - Medical consultation regarding medication for pain, arousal, and spasticity	- Postural work - Strengthening - Endurance - Neuromuscular re-education for coordination - Electrical stimulation - Adaptive equipment training - Self-care training - IADL training - Standardized assessment - Home evaluation - Community re-entry outing - Coping strategies - Social skills training - Cognitive re-training - Visual perceptual skill training - Consultation with social worker/psychologist regarding readiness for return home	- Hands-on education for care of all functional needs - Hands-on education for use of therapeutic equipment/strategies - Hands-on education on home programming - Education on importance of home programming - Education on results of standardized assessments	- Precautions - Prevention of orthostatic hypotension
Outpatient rehabilitation/community re-entry	- Positioning - ROM - Splinting - Soft tissue mobility - Sensory stimulation - Scar massage - Pressure therapy - Medical consultation regarding medication for pain, arousal, and spasticity	- Postural work - Strengthening - Endurance - Neuromuscular re-education for coordination - Electrical stimulation - Adaptive equipment training - Self-care training - IADL training - Standardized assessment - Coping strategies - Social skills training - Cognitive re-training - Cognitive strategies - Visual perceptual skill training - Consultation with school - Community integration - Referral to community resources for supports and recreational opportunities - Referral to other disciplines - Referral to certified driver rehabilitation specialist	- Hands-on education for use of therapeutic equipment/strategies - Hands-on education on home programming - Education on importance of home programming - Education on results of standardized assessments - Education on problem-solving barriers to participation and home program implementation	Precautions

post-trauma. The following sections describe the role of the therapist at each stage of care. Further interventions specific to diagnosis at each stage of care are described to illustrate the unique needs associated with different trauma conditions.

Intensive Care Unit

In the ICU, the child's care is focused on medical recovery. The child typically presents as sedated by either a naturally occurring or pharmacologically induced coma, limiting the active engagement of the child with other people or the environment. Occupational therapy services are initiated in the ICU to prevent secondary complications from the body's state of immobility and impaired ability to maintain homeostasis.⁵ The child's primary occupations at this stage, rest and sleep, are critical to healing.

Goals for ICU intervention include contracture and pressure ulcer prevention, pain management, and safety. The child's vital signs should be monitored throughout interventions to ensure stability of cardiovascular and respiratory functions. Preparatory methods to maximize range of motion include stretches, soft tissue mobilization, splinting, and positioning. Beyond contracture prevention, the occupational therapist may develop a positioning plan to prevent pressure ulcers, because unconscious children and those who have limited movement and/or sensation are at risk for skin breakdown. The occupational therapist may also use positioning plans and range of motion programs to help control pain in collaboration with physician-directed pharmacologic pain management. Pain management can also include developmentally appropriate comfort measures such as soothing music. Collaboration with nursing staff is essential for development and consistent implementation of range of motion, splinting, and positioning plans.

Ensuring the child's safety is the highest priority in treatment delivery. Therapists address safety by adhering to medically necessary movement restrictions and protective medical equipment, such as a helmet following removal of a portion of the skull. For children who become agitated the occupational therapist collaborates with the medical team to help determine the need for physician-ordered physical restraints to prevent self-injury. Examples include elbow immobilizers to prevent pulling at tubes and bed barriers such as one with zippered sides to protect the child from falls. An occupational therapist must be vigilant regarding wounds, incisions, and the placement of medical lines when transferring a child to prevent harm. It is important to be aware of seizure status and presentation as well. The occupational therapist may also help prevent critical secondary conditions, such as pressure ulcers. Maintaining awareness of all safety factors may seem overwhelming to an occupational therapist unfamiliar with this complex population. It is important to recognize one's limitations; the therapist and child benefit from use of other medical team members at key times to ensure provision of safe and appropriate care. The entire care team is committed to working closely to ensure the child's safety throughout his or her recovery.

In the ICU, the occupational therapist facilitates the caregiver's return to his or her role as the child's provider. During the assessment process, the occupational therapist seeks information from the caregiver about the child including the child's interests, premorbid levels of development and function, and

family dynamics. Although the caregiver may not be an expert regarding the child's medical needs, he or she is the expert on his or her child. The occupational therapist educates the caregiver on the therapist's role to facilitate skill progression toward the child's prior level of function throughout the continuum of care. The occupational therapist also suggests ways the caregiver may collaborate with the medical care team to participate in the child's care in the hospital environment.

Children with Spinal Cord Injury in the Intensive Care Unit

Preparatory methods:

- It is estimated that 26% to 96% of clients post-SCI experience pain.³⁶ Neuropathic pain, which is caused by the nervous system rather than external stimuli, along with pain from injuries may limit a child's participation, making collaboration with physicians on pain management especially important.

Purposeful activities and occupation-based interventions:

- If the child is conscious, the occupational therapist can prevent the child's anxiety about mobility limitations by providing adapted call lights.

Education:

- Caregivers may benefit from general education on their child's SCI.
- Education also includes autonomic dysreflexia. Of note, children with SCI usually have lower blood pressure than those without, so elevations 20 to 40 mmHg above baseline may be a sign of autonomic dysreflexia.⁵³ Symptoms of autonomic dysreflexia may be managed conservatively (e.g., using removal of precipitating stimulus or positioning) and/or pharmacologically.⁷⁷

Children with Traumatic Brain Injury in the Intensive Care Unit

Preparatory methods:

- Autonomic storming occurs in some children with brain injury and presents as cyclic symptoms that occur after a severe insult to the brain. Physical manifestations may include posturing of the limbs and trunk and increase in heart rate, respiratory rate, blood pressure, and sweating. Although the physician manages pharmacologic interventions to address autonomic storming, the occupational therapist may communicate to the medical team whether interventions are supporting improved tolerance of therapy interventions.⁸²
- A low stimulation environment may promote brain healing.⁵ After brain injury, loud noises, bright lights, and tactile input may overstimulate the child and lead to increased agitation and blood pressure. Increased blood pressure is dangerous to healing brain tissues because the child is already experiencing increased intracranial pressure resulting from swelling.^{63,82}

Purposeful activities and occupation-based interventions:

- Depending on the child's level of consciousness, the occupational therapist may introduce appropriate sensory stimulation in a controlled manner in an effort to evoke a localized, volitional response to the environment.^{5,19} Monitoring the autonomic nervous system's response to

sensory stimulation can provide information on the client's potential return to consciousness.¹²⁷

Education:

- Caregivers may benefit from general education on brain injury including how arousal, acceptance of stimulation, and body movements are impacting their child. The Rancho Levels^{54,99} may facilitate understanding of the phases of recovery post brain injury and projected outcome.

Children with Burn Injury in the Intensive Care Unit

Preparatory methods:

- As the body heals from severe tissue injury, the child often seeks a position of comfort (fetal position), which unfortunately contributes to the development of contractures. Therefore the therapist must ensure that burned areas are positioned in extension to promote future function.⁸⁰ If bed positioning cannot be maintained, splinting should be used to maintain tissue length.³⁴
- Splinting is also used to protect injured or exposed body structures.
- If the child has a tracheotomy, positioning the neck in adequate extension is essential to prevent contracture and has been shown to reduce the need for early reconstruction.¹⁰⁷
- Passive range of motion should be completed to terminal stretch for all involved joints once per day with caution in respect to exposed body structures.⁴²

Purposeful activities and occupation-based interventions:

- Despite likely low level of consciousness, it is important to acknowledge the child and his or her interests during early range of motion and dressing changes.

Education:

- Caregivers may benefit from general education on burns, including description of burn depths and locations, and how those factors may influence functional and aesthetic outcome.

Acute Care

In this stage of the continuum of care, the child who sustained a traumatically induced condition is more medically stable and hopefully starting to demonstrate an ability to interact with his or her environment. The occupational therapist continues to use preparatory methods to address injured body structures and impaired body functions, including promotion of homeostasis and prevention of secondary complications of immobility. Maintaining skin integrity is a high priority when the child experiences prolonged bed rest. The occupational therapist continually monitors if and how pain is inhibiting the child's ability to participate in functional tasks and collaborates with care team members as needed to update the pain management plan, including pharmacologic interventions and coping mechanisms. Although the body systems are functioning in a more stable manner than in the ICU, the occupational therapist continues to closely monitor vital signs during interventions.

If the child indicates wants and needs, it is important for the occupational therapist to actively engage the child in the therapy session. If the child remains relatively sedate, the occupational therapist observes the child's body language and vital signs to monitor the child's response to interventions. The occupational therapist facilitates the child's ability to resume available motor functions, including trunk control. For example, the occupational therapist assists the child to transition to different positions, including upright in bed and edge of bed sitting, and transfer to a wheelchair as appropriate. When facilitating postural control, the occupational therapist must carefully monitor for signs of pain or orthostatic hypotension, position-related low blood pressure. The child may need to slowly re-build upright tolerance.

The occupational therapist continues to build rapport with the caregiver in acute care and each subsequent stage in the continuum of care. At each stage it is also important for the occupational therapist to remain cautiously hopeful when discussing the child's prognosis and outcomes with caregivers. Information on the child's care and rehabilitation often needs to be reiterated several times throughout stages depending on caregiver readiness. New education at this stage includes the prevention of orthostatic hypotension, which is important before teaching caregivers to facilitate position changes. Caregivers may also be educated on the importance of appropriate movement to aid the prevention of deep vein thrombosis, or blood clotting, for children who are immobile for extended periods.

Children with Spinal Cord Injury in Acute Care

Preparatory methods:

- Muscle hypertonia may become more evident at this stage of recovery, in which case interventions to maximize range of motion are initiated (Figure 30-2).
- Collaboration with physicians on pharmacological management of spasticity¹¹⁹ in addition to pain may support improved participation in therapy and response to interventions.

FIGURE 30-2 Occupational therapists may fabricate splints as a means to maximize range of motion and prevent deformity.

- Orthostatic hypotension may be managed conservatively (e.g., using functional electrical stimulation) and/or pharmacologically following SCI.⁷⁶
- Vital sign instability may be caused by autonomic dysreflexia.

Purposeful activities and occupation-based interventions:

- Resumption of motor functions must remain within restrictions of spinal orthopedic equipment such as a neck or back brace. Unfortunately, this equipment may limit independent function.²¹
- Neuromuscular re-education, including hand-over-hand and sensorimotor therapeutic interventions, supports restoration of motor functions. For example, when children are beginning to re-initiate purposeful movements, they often have difficulty with precision and control. The occupational therapist can use his or her own hands, by placing them over the child's hands, as an assist to the child's action. The occupational therapist's assist to the child's movement provides the child with kinesthetic input for the movement pattern. Additionally, the occupational therapist may use vibration or muscle and tendon tapping techniques to elicit active movement in the context of a functional task and to provide the child with the sensorimotor input of how a particular action of the body should feel.
- Adaptive equipment and assistive technology should be introduced to maximize the child's function amidst new motor deficits. This may include provision of alternative call light and bed controls, abdominal binder, compression stockings, and loaner durable medical equipment, for example, wheelchair, air mattress, and commode chair. A wheelchair evaluation will determine which model and features are best for each child; optimal fit is important to maximize the child's safety and function.

Education:

- Therapists may model how to support children's ability to direct their care as appropriate. When children may have long-term movement limitations it is important to empower them to instruct those who assist them. For example, children can increase their sense of control over their bodies by communicating how they prefer to be transferred or how to position a piece of equipment most effectively for them.

Children with Traumatic Brain Injury in Acute Care

Preparatory methods:

- Muscle hypertonia may become more evident at this stage of recovery, in which case interventions to maximize range of motion are initiated.¹³²
- Collaboration with physicians on pharmacologic management of muscle tone, agitation, and/or arousal in addition to pain may support improved participation in therapy and response to interventions.¹³²
- Ongoing assessment of the child's mental functions is essential to monitor his or her ability to perceive or interact with the environment.⁵ Examples include the ability to localize touch, blink to threat, visually track, startle to sound, localize to sound, or react to smells or tastes.

- Sensory stimulation may be used to increase or decrease alertness as appropriate to facilitate participation in functional tasks.⁵
- Physical restlessness typically increases in this stage owing to decreased pharmacologic sedation.⁵ The need for safety measures, such as padding to prevent skin shearing, is continuously assessed.

Purposeful activities and occupation-based interventions:

- Once the child is able to perceive environmental stimuli, facilitation of the child's ability to interact with the environment progresses from basic functioning to more complex.⁵ For example, if a child is demonstrating the ability to visually track and is initiating basic upper extremity movement, facilitating reach for a preferred object in a gravity-lessened, side-lying position may be an appropriate next step for intervention. From this position, the task can be graded in complexity in a variety of ways, including requiring the child to reach against gravity and increasing the distance of the object from the child to incorporate practice of trunk control.
- Neuromuscular re-education, including active assist of arm and hand movement and sensorimotor therapeutic interventions, supports restoration of motor functions.

Education:

- Caregivers may benefit from education on how environmental stimuli and the child's level of alertness may affect the child's ability to participate in functional tasks. The occupational therapist may then model how the caregiver can facilitate purposeful interactions.
- Caregivers may benefit from education on how the repetition of motor tasks reinforces motor learning and subsequent function.

Children with Burn Injury in Acute Care

Preparatory methods:

- Multiple changes occur at the cellular level which alter the pathology from normal wound healing to development of hypertrophic scarring. During excessive scar formation, a dysfunction of the underlying regulatory mechanisms may lead to persistent inflammation, excessive collagen synthesis, or deficient tissue degradation and remodeling.⁵¹ This stage of active abnormal scar development peaks around 6 months postinjury and can persist an additional 12 to 18 months. Therapeutic interventions to promote optimal scar outcomes must be maintained throughout this entire period.
- Scar massage should be initiated as soon as the wound is closed to mechanically counteract the contractile forces of the healing skin. Scar massage should be completed with enough pressure to blanch the skin, and should be completed 3 to 5 minutes per area, two to three times per day.^{44,103,104} Alcohol-free lotion or cream assists in skin conditioning but does not itself contribute to scar maturation or healing.
- Passive range of motion should be initiated immediately on open wounds or 5 to 10 days following graft placement and be completed in conjunction with scar massage twice per day.^{42,80} It is essential to monitor for loss of range of motion as contractures are likely to begin to

FIGURE 30-3 Pressure therapy for scar management can be accomplished through custom pressure garments or simple elastic wraps.

develop at this stage owing to the heightened contractile forces of the hypertrophic scar.¹²¹

- When full passive range cannot be achieved within a therapy session, tissues should be placed on prolonged stretch through splinting.^{8,9,11,31,42,51,80,91,94,95,102,113} Pressure therapy using compressive wraps or garments promotes optimal outcomes as soon as the healing skin can tolerate the pressure and/or shear force generated by the intervention (Figure 30-3).^{11,31,42,51,73,80,91,95,102,113} Pressure therapy is initiated 5 to 10 days following wound closure or graft placement.
- Pressure wraps or garments should be fit to achieve pressure near capillary pressure (20 to 30 mmHg) to promote optimal scar outcome^{9,11,17,31,41,50,80,113,123,130} and should be applied for 23 hours per day for approximately 12 months, or until scar maturation is achieved (Figure 30-4).^{9,11,31,55,80,94}

Purposeful activities and occupation-based interventions:

- As the child's alertness and awareness increases, the need for pain management increases. The occupational therapist should assess the client's interests and incorporate age- and interest-appropriate distractions during painful range of motion and wound care procedures.^{71,110}
- Although the child remains on bed rest for the most part, it's important to provide a glimpse of future functionality. Passive stretches may be followed by simple

FIGURE 30-4 Scar maturation is defined by restoration of tissue aesthetics and function as close to normal skin as possible. This donor site scar was treated with massage and pressure therapy for approximately 12 months, and has regained its normal vascularity, pigmentation, and pliability. Scar height continues to persist in this client, however, and will likely remain. Every individual presents with different skin make-up and can have different responses to the standard of care.

activities that reinforce range of motion and strength, such as tossing a ball while in bed.

Education:

- Caregivers should observe therapy sessions, which are often difficult and painful, in order to prepare themselves emotionally to complete the exercises with their child upon discharge.
- Providing samples of therapy devices (e.g., pressure garments, splints, adaptive equipment) as well as photographs of scar progression may facilitate future adherence.⁶⁴

See Case Study 30-1.

Inpatient Rehabilitation

During inpatient rehabilitation, the child is medically stable and is physically able to tolerate a structured therapy program, which may consist of twice-daily sessions of occupational therapy, physical therapy, and speech-language pathology. If available, school services, therapeutic recreation, massage therapy, and behavioral medicine services may be included in the child's care. In this stage, the occupational therapist continues to address underlying client factors that inhibit overall function as needed.

However, the focus of therapy in this stage is to facilitate the child's independence with participation in self-care and play or leisure to prepare for the child's transition home. Self-care

CASE STUDY 30-1 Keegan

History

Keegan is a 3-year-old boy admitted to the ICU following a car accident. He was restrained by a lap belt without a booster seat in the back seat when his mother lost control of her car, which sustained front-end impact and caught on fire. He was transported to the emergency room by ambulance where his immediate injuries were treated and later transitioned to the ICU. Before injury, Keegan was a typically developing boy who lived with his parents and older brother. He attended half-day preschool after which his grandmother cared for him. Keegan was outgoing and loved to explore the outdoors and wrestle with his brother.

Assessment

Keegan sustained a T-12 ASIA B spinal cord injury and 30% total body surface area, full-thickness burns to the neck, right shoulder, and upper extremity proximal to the elbow; he had a nasogastric feeding tube, back brace, and indwelling Foley catheter, was intubated, and was in a pharmacologically induced coma. Therapy was initiated to prevent secondary complications. Burn wound assessment revealed that full-thickness burns crossed joints including the neck and anterior axilla. Passive range of motion was measured to be normal at these joints at this point in care.

Interventions

Intensive Care Unit

The occupational therapist coordinated a positioning schedule with nursing staff to ensure Keegan was turned in bed at least every 2 hours to prevent skin breakdown and prevent deformity caused by wound contracture; he was also issued multi-podus boots to avoid direct pressure to his heels while positioning the ankles for future weight bearing. The occupational therapist educated Keegan's parents on his positioning schedule, posted in his hospital room, and on how they could help nursing staff keep track of his schedule. Following instruction, she asked that each parent demonstrate how to safely assist transitioning Keegan's position. The therapist completed passive range of motion (PROM) daily to the neck and shoulder, increasing stretch as tolerated, and provided splinting without any loss in range of motion (ROM). The

surgeons performed split-thickness autografting of the burned areas following wound demarcation, and 5 days after surgery, the therapists initiated twice-daily PROM. Keegan began to demonstrate decreased shoulder and neck ROM, so the therapist initiated splinting of the shoulder into abduction and neck extension over a rolled towel when in bed. At that time, Keegan demonstrated improved medical stability; his physician ordered weaning from the coma-inducing medications and transitioned Keegan to acute care.

Acute Care

As Keegan's level of consciousness increased, he demonstrated significant difficulty tolerating therapy owing to both pain from his burn injury and neuropathic pain in his lower extremities. The occupational therapist provided his physician with input regarding potential pharmacologic pain management in hopes of balancing Keegan's tolerance for therapy with a level of alertness that allowed him to begin participating during sessions. Keegan's mother brought music from his favorite television show and the therapist began to play it during each session. When Keegan was able to follow simple commands, the occupational therapist let him know that it would hurt and assessed his active shoulder and cervical range by asking him to reach for and turn to look at different toys from home. The occupational therapist asked Keegan's brother to hold his tablet computer in a position so Keegan could only see it if he was upright; she slowly helped Keegan transition to sitting at the edge of the bed and assessed his postural control while he was watching a video clip. He cried and told the therapist not to let go, and she responded by reassuring and engaging Keegan. The occupational therapist instructed his parents on safe transfers so he could sit in a chair with supportive pillows for periods of time during the day as part of his updated positioning plan. During sessions, the therapist encouraged Keegan to perform active range as much as possible throughout stretches and let him know when she needed to passively range his joints further. She provided distraction during stretching and worked with nursing to complete ROM shortly after receiving scheduled pain medication. He then transitioned to inpatient rehabilitation.

skills addressed include bathing, dressing, feeding, functional mobility, and toileting (Figure 30-5). The occupational therapist may encourage the caregiver to bring in personal pictures or toys to motivate or comfort the child. When appropriate, siblings and other close family members may take part in therapy sessions to make the artificial hospital setting more comparable to the child's natural environment.

Therapists use a combination of restorative and adaptive treatment approaches to accommodate children's fluctuations in skill progression during the recovery process.^{5,19} The restorative approach facilitates the child's performance skill progression toward his or her prior level of function. The child may reach a plateau in performance skill improvement owing to limitations in child readiness or body structure and function.

For example, a child may have difficulty increasing independence with dressing because of persistent hemiplegic spasticity despite optimal pharmacologic management. At this time the occupational therapist may use an adaptive, or compensatory, approach, modifying activity demands to support increased child success. Modifying activity demands, including the use of adaptive equipment and strategies, gives children a sense of accomplishment during an otherwise potentially frustrating time (see e.g., Chapter 17, Table 17-2, and Chapter 25, Box 25-1). An occupational therapist may likely use a restorative approach with some goal-directed activities while simultaneously using an adaptive approach with other activities with the same child. The balance between approaches also depends on a variety of factors, including the child's and caregiver's priorities,

FIGURE 30-5 Self-care training is an integral focus of the inpatient rehabilitation stage of care in preparation for discharge home.

medical status, contexts for occupational performance, and current level of skill performance.

As the date of discharge becomes imminent, the inpatient rehabilitation team begins to prepare the child and caregiver for re-integration into the home, school, and community settings.⁵ When necessary, an occupational or physical therapist may complete a home evaluation to provide recommendations on how to structure the home to promote safety and independence. The occupational therapist may begin to focus on school re-entry readiness and higher-level instrumental activities of daily living such as meal preparation and home management tasks given the child's functional and developmental levels. He or she may further prepare the family for return to home, school, and the community using outcome measures, hands-on caregiver education, a community re-entry outing, and collaboration with other team members on psychosocial needs.

The use of outcome measures allows for the measurement of progress during inpatient rehabilitation and helps support recommendations for school. The WeeFIM is one assessment tool used to evaluate the functional skill level of the child in various areas related to self-care, mobility, cognition, and social interaction.^{88,101} The occupational therapist and multidisciplinary care team may use assessment results to determine appropriate accommodations for school and support a successful return to the classroom. To further ease the child's transition back into the natural environment, the rehabilitation team

may prepare a video and/or in-service to share with the school about the child's injury and progress.

Because of the varying rate and extent of recovery associated with trauma recovery, the occupational therapist may use hands-on education to prepare the child and caregiver for a "safe" discharge to home rather than an "ideal" discharge in which the child would have returned to his or her prior level of functioning. In preparation for the return home, the caregiver must demonstrate understanding of how to manage the child's medical and functional needs, which may include medication administration, wound care, splinting and positioning schedules, and providing assistance with self-care using adaptive equipment and/or adapted strategies. Some caregivers may not be receptive to modifications or equipment that make the child appear different or "disabled." Establishing therapeutic relationships may facilitate a caregiver's ability to follow through with recommendations required for safety and participation or help determine family-centered alternatives when appropriate. For example, if a caregiver does not put a protective helmet on the child when the child is out of bed, the occupational therapist may ask open-ended questions to find out what is preventing use of the helmet, followed by delivery of necessary education and/or support of the caregiver's ability to problem solve the obstacle.

Just before the child's return to home and school, a member of the medical team (typically an occupational therapist or a recreational therapist) may complete a community re-entry outing with the child and his or her caregivers. This experience provides the therapist with insight into the child's strengths and deficits in the community; the outing also gives caregivers insight into how to navigate the community, both physically and emotionally, when their child has functional limitations. The therapist may discuss how to talk about the trauma and the functional ramifications of the injury with community members; it may empower the family to know that they are in control of how much information they give and to whom. The therapist may even role play difficult interactions the child and caregivers may encounter, especially in regard to changes in the child's appearance, behaviors, means of communication, or use of adaptive equipment.

Collaboration with a social worker and/or psychologist may be appropriate to address the child's and caregivers' emotional readiness for return to home, school, and the community.¹¹⁵ During the inpatient rehabilitation stay, the lingering effects and potential permanence of the traumatic injury become more real to the caregiver. The occupational therapist may suggest coping strategies to address a caregiver's anxiety about transitioning home with a child who remains different from how he or she was before the traumatic incident. In particular, a therapist empathetically supports a caregiver whose child has not made significant improvements in function. The occupational therapist may problem solve with the caregiver how to balance the new demands of having a child with a disability and the typical demands of home, work, and family life. Furthermore, an occupational therapist must be nonjudgmental if a caregiver determines that he or she cannot care for a severely injured child with significant medical needs and chooses to pursue a long-term care placement for the child.

Often the child and caregiver have established a close working relationship with the inpatient health care providers. The occupational therapist may help ease the transition to the

FIGURE 30-6 Aquatic therapy makes use of buoyant and resistive properties of the warm water environment to promote ROM, strengthening, and function beyond what is achievable on land for children with many conditions following trauma. This child, who presents with right hemiplegia following a TBI, is able to attain increased AROM and is more motivated than in the typical therapy environment.

outpatient stage of recovery by educating the child and the caregiver on what to expect in the school and outpatient clinic settings. He or she may also reassure the caregiver of the continuity of family-centered occupational therapy intervention throughout the stages of care.⁹²

Children with Spinal Cord Injury in Inpatient Rehabilitation

Preparatory methods:

- Pain and tone management continue to be addressed by previous interventions and medical consultation as needed. In addition to previous interventions, aquatic therapy⁶⁹ (Figure 30-6), vibration input to muscles,⁹⁰ strengthening exercises, and electrical stimulation⁴⁰ may support spasticity management.
- Updated positioning schedules include a pressure relief routine because children are upright for longer periods at this stage. Pressure relief should be completed with a lateral or, preferably, anterior weight shift or pushing up on arms for 2 minutes every 15 minutes.⁶¹ For children who cannot complete pressure relief independently, caregivers should change their position at least once an hour.⁶¹
- Children with active wrist extension and no active finger movement may be appropriate for promotion of a functional grasping pattern called tenodesis. The therapist uses splinting to encourage therapeutic shortening of flexor intrinsic muscles to facilitate digit flexion during wrist extension with a hand position similar to a lateral pinch grasp.⁵⁶

Purposeful activities and occupation-based interventions:

- For small children, participation in developmentally appropriate floor play should be supported regardless of physical deficits.⁶⁵

- Neuromuscular re-education continues to support restoration of motor functions. For example, task training, or practicing a task repeatedly, has been shown to improve function of clients with SCI¹¹² and may be supported by brain plasticity.⁷⁴ Of note, family-centered goal setting and specificity of task training results in improved performance of the practiced task but does not necessarily translate to other tasks.¹¹²
- Electrical stimulation may be used to restore coordination and strength when integrated into a functional task at a motor or sensory threshold level.⁶⁷ Electrical stimulation must be ordered by a physician and used with caution; the risk of electrical burn is significant owing to probable decreased skin sensation as well as potential intolerance, especially with the pediatric population.
- Training on optimal movement patterns promotes muscle balance and may prevent secondary injury and chronic pain. A clinical practice guideline for preserving upper extremity function published by Paralyzed Veterans of America Consortium for Spinal Cord Medicine⁹⁷ explains use of ergonomics, exercise, equipment selection and training, and environmental adaptations for prevention and management of injury and pain.
- Collaboration with nursing staff may help to facilitate the child's participation in bowel and bladder management. A bowel management program generally begins with a conservative approach (e.g., transanal irrigation or electrical stimulation of abdominal muscles), then pharmacologic, followed by a surgical approach as appropriate, with the highest level of evidence supporting pharmacologic management.⁷⁵
- Children may be educated to perform skin inspections for pressure ulcer prevention when age appropriate.

Education:

- Information on sexual function, which may be affected by SCI, may be provided to children and adolescents in a developmentally appropriate manner.⁵³ For example, a teenage girl may be curious about her ability to conceive a child or want to inquire about necessary changes to her contraceptive methods without her caregivers being present.⁵³
- Education on the importance of pressure relief and adherence to the bowel and bladder program is emphasized, because poor follow-through with these routines can result in re-hospitalization.

Children with Traumatic Brain Injury in Inpatient Rehabilitation

Preparatory methods:

- Arousal level and agitation can influence the child's ability to attend to and complete functional tasks.⁴⁶ Arousal, pain, and tone management continue to be addressed by previous interventions and medical consultation as needed.^{46,106,132}

Purposeful activities and occupation-based interventions:

- Neuromuscular re-education continues to support restoration of motor functions. The occupational therapist promotes fine motor and visuomotor skills through activities that challenge current level of function.

- Electrical stimulation may be used to restore coordination and strength when integrated into a functional task at a motor or sensory threshold; precautions must be taken as described for children with SCI.
- Cognitive performance is a significant focus for children after TBI. Often the earlier children experience a brain injury, the poorer their cognitive prognosis, owing to a smaller foundation of typical development on which to rely during the recovery process.^{5,52,132} Therefore it may be more difficult for the child to use prior experiences to restore skills postinjury.
- Cognitive re-training facilitates restoration of mental functions, including attention to task, memory, command following, sequencing, and organization. The child is given opportunities to practice adapted cognitive strategies for problem solving and safety awareness. The occupational therapist monitors, prompts, and reinforces safety awareness in a variety of contexts.¹³²
- It is common for children and adolescents who have experienced a TBI to demonstrate behavioral difficulties. It may be beneficial for the occupational therapist to identify antecedents to problematic behaviors and develop strategies to promote cognitive function, executive functioning, and appropriate behavior.^{63,132}
- Assessment of visual perceptual skills may be indicated at this time, as well as further cognitive and neuropsychological testing by other disciplines. Results of the assessments may support successful transition to school and subsequent improved quality of life for the child post injury.⁶³

Education:

- Education on the results of standardized assessments prepares the caregiver for his or her child's return to school. If the child is able to maintain average academic performance compared with same-aged peers following a TBI, caregivers and children perceive the child to have a higher quality of life.⁶³
- A child who has sustained a severe, global TBI or anoxic brain injury may not demonstrate functional progress before discharge to home. Autonomic storming, posturing, and severe agitation may remain. Significant support from the entire medical team is required to enable the caregiver to meet the medical and self-care needs of the child at home.⁸⁴

Children with Burn Injury in Inpatient Rehabilitation

Preparatory methods:

- Aggressive range of motion and pressure therapy may continue as needed. Stretches should be completed to terminal range and held for 1 to 2 minutes because the amount of force needed for stretch is significantly more than in most diagnoses⁴⁵ (Figure 30-7). Stretches need to be completed until full active range of motion is easily achieved daily, which typically does not occur until 12 to 18 months postinjury.
- Splinting remains appropriate when full passive range of motion is not easily achieved within a therapy session. Evidence supports splinting to provide successive increase in tissue elongation, which ultimately promotes increased function.³⁴

FIGURE 30-7 Healing burns and skin grafts contract with tensile force that is much stronger than normal skin during the weeks and months following injury and surgical repair. This is often seen in the inpatient rehabilitation phase. It is crucial for the therapist to complete stretches to maximal ROM twice a day, and this often takes significantly more time and force than stretches completed for other conditions.

Purposeful activities and occupation-based interventions:

- As the child regains strength and range, range of motion exercises should be followed with age- and interest-appropriate functional skills (Figure 30-8).

Education:

- Demonstration and hands-on opportunities are essential to caregivers' successful completion of the post-burn home exercise program. The occupational therapist provides home program instruction, explains its importance, facilitates practice of the home program, and gives caregivers feedback on their performance. The home program should include twice-daily range of motion and massage to all affected joints. Depending on the size of the burn, these sessions may take several hours and are often quite uncomfortable for the child. Caregivers must gain comfort and mastery with this program before discharge, as missing even a single home program session may result in a loss of range of motion.
- The occupational therapist further explains information on the child's condition. The therapist also recommends psychosocial resources and community supports as needed. Family support is essential for successful recovery from a childhood skin injury.⁷⁸
- This period is often overwhelming and difficult for the caregivers; staff modeling of therapeutic and empathetic ways to manage the child's likely intolerance of painful interventions is crucial.

Outpatient Rehabilitation and Community Reintegration

Post-trauma, the outpatient stage of care involves addressing the child's and caregivers' needs once they have returned to their natural environments of home and community.⁵ The occupational therapist examines a variety of factors during the outpatient rehabilitation evaluation. Chart review, assessment

FIGURE 30-8 As strength and range of motion are regained during recovery from a burn injury, stretches should be followed with age- and interest-appropriate functional activities. This is also helpful in modeling to parents the fact that the child can participate in normal activities while wearing necessary pressure wrappings or garments.

of injured body structures and impaired body functions, and family interview are used to obtain the history and current performance, including precautions; impairments; level of participation in activities of daily living, instrumental activities of daily living, school or work, play, or leisure, and social opportunities; barriers, including context or activity demands (e.g., equipment needs); caregiver education needs; and consultation needs. The occupational therapist administers outcome measures to establish a baseline for the outpatient rehabilitation program. He or she re-administers assessments regularly to ensure efficacy of interventions, document progress, and guide occupational therapy treatment plan updates. The therapist shares results with the family and other health care team members to promote consistent, coordinated care.⁶³

When appropriate, the outpatient therapist continues to use preparatory methods to address impairments that inhibit performance skills; however, the focus of therapy in this stage is on purposeful activities and occupation-based interventions.⁵ The occupational therapist facilitates optimal, age-appropriate participation in self-care, school, work, and leisure. He or she collaborates with the family during occupational therapy plan of care development to create client-centered goals that address the child's short- and long-term function.

The family's priorities at initiation of outpatient rehabilitation often include safety and functional issues that have arisen since discharge home. For example, a significant number of

adaptive devices issued by an inpatient therapist to clients with SCI⁴⁹ and other diagnoses are not used by the 1-year anniversary of discharge from the hospital. Families benefit from ongoing outpatient occupational therapy consultation to determine updated equipment recommendations. To address context-dependent functional issues in the outpatient setting, the occupational therapist relies on the child and caregiver to accurately report the child's participation in his or her natural environments¹³² and, when appropriate, arranges the therapy space to simulate the natural environment. The occupational therapist continues to use both restorative and adaptive approaches to treatment as appropriate to maximize the child's participation while working toward return to his or her pre-morbid level of function.

Another common family priority post-hospital discharge is the child's school re-entry.⁵ A child's re-integration into the school environment may be delayed because of medical issues and/or be gradual (i.e., initially returning to school with a partial-day schedule). In-home instruction may also be instituted. Communicating with the school may help the staff understand the child's changing needs post-discharge. Collaboration to develop school accommodations facilitates the child's optimal performance in school despite ongoing deficits post-trauma. Ongoing communication with school throughout outpatient rehabilitation promotes a consistent approach to the child's care and an ability to determine any differences in the child's function depending on context.

Once a family's daily routine, including home and school, is manageable post-discharge, the occupational therapist may facilitate community involvement. The therapist educates the child and caregiver regarding resources and opportunities for community engagement,^{48,129} including adapted recreational programs and peer-based groups. The occupational therapist may deliver intervention during family outings in natural, community environments.¹⁴ These opportunities can be a powerful way to observe how the family functions, e.g., how a family navigates in various settings and how the caregiver uses coping strategies in public places. If community outings are not feasible because of logistical or funding barriers, the occupational therapist may set up mock public environments or use a more public area of the therapy facility to accomplish community re-integration goals.

A self-management approach, including motivational interviewing (an open-ended, empathetic method of talking with caregivers) may help the practitioner identify sources of family's stress when returning home.²⁴ Stressors may include caring for their child without the supports of the hospital environment, equipment management, altered family dynamics, school re-entry issues, community participation barriers, schedule demands, coming to terms with their child's functional limitations, and uncertainty about the future.⁴⁸ Once identified, the occupational therapist may direct caregivers to appropriate community resources, including respite care and support groups (e.g., online, hospital-based, local, or national groups). Referral to other health care professionals, including a care coordinator, social worker, or psychologist, may also be appropriate.

Occupational therapists also use self-management to assess family readiness for change. Some education topics provided during the inpatient stage are re-stated to demonstrate continuity of care⁴⁸ and ensure caregiver understanding. New

education at this stage includes home programming to support the child's progress.¹⁴ A self-management approach may be used to support caregivers' ability to identify and problem solve barriers preventing implementation of home programs, because the occupational therapist no longer has the benefit of a controlled environment to ensure follow-through with necessary therapeutic recommendations.

As the outpatient rehabilitation episode of care continues, the caregiver's ability to manage the child's needs at home progresses. The child and his or her family members often become more cohesive and re-integrated into the community as they continue with the post-injury stage of life. The need for skilled intervention decreases as a child approaches a pre-morbid level of function or functional recovery slows, at which time decreasing therapy frequency or discharge from therapy may be appropriate. The Cincinnati Children's Hospital Guidelines for determining frequency of therapy⁷ describe clinical reasoning to determine how frequently a child should receive therapy and when he or she should be discharged. Often survivors of pediatric trauma return to occupational therapy for future episodes of care when different functional concerns arise or new demands are placed on them throughout the life span.^{23,100}

Children with Spinal Cord Injury in Outpatient Rehabilitation and Community Reintegration

Preparatory methods:

- Pain and tone management continue to be addressed by previous interventions and medical consultation as needed.

Purposeful activities and occupation-based interventions:

- Neuromuscular re-education continues to support restoration of motor functions.
- For some clients electrical stimulation may be used as adaptive equipment long-term to compensate for grasp deficits in the form of a surgically implanted or transcutaneous upper extremity neuroprosthesis.⁶⁷
- Depending on level of injury and whether spasticity is adequately controlled, some arm and hand function may be restored surgically with tendon transfer or nerve transfer followed by neuromuscular re-education.^{16,27,39}
- Common instrumental activities of daily living for children with SCI include communication device use, community mobility, meal preparation and clean up, safety procedures, health management, and shopping, as developmentally appropriate.
- A child's participation in health management may be limited by accessibility of community recreation programs. Children with SCI may benefit from development of age-appropriate and client-centered exercise programs, including upper-body ergometry via arm cycling, functional electrical stimulation, resistance strengthening, or functional strengthening. For adults with SCI, exercise has been shown to improve physical capacity, extremity strength,^{57,60,98,122} respiratory strength and endurance,¹⁰⁹ cardiovascular function,⁹⁸ subjective well-being,⁸⁵ and upper extremity motor control and function.⁷² Exercise may also prevent bone loss.^{6,10} Functional electrical stimulation combined with ergometry may be an appropriate option for children.⁶⁶

- The outpatient occupational therapist may collaborate with school therapists or teachers on classroom adaptations for children with SCI, the most common of which include writing aids; program accommodations; and physical assistance for functional mobility, health maintenance, self-care, and manipulating learning materials.³⁸
- After restrictions are lifted by the physician, a teenager may resume driving with necessary car modifications as determined by a certified driving specialist.⁵³
- Participation during occupational therapy is a significant predictor of functional outcomes for clients with SCI⁹⁶ therefore it is vital to maximize a child's engagement by adopting family-centered goals and integrating the child's interest into therapy interventions.
- Occupational therapy interventions increase quality of life for clients with SCI post-discharge²⁵ by addressing their foremost priorities, which include motor function (i.e., upper extremity function for clients with quadriplegia and functional mobility for clients with paraplegia), bowel and bladder function, and sexual function as appropriate for age.¹¹¹

Education:

- Education must address problem-solving barriers to participation in the natural environment,⁸⁶ as well as health care topics, including safety with decreased sensation and impaired body temperature regulation.
- Referral to other health care professionals, including neuropsychologists when appropriate, may improve quality of life, because approximately 30% of individuals with SCI may be at risk for depression.²⁸
- Educating on accessible community resources is also important because handicap is significantly associated with lower quality of life in clients with SCI.³⁵
- Accessing social supports in the community is associated with improved physical and mental health, including improved life satisfaction and decreased pain.⁸⁹

Children with Traumatic Brain Injury in Outpatient Rehabilitation and Community Reintegration

Preparatory methods:

- A child with a severe global injury may continue to experience significant spasticity and/or autonomic storming. Medical consultation or interventions to manage muscle tone,¹³² arousal levels, and pain may continue.
- As previously discussed, if a child has become more neurologically regulated and begins to progress in recovery stages (i.e., Rancho Levels of Cognitive Functioning),^{54,99} the occupational therapist may modify the therapy treatment plan to maximize purposeful engagement.

Purposeful activities and occupation-based interventions:

- Neuromuscular re-education continues to support restoration of motor functions (Figure 30-9).^{5,132} For example, constraint-induced movement therapy is an intervention technique well supported in the literature to promote function of a hemiplegic upper extremity and has been used with children who have experienced a TBI (Figure 30-10).^{22,108}

FIGURE 30-9 A supportive upper extremity mobility device can promote neuromuscular re-education through virtual reality.

FIGURE 30-10 Constraint-induced movement therapy involves limiting use of the more functional upper extremity to promote increased strength and function of the impaired side. It is widely supported and can be used following TBI or any condition that results in hemiplegia.

- Cognitive re-training continues to support restoration of process functions.^{5,19,47,132} Deficits may further emerge after school re-entry.
- Compensatory cognitive strategies may include visual schedules or reminders,⁴⁷ cueing techniques, schedule management, organization tools, and environmental modifications.¹⁹

Education:

- Ongoing behavioral issues are common in this population. For example, teenagers who have sustained a severe TBI demonstrate significant difficulties in behavior and mental health. These problems have significant family impact.¹¹⁴ The family's ability to manage is dependent

on the severity of the injury, family cohesiveness, and the resources available.^{5,131,132}

- Education may include information and instruction for using adapted strategies and equipment. Caregivers are educated in methods to support the child's functional capabilities.^{5,19,132}
- The caregivers may begin to seek respite opportunities because of the vast, ongoing demands on the caregiver.⁹³

See [Case Study 30-2](#).

Children with Burn Injury in Outpatient Rehabilitation and Community Reintegration

Preparatory methods:

- Range of motion exercises, scar massage, pressure therapy, and splinting must be continued to maintain or regain lost range of motion as scars mature, which typically occurs 12 to 18 months postinjury. Although these are monitored by the occupational therapist, they are the responsibility of the caregiver to perform daily.
- Supervised aerobic and progressive resistance training programs have been shown to be useful in rehabilitation following burn injuries and to significantly reduce the need for surgical reconstruction owing to joint contracture.^{20,29,116-118}

Purposeful activities and occupation-based interventions:

- Therapeutic activities that follow range of motion exercises focus on resuming engagement in chosen activities and age-appropriate occupations. The occupational therapist may help facilitate the child's redefinition of self as a "burn survivor" (versus burn victim) through personal exploration.

Education:

- It is essential for the occupational therapist to continue to stress the importance of maintaining the home program during the active scarring phase, despite difficulty with child cooperation and tolerance. As always, therapeutic relationships may provide needed support and reassurance during this time.

Conclusion

Occupational therapists can be inspired by children's ability to offer a refreshing perspective on their current life situation, regardless of how daunting the circumstances may seem. A child who has been traumatically injured and his or her family must face and overcome an unexpected landmark that occurs in an instant and lasts a lifetime. They grapple with the consequences, move forward, and begin to heal their wounds, external and internal, real and metaphoric. Nothing is as motivating and inspiring as watching a child overcome horrendous obstacles in an innocent and positive way. It is difficult to match the value one can experience when a parent learns to take on the role of mom or dad again after weeks of feeling vulnerable and intimidated by his or her child's fragile medical status. The occupational therapist often has a strong impact on facilitating function during the recovery process, both the function of the child and the function of the caregivers. Few experiences are as professionally, or personally, rewarding.

CASE STUDY 30-2 Sam

History

Sam is an 8-year-old boy who was riding his bicycle in a wind storm and was hit in the head by a large tree branch. He sustained a brain injury, including a large left frontal lobe laceration with an extensive shear injury, multiple subdural hematomas, and many regions of diffuse damage. His skull was fractured in multiple locations, along with fractures of the C7 spinous process and T1-T3 compression fractures. On admission, he underwent emergency bilateral craniectomy surgeries to relieve the intracranial pressure and address the significant subdural hemorrhaging. He spent 1 month in the ICU and was transferred to the inpatient pediatric rehabilitation unit. During his hospital stay, he experienced significant muscle spasticity managed by medication, serial casting, and splinting. His body's ability to regulate itself was inadequate, causing autonomic storming episodes with a consistent decorticate posturing pattern (tonal pattern involving intense spasticity with shoulders adducted and internally rotated, elbows flexed, forearms pronated, wrists flexed, and digits in composite flexion). He wore a back brace at all times to address his spinal stability needs and a helmet was placed on his head when out of bed. During his inpatient stages of care, his occupational therapist focused on facilitating consistent, localized responses to stimulation; decreasing his agitation via environmental adjustments and positioning methods; spasticity management via positioning and splinting during times of decreased agitation; facilitating upright and out-of-bed positioning in his wheelchair and in therapy gyms within limited tolerance; caregiver education regarding necessary adaptive equipment (fully supportive shower chair, tilt-in-space wheelchair with full support); transfers; and handling methods used to facilitate purposeful responses. In addition, hypertrophic scar development was noted on his left cheek owing to deep skin wounds sustained during the accident. These scars were managed in a manner similar to burn care, using scar massage and monitoring for the need for pressure therapy. After 3 months of hospitalization, Sam was discharged home. His recovery had stabilized and had not progressed significantly; he was fully dependent for all self-care and communication needs. Sam continued to have consistent, yet decreasing, periods of autonomic storming, hypertonicity, and agitation and was beginning to visually track for brief periods. He was assigned a home nurse who was trained in managing his care during the day while his parents worked. It was decided that he would participate in intensive occupational, physical, and speech pathology treatments on an outpatient basis.

Assessment

Sam's parents and home health nurse attended the outpatient occupational therapy evaluation. His parents reported feeling overwhelmed with Sam's care and wanting to know how the recovery process for their son would proceed. Sam was agitated and storming during the initial evaluation, making it difficult to fully assess his passive upper extremity range of motion. He postured in a modified decorticate pattern with his trunk in right rotation and pelvis in left rotation,

particularly when placed in a supine position on the mat table. His parents reported that the periods of time when this posturing occurred were becoming less frequent. The occupational therapist noted that his tonal pattern decreased when he was placed in a right side-lying position, allowing his shoulders to depress and protract. The occupational therapist placed Sam in various supported positions on the mat to observe his tolerance to transitional movements, spasticity patterns, and head and trunk muscle facilitation. He did not demonstrate the ability to visually track during the evaluation; however, his parents reported that he would, at times, demonstrate purposeful visual attention in the home environment (i.e., with the television). During times of increased alertness, Sam's parents reported that he appropriately smiled to auditory input. The occupational therapist explored the family's current adaptive equipment, discussed the parents' and nurse's comfort with using the equipment, observed Sam in his wheelchair and discussed the home set up. Additionally, she asked the family questions about Sam's premorbid recreational interests, which included baseball, playing with his friends, karate, telling jokes, and spending time with his older brother.

Intervention

As outpatient therapies were initiated and his doctors refined his medications, Sam's autonomic storming episodes decreased. As this happened, bilateral upper extremity hypertonicity decreased and he presented in a hemiplegic manner. Sam's began to demonstrate purposeful use of his left upper extremity, and his right presented as flaccid proximally with simultaneous distal tightness of his long finger flexors and wrist flexors. He continued to hold his left elbow at approximately 90 degrees of flexion with internal rotation and adduction of the shoulder.

The first stage of his outpatient occupational therapy intervention facilitated his emerging purposeful left upper extremity movement. Sam was placed in a right side-lying position on the mat table to eliminate gravity to promote left upper extremity reach. For example, Sam demonstrated early motivation when exposed to a water toy. A basic button switch was connected to the water toy that poured water into a spout with activation. Initially the therapist used a hand-over-hand strategy to elicit reach in this position. From there, Sam began to visually attend to this toy and engaged in purposeful reach for the switch. The occupational therapist talked with Sam and his parents in a conversational way, making an effort to discuss with Sam professional baseball scores and tell him silly jokes. During these interactions, Sam demonstrated appropriate smiling and laughing and visually attended to the occupational therapist when she spoke.

Early outpatient sessions also included supported sitting on the edge of the mat table with a mirror in front of Sam for visual feedback to address basic head control, visual attention, and tracking. After a few weeks, he demonstrated independent head control, and trunk control became a more

Continued

CASE STUDY 30-2 Sam—cont'd

significant focus of intervention. Functional activity was incorporated throughout each stage, engaging Sam's interests while maximizing his ability to move his left upper extremity against gravity. He reached for a baseball while seated, placed a small plastic basketball into a hoop, and participated in self-care. His parents were involved in one session per week on a common day off of work, learning how to work with Sam at home. The occupational therapist developed a splinting protocol for use with his right upper extremity at night, and functional electrical stimulation program. After a few months, Sam began to demonstrate basic reach and grasp with his more affected right side.

The occupational therapist participated in ongoing, consistent communication with other care team members regarding Sam's progress. As Sam's agitation diminished, his performance increased with left-sided functional use and fine motor skills, improved cognition, visual processing, motor planning, and emerging right-sided mobility. His self-care participation became a greater focus in occupational therapy as his independence increased. He began to assist with stand

pivot transfers and used a gait trainer with physical therapy. He began attending school 2 days per week. Sam's large, tilt-in-space manual wheelchair was becoming a barrier to his function owing to components no longer needed. In therapy he trialed power wheelchairs with an equipment vendor on multiple occasions and, after educating the family and understanding his capabilities, he was deemed appropriate to use a power wheelchair. He received a new wheelchair and additional training on its use; within a few short weeks, he was able to navigate his school, home, and community environments with supervision. Sam's mindset greatly improved with his new-found independence.

Sam's outpatient rehabilitation then incorporated aquatic therapy and weekly exercises for upper extremity and trunk strength. His ataxia and right upper extremity mobility continued to improve, allowing him to focus on bimanual skills. The occupational therapist balanced the use of compensation and restoration techniques as his progress continued. Continued outpatient sessions focused on any barriers to functioning fully in the home, school, and community environments.

Summary

- Occupational therapists use restorative approaches to facilitate the child's performance skill progression toward his or her prior level of function. Alternatively, they use compensatory approaches when immediate increase in function is needed to give the child a sense of accomplishment, when a plateau in performance improvement is experienced, or when an alternative approach to increase function is needed. These approaches may be used in tandem; that is, certain child and family goals may require a restorative approach and others a compensatory approach. It is often this balance that promotes the most function and success.
- Regardless of diagnosis, the occupational therapist addresses injured body structures and impaired body functions by applying preparatory methods to promote homeostasis and prevent secondary injury. Interventions to maximize range of motion include stretches, soft tissue mobilization, splinting, and positioning and are used with children with SCI, TBI, or burn injury. Positioning is also used for pressure ulcer and pain prevention across diagnoses. For children with TBI, environmental sensory stimulation is modulated to prevent agitation. Wound care and scar massage are preparatory methods specific to children with burn injury.
- A child ideally progresses through the recovery continuum with a different therapy focus at each stage, though interventions from previous stages continue to be utilized as appropriate, e.g., splinting may be used from the ICU to outpatient rehabilitation. In the ICU, the focus is on preventing secondary complications such as pain, contracture, and pressure ulcers from the body's state of immobility and impaired ability to maintain homeostasis. The focus in acute care is on the child's ability to resume available motor functions, often beginning with basic tolerance for upright positioning and head and trunk control. The occupational therapist continues to closely monitor vital signs and tolerance of intervention. During inpatient rehabilitation the focus of therapy is to facilitate the child's independence in self-care and play or leisure activities. Caregivers require hands-on education to prepare for the child's transition back to his or her home, school, and community settings. Outpatient therapy may focus on IADL, school participation, and community re-integration.
- Coordinated care among professionals promotes the child's safety, increases the team's consistency of care provision, prevents the delivery of conflicting information, and facilitates the child's ability to carry over restored skills to various contexts. Consistency not only promotes the child's rehabilitation, but also provides the child and caregiver with a sense of security during potentially stressful transitions.
- Moses⁸⁷ suggests that a child's trauma and subsequent disability "shatter the dreams" a caregiver has for the child and begin a grieving process. A family's grieving process must be taken into account when providing education post-trauma, because a child or caregivers may be better able to take in and/or benefit from certain information in a different grieving state.
- An occupational therapist uses different methods to establish rapport with severely impaired children depending on their level of consciousness. To increase the child's comfort with and trust in the therapist, the therapist may provide the child with adaptive equipment to improve function, educate the child in directing his or her care, use developmentally appropriate comfort measures to address pain, ensure safe and consistent care provision, help create a low stimulation environment, incorporate the child's interests into all interventions, closely monitor the child's responses to interventions, and/or explain what he or she is doing with the child in a developmentally appropriate manner. For intervention directed at the caregivers, the occupational

therapist may provide an appropriate level of information, give hands-on instruction to support the ability to resume caring for the child, use family-friendly language, acknowledge their grieving process, remember their unique perspective on their child's progress, and remain cautiously hopeful.

- Rehabilitation with children differs from that with adults because of the additional consideration of each child's

developmental stage. Working with children post-trauma involves focusing treatment on both the child and caregiver's priorities and needs. Compared with developmental pediatric treatment, the occupational therapist must be mindful that caregivers post-trauma are not only adjusting to sudden differences in their child, but also to differences in the breadth and depth of the caregivers' responsibilities.
